ASYNCHRONOUS TRANSFER MODE NETWORKS

Asynchronous transfer mode, or ATM, is a network transfer technique capable of supporting a wide variety of multimedia applications with diverse service and performance requirements. It supports traffic bandwidths ranging from a few kilobits per second (e.g., a text terminal) to several hundred megabits per second (e.g., high-definition video) and traffic types ranging from continuous, fixed-rate traffic (e.g., traditional telephony and file transfer) to highly bursty traffic (e.g., interactive data and video). Because of its support for such a wide range of traffic, ATM was designated by the telecommunication standardization sector of the International Telecommunications Union (ITU-T, formerly CCITT) as the multiplexing and switching technique for Broadband, or high-speed, ISDN (B-ISDN) (1).

ATM is a form of packet-switching technology. That is, ATM networks transmit their information in small, fixed-length packets called cells, each of which contains 48 octets (or bytes) of data and 5 octets of header information. The small, fixed cell size was chosen to facilitate the rapid processing of packets in hardware and to minimize the amount of time required to fill a single packet. This is particularly important for real-time applications such as voice and video that require short packetization delays.

ATM is also connection-oriented. In other words, a virtual circuit must be established before a call can take place, where a call is defined as the transfer of information between two or more endpoints. The establishment of a virtual circuit entails the initiation of a signaling process, during which a route is selected according to the call's quality of service requirements, connection identifiers at each switch on the route are established, and network resources such as bandwidth and buffer space may be reserved for the connection.

Another important characteristic of ATM is that its network functions are typically implemented in hardware. With the introduction of high-speed fiber optic transmission lines, the communication bottleneck has shifted from the communication links to the processing at switching nodes and at terminal equipment. Hardware implementation is necessary to overcome this bottleneck because it minimizes the cell-processing overhead, thereby allowing the network to match link rates on the order of gigabits per second.

Finally, as its name indicates, ATM is asynchronous. Time is slotted into cell-sized intervals, and slots are assigned to calls in an asynchronous, demand-based manner. Because slots are allocated to calls on demand, ATM can easily accommodate traffic whose bit rate fluctuates over time. Moreover, in ATM, no bandwidth is consumed unless information is actually transmitted. ATM also gains bandwidth efficiency by being able to multiplex bursty traffic sources statistically. Because bursty traffic does not require continuous allocation of the bandwidth at its peak rate, statistical multiplexing allows a large number of bursty sources to share the network's bandwidth.

Since its birth in the mid-1980s, ATM has been fortified by a number of robust standards and realized by a significant number of network equipment manufacturers. International standards-making bodies such as the ITU and independent consortia like the ATM Forum have developed a significant body of standards and implementation agreements for ATM (1,4). As networks and network services continue to evolve toward greater speeds and diversities, ATM will undoubtedly continue to proliferate.

ATM STANDARDS

The telecommunication standardization sector of the ITU, the international standards agency commissioned by the United Nations for the global standardization of telecommunications, has developed a number of standards for ATM networks. Other standards bodies and consortia (e.g., the ATM Forum, ANSI) have also contributed to the development of ATM standards. This section presents an overview of the standards, with particular emphasis on the protocol reference model used by ATM (2).

Protocol Reference Model

The B-ISDN protocol reference model, defined in ITU-T recommendation I.321, is shown in Fig. 1(1). The purpose of the protocol reference model is to clarify the functions that ATM networks perform by grouping them into a set of interrelated, function-specific layers and planes. The reference model consists of a user plane, a control plane, and a management plane. Within the user and control planes is a hierarchical set of layers. The user plane defines a set of functions for the transfer of user information between communication endpoints; the control plane defines control functions such as call establishment, call maintenance, and call release; and the management plane defines the operations necessary to control information flow between planes and layers and to maintain accurate and fault-tolerant network operation.

Within the user and control planes, there are three layers: the physical layer, the ATM layer, and the ATM adaptation layer (AAL). Figure 2 summarizes the functions of each layer (1). The physical layer performs primarily bit-level functions, the ATM layer is primarily responsible for the switching of ATM cells, and the ATM adaptation layer is responsible for the conversion of higher-layer protocol frames into ATM cells. The functions that the physical, ATM, and adaptation layers perform are described in more detail next.

Physical Layer

The physical layer is divided into two sublayers: the physical medium sublayer and the transmission convergence sublayer (1).

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

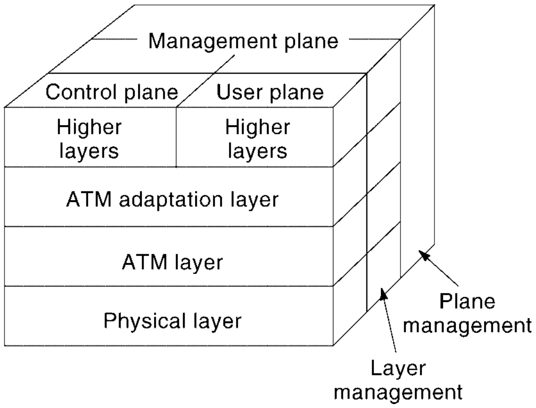

Figure 1. Protocol reference model for ATM.

Physical Medium Sublayer. The physical medium (PM) sublayer performs medium-dependent functions. For example, it provides bit transmission capabilities including bit alignment, line coding and electrical/optical conversion. The PM sublayer is also responsible for bit timing (i.e., the insertion and extraction of bit timing information). The PM sublayer currently supports two types of interface: optical and electrical.

Transmission Convergence Sublayer. Above the physical medium sublayer is the transmission convergence (TC) sublayer, which is primarily responsible for the framing of data transported over the physical medium. The ITU-T recommendation specifies two options for TC sublayer transmission frame structure: cell-based and synchronous digital hierarchy (SDH). In the cell-based case, cells are transported continuously without any regular frame structure. Under SDH, cells are carried in a special frame structure based on the North American SONET (synchronous optical network) protocol (3). Regardless of which transmission frame structure is used, the TC sublayer is responsible for the following four functions: cell rate decoupling, header error control, cell delineation, and transmission frame adaptation. Cell rate decoupling is the insertion of idle cells at the sending side to adapt the ATM cell stream's rate to the rate of the transmission path. Header error control is the insertion of an 8-bit CRC in the ATM cell header to protect the contents of the ATM cell header. Cell delineation is the detection of cell boundaries. Transmission frame adaptation is the encapsulation of departing cells into an appropriate framing structure (either cell-based or SDH-based).

ATM Layer

The ATM layer lies atop the physical layer and specifies the functions required for the switching and flow control of ATM cells (1).

There are two interfaces in an ATM network: the user-network interface (UNI) between the ATM endpoint and the ATM switch, and the network-network interface (NNI) between two ATM switches. Although a 48-octet cell payload is used at both interfaces, the 5-octet cell header differs slightly at these interfaces. Figure 3 shows the cell header structures used at the UNI and NNI (1). At the UNI, the header contains a 4-bit generic flow control (GFC) field, a 24-bit label field containing virtual path identifier (VPI) and virtual channel identifier (VCI) subfields (8 bits for the VPI and 16 bits for the VCI), a 2-bit payload type (PT) field, a 1-bit cell loss priority (CLP) field, and an 8-bit header error check (HEC) field. The cell header for an NNI cell is identical to that for the UNI cell, except that it lacks the GFC field; these four bits are used for an additional 4 VPI bits in the NNI cell header.

The VCI and VPI fields are identifier values for virtual channel (VC) and virtual path (VP), respectively. A virtual channel connects two ATM communication endpoints. A virtual path connects two ATM devices, which can be switches or endpoints, and several virtual channels may be multiplexed onto the same virtual path. The 2-bit PT field identifies whether the cell payload contains data or control information. The CLP bit is used by the user for explicit indication of cell loss priority. If the value of the CLP is 1, then the cell is subject to discarding in case of congestion. The HEC field is an 8-bit CRC that protects the contents of the cell header. The GFC field, which appears only at the UNI, is used to assist the customer premises network in controlling the traffic flow. At the time of writing, the exact procedures for use of this field have not been agreed upon.

Layer management	Higher layer functions	Higher layers	
	Convergence	CS	AAL
	Segmentation and reassembly	SAR	
	Generic flow control Cell header generation/extraction Cell VPI/VCI translation Cell multiplex and demultiplex	ATM	
	Cell rate decoupling Header error control (HEC) Cell delineation Transmission frame adaptation Transmission frame generation/recovery	TC	Physical layer
	Bit timing Physical medium	PM	

Figure 2. Functions of each layer in the protocol reference model.

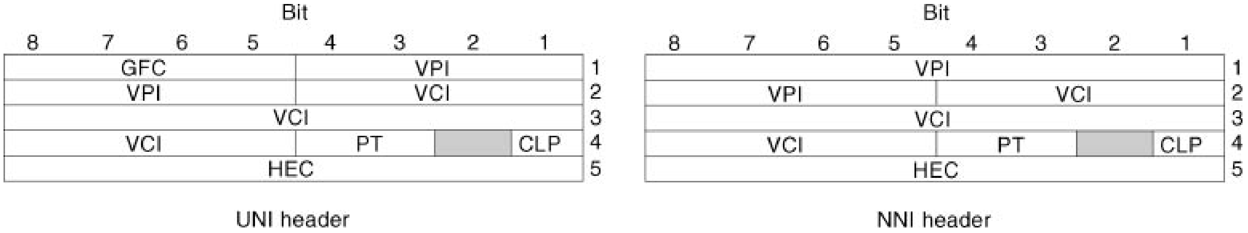

Figure 3. ATM cell header structure.

ATM Layer Functions

The primary function of the ATM layer is VPI/VCI translation. As ATM cells arrive at ATM switches, the VPI and VCI values contained in their headers are examined by the switch to determine which outport port should be used to forward the cell. In the process, the switch translates the cell's original VPI and VCI values into new outgoing VPI and VCI values, which are used in turn by the next ATM switch to send the cell toward its intended destination. The table used to perform this translation is initialized during the establishment of the call.

An ATM switch may either be a VP switch, in which case it translates only the VPI values contained in cell headers, or it may be a VP/VC switch, in which case it translates the incoming VPI/VCI value into an outgoing VPI/VCI pair. Because VPI and VCI values do not represent a unique end-to-end virtual connection, they can be reused at different switches through the network. This is important because the VPI and VCI fields are limited in length and would be quickly exhausted if they were used simply as destination addresses.

The ATM layer supports two types of virtual connections: switched virtual connections (SVC) and permanent, or semipermanent, virtual connections (PVC). Switched virtual connections are established and torn down dynamically by an ATM signaling procedure. That is, they exist only for the duration of a single call. Permanent virtual connections, on the other hand, are established by network administrators and continue to exist as long as the administrator leaves them up, even if they are not used to transmit data.

Other important functions of the ATM layer include cell multiplexing and demultiplexing, cell header creation and extraction, and generic flow control. Cell multiplexing is the merging of cells from several calls onto a single transmission path, cell header creation is the attachment of a 5-octet cell header to each 48-octet block of user payload, and generic flow control is used at the UNI to prevent short-term overload conditions from occurring within the network.

ATM Layer Service Categories

The ATM Forum and ITU-T have defined several distinct service categories at the ATM layer (1,4). The categories defined by the ATM Forum include constant bit rate (CBR), real-time variable bit rate (VBR-rt), non-real-time variable bit rate (VBR-nrt), available bit rate (ABR), and unspecified bit rate (UBR). ITU-T defines four service categories, namely, deterministic bit rate (DBR), statistical bit rate (SBR), available bit rate (ABR), and ATM block transfer (ABT). The first of the three ITU-T service categories correspond roughly to the ATM Forum's CBR, VBR, and ABR classifications, respectively. The fourth service category, ABT, is solely defined by ITU-T and is intended for bursty data applications. The UBR category defined by the ATM Forum is for calls that request no quality of service guarantees at all. Figure 4 lists the ATM service categories, their quality of service (QoS) parameters, and the traffic descriptors required by the service category during call establishment (1,4).

The constant bit rate (or deterministic bit rate) service category provides a very strict QoS guarantee. It is targeted at real-time applications, such as voice and raw video, which mandate severe restrictions on delay, delay variance (jitter), and cell loss rate. The only traffic descriptors required by the CBR service are the peak cell rate and the cell delay variation tolerance. A fixed amount of bandwidth, determined primarily by the call's peak cell rate, is reserved for each CBR connection.

The real-time variable bit rate (or statistical bit rate) service category is intended for real-time bursty applications (e.g., compressed video), which also require strict QoS guarantees. The primary difference between CBR and VBR-rt is in the traffic descriptors they use. The VBR-rt service requires the specification of the sustained (or average) cell rate and burst tolerance (i.e., burst length) in addition to the peak cell rate and the cell delay variation

ITU-T service categories	DBR	SBR	ABT	ABR	
ATM forum service categories	CBR	VBR-rt	VBR-nrt	ABR	UBR
Cell loss rate	Specified				Unspecified
Cell transfer delay	Specified			Unspecified	
Cell delay variation	Specified		Unspecified		
Traffic descriptors (contract)	PCR/CDVT	PCR/CDVT SCR/BT		PCR/CDVT MCR/ACR	PCR/CDVT

PCR = Peak Cell Rate; SCR = Sustained Cell Rate; CDVT = Cell Delay Variation Tolerance; BT = Burst Tolerance; MCR = Minimum Cell Rate; ACR = Allowed Cell Rate.

Figure 4. ATM layer service categories.

tolerance. The ATM Forum also defines a VBR-nrt service category, in which cell delay variance is not guaranteed.

The available bit rate service category is defined to exploit the network's unused bandwidth. It is intended for non-real-time data applications in which the source is amenable to enforced adjustment of its transmission rate. A minimum cell rate is reserved for the ABR connection and therefore guaranteed by the network. When the network has unused bandwidth, ABR sources are allowed to increase their cell rates up to an allowed cell rate (ACR), a value that is periodically updated by the ABR flow control mechanism (to be described in the section entitled "ATM Traffic Control"). The value of ACR always falls between the minimum and the peak cell rate for the connection and is determined by the network.

The ATM Forum defines another service category for non-real-time applications called the unspecified bit rate (UBR) service category. The UBR service is entirely best effort; the call is provided with no QoS guarantees. The ITU-T also defines an additional service category for non-real-time data applications. The ATM block transfer service category is intended for the transmission of short bursts, or blocks, of data. Before transmitting a block, the source requests a reservation of bandwidth from the network. If the ABT service is being used with the immediate transmission option (ABT/IT), the block of data is sent at the same time as the reservation request. If bandwidth is not available for transporting the block, then it is simply discarded, and the source must retransmit it. In the ABT service with delayed transmission (ABT/DT), the source waits for a confirmation from the network that enough bandwidth is available before transmitting the block of data. In both cases, the network temporarily reserves bandwidth according to the peak cell rate for each block. Immediately after transporting the block, the network releases the reserved bandwidth.

ATM Adaptation Layer

The ATM adaptation layer, which resides atop the ATM layer, is responsible for mapping the requirements of higher layer protocols onto the ATM network (1). It operates in ATM devices at the edge of the ATM network and is totally absent in ATM switches. The adaptation layer is divided into two sublayers: the convergence sublayer (CS), which performs error detection and handling, timing, and clock recovery; and the segmentation and reassembly (SAR) sublayer, which performs segmentation of convergence sublayer protocol data units (PDUs) into ATM cell-sized SAR sublayer service data units (SDUs) and vice versa.

In order to support different service requirements, the ITU-T has proposed four AAL-specific service classes. Figure 5 depicts the four service classes defined in recommendation I.362 (1). Note that even though these AAL service classes are similar in many ways to the ATM layer service categories defined in the previous section, they are not the same; each exists at a different layer of the protocol reference model, and each requires a different set of functions.

	Class A	Class B	Class C	Class D
Timing relation between source and destination	Required		Not required	
Bit rate	Constant	Variable		
Connection mode	Connection oriented		Connectionless	

Figure 5. Service classification for AAL.

AAL service class A corresponds to constant bit rate services with a timing relation required between source and destination. The connection mode is connection-oriented. The CBR audio and video belong to this class. Class B corresponds to variable bit rate (VBR) services. This class also requires timing between source and destination, and its mode is connection-oriented. The VBR audio and video are examples of class B services. Class C also corresponds to VBR connection-oriented services, but the timing between source and destination needs not be related. Class C includes connection-oriented data transfer such as X.25, signaling, and future high-speed data services. Class D corresponds to connectionless services. Connectionless data services such as those supported by LANs and MANs are examples of class D services.

Four AAL types (Types 1, 2, 3/4, and 5), each with a unique SAR sublayer and CS sublayer, are defined to support the four service classes. AAL Type 1 supports constant bit rate services (class A), and AAL Type 2 supports variable bit rate services with a timing relation between source and destination (class B). AAL Type 3/4 was originally specified as two different AAL types (Type 3 and Type 4), but because of their inherent similarities, they were eventually merged to support both class C and class D services. AAL Type 5 also supports class C and class D services.

AAL Type 5. Currently, the most widely used adaptation layer is AAL Type 5. AAL Type 5 supports connection-oriented and connectionless services in which there is no timing relation between source and destination (classes C and D). Its functionality was intentionally made simple in order to support high-speed data transfer. AAL Type 5 assumes that the layers above the ATM adaptation layer can perform error recovery, retransmission, and sequence numbering when required, and thus, it does not provide these functions. Therefore, only nonassured operation is provided; lost or corrupted AAL Type 5 packets will not be corrected by retransmission.

Figure 6 depicts the SAR-SDU format for AAL Type 5 (5,6). The SAR sublayer of AAL Type 5 performs segmentation of a CS-PDU into a size suitable for the SAR-SDU payload. Unlike other AAL types, Type 5 devotes the entire 48-octet payload of the ATM cell to the SAR-SDU; there is no overhead. An AAL specific flag (end-of-frame) in the

Figure 7. CS-PDU format, segmentation and reassembly of AAL Type 5.

ATM PT field of the cell header is set when the last cell of a CS-PDU is sent. The reassembly of CS-PDU frames at the destination is controlled by using this flag.

Figure 7 depicts the CS-PDU format for AAL Type 5 (5,6). It contains the user data payload, along with any necessary padding bits (PAD) and a CS-PDU trailer, which are added by the CS sublayer when it receives the user information from the higher layer. The CS-PDU is padded using 0 to 47 bytes of PAD field to make the length of the CS-PDU an integral multiple of 48 bytes (the size of the SAR-SDU payload). At the receiving end, a reassembled PDU is passed to the CS sublayer from the SAR sublayer, and CRC values are then calculated and compared. If there is no error, the PAD field is removed by using the value of length field (LF) in the CS-PDU trailer, and user data is passed to the higher layer. If an error is detected, the erroneous information is either delivered to the user or discarded according to the user's choice. The use of the CF field is for further study.

AAL Type 1. AAL Type 1 supports constant bit rate services with a fixed timing relation between source and destination users (class A). At the SAR sublayer, it defines a 48-octet service data unit (SDU), which contains 47 octets of user payload, 4 bits for a sequence number, and a 4-bit CRC value to detect errors in the sequence number field. AAL Type 1 performs the following services at the CS sublayer: forward error correction to ensure high quality of audio and video applications, clock recovery by monitoring the buffer filling, explicit time indication by inserting a time stamp in the CS-PDU, and handling of lost and misinserted cells that are recognized by the SAR. At the time of writing, the CS-PDU format has not been decided.

AAL Type 2. AAL Type 2 supports variable bit rate services with a timing relation between source and destination (class B). AAL Type 2 is nearly identical to AAL Type 1, except that it transfers service data units at a variable bit rate, not at a constant bit rate. Furthermore, AAL Type 2 accepts variable length CS-PDUs, and thus, there may exist some SAR-SDUs that are not completely filled with user data. The CS sublayer for AAL Type 2 performs the following functions: forward error correction for audio and video services, clock recovery by inserting a time stamp in the CS-PDU, and handling of lost and misinserted cells. At the time of writing, both the SAR-SDU and CS-PDU formats for AAL Type 2 are still under discussion.

AAL Type 3/4. AAL Type 3/4 mainly supports services that require no timing relation between the source and destination (classes C and D). At the SAR sublayer, it defines a 48-octet service data unit, with 44 octets of user payload; a 2-bit payload type field to indicate whether the SDU is at the beginning, middle, or end of a CS-PDU; a 4-bit cell sequence number; a 10-bit multiplexing identifier that allows several CS-PDUs to be multiplexed over a single VC; a 6-bit cell payload length indicator; and a 10-bit CRC code that covers the payload. The CS-PDU format allows for up to 65535 octets of user payload and contains a header and trailer to delineate the PDU.

The functions that AAL Type 3/4 performs include segmentation and reassembly of variable-length user data and error handling. It supports message mode (for framed data transfer) as well as streaming mode (for streamed data transfer). Because Type 3/4 is mainly intended for data services, it provides a retransmission mechanism if necessary.

ATM Signaling

ATM follows the principle of out-of-band signaling that was established for N-ISDN. In other words, signaling and data channels are separate. The main purposes of signaling are (1) to establish, maintain, and release ATM virtual connections and (2) to negotiate (or renegotiate) the traffic parameters of new (or existing) connections (7). The ATM signaling standards support the creation of point-to-point as well as multicast connections. Typically, certain VCI and VPI values are reserved by ATM networks for signaling messages. If additional signaling VCs are required, they may be established through the process of metasignaling.

ATM TRAFFIC CONTROL

The control of ATM traffic is complicated as a result of ATM's high-link speed and small cell size, the diverse service requirements of ATM applications, and the diverse characteristics of ATM traffic. Furthermore, the configuration and size of the ATM environment, either local or wide area, has a significant impact on the choice of traffic control mechanisms.

The factor that most complicates traffic control in ATM is its high-link speed. Typical ATM link speeds are 155.52 Mbit/s and 622.08 Mbit/s. At these high-link speeds, 53-byte ATM cells must be switched at rates greater than one cell per 2.726 μs or 0.682 μs, respectively. It is apparent that the cell processing required by traffic control must perform at speeds comparable to these cell-switching rates. Thus, traffic control should be simple and efficient, without excessive software processing.

Such high speeds render many traditional traffic control mechanisms inadequate for use in ATM because of their reactive nature. Traditional reactive traffic control mechanisms attempt to control network congestion by responding to it after it occurs and usually involves sending feedback to the source in the form of a choke packet. However, a large bandwidth-delay product (i.e., the amount of traffic that can be sent in a single propagation delay time) renders many reactive control schemes ineffective in high-speed networks. When a node receives feedback, it may have already transmitted a large amount of data. Consider a cross-continental 622 Mbit/s connection with a propagation delay of 20 ms (propagation-bandwidth product of 12.4 Mbit). If a node at one end of the connection experiences congestion and attempts to throttle the source at the other end by sending it a feedback packet, the source will already have transmitted over 12 Mb of information before feedback arrives. This example illustrates the ineffectiveness of traditional reactive traffic control mechanisms in high-speed networks and argues for novel mechanisms that take into account high propagation-bandwidth products.

Not only is traffic control complicated by high speeds, but it also is made more difficult by the diverse QoS requirements of ATM applications. For example, many applications have strict delay requirements and must be delivered within a specified amount of time. Other applications have strict loss requirements and must be delivered reliably without an inordinate amount of loss. Traffic controls must address the diverse requirements of such applications.

Another factor complicating traffic control in ATM networks is the diversity of ATM traffic characteristics. In ATM networks, continuous bit rate traffic is accompanied by bursty traffic. Bursty traffic generates cells at a peak rate for a very short period of time and then immediately becomes less active, generating fewer cells. To improve the efficiency of ATM network utilization, bursty calls should be allocated an amount of bandwidth that is less than their peak rate. This allows the network to multiplex more calls by taking advantage of the small probability that a large number of bursty calls will be simultaneously active. This type of multiplexing is referred to as statistical multiplexing. The problem then becomes one of determining how best to multiplex bursty calls statistically such that the number of cells dropped as a result of excessive burstiness is balanced with the number of bursty traffic streams allowed. Addressing the unique demands of bursty traffic is an important function of ATM traffic control.

For these reasons, many traffic control mechanisms developed for existing networks may not be applicable to ATM networks, and therefore novel forms of traffic control are required (8,9). One such class of novel mechanisms that work well in high-speed networks falls under the heading of preventive control mechanisms. Preventive control attempts to manage congestion by preventing it before it occurs. Preventive traffic control is targeted primarily at real-time traffic. Another class of traffic control mechanisms has been targeted toward non-real-time data traffic and relies on novel reactive feedback mechanisms.

Preventive Traffic Control

Preventive control for ATM has two major components: call admission control and usage parameter control (8). Admission control determines whether to accept or reject a new call at the time of call set-up. This decision is based on the traffic characteristics of the new call and the current network load. Usage parameter control enforces the traffic parameters of the call after it has been accepted into the network. This enforcement is necessary to ensure that the call's actual traffic flow conforms with that reported during call admission.

Before describing call admission and usage parameter control in more detail, it is important to first discuss the nature of multimedia traffic. Most ATM traffic belongs to one of two general classes of traffic: continuous traffic and bursty traffic. Sources of continuous traffic (e.g., constant bit rate video, voice without silence detection) are easily handled because their resource utilization is predictable and they can be deterministically multiplexed. However, bursty traffic (e.g., voice with silence detection, variable bit rate video) is characterized by its unpredictability, and this kind of traffic complicates preventive traffic control.

Burstiness is a parameter describing how densely or sparsely cell arrivals occur. There are a number of ways to express traffic burstiness, the most typical of which are the ratio of peak bit rate to average bit rate and the average burst length. Several other measures of burstiness have also been proposed (8). It is well known that burstiness plays a critical role in determining network performance, and thus, it is critical for traffic control mechanisms to reduce the negative impact of bursty traffic.

Call Admission Control. Call admission control is the process by which the network decides whether to accept or reject a new call. When a new call requests access to the network, it provides a set of traffic descriptors (e.g., peak rate, average rate, average burst length) and a set of quality of service requirements (e.g., acceptable cell loss rate, acceptable cell delay variance, acceptable delay). The network then determines, through signaling, if it has enough resources (e.g., bandwidth, buffer space) to support the new call's requirements. If it does, the call is immediately accepted and allowed to transmit data into the network. Otherwise it is rejected. Call admission control prevents network congestion by limiting the number of active connections in the network to a level where the network resources are adequate to maintain quality of service guarantees.

One of the most common ways for an ATM network to make a call admission decision is to use the call's traffic descriptors and quality of service requirements to predict the "equivalent bandwidth" required by the call. The equivalent bandwidth determines how many resources need to be reserved by the network to support the new call at its requested quality of service. For continuous, constant bit rate calls, determining the equivalent bandwidth is simple. It is merely equal to the peak bit rate of the call. For bursty connections, however, the process of determining the equivalent bandwidth should take into account such factors as a call's burstiness ratio (the ratio of peak bit rate to average bit rate), burst length, and burst interarrival time. The equivalent bandwidth for bursty connections must be chosen carefully to ameliorate congestion and cell loss while maximizing the number of connections that can be statistically multiplexed.

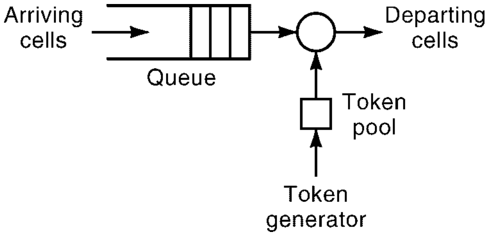

Figure 8. Leaky bucket mechanism.

Usage Parameter Control. Call admission control is responsible for admitting or rejecting new calls. However, call admission by itself is ineffective if the call does not transmit data according to the traffic parameters it provided. Users may intentionally or accidentally exceed the traffic parameters declared during call admission, thereby overloading the network. In order to prevent the network users from violating their traffic contracts and causing the network to enter a congested state, each call's traffic flow is monitored and, if necessary, restricted. This is the purpose of usage parameter control. (Usage parameter control is also commonly referred to as policing, bandwidth enforcement, or flow enforcement.)

To monitor a call's traffic efficiently, the usage parameter control function must be located as close as possible to the actual source of the traffic. An ideal usage parameter control mechanism should have the ability to detect parameter-violating cells, appear transparent to connections respecting their admission parameters, and rapidly respond to parameter violations. It should also be simple, fast, and cost effective to implement in hardware. To meet these requirements, several mechanisms have been proposed and implemented (8).

The leaky bucket mechanism (originally proposed in Ref. 10) is a typical usage parameter control mechanism used for ATM networks. It can simultaneously enforce the average bandwidth and the burst factor of a traffic source. One possible implementation of the leaky bucket mechanism is to control the traffic flow by means of tokens. A conceptual model for the leaky bucket mechanism is illustrated in Fig. 5.

In Fig. 8, an arriving cell first enters a queue. If the queue is full, cells are simply discarded. To enter the network, a cell must first obtain a token from the token pool; if there is no token, a cell must wait in the queue until a new token is generated. Tokens are generated at a fixed rate corresponding to the average bit rate declared during call admission. If the number of tokens in the token pool exceeds some predefined threshold value, token generation stops. This threshold value corresponds to the burstiness of the transmission declared at call admission time; for larger threshold values, a greater degree of burstiness is allowed. This method enforces the average input rate while allowing for a certain degree of burstiness.

One disadvantage of the leaky bucket mechanism is that the bandwidth enforcement introduced by the token pool is in effect even when the network load is light and there is no need for enforcement. Another disadvantage of the leaky bucket mechanism is that it may mistake nonviolating cells for violating cells. When traffic is bursty, a large number of cells may be generated in a short period of time, while conforming to the traffic parameters claimed at the time of call admission. In such situations, none of these cells should be considered violating cells. Yet in actual practice, leaky bucket may erroneously identify such cells as violations of admission parameters. A virtual leaky bucket mechanism (also referred to as a marking method) alleviates these disadvantages (11). In this mechanism, violating cells, rather than being discarded or buffered, are permitted to enter the network at a lower priority (CLP = 1). These violating cells are discarded only when they arrive at a congested node. If there are no congested nodes along the routes to their destinations, the violating cells are transmitted without being discarded. The virtual leaky bucket mechanism can easily be implemented using the leaky bucket method described earlier. When the queue length exceeds a threshold, cells are marked as "droppable" instead of being discarded. The virtual leaky bucket method not only allows the user to take advantage of a light network load but also allows a larger margin of error in determining the token pool parameters.

Reactive Traffic Control

Preventive control is appropriate for most types of ATM traffic. However, there are cases where reactive control is beneficial. For instance, reactive control is useful for service classes like ABR, which allow sources to use bandwidth not being used by calls in other service classes. Such a service would be impossible with preventive control because the amount of unused bandwidth in the network changes dynamically, and the sources can only be made aware of the amount through reactive feedback.

There are two major classes of reactive traffic control mechanisms: rate-based and credit-based (12,13). Most rate-based traffic control mechanisms establish a closed feedback loop in which the source periodically transmits special control cells, called resource management cells, to the destination (or destinations). The destination closes the feedback loop by returning the resource management cells to the source. As the feedback cells traverse the network, the intermediate switches examine their current congestion state and mark the feedback cells accordingly. When the source receives a returning feedback cell, it adjusts its rate, either by decreasing it in the case of network congestion or increasing it in the case of network underuse. An example of a rate-based ABR algorithm is the Enhanced Proportional Rate Control Algorithm (EPRCA), which was proposed, developed, and tested through the course of ATM Forum activities (12).

Credit-based mechanisms use link-by-link traffic control to eliminate loss and optimize use. Intermediate switches exchange resource management cells that contain "credits," which reflect the amount of buffer space available at the next downstream switch. A source cannot transmit a new data cell unless it has received at least one credit from its downstream neighbor. An example of a credit-based mechanism is the Quantum Flow Control (QFC) algorithm, developed by a consortium of reseachers and ATM equipment manufacturers (13).

HARDWARE SWITCH ARCHITECTURES FOR ATM NETWORKS

In ATM networks, information is segmented into fixed-length cells, and cells are asynchronously transmitted through the network. To match the transmission speed of the network links and to minimize the protocol processing overhead, ATM performs the switching of cells in hardware-switching fabrics, unlike traditional packet switching networks, where switching is largely performed in software.

A large number of designs has been proposed and implemented for ATM switches (14). Although many differences exist, ATM switch architectures can be broadly classified into two categories: asynchronous time division (ATD) and space-division architectures.

Asynchronous Time Division Switches

The ATD, or single path, architectures provide a single, multiplexed path through the ATM switch for all cells. Typically a bus or ring is used. Figure 9 shows the basic structure of the ATM switch proposed in (15). In Fig. 6, four input ports are connected to four output ports by a time-division multiplexing (TDM) bus. Each input port is allocated a fixed time slot on the TDM bus, and the bus is designated to operate at a speed equal to the sum of the incoming bit rates at all input ports. The TDM slot sizes are fixed and equal in length to the time it takes to transmit one ATM cell. Thus, during one TDM cycle, the four input ports can transfer four ATM cells to four output ports.

In ATD switches, the maximum throughput is determined by a single, multiplexed path. Switches with N input ports and N output ports must run at a rate N times faster than the transmission links. Therefore, the total throughput of ATD ATM switches is bounded by the current capabilities of device logic technology. Commercial examples of ATD switches are the Fore Systems ASX switch and Digital's VNswitch.

Space-Division Switches

To eliminate the single-path limitation and increase total throughput, space-division ATM switches implement multiple paths through switching fabrics. Most space-division switches are based on multistage interconnection networks, where small switching elements (usually 2 × 2 cross-point switches) are organized into stages and provide multiple paths through a switching fabric. Rather than being multiplexed onto a single path, ATM cells are space-switched through the fabric. Three typical types of space-division switches are described next.

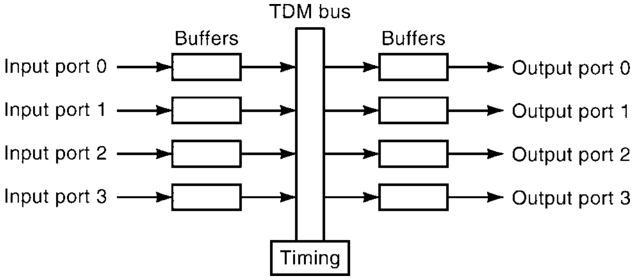

Figure 9. A 4 × 4 asynchronous time division switch.

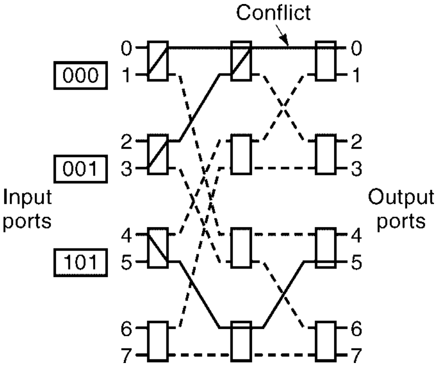

Figure 10. A 8 × 8 Banyan switch with binary switching elements.

Banyan Switches. Banyan switches are examples of space-division switches. An $N \times N$ Banyan switch is constructed by arranging a number of binary switching elements into several stages ($\log_2 N$ stages). Figure 10 depicts an 8 × 8 self-routing Banyan switch (14). The switch fabric is composed of twelve 2 × 2 switching elements assembled into three stages. From any of the eight input ports, it is possible to reach all the eight output ports. One desirable characteristic of the Banyan switch is that it is self-routing. Because each cross-point switch has only two output lines, only one bit is required to specify the correct output path. Very simply, if the desired output addresses of a ATM cell is stored in the cell header in binary code, routing decisions for the cell can be made at each cross-point switch by examining the appropriate bit of the destination address.

Although the Banyan switch is simple and possesses attractive features such as modularity, which makes it suitable for VLSI implementation, it also has some disadvantages. One of its disadvantages is that it is internally blocking. In other words, cells destined for different output ports may contend for a common link within the switch. This results in blocking all cells that wish to use that link, except for one. Hence, the Banyan switch is referred to as a blocking switch. In Fig. 10, three cells are shown arriving on input ports 1, 3, and 4 with destination port addresses of 0, 1, and 5, respectively. The cell destined for output port 0 and the cell destined for output port 1 end up contending for the link between the second and third stages. As a result, only one of them (the cell from input port 1 in this example) actually reaches its destination (output port 0), while the other is blocked.

Batcher–Banyan Switches. Another example of space-division switches is the Batcher–Banyan switch (14). (See Fig. 11.) It consists of two multistage interconnection networks: a Banyan self-routing network and a Batcher sorting network. In the Batcher–Banyan switch, the incoming cells first enter the sorting network, which takes the cells and sorts them into ascending order according to their output addresses. Cells then enter the Banyan network, which routes the cells to their correct output ports.

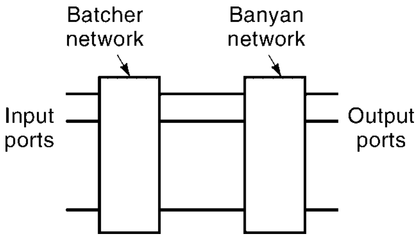

Figure 11. Batcher–Banyan switch.

As shown earlier, the Banyan switch is internally blocking. However, the Banyan switch possesses an interesting feature. Namely, internal blocking can be avoided if the cells arriving at the Banyan switch's input ports are sorted in ascending order by their destination addresses. The Batcher–Banyan switch takes advantage of this fact and uses the Batcher soring network to sort the cells, thereby making the Batcher–Banyan switch internally nonblocking. The Starlite switch, designed by Bellcore, is based on the Batcher–Banyan architecture (16).

Crossbar Switches. The crossbar switch interconnects N inputs and N outputs into a fully meshed topology; that is, there are N^2 cross points within the switch (14). (See Fig. 12.) Because it is always possible to establish a connection between any arbitrary input and output pair, internal blocking is impossible in a crossbar switch.

The architecture of the crossbar switch has some advantages. First, it uses a simple two-state cross-point switch (open and connected state), which is easy to implement. Second, the modularity of the switch design allows simple expansion. One can build a larger switch by simply adding more cross-point switches. Lastly, compared to Banyan-based switches, the crossbar switch design results in low transfer latency, because it has the smallest number of connecting points between input and output ports. One disadvantage to this design, however, is the fact that it uses the maximum number of cross points (cross-point switches) needed to implement an $N \times N$ switch.

The knockout switch by AT&T Bell Labs is a nonblocking switch based on the crossbar design (17,18). It has N inputs and N outputs and consists of a crossbar-based switch with a bus interface module at each output (Fig. 12).

Nonblocking Buffered Switches

Although some switches such as Batcher–Banyan and crossbar switches are internally nonblocking, two or more cells may still contend for the same output port in a nonblocking switch, resulting in the dropping of all but one cell. In order to prevent such loss, the buffering of cells by the switch is necessary. Figure 13 illustrates that buffers may be placed (1) in the inputs to the switch, (2) in the outputs to the switch, or (3) within the switching fabric itself, as a shared buffer (14). Some switches put buffers in both the input and output ports of a switch.

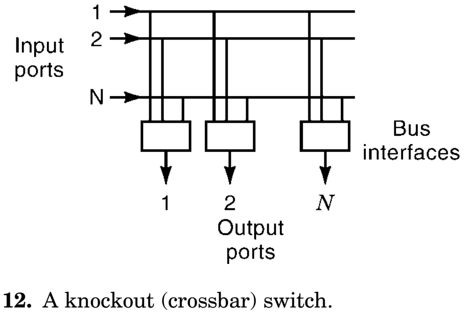

Figure 12. A knockout (crossbar) switch.

The first approach to eliminating output contention is to place buffers in the output ports of the switch (14). In the worst case, cells arriving simultaneously at all input ports can be destined for a single output port. To ensure that no cells are lost in this case, the cell transfer must be performed at N times the speed of the input links, and the switch must be able to write N cells into the output buffer during one cell transmission time. Examples of output buffered switches include the knockout switch by AT&T Bell Labs, the Siemens & Newbridge MainStreetXpress switches, the ATML's VIRATA switch, and Bay Networks' Lattis switch.

The second approach to buffering in ATM switches is to place the buffers in the input ports of the switch (14). Each input has a dedicated buffer, and cells that would otherwise be blocked at the output ports of the switch are stored in input buffers. Commercial examples of switches with input buffers as well as output buffers are IBM's 8285 Nways switches, and Cisco's Lightstream 2020 switches.

A third approach is to use a shared buffer within the switch fabric. In a shared buffer switch, there is no buffer at the input or output ports (14). Arriving cells are immediately injected into the switch. When output contention happens, the winning cell goes through the switch, while the losing cells are stored for later transmission in a shared buffer common to all of the input ports. Cells just arriving at the switch join buffered cells in competition for available outputs. Because more cells are available to select from, it is possible that fewer output ports will be idle when using the shared buffer scheme. Thus, the shared buffer switch can achieve high throughput. However, one drawback is that cells may be delivered out of sequence because cells that arrived more recently may win over buffered cells during contention (19). Another drawback is the increase in the number of input and output ports internal to the switch. The Starlite switch with trap by Bellcore is an example of the shared buffer switch architecture (16). Other examples of shared buffer switches include Cisco's Lightstream 1010 switches, IBM's Prizma switches, Hitachi's 5001 switches, and Lucent's ATM cell switches.

CONTINUING RESEARCH IN ATM NETWORKS

ATM is continuously evolving, and its attractive ability to support broadband integrated services with strict quality of service guarantees has motivated the integration of ATM and existing widely deployed networks. Recent additions to ATM research and technology include, but are not limited to, seamless integration with existing LANs [e.g., LAN emulation (20)], efficient support for traditional Internet IP networking [e.g., IP over ATM (21), IP switching (22)], and further development of flow and congestion control

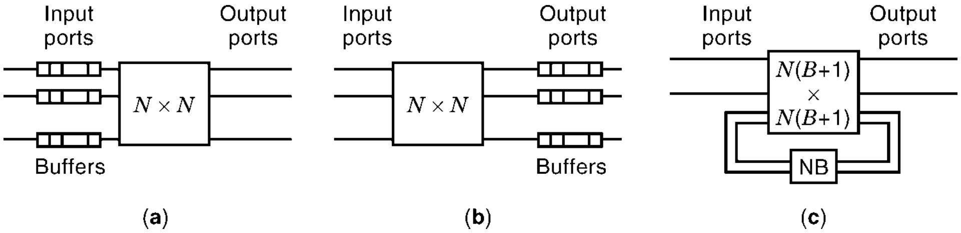

Figure 13. Nonblocking buffered switches.

algorithms to support existing data services [e.g., ABR flow control (12)]. Research on topics related to ATM networks is currently proceeding and will undoubtedly continue to proceed as the technology matures.

AIRCRAFT COMPUTERS

AIRCRAFT ANALOG COMPUTERS

Early aircraft computers were used to take continuous streams of inputs to provide flight assistance. Examples of aircraft analog inputs are fuel gauge readings, throttle settings, and altitude indicators. Landau (1) defines an analog computer as a computer for processing data represented by a continuous physical variable, such as electric current. Analog computers monitor these inputs and implement a predetermined service when some set of inputs calls for a flight control adjustment. For example, when fuel levels are below a certain point, the analog computer would read a low fuel level in the aircraft's main fuel tanks and would initiate the pumping of fuel from reserve tanks or the balancing of fuel between wing fuel tanks. Some of the first applications of analog computers to aircraft applications were for automatic pilot applications, where these analog machines took flight control inputs to hold altitude and course. The analog computers use operational amplifiers to build the functionality of summers, adders, subtracters, and integrators on the electric signals.

Aircraft Digital Computers

As the technologies used to build digital computers evolved, digital computers became smaller, lighter, and less power-hungry, and produced less heat. This improvement made them increasingly acceptable for aircraft applications. Digital computers are synonymous with stored-program computers. A stored-program computer has the flexibility of being able to accomplish multiple different tasks simply by changing the stored program. Analog computers are hard-wired to perform one and only one function. Analog computers' data, as defined earlier, are continuous physical variables. Analog computers may be able to recognize and process numerous physical variables, but each variable has its unique characteristics that must be handled during processing by the analog computer. The range of output values for the analog computer is bounded as a given voltage range; if they exceed this range, they saturate. Digital computers are not constrained by physical variables. All the inputs and outputs of the digital computer are in a digital representation. The processing logic and algorithms performed by the computer work in a single representation of the cumulative data. It is not uncommon to see aircraft applications that have analog-to-digital and digital-to-analog signal converters. This method is more efficient than having the conversions done within the computers. Analog signals to the digital computer are converted to digital format, where they are quickly processed digitally and returned to the analog device through a digital-to-analog converter as an analog output for that device to act upon. These digital computers are smaller, more powerful, and easier to integrate into multiple areas of aircraft applications.

Landau (1) defines a digital computer as a computer for processing data represented by discrete, localized physical signals, such as the presence or absence of an electric current. These signals are represented as a series of bits with word lengths of 16, 32, and 64 bits. See ***micro-computers*** for further discussion.

Wakerly (2) shows number systems and codes used to process binary digits in digital computers. Some important number systems used in digital computers are binary, octal, and hexadecimal numbers. He also shows conversion between these and base-10 numbers, as well as simple mathematical operations such as addition, subtraction, division, and multiplication. The American Standard Code for Information Interchange (ASCII) of the American National Standard Institute (ANSI) is also presented, which is Standard No. X3.4-1968 for numerals, symbols, characters, and control codes used in automatic data processing machines, including computers. Figure 1 shows a typical aircraft central computer.

Microcomputers

The improvements in size, speed, and cost through computer technologies continually implement new computer consumer products. Many of these products were unavailable to the average consumer until recently. These same breakthroughs provide enormous functional improvements in aircraft computing. Landau (1) defines microcomputers as very small, relatively inexpensive computers whose central processing unit (CPU) is a microprocessor. A microprocessor (also called MPU or central processing unit) communicates with other devices in the system through wires (or fiber optics) called lines. Each device has a unique address, represented in binary format, which the MPU recognizes. The number of lines is also the address size in bits. Early MPU machines had 8-bit addresses. Machines of 1970 to 1980 typically had 16-bit addresses; modern MPU machines have 256 bits.

Common terminology for an MPU is *random access memory* (RAM), *read only memory* (ROM), *input-output*, clock, and *interrupts*. RAM is volatile storage. It holds both data and instructions for the MPU. ROM may hold both instructions and data. The key point of ROM is that it is nonvolatile. Typically, in an MPU, there is no operational difference between RAM and ROM other than its volatility. Input-output is how data are transferred to and from the microcomputer. Output may be from the MPU, ROM, or RAM. Input may be from the MPU or the RAM. The clock of an MPU synchronizes the execution of the MPU instructions. Interrupts are inputs to the MPU that cause it to (temporarily) suspend one activity in order to perform a more important activity.

An important family of MPUs that greatly improved the performance of aircraft computers is the Motorola M6800 family of microcomputers. This family offered a series of

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

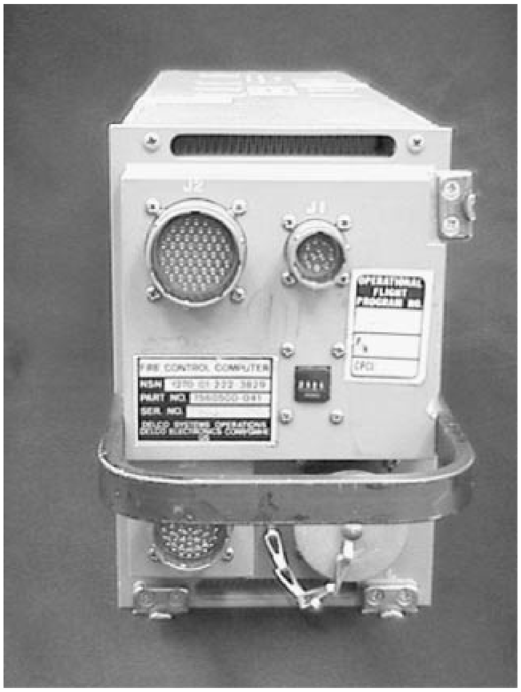

Figure 1. Typical aircraft central computer.

improvements in memory size, clock speeds, functionality, and overall computer performance.

Personal Computers

Landau (1) defines personal computers as electronic machines that can be owned and operated by individuals for home and business applications such as word processing, games, finance, and electronic communications. Hamacher et al. (3) explain that rapidly advancing very large-scale integrated circuit (VLSI) technology has resulted in dramatic reductions in the cost of computer hardware. The greatest impact has been in the area of small computing machines, where it has led to an expanding market for personal computers.

The idea of a personally owned computer is fairly new. The computational power available in handheld toys today was only available through large, costly computers in the late 1950s and early 1960s. Vendors such as Atari, Commodore, and Compaq made simple computer games household items. Performance improvements in memory, throughput, and processing power by companies such as IBM, Intel, and Apple made facilities such as spreadsheets for home budgets, automated tax programs, word processing, and three-dimensional virtual games common household items. The introduction of Microsoft's Disk Operating System (DOS) and Windows has also added to the acceptance of the personal computers through access to software applications. Improvements in computer technology offer continual improvements, often multiple times a year. The durability and portability of these computers is beginning to allow them to replace specialized aircraft computers that had strict weight, size, power, and functionality requirements.

AVIONICS

In the early years of aircraft flight, technological innovation was directed at improving flight performance through rapid design improvements in aircraft propulsion and airframes. Secondary development energies went to areas such as navigation, communication, munitions delivery, and target detection. The secondary functionality of aircraft evolved into the field of avionics. Avionics now provides greater overall performance and accounts for a greater share of aircraft lifecycle costs than either propulsion or airframe components.

Landau (1) defines avionics [avi(ation) + (electr)onics] as the branch of electronics dealing with the development and use of electronic equipment in aviation and astronautics. The field of avionics has evolved rapidly as electronics has improved all aspects of aircraft flight. New advances in these disciplines require avionics to control flight stability, which was traditionally the pilot's role.

Aircraft Antennas

An important aspect of avionics is receiving and transmitting electromagnetic signals. Antennas are devices for transmitting and receiving radio-frequency (RF) energy from other aircraft, space applications, or ground applications. Perry and Geppert (4) illustrate the aircraft electromagnetic spectrum, influenced by the placement and usage of numerous antennas on a commercial aircraft. Golden (5) illustrates simple antenna characteristics of dipole, horn, cavity-backed spiral, parabola, parabolic cylinder, and Cassegrain antennas.

Radiation pattern characteristics include elevation and azimuth. The typical antenna specifications are polarization, beam width, gain, bandwidth, and frequency limit.

Computers are becoming increasingly important for the new generation of antennas, which include phased-array antennas and smart-skin antennas. For phased-array antennas, computers are needed to configure the array elements to provide direction and range requirements between the radar pulses. Smart-skin antennas comprise the entire aircraft's exterior fuselage surface and wings. Computers are used to configure the portion of the aircraft surface needed for some sensor function. The computer also handles sensor function prioritization and deinterleaving of conflicting transmissions.

Aircraft Sensors

Sensors, the eyes and ears of an aircraft, are electronic devices for measuring external and internal environmental conditions. Sensors on aircraft include devices for sending and receiving RF energy. These types of sensors include radar, radio, and warning receivers. Another group of sensors are the infrared (IR) sensors, which include lasers and heat-sensitive sensors. Sensors are also used to measure direct analog inputs; altimeters and airspeed indicators are examples. Many of the sensors used on aircraft have their own built-in computers for serving their own functional requirements such as data preprocessing, filtering, and analysis. Sensors can also be part of a computer interface suite that provides key aircraft computers with the direct environmental inputs they need to function.

Aircraft Radar

Radar (radio detection and ranging) is a sensor that transmits RF energy to detect air and ground objects and determines parameters such as the range, velocity, and direction of these objects. The aircraft radar serves as its primary sensor. Several services are provided by modern aircraft radar, including tracking, mapping, scanning, and identification. Golden (5) states that radar is tasked either to detect the presence of a target or to determine its location. Depending on the function emphasized, a radar system might be classified as a search or tracking radar.

Stimson (6) describes the decibel (named after Alexander Graham Bell) as one of the most widely used terms in the design and description of radar systems. The decibel (dB) is a logarithmic unit originally devised to express power ratios, but also used to express a variety of other ratios. The power ratio in dB is expressed as 10 $\log_{10} P_2/P_1$, where P_2 and P_1 are the power levels being compared. Expressed in terms of voltage, the gain is $(V_2/V_1)^2$ dB provided the input voltage V_1 and output voltage V_2 are across equal resistances.

Stimson (6) also explains the concept of the pulse repetition frequency (PRF), which is the rate at which a radar system's pulses are transmitted: the number of pulses per second. The interpulse period T of a radar is given by $T = 1/\mathrm{PRF}$. For a PRF of 100 Hz, the interpulse period would be 0.01 s.

The Doppler Effect, as described by Stimson (6), is a shift in the frequency of a radiated wave, reflected or received by an object in motion. By sensing Doppler frequencies, radar not only can measure range rates, but can also separate target echoes from clutter, or can produce high-resolution ground maps. Computers are required by an aircraft radar to make numerous and timely calculations with the received radar data, and to configure the radar to meet the aircrew's needs.

Aircraft Data Fusion

Data fusion is a method for integrating data from multiple sources in order to give a comprehensive solution to a problem (multiple inputs, single output). For aircraft computers, data fusion specifically deals with integrating data from multiple sensors such as radar and infrared sensors. For example, in ground mapping, radar gives good surface parameters, whereas the infrared sensor provides the height and size of items in the surface area being investigated. The aircraft computer takes the best inputs from each sensor, provides a common reference frame to integrate these inputs, and returns a more comprehensive solution than either single sensor could have given.

Data fusion is becoming increasingly important as aircrafts' evolving functionality depends on off-board data (information) sources. New information such as weather, flight path re-routing, potential threats, target assignment, and enroute fuel availability are communicated to the aircraft from its command and control environment. The aircraft computer can now expand its own solution with these off-board sources.

Aircraft Navigation

Navigation is the science of determining present location, desired location, obstacles between these locations, and best courses to take to reach these locations. An interesting pioneer of aircraft navigation was James Harold Doolittle (1886–1993). Best known for his aircraft-carrier-based bomber raid on Tokyo in World War II, General Doolittle received his Master's and Doctor of Science degrees in aeronautics from Massachusetts Institute of Technology, where he developed instrumental *blind flying* in 1929. He made navigation history by taking off, flying a set course, and landing without seeing the ground. For a modern aircraft, with continuous changes in altitude, airspeed, and course, navigation is a challenge. Aircraft computers help meet this challenge by processing the multiple inputs and suggesting aircrew actions to maintain course, avoid collision and weather, conserve fuel, and suggest alternative flight solutions.

An important development in aircraft navigation is the Kalman filter. Welch and Bishop (7) state that in 1960, R.E. Kalman published his famous paper describing a recursive solution to the discrete-data linear filtering problem. Since that time, due in large part to advances in digital computing, the Kalman filter has been the subject of extensive research and application, particularly in the area of autonomous or assisted navigation. The Kalman filter is a set of mathematical equations that provides an efficient computational (recursive) implementation of the least-squares method. The filter is very powerful in several aspects: It supports estimation of past, present, and even future states, and it can do so even when the precise nature of the modeled system is unknown.

The global positioning system (GPS) is a satellite reference system that uses multiple satellite inputs to determine location. Many modern systems, including aircraft, are equipped with GPS receivers, which allow the system access to the network of GPS satellites and the GPS services. Depending on the quality and privileges of the GPS receiver, the system can have an instantaneous input of its current location, course, and speed within centimeters of accuracy. GPS receivers, another type of aircraft computer, can also be programmed to inform aircrews of services related to their flight plan.

Before the GPS receiver, the inertial navigation systems (INS) were the primary navigation system on aircraft. Fink and Christiansen (8) describe inertial navigation as the most widely used "self-contained" technology. In the case of an aircraft, the INS is contained within the aircraft, and is not dependent on outside inputs. Accelerometers constantly sense the vehicle's movements and convert them, by double integration, into distance traveled. To reduce errors caused by vehicle attitude, the accelerometers are mounted on a gyroscopically controlled stable platform.

Aircraft Communications

Communication technologies on aircraft are predominately radio communication. This technology allows aircrews to communicate with ground controllers and other aircraft. Aircraft computers help establish, secure, and amplify these important communication channels.

These communication technologies are becoming increasingly important as aircraft become interoperable. As the dependency of aircraft on interoperability increases, the requirements to provide better, more reliable, secure point-to-point aircraft communication also increases. The aircraft computer plays a significant role in meeting this challenge by formatting and regulating this increased flow of information.

Aircraft Displays

Displays are visual monitors in aircraft that present desired data to aircrews and passengers. Adam and Gibson (9) illustrate F-15E displays used in the Gulf War. These illustrations show heads-up displays (HUDs), vertical situation displays, radar warning receivers, and low-altitude navigation and targeting system (Lantirn) displays typical of modern fighter aircraft. Sweet (10) illustrates the displays of a Boeing 777, showing the digital bus interface to the flight-deck panels and an optical-fiber data distribution interface that meets industry standards.

Aircraft Instrumentation

Instrumentation of an aircraft means installing data collection and analysis equipment to collect information about the aircraft's performance. Instrumentation equipment includes various recorders for collecting real-time flight parameters such as position and airspeed. Instruments also capture flight control inputs, environmental parameters, and any anomalies encountered in flight test or in routine flight. One method of overcoming this limitation is to link flight instruments to ground recording systems, which are not limited in their data recording capacities. A key issue here is the bandwidth between the aircraft being tested and its ground (recording) station. This bandwidth is limited and places important limitations on what can be recorded. This type of data link is also limited to the range of the link, limiting the aircraft's range and altitude during this type of flight test. Aircraft computers are used both in processing the data as they are being collected on the aircraft and in analyzing the data after they have been collected.

Aircraft Embedded Information Systems

Embedded information system is the latest terminology for an embedded computer system. The software of the embedded computer system is now referred to as embedded information. The purpose of the aircraft embedded information system is to process flight inputs (such as sensor and flight control) into usable flight information for further flight system or aircrew use. The embedded information system is a good example of the merging of two camps of computer science applications. The first, and larger, camp is the management of information systems (MIS). The MIS dealt primarily with large volumes of information, with primary applications in business and banking. The timing requirements of processing these large information records are measured in minutes or hours. The second camp is the real-time embedded computer camp, which was concerned with processing a much smaller set of data, but in a very timely fashion. The real-time camp's timing requirement is in microseconds. These camps are now merging, because their requirements are converging. MIS increasingly needs real-time performance, while real-time systems are required to handle increased data processing workloads. The embedded information system addresses both needs.

Aircraft and the Year 2000

The year 2000 (Y2K) was a major concern for the aircraft computer industry. Many of the embedded computers on aircraft and aircraft support functions were vulnerable to Y2K faults because of their age. The basic problem with those computers was that a year was represented by its low-order two digits. Instead of the year having four digits, these computers saved processing power by using the last two digits of the calendar year. For example, 1999 is represented as 99, which is not a problem until you reach the year 2000, represented as 00. Even with this representation, problems are limited to those algorithms sensitive to calendar dates. An obvious problem is when an algorithm divides by the calendar date, which is division by 0. Division by 0 is an illegal computer operation, causing problems such as infinite loops, execution termination, and system failure. The most commonly mentioned issue is the subtraction of dates to determine time durations and to compare dates. The problem is not that the computer programs fail in a very obvious way (e.g., divide-by-zero check) but rather that the program computes an incorrect result without any warning or indication of error. Lefkon and Payne (11) discuss Y2K and how to make embedded computers Y2K-compliant.

Aircraft Application Program Interfaces

An application programming interface (API) is conventionally defined as an interface used by one program to make use of the services of another program. The human interface to a system is usually referred to as the user interface, or, less commonly, the human–computer interface. Application programs are software written to solve specific problems. For example, the embedded computer software that paints the artificial horizon on a heads-up display is an application program. A switch that turns the artificial horizon on or off is an API. Gal-Oz and Isaacs (12) discuss APIs and how to relieve bottlenecks of software debugging.

Aircraft Control

Landau (1) defines a control as an instrument or apparatus used to regulate a mechanism or a device used to adjust or control a system. There are two concepts with control. One is the act of control. The other is the type of device used to enact control. An example of an act of control is when a pilot initiates changes to throttle and stick settings to alter flight path. The devices of control, in this case, are the throttle and stick.

Control can be active or passive. Active control is force-sensitive. Passive control is displacement-sensitive.

Mechanical control is the use of mechanical devices, such as levers or cams, to regulate a system. The earliest form of mechanical flight control was wires or cables, used to activate ailerons and stabilizers through pilot stick and foot pedal movements. Today, hydraulic control, the use of fluids for activation, is typical. Aircraft control surfaces are connected to stick and foot pedals through hydraulic lines. Pistons in the control surfaces are pushed or pulled by associated similar pistons in the stick or foot pedal. The control surfaces move accordingly.

Electronic control is the use of electronic devices, such as motors or relays, to regulate a system. A motor is turned on by a switch, and it quickly changes control surfaces by pulling or pushing a lever on the surface. Automatic control is a system-initiated control, which is a system-initiated response to a known set of environmental conditions. Automatic control was used for early versions of automatic pilot systems, which tied flight control feedback systems to altitude and direction indicators. The pilot sets his desired course and altitude, which is maintained through the flight control's automatic feedback system.

To understand the need for computers in these control techniques, it is important to note the progression of the complexity of the techniques. The earliest techniques connected the pilot directly to his control surfaces. As the aircraft functionality increased, the pilot's workload also increased, requiring his (or his aircrew's) being free to perform other duties. Additionally, flight characteristics became more complex, requiring more frequent and instantaneous control adjustments. The use of computers helped offset and balance the increased workload in aircraft. The application of computers to flight control provides a means for processing and responding to multiple complex flight control requirements.

Aircraft Computer Hardware

For aircraft computers, hardware includes the processors, buses, and peripheral devices inputting to and outputting from the computers. Landau (1) defines hardware as apparatus used for controlling a spacecraft; the mechanical, magnetic, and electronic design, structure, and devices of a computer; and the electronic or mechanical equipment that uses cassettes, disks, and so on. The computers used on an aircraft are called *processors*. The processor takes inputs from peripheral devices and provides specific computational services for the aircraft.

There are many types and functions of processors on an aircraft. The most obvious processor is the central computer, also called the mission computer. The central computer provides direct control and display to the aircrew. The federated architecture (discussed in more detail later) is based on the central computer directing the scheduling and tasking of all the aircraft subsystems. Other noteworthy computers are the data processing and signal processing computers of the radar subsystem and the computer of the inertial navigation system. Processors are in almost every component of the aircraft. Through the use of an embedded processor, isolated components can perform independent functions as well as self-diagnostics.

Distributed processors offer improved aircraft performance and, in some cases, redundant processing capability. *Parallel* processors are two or more processors configured to increase processing power by sharing tasks. The workload of the shared processing activity is distributed among the pooled processors to decrease the time it takes to form solutions. Usually, one of the processors acts as the lead processor, or master, while the other processor(s) act as slave(s). The master processor schedules the tasking and integrates the final results, which is particularly useful on aircraft in that processors are distributed throughout the aircraft. Some of these computers can be configured to be parallel processors, offering improved performance and redundancy. Aircraft system redundancy is important because it allows distributed parallel processors to be reconfigured when there is a system failure. Reconfigurable computers are processors that can be reprogrammed to perform different functions and activities. Before computers, it was very difficult to modify systems to adapt to their changing requirements. A reconfigurable computer can be dynamically reprogrammed to handle a critical situation, and then it can be returned to its original configuration.

Aircraft Buses

Buses are links between computers (processors), sensors, and related subsystems for transferring data inputs and outputs. Fink and Christiansen (8) describe two primary buses as data buses and address buses. To complete the function of an MPU, a microprocessor must access memory and peripheral devices, which is accomplished by placing data on a bus, either an address bus or a data bus, depending on the function of the operation. The standard 16-bit microprocessor requires a 16-line parallel bus for each function. An alternative is to multiplex the address or data bus to reduce the number of pin connections. Common buses in aircraft are the Military Standard 1553 Bus (Mil-Std-1553) and the General-Purpose Interface Bus (GPIB), which is the IEEE Standard 488 Bus.

Aircraft Software

Landau (1) defines software as the programs, routines, and so on for a computer. The advent of software has provided great flexibility and adaptability to almost every aspect of life, which is especially true in all areas of aerospace sciences, where flight control, flight safety, in-flight entertainment, navigation, and communications are continuously being improved by software upgrades.

Operation Flight Programs. An operational flight program (OFP) is the software of an aircraft embedded computer system. An OFP is associated with an aircraft's primary flight processors, including the central computer, vertical and multiple display processors, data processors, signal processors, and warning receivers. Many OFPs in use today require dedicated software integrated support environments to upgrade and maintain them as the mission requirements of their parent aircraft are modified. The software integrated support environment [also called avionics integrated support environment (AISE), centralized software support activity (CSSA), and software integration laboratory (SIL)] not only allows an OFP to be updated and maintained, but also provides capabilities to perform unit testing, subsystem testing, and some of the integrated system testing.

Assembly Language. Assembly language is a machine (processor) language that represents inputs and outputs as digital data and that enables the machine to perform operations with those data. For a good understanding of the Motorola 6800 Assembler Language, refer to Bishop (13). According to Seidman and Flores (14), the *lowest-level* (closest to machine) language available to most computers is assembly language. When one writes a program in assembly code, alphanumeric characters are used instead of binary code. A special program called an assembler (provided with the machine) is designed to take the assembly statements and convert them to machine code. Assembly language is unique among programming languages in its one-to-one correspondence between the machine code statements produced by the assembler and the original assembly statements. In general, each line of assembly code assembles into one machine statement.

Higher-Order Languages. Higher-order languages (HOLs) are computer languages that facilitate human language structures to perform machine-level functions. Seidman and Flores (14) discuss the level of discourse of a programming language as its distance from the underlying properties of the machine on which it is implemented. A low-level language is close to the machine, and hence provides access to its facilities almost directly; a high-level language is far from the machine, and hence insulated from the machine's peculiarities. A language may provide both high-level and low-level constructs. Weakly typed languages are usually high-level, but often provide some way of calling low-level subroutines. Strongly typed languages are always high-level, and they provide means for defining entities that more closely match the real-world objects being modeled. Fortran is a low-level language that can be made to function as a high-level language by use of subroutines designed for the application. APL, Sobol, and SETL (a set-theoretic language) are high-level languages with fundamental data types that pervade their language. Pascal, Cobol, C, and PL/I are all relatively low-level languages, in which the correspondence between a program and the computations it causes to be executed is fairly obvious. Ada is an interesting example of a language with both low-level properties and high-level properties. Ada provides quite explicit mechanisms for specifying the layout of data structures in storage, for accessing particular machine locations, and even for communicating with machine interrupt routines, thus facilitating low-level requirements. Ada's strong typing qualities, however, also qualify it as a high-level language.

High-level languages have far more expressive power than low-level languages, and the modes of expression are well integrated into the language. One can write quite short programs that accomplish very complex operations. Gonzalez (15) developed an *Ada Programmer's Handbook* that presents the terminology of the HOL Ada and examples of its use. He also highlights some of the common programmer errors and examples of those errors. Sodhi (16) discusses the advantages of using Ada. Important discussions of software lifecycle engineering and maintenance are presented, and the concept of configuration management is presented.

The package concept is one of the most important developments to be found in modern programming languages, such as Ada, Modula-2, Turbo Pascal, C++, and Eiffel. The designers of the different languages have not agreed on what terms to use for this concept: Package, module, unit, and class are commonly used. It is generally agreed, however, that the package (as in Ada) is the essential programming tool to be used for going beyond the programming of very simple class exercises to what is generally called software engineering or building production systems. Packages and package-like mechanisms are important tools used in software engineering to produce production systems. Feldman (17) illustrates the use of Ada packages to solve problems.

Databases. Database are essential adjuncts to computer programming. Databases allow aircraft computer applications the ability to carry pertinent information (such as flight plans or navigation waypoints) into their missions, rather than generating them enroute. Databases also allow the aircrew to collect performance information about the aircraft's various subsystems, providing a capability to adjust the aircraft in flight and avoid system failures.

Elmasri and Navathe (18) define a database as a collection of related data. Data are described as known facts that can be recorded and have implicit meaning. A simple example consists of the names, telephone numbers, and addresses of an indexed address book. A database management system (DBMS) is a collection of programs that enable users to create and maintain a database. The DBMS is hence a general-purpose software system that facilitates the processes of defining, constructing, and manipulating databases for various applications.

Verification and Validation. A significant portion of the aircraft computer's lifecycle cost is system and software testing, performed in various combinations of unit-level, subsystem-level, integrated-system-level, developmental, and operational testing. These types of tests occur frequently throughout the life of an aircraft system because there are frequent upgrades and modifications to the aircraft and its various subsystems. It is possible to isolate acceptance testing to particular subsystems when minor changes are made, but this is the exception. Usually, any change made to a subsystem affects other multiple parts of the system. As aircraft become increasingly dependent on computers (which add complexity by the nature of their interdependences), and as their subsystems become increasingly integrated, the impact of change also increases drastically. Cook (19) shows that a promising technology to help understand the impact of aircraft computer change is the Advanced Avionics Verification and Validation (AAV&V) program developed by the Air Force Research Laboratory.

Sommerville (20) develops the concepts of program verification and validation. Verification involves checking that the program conforms to its specification. Validation involves checking that the program as implemented meets the expectations of the user.

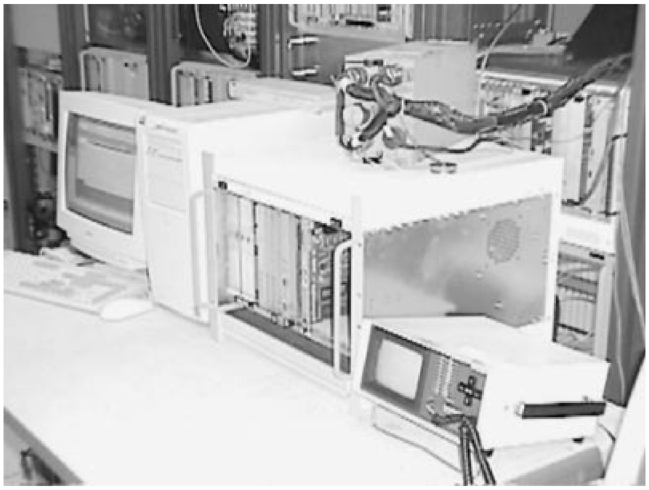

Figure 2. An aircraft avionics support bench.

Figure 2 shows an aircraft avionics support bench, which includes real components from the aircraft such as the FCC line replaceable unit (LRU) sitting on top of the pictured equipment. Additional equipment includes the buses, cooling, and power connection interfaces, along with monitoring and displays. On these types of benches, it is common to emulate system and subsystem responses with testing computers such as the single-board computers illustrated.

Figure 3 shows another verification and validation asset called the workstation-based support environment. This environment allows an integrated view of the aircraft's performance by providing simulations of the aircraft's controls and displays on computer workstations. The simulation is interfaced with stick and throttle controls, vertical situation displays, and touch-screen avionics switch panels.

Object-Oriented Technology. Object-oriented (OO) technology is one of the most popular computer topics of the 1990s. OO languages such as C++ and Ada 95 offer tremendous opportunities to capture complex representations of data and then save these representations in reusable objects. Instead of using several variables and interactions to describe some item or event, this same item or event is described as an object. The object contains its variables, control-flow representations, and data-flow representations. The object is a separable program unit, which can be reused, reengineered, and archived as a program unit. The power of this type of programming is that when large libraries of OO programming units are created, they can be called on to greatly reduce the workload of computer software programming. Gabel (21) says that OO technology lets an object (a software entity consisting of the data for an action and the associated action) be reused in different parts of the application, much as an engineered hardware product can use a standard type of resistor or microprocessor. Elmasri and Navathe (18) describe an OO database as an approach with the flexibility to handle complex requirements without being limited by the data types and query languages available in traditional database systems.

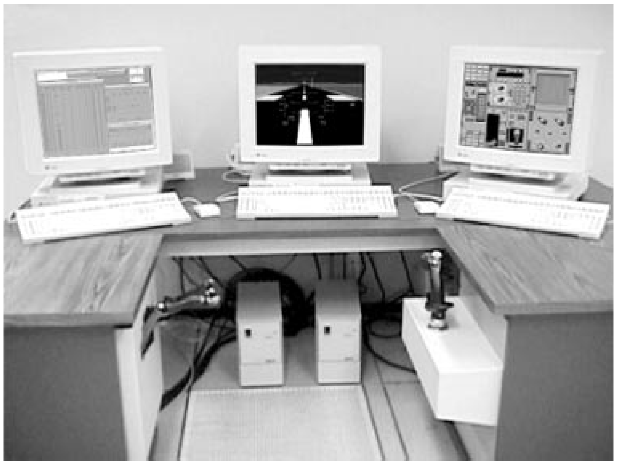

Figure 3. A workstation-based aircraft avionics support environment.

Open System Architecture. Open system architecture is a design methodology that keeps options for updating systems open by providing liberal interfacing standards. Ralston and Reilly (22) state that open architectures pertain primarily to personal computers. An open architecture is one that allows the installation of additional logic cards in the computer chassis beyond those used with the most primitive configuration of the system. The cards are inserted into slots in the computer's motherboard—the main logic board that holds its CPU and memory chips. A computer vendor that adopts such a design knows that, because the characteristics of the motherboard will be public knowledge, other vendors that wish to do so can design and market customized logic cards. Open system architectures are increasingly important in modern aircraft applications because of the constant need to upgrade these systems and use the latest technical innovations. It is extremely difficult to predict interconnection and growth requirements for next-generation aircraft, which is exactly what an open architecture attempts to avoid the need for.

Client-Server Systems. A client-server system is one in which one computer provides services to another computer on a network. Ralston and Reilly (22) describe the file-server approach as an example of client-server interaction. Clients executing on the local machine forward all file requests (e.g., open, close, read, write, and seek) to the remote file server. The server accepts a client's requests, performs its associated operation, and returns a response to the client. Indeed, if the client software is structured transparently, the client need not even be aware that files being accessed physically reside on machines located elsewhere on the network. Client-server systems are being applied on modern aircraft, where highly distributed resources and their aircrew and passenger services are networked to application computers.

Subsystems. The major subsystems of an aircraft are its airframe, power plant, avionics, landing gear, and controls. Landau (1) defines a subsystem as any system that is part of a larger system. Many of the subsystems on an aircraft have one or more processors associated with them. It is a complex task to isolate and test the assorted subsystems.

Another layer of testing below subsystem testing is *unit testing*. A *unit* of a subsystem performs a function for it. For example, in the radar subsystem, the units include its signal processor and its data processor. In order to test a system adequately, each of its lowest-level items (units) must be tested. As the units affect and depend on each other, another layer of testing addresses that layer of dependences. In the same fashion, subsystem testing is performed and integrated with associated subsystems. It is important to test not only at the unit and the subsystem level, but at the system and operational level. The system level is where the subsystems are brought together to offer the system functionality. *System integration* is the process of connecting subsystem components into greater levels of system functionality until the complete system is realized. The *operational level* of testing is where the subsystem is exercised in its actual use.

Line Replaceable Units. LRUs are subsystems or subsystem components that are self-contained in durable boxes containing interface connections for data, control, and power. Many LRUs also contain built-in test (BIT) capabilities that notify air and maintenance crews when a failure occurs. A powerful feature of LRUs is that functionality can be compartmentalized. When a failure is detected, the LRU can easily be pulled and replaced, restoring the aircraft to service within moments of detection.

Graceful Degradation. All systems must have plans to address partial or catastrophic failure. System failure in flight controls is often catastrophic, whereas system failure in avionics can be recovered from. For this reason, most flight-critical systems have built-in redundant capabilities (sometimes multiple layers of redundancy), which are automatically activated when the main system or subsystem fails. Degraded system behavior occurs when the main system fails and backup systems are activated. The critical nature of system failure requires immediate activation of backup systems and recognition by all related subsystems of the new state of operation. *Graceful degradation* is the capability of aircraft computers to continue operating after incurring system failure. Graceful degradation is less than optimal performance, and may activate several layers of decreasing performance before the system fails. The value of graceful degradation is that the aircrew has time to respond to the system failure before a catastrophic failure occurs.

AEROSPACE

Computer technologies have helped provide a continuum of improvements in aircraft performance that has allowed the airspace where aircraft operate to increase in range and altitude. Landau (1) defines aerospace as the Earth's atmosphere and the space outside it, considered as one continuous field. Because of its rapidly increasing domain of air and space travel, the U. S. Air Force is beginning to refer to itself as the U. S. Aerospace Force. Modern air-space vehicles are becoming increasingly dependent on information gleaned from ground stations, satellites, other air-space vehicles, and onboard sensors to perform their mission. These vehicles use signals across the electromagnetic spectrum. Antennas can be found in multiple locations on wings, the fuselage, tails, and draglines. If antennas are located too close together, their signals can interfere with each other, called crossed frequency transmission. This interference reduces the efficiency of each affected antenna. Placement of multiple antennas requires minimizing the effects of crossed frequency transmissions. Techniques for minimization include antenna placement, filtering, and timing, which presents another challenge for aircraft computers to sort and process these multiple signals. Perry and Geppert (4) show how the aircraft electromagnetic spectrum is becoming busy, and thus, dangerous for aerospace communications.

Legacy Systems

Legacy systems are fielded aircraft, or aircraft that are in active use. Probably the only nonlegacy aircraft are experimental or prototype versions. Legacy aircraft are often associated with aging issues, more commonly known as parts obsolescence. A growing problem in these systems is the obsolescence of entire components, including the many computers used on them. Aircraft, like many other systems, are designed with expected lifetimes of 10 to 15 years. Because of the high replacement costs, lifetimes are often doubled and tripled by rebuilding and updating the aircraft. To reduce costs, as many of the original aircraft components as possible are kept. Problems develop when these components are no longer produced or stockpiled. Sometimes, subsystems and their interfaces have to be completely redesigned and produced at great cost in order to keep an aircraft in service. System architectures and standard interfaces are constantly being modified to address these issues. Aircraft evolve during their lifetimes to a more open architecture. This open architecture, in turn, allows the aircraft components to be more easily replaced, thus making further evolution less expensive.

Unmanned Air Vehicles

Unmanned air vehicles (UAVs) are aircraft that are flown without aircrews. Their use is becoming increasingly popular for military applications. Many of the new capabilities of UAVs come from the improved computers. These computers allow the vehicles to have increased levels of autonomy and to perform missions that once required piloted aircraft. Some of these missions include reconnaissance and surveillance. These same types of missions are finding increasing commercial importance. UAVs offer tremendous advantages in lifecycle cost reductions because of their small size, ease of operation, and ability to be adapted to missions.

MAN–MACHINE SYSTEMS

An aircraft is an example of a man–machine system. Other examples are automobiles and boats. These machines have the common attribute of being driven by a human. Landau (1) defines man–machine systems as sets of manually performed and machine-performed functions, operated in conjunction to perform an operation. The aircraft computer is constantly changing the role of the human in the aircraft machine. The earliest aircraft required the constant attention of the pilot. Improved flight control devices allowed the pilot freedom for leisure or for other tasks. Modern aircraft computers have continued the trend of making the aircraft more the machine and less the man system.

Human Factors of Aircraft Computers

Human factors is the science of optimal conditions for human comfort and health in the human environment. The human factors of aircraft computers include the positioning of the controls and displays associated with the aircrew's workloads. They also provide monitoring and adjustment of the aircraft human environment, including temperature, oxygen level, and cabin pressure.

Man–Machine Interface

The *man–machine interface* is the place where man's interactions with the aircraft coordinate with the machine functionality of the aircraft. An example of a man–machine interface is the API, which is where a person provides inputs to and receives outputs from computers. These types of interfaces include keyboards (with standard ASCII character representation), mouse pads, dials, switches, and many varieties of monitors. A significant interface in aircraft comprises their associated controls and displays, which provide access to the flight controls, the sensor suite, the environmental conditions, and the aircraft diagnostics through the aircraft's central computer. Control sticks, buttons, switches, and displays are designed based on human standards and requirements such as seat height, lighting, accessibility, and ease of use.

Voice-Activated Systems. Voice-activated systems are interfaces to aircraft controls that recognize and respond to aircrew's verbal instructions. A voice-activated input provides multiple input possibilities beyond the limited capabilities of hands and feet. Voice-activated systems have specified sets of word commands and are trained to recognize a specific operator's voice.

Aircraft Computer Visual Verification

Visual verification is the process of physically verifying (through sight) the correct aircraft response to environmental stimuli. This visual verification is often a testing requirement. It is usually done through the acceptance test procedure (ATP) and visual inspections of displays through a checklist of system and subsystem inputs. Until recently, visual verification has been a requirement for pilots, who have desired the capability to see every possibility that their aircraft might encounter. This requirement is becoming increasingly difficult to implement because of the growing complexity and workload of the aircraft's computers and their associated controls and displays. In the late 1980s to early 1990s, it required about 2 weeks to visually verify the suite of an advanced fighter system's avionics. This verification can no longer be accomplished at all with current verification and validation techniques. Several months would be required to achieve some level of confidence that today's modern fighters are flight-safe.

Air Traffic Control

Air traffic control is the profession of monitoring and controlling aircraft traffic through an interconnected ground-based communication and radar system. Perry (23) describes the present capabilities and problems in air traffic control. He also discusses the future requirements for this very necessary public service. Air traffic controllers view sophisticated displays, which track multiple aircraft variables such as position, altitude, velocity, and heading. Air traffic control computers review these variables and give the controllers continuous knowledge of the status of each aircraft. These computers continuously update and display the aircraft in the ground-based radar range. When potential emergency situations, such as collision, develop, the computer highlights the involved aircraft on the displays, with plenty of lead time for the controller to correct each aircraft's position.

AIRCRAFT CONTROL AND COMPUTERS

D' Azzo and Houpis (24) give a good explanation of the complexity of what is needed for an aircraft control system. The feedback control system used to keep an airplane on a predetermined course or heading is necessary for the navigation of commercial airliners. Despite poor weather conditions and lack of visibility, the airplane must maintain a specified heading and altitude in order to reach its destination safely. In addition, in spite of rough air, the trip must be made as smooth and comfortable as possible for the passengers and crew. The problem is considerably complicated by the fact that the airplane has six degrees of freedom, which makes control more difficult than control of a ship, whose motion is limited to the surface of the water.

A flight controller is used to control aircraft motion. Two typical signals to the system are the correct flight path, which is set by the pilot, and the level position of the airplane. The ultimately controlled variable is the actual course and position of the airplane. The output of the control system, the controlled variable, is the aircraft heading.

In conventional aircraft, three primary control surfaces are used to control the physical three-dimensional attitude of the airplane: the elevators, the rudder, and the ailerons. A directional gyroscope (gyro) is used as the error-measuring device. Two gyros must be used to provide control of both heading and attitude of the airplane. The error that appears in the gyro as an angular displacement between the rotor and case is translated into a voltage by various methods, including the use of transducers such as potentiometers, synchros, transformers, or microsyns. Selection of the method used depends on the preference of the gyro manufacturer and the sensitivity required. Additional stabilization for the aircraft can be provided in the control system by rate feedback. In other words, in addition to the primary feedback, which is the position of the airplane, another signal proportional to the angular rate of rotation of the airplane around the vertical axis is fed back in order to achieve a stable response. A *rate gyro* is used to supply this signal. This additional stabilization may be absolutely necessary for some of the newer high-speed aircraft.

In reading through this example, it should be obvious that as the complexity of the control feedback system of the aircraft increases, a need for computer processing to evaluate the feedback and to adjust or recommend flight control adjustments exists. Additional feedback may come from global positioning, from ground-based navigation systems through radio inputs, and from other aircraft. The computer is able to integrate these inputs into the onboard flight control inputs and provide improved recommendations for stable flight.

REAL-TIME SYSTEMS

The computers on aircraft are required to perform their functions within short times. Flight control systems must make fine adjustments quickly in order to maintain stable flight. Sensor suites must detect and analyze potential threats before it is too late. Cabin pressure and oxygen must be regulated as altitude changes. All these activities, plus many others on aircraft, must happen in real time.

Nielsen (25) defines a real-time system as a controlled (by software or firmware) system that performs all of its process functions within specified time constraints. A real-time system usually includes a set of independent hardware devices that operate at widely differing speeds. These devices must be controlled so that the system as a whole is not dependent on the speed of the slowest device. Hatley and Pirbhai (26) describe timing as one of the most critical aspects of modern real-time systems. Often, the system's response must occur within milliseconds of a given input event, and every second it must respond to many such events in many different ways.

Flight-Critical Systems

Flight-critical systems are those activities of an aircraft that must be completed without error in order to maintain life and flight. The aircraft flight controls, engines, landing gear, and cabin environment are examples of flight-critical systems. Failures in any of these systems can have catastrophic results. Flight-critical systems are held to tight levels of performance expectations, and often have redundant backups in case of failure.

Federated Systems

Federated systems are loosely coupled distributed systems frequently used in aircraft system architectures to tie multiple processors in multiple subsystems together. The loose coupling allows the multiple subsystems to operate somewhat autonomously, but have the advantage of the shared resources of the other subsystems. A typical aircraft federated system might include its central computer, its INS, its radar system, and its air-vehicle management system. The INS provides the radar with the aircraft's present position, which is reported to the pilot through displays put forth by the central computer. The pilot adjusts his course through the air-vehicle management system, which is updated by the INS, and the cycle is repeated. These subsystems perform their individual functionality while providing services to each other.

Cyclic Executive

A *cyclic executive* on an aircraft computer provides a means to schedule and prioritize all the functions of the computer. The executive routine assigns the functions and operations to be performed by the computer. These assignments are given a specific amount of clock time to be performed. If the assignment does not complete its task in its allocated time, it is held in a wait state until its next clock period. From the beginning of the clock period to its end is one clock cycle. High-priority functions are assigned faster clock cycles, whereas low-priority functions are assigned slower cycles. For example, the high-priority executive function might be assigned a speed of 100 cycles per second, whereas some lower-priority function might have 5 cycles per second to complete its tasks. Sometimes, the latter might take several clock cycles to perform a task. An additional feature of cyclic executives is that they are equipped with interrupts, which allow higher-priority systems to break into the executive assignments for system-level assigned tasking.

There are several types of scheduling methodologies that provide performance improvements in cyclic executives. One of the more prominent is rate monotonic analysis (RMA), which determines the time requirement for each function and the spare time slots, and then makes time assignments.

THE NETWORK-CENTRIC AIRCRAFT

In the age of the World Wide Web (www), it is hard to imagine the concept of platform-centric systems, such as many of the aircraft that are in service today. These aircraft were built with the requirement to be self-sufficient, safe, and survivable. Dependency on off-board inputs was minimized as advanced avionics technologies allowed aircraft to assess and respond to their environment flight dynamics independently. These aircraft have been conceived, created, and maintained right up to this new information age. It takes significant effort to open the architectures of these aircraft, in order for their existing capabilities to be enhanced by outside information. Fortunately, the adaptability and flexibility of aircraft computers makes this process possible for many of these aircraft.

The modern aircraft (conceived, created, and maintained since the mid-1990s) is a network-centric aircraft. These aircraft take full advantage of the platform-centric systems with independent suites of avionics and aircraft computers. However, they have the additional ability to adapt to their environmental flight dynamics, which is possible because these systems have access to the most recent information about their environment. They can interactively communicate with other aircraft entering and leaving their environment, as well as take advantage of the information services available in that environment. The aircraft computers work very much the same as in the platform-centric aircraft, but with improved and broader information than was available before (27,28).

The network-centric aircraft can take full advantage of route changes caused by heavy air traffic, threats, or weather. It can send its systems self-diagnostics ahead to maintenance crews, who can have parts and resources available reducing the service re-cycling time of the aircraft. It can inform passengers and crew about their individual travel plans and the options available to them as they arrive at their destinations. It can help air traffic controllers and flight planners manage the dynamic workload of the many aircraft in service.

COMPUTERIZED DICTIONARIES: INTEGRATING PORTABLE DEVICES, TRANSLATION SOFTWARE, AND WEB DICTIONARIES TO MAXIMIZE LEARNING

BACKGROUND STUDIES ON BILINGUAL AND ELECTRONIC DICTIONARIES

Many articles comparing various types of dictionaries may be found in the first fully annotated bibliographic review of studies in this broad field of **lexicography** (the making of dictionaries, whether print or electronic), entitled *Pedagogical Lexicography Today* by Dolezal and McCreary (1), under either the *learner dictionary* category or under *traditional dictionaries* designed for native readers. Articles on learner dictionaries are grouped by their central focus, namely by whether they are mainly dealing with *bilingual* (giving first language or L1 translations), *bilingualized* (including both L1 and L2 information), or only *monolingual* (providing only English-to-English or other L2 to/from L2 definitions) explanations of target language (TL) vocabulary. Laufer and Kimmel (2) described patterns of use, comparing a particular dictionary's degree of accessibility versus difficulty for learners, finding that "Each learner was classified by his favorite look-up pattern...on the basis of these, we argue that the bilingualised dictionary is very effective as it is compatible with all types of individual preferences." (p. 361) (for more information on computerized dictionary writing systems, see http://nlp.fi.muni.cz/dws06/).

Lexical computing is a field of most concern to language teachers, computational linguists, and lexicographers involved in making dictionary writing systems (DWS), software for writing and producing a dictionary. It might include an editor, a database, a web interface, and various management tools (for allocating work, etc.), operating with a dictionary grammar, which specifies the internal structure of the dictionary. Robert Lew (3), whose dissertation provides a massive database for further research in this field, considered the receptive use of bilingual, monolingual, and semi-bilingual dictionaries by Polish learners of English, asking the most basic question for language teachers and dictionary designers (lexicographers) to consider, namely the question of which dictionary is best for whom? Other studies have compared the use of various types of glosses, such as "(paper, electronic textual, electronic pictorial, electronic, and video) on reading comprehension, translation, the number of words looked up, time-on-task and satisfaction of dictionary users. Others investigated incidental vocabulary learning via computer glosses, as reported by Laufer and Levitzky-Aviad (4). Loucky (5–8) compared Japanese college students' accessing speeds for portable devices with using software or mobile phone dictionaries.

Akbulut (9–11) compared the supposed advantage that adding various types of multimedia glossing might bring to language learners. Two crucial findings are well summarized in Chun (12): "...previous studies have found that L2 vocabulary is remembered better when learners look up picture or video glosses in addition to translations of unfamiliar words, but that when given the choice, learners tend to prefer and use the simple translation of words... In summary, research during the last ten years (1995–2005) has found that bilingual dictionaries and multimedia glosses have a more direct impact on vocabulary acquisition than on overall reading comprehension. ..." (pp. 78–81).

A history of lexicography and dictionary development in Japan may be found in Nakao's (13)*The State of Bilingual Lexicography in Japan: Learners' English-Japanese/ Japanese-English Dictionaries*. Other researchers who have examined the individual preferences, needs, and skills of dictionary users (both monolingual and bilingual) include Baxter (14), Tomaszczyk (15), Hartmann (16), Piotrowski (17), Atkins and Knowles (18), and Nuccorini (19). Hulstijn and Atkins (20) suggested that use of electronic dictionaries be studied more systematically. Laufer and Hill (21) examined how users' CALL dictionary look-up behaviors affected their retention. Those who design dictionaries for language learners, whether traditional text or electronic types of dictionaries, can gain much insight from more individualized, long-term studies done in countries where they have a consumer base.

Tomaszczyk (15), who first questioned foreign language learners regarding their preferences and dictionary usage, stated that the vast majority of his close to 450 Polish respondents "would like their dictionaries to give much more extensive treatment to every type of information... would like to have an omnibus dictionary which would cover everything anyone has ever thought of including in dictionaries and encyclopedias" (p. 115). Today, Internet search engines seem to do just that, but are often far too broad, especially for limited English proficiency (LEPs) learners to use efficiently. One solution to this problem is to use the writer's Virtual Language Learning Encyclopedia site at *www.CALL4ALL.us*. Providing instant links to most web dictionaries found on its Dictionaries (D) page <at http://www.call4all.us///home/_all.php?fi=d>, this site enables anyone to find vocabulary information for 500 language pairs systematically, by giving simultaneous instant free access to over 2500 online dictionaries. Moreover, this online multilingual dictionary portal now integrates the many functions of *Wordchamp.com's* versatile *Webreader* on each of its pages, thereby providing automatic glossing from English into over 100 languages for any website, including 40 online newspapers in 10 major languages.

Paper Versus Electronic Dictionaries

Electronic dictionaries are undoubtedly greatly gaining in popularity, so much so that they will soon dominate the

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

dictionary scene (22–26). Lew (3) noted these recent trends stating:

> It has been claimed that with the move from paper to online dictionaries, restrictions of space would disappear. That, however, is a simplification at best. While storage space may indeed become irrelevant, there are still severe restrictions as to how much information can be displayed at a time. In fact, even the best currently available display devices are still easily beaten by the old-fashioned printed paper in terms of visual resolution. So space-saving issues will still be with for at least as long as the visual modality is primarily used for information transfer from dictionary to user. . .on-screen presentation of entries has much to offer. . .to the researcher by way of convenience, including a potential to log responses automatically, thus obviating the need for the laborious paperwork and keyboarding at the data entry stage, as well as allowing "unobtrusive observation". (p. 157)

The equivalence of on-screen and paper formats should not be taken for granted, as Laufer (27) found significant and substantial differences in word recall scores between marginal paper glosses and on-screen pop-up window glosses.

DOING LEXICOGRAPHY IN AN ELECTRONIC AGE

Tono (28) predicted the advantages of online media using machine translation, saying "Electronic dictionaries have great potential for adjusting the user interface to users' skill level[s] so that learners with different needs and skills can access information in. . . different way[s]." (p. 216)

First of all, one must note that electronic dictionaries have developed based on a healthy integration of developments in **computerized corpus linguistics** and modern technology, used to enhance learning in many fields, particularly **computer-assisted language learning (or CALL)** or **computer-mediated communications (CMC).**

Laufer and Kimmel (2) provide a clear summary of this field, noting that

> If the consumer is to benefit from the lexicographer's product, the dictionary should be both useful and usable. We suggest a definition of dictionary usefulness as the extent to which a dictionary is helpful in providing the necessary information to its user. Dictionary usability, on the other hand, can be defined as the willingness on the part of the consumer to use the dictionary in question and his/her satisfaction from it. Studies of dictionary use by L2 learners . . . reveal that dictionary usefulness and dictionary usability do not necessarily go hand in hand. (pp. 361–362)

Laufer and Levitzky-Aviad's (4) study recommends working toward designing a bilingualized electronic dictionary (BED) more clear and useful for second language production. Whereas conventional bilingual L1-L2 dictionaries list translation options for L1 words without explaining differences between them or giving much information about how to use various functions, Laufer and Levitzky-Aviad (4) examined the usefulness of an electronic Hebrew-English-English (L1-L2-L2) minidictionary designed for production. Their results demonstrated the superiority of fully bilingualized L1-L2-L2 dictionaries and some unique advantages of the electronic format. Their literature review provides a good overview of this field:

> Surveys of dictionary use indicate that the majority of foreign language learners prefer bilingual L2-L1 dictionaries and use them mainly to find the meaning of unknown foreign (L2) words (Atkins 1985; Piotrowsky 1989). However, if learners writing in L2 need an L2 word designating a familiar L1 concept, they do not readily turn to an L1-L2 dictionary for help. The reason for this may lie in a serious limitation of most L1-L2 bilingual dictionaries. They rarely differentiate between the possible L2 translations of the L1 word, nor do they provide information regarding the use of each translation option. . . An electronic dictionary can fulfill the above requirements since it can combine the features of an L2-*L1bilingual dictionary*, an L1-L2 bilingual dictionary and an L2 monolingual dictionary. The advent of electronic dictionaries has already inspired research into their use and their usefulness as on-line helping tools and as contributors to incidental vocabulary learning. The built in log files can keep track of words looked up, type of dictionary information selected (definition, translation, example, etc.), the number of times each word was looked up, and the time spent on task completion. (pp. 1–2)

Although most electronic dictionaries do **auto-archiving** of any new words by means of their **history search function**, most online dictionaries do not have a means of tracking student use, except for programs like *Wordchamp.com* or *Rikai.com*, which give students a way to archive words they have double-clicked. These words may later be seen, printed, and reviewed. In fact, Wordchamp.com, by far the most sophisticated online electronic dictionary and vocabulary development program, allows users to make online flashcards with sentence examples and links to online texts where target words are found in context. It can also automatically generate about 10 types of online vocabulary quizzes and provides a free **course management system (CMS)** for monitoring students' work online. Wordchamp's Webreader provides the most versatile online glossing engine known, already for over 100 languages, with more being added regularly.

Teachers need to show learners how to best integrate the use of such portable and online dictionaries to make them maximally effective for their language development, in both receptive and productive aspects. Chun (12) noted that learners who could read online text with "access to both internally (instructor-created) glossed words as well as externally glossed words. . . recalled a significantly greater number of important ideas than when they read an online text and had access only to an external (portable electronic) dictionary" (p. 75).

Loucky (29) also examined how to best maximize L2 vocabulary development by using a depth of lexical processing (DLP) scale and vocabulary learning strategies (VLSs) taxonomy together with online CALL resources and systematic instruction in the use of such strategies. It used 40 of the 58 VLSs identified in Schmitt's earlier taxonomy. An electronic dictionary use survey (see Appendix) was designed to solicit information about how students used various computerized functions of electronic or online dictionaries at each major phase of lexical processing to help learners maximize processing in the following eight stages of vocabulary learning: (1) assessing degree of word knowledge, (2) accessing new word meanings, (3) archiving new information for study, (4) analyzing word parts and origins, (5) anchoring new words in short-term memory, (6) associating words in related groups for long-term retention, (7) activating words through productive written or oral use, and (8) reviewing/recycling and then retesting them. Portable devices or online programs that could monitor and guide learners in using these essential strategies should be further developed.

In Loucky's (7) findings, despite being one grade level higher in their proficiency, English majors were outperformed on all types of electronic dictionaries by Computer majors. The author concluded that familiarity with computerized equipment or computer literacy must have accounted for this, and therefore should be carefully considered when developing or using electronic dictionary programs of any sort for language or content learning. His study compared vocabulary learning rates of Japanese college freshmen and functions of 25 kinds of electronic dictionaries, charting advantages, disadvantages, and comments about the use of each (for details, see Loucky (7) Table 1 and Appendix 3; Loucky (8) Tables 1 and 2. For a comparative chart of six most popular EDs for English<->Japanese use, see www.wordtankcentral.com/compare.html).

Generally speaking, language learners prefer access to both first and second language information, and beginning to intermediate level learners are in need of both kinds of data, making monolingual dictionaries alone insufficient for their needs. As Laufer and Hadar (30) and others have shown the benefits of learners using fully bilingualized dictionaries, the important research question is to try to determine which kinds of electronic portable, software, or online dictionaries offer the best support for their needs. Grace (31) found that sentence-level translations should be included in dictionaries, as learners having these showed better short- and long-term retention of correct word meanings. This finding suggests a close relationship exists between processing new terms more deeply, verifying their meanings, and retaining them.

Loucky (32) has researched many electronic dictionaries and software programs, and more recently organized links to over 2500 web dictionaries, which are now all accessible from the site http://www.call4all.us///home/_all.php?fi=d. His aim was to find which kind of EDs could offer the most language learning benefits, considering such educational factors as: (1) better learning rates, (2) faster speed of access, (3) greater help in pronunciation and increased comprehensibility, (4) providing learner satisfaction with ease of use, or user-friendliness, and (5) complete enough meanings to be adequate for understanding various reading contexts.

As expected, among learners of a common major, more proficient students from four levels tested tended to use EDs of all types more often and at faster rates than less language-proficient students did. In brief, the author's studies and observations and those of others he has cited [e.g., Lew (3)] have repeatedly shown the clear benefits of using EDs for more rapid accessing of new target vocabulary. They also point out the need for further study of archiving, and other lexical processing steps to investigate the combined effect of how much computers can enhance overall lexical and language development when used more intelligently and systematically at each crucial stage of first or second language learning. Regular use of portable or online electronic dictionaries in a systematic way that uses these most essential phases of vocabulary acquisition certainly does seem to help stimulate vocabulary learning and retention, when combined with proper activation and recycling habits that maximize interactive use of the target language. A systematic taxonomy of vocabulary learning strategies (VLSs) incorporating a 10-phase set of specific recyclable strategies is given by Loucky (7,29) to help advance research and better maximize foreign language vocabulary development (available at http://www.call4all.us///home/_all.php?fi=../misc/forms).

A summary of Laufer and Levitzky-Aviad's (4) findings is useful for designers, sellers, and users of electronic dictionaries to keep in mind, as their study showed that: "the best dictionaries for L2 written production were the L1-L2-L2 dictionaries... Even though the scores received with the paper version of the L1-L2-L2 dictionary were just as good, the electronic dictionary was viewed more favorably than the paper alternative by more learners. Hence, in terms of usefulness together with user preference, the electronic version fared best" (p. 5). Such results should motivate CALL engineers and lexicographers to produce fully bilingualized electronic dictionaries (as well as print versions), specifically designed not merely to access receptive information to understand word meanings better, but also for L2 production, to practically enable students to actively use new terms appropriately as quickly as possible.

SURVEYING USE OF ELECTRONIC DICTIONARIES

To more thoroughly analyze and compare the types of dictionaries being used by Japanese college students in three college engineering classes, two kinds of surveys were designed by Loucky (29). The first was a general survey about purchase, use, and preferences regarding electronic dictionaries. The second survey (shown in the Appendix) asked questions about how various computerized functions were used at each major phase of lexical processing. The aim was to help learners maximize these eight essential phases of vocabulary learning: (1) assessing degree of word knowledge; (2) accessing new word meanings; (3) archiving new information for study; (4) analyzing word parts and origins; (5) anchoring new words in short-term memory; (6) associating words in related groups for long-term retention; (7) activating words through productive written or oral use; and (8) reviewing/recycling and re-testing them. After re-evaluating how well new words are learned by post-tests, any words not fully understood should be remet through planned re-encounters, retellings, and activities that encourage learners to repeat the vocabulary learning cycle again so that relearning and reactivation can take place.

Table 1. Comparative Chart of Some Translation Software[*]

Al Misbar Translation http://www.almisbar.com/salam_trans.html • Paid Subscription	1 Language Pair • English <-> Arabic
Amikai http://www.amikai.com/products/enterprise/ (under *Translation Demo*) • Free demo version (up to 100 characters) • Full version can be customized with dictionaries.	13 Language Pairs
Babel Fish http://babelfish.altavista.com/ • Can translate a web page or up to 150 words of text.	18 Language Pairs
Ectaco LingvoBit http://www.poltran.com/	1 Language Pair • English <-> Polish
Kielikone WebTranSmart https://websmart.kielikone.fi/eng/kirjaudu.asp • Registration Required • Per-word fee must be paid in advance for translations.	1 Language Pair • English <-> Finnish
ParsTranslator http://www.parstranslator.com/	1 Language Pair • English <-> Farsi
PROMT-Online http://translation2.paralink.com/	7 Language Pairs
Reverso http://www.reverso.net/text_translation.asp • Can translate text or web pages. • Special characters can be inserted onscreen.	5 Language Pairs
SDL Enterprise Translation Server http://www.sdl.com/enterprise-translation-server • Free demonstration (up to 200 words) • Can translate text or web pages. • Used by FreeTranslation.com	5 Language Pairs
SYSTRANBox http://www.systranbox.com/ • Can translate a web page or up to 150 words of text. • Used by AOL, Lycos, Terra, Google, Voila, Wanadoo, Free.fr, and others. • Check results with a human translator.	16 Language Pairs
SYSTRANet http://www.systranet.com/systran/net • More tools than SYSTRANsoft • More language pairs • Quality varies by language pair and subject matter. Check results with a human translator. • Must sign up for a password, but delivery of password is in seconds.	18 Language Pairs

SYSTRANSoft http://www.systransoft.com/ • Can translate a web page, a file (TXT, RTF, or HTML) or up to 150 words of text. • Quality varies by language pair and subject matter. Check results with a human translator.	15 Language Pairs
Tarjim (Registration Required) http://tarjim.ajeeb.com/	1 Language Pair • English > Arabic
Wordchamp.com http://wordchamp.com • Free to all.	Over 100 Language Pairs Instant Glossing; Auto-Archiving; Online Flashcard and Test Creation; Files can be shared internationally between distance learners, as well as internally within intact classes, using its currently free Course Management System (CMS).

*Free unless stated otherwise. Summarized from site by author.

The first survey described Japanese college students' preferences and reasons for purchasing EDs. The second showed self-reported use of PEDS and how their respective functions were seen to aid in different phases of L2 vocabulary learning. Students compared their use to that of print dictionaries. A majority of East Asian students surveyed expressed a preference for using mobile or online dictionaries rather than carry bulkier book dictionaries, although a few English students carry both. These ED preferences and patterns of use need more investigation, but probably hold true wherever the level of economic development is sufficient to support their purchase, as well as the use and availability of Internet access to online dictionary and Webreader glossing functions.

Kobayashi (33) compared the use of pocket electronic versus printed dictionaries to examine the effects of their use on LPSs used. The three major strategies she distinguished were consulting, inferring versus ignoring new terms. She found that "Pocket electronic dictionaries (PEDs) are rapidly becoming popular among L2 learners. Although many L2 learners depend on dictionaries, the prevalent view among L2 researchers and educators is that learners should use dictionaries sparsely. They encourage students to use another lexical processing strategy (LPS), contextual guessing, for better vocabulary learning and reading comprehension. [But] are dictionaries indeed so harmful?" (p. 2).

As some educators and researchers have been concerned about the pedagogical value of EDs because of their perceived limitations, such as insufficient information provided, the possibility of discouraging contextual guessing, and a supposed negative impact on word retention (34-38), these educators' and researchers' concerns require more investigation. So far, however, language learners' preference for them, and EDs' rapidly improving functions appear to be scuttling most of these previous claims. Although native readers have far larger working vocabularies to guess from context, most second language readers prefer and benefit greatly from having both monolingual and bilingual/mother tongue glosses available to them. Kobayashi (39) found that

1. More than two-thirds of the students owned a PED, and most of those who owned a PED exclusively used it regardless of purposes.
2. The PEDs owned by most students cost $100–$400, were of high quality, and did not have the disadvantages identified in other studies, such as brief definitions, the absence of examples, and inaccurate information.
3. Most students were satisfied with their PEDs, especially with their portability, and ease to look up a word, and ease to change from one dictionary to another.
4. The perceived disadvantages included the relative unavailability (or inaccessibility) of detailed usage information, examples, and grammatical information.
5. PEDs enabled students to use different types of dictionaries in different places.
6. Although both PED users and PD users depended on dictionaries, PED users used dictionaries more often. This was especially the case with smaller vocabulary size students.
7. PD users and PED users did not significantly differ in terms of their LPS use, except for the sheer frequency of dictionary consultation.
8. There was a possibility that PED users consulted dictionaries at the expense of contextual guessing.
9. Although students depended on dictionaries, whether PEDs or PDs, they also used guessing strategies frequently. They often used a dictionary to confirm guessed meaning. This was particularly the case with successful students.
10. Larger and smaller vocabulary size students differed in their use of LPSs such as basic dictionary use, extended dictionary use for meaning, extended dictionary use for usage, extended dictionary use for grammatical information, lookup strategies, note-taking strategies, guessing strategies using immediate context, guessing strategies using wider context, combined use of LPSs, and selective use of LPSs.
11. Higher and lower reading ability students differed in their use of LPSs such as basic dictionary use, extended dictionary use for meaning, extended dictionary use for usage, extended dictionary use for grammatical information, lookup strategies, self-initiation, note-taking strategies,

> guessing strategies using immediate context, guessing strategies using wider context, and selective use of LPSs (p.2).

SURVEYING AND MONITORING USE OF VOCABULARY LEARNING STRATEGIES

Vocabulary researchers such as Schmitt (40), Kudo (41), Orita (42), and Loucky (29) have examined more than 50 other effective vocabulary learning strategies, coming up with some useful taxonomies that makers of dictionaries should be aware of and seek to maximize in their design of electronic features and functions in particular. Language learners do appear to benefit greatly from specific strategy training in this essential area of language development (43).

Loucky (29) has presented useful surveys of CBDs or EDs presented in *CALICO Journal*. He also included many recommendations for how to properly integrate computerized lexicons, both portable and online, into CALL as effectively and enjoyably as possible. He explained a useful taxonomy of VLS for all designers and users of computerized dictionaries to help students maximize their learning of target language vocabulary. *CALL Journal* in December, 2005, highlighted the www.CALL4All.us website, showing how learners and teachers may use its extensive encyclopedia of preorganized online dictionaries and language learning links to produce more effective and enjoyable reading and vocabulary learning lessons. These tools include the use of online glossing engines and reading labs, word-surfing games, vocabulary profilers most useful for text analysis and simplification, readability analyzers, and so on.

State-of-the-Art Technical Features

Probably the company offering the largest variety of functions and types of computerized dictionaries for the most languages is Ectaco, whose U.K. site enables one to search for both type of software/platform and particular language pair combination sought. It can be accessed at http://www.ectaco.co.uk/how-find/. Their programs for handheld, portable devices may be found at http://www.ectaco.co.uk/Software-for-Pocket-PC/.

Electronic Dictionaries

Electronic dictionary and electronic translator handhelds are modern, lightweight, and fashionable gadgets with a great variety of features. An electronic translator or dictionary is becoming a definite must-have in many areas of business. More expensive devices are based on advanced speech recognition and text-to-speech technologies. Advanced models may include these useful functions: 1) a business organizer, 2) bidirectional, 3) voice recognition or synthesis, 4) extensive vocabularies (up to 1,000,000 words), 5) grammar references, and 6) phrase banks containing colloquial expressions and common phrases, irregular verbs, and more. Ectaco offers more than 70 titles for over 20 languages at: http://www.ectaco.co.uk/Electronic-Dictionaries/.

Translation Software

For example, Ectaco has devices featuring a wide range of software products, over 220 titles, translation tools, and learning aids for over 35 languages designed for all standard computer platforms, such as Windows, Pocket PC, and Palm OS. Many devices have tools for various language goals (e.g., text translators, accent removers, bidirectional talking dictionaries, localization tools, and language office tools), which include speaking and nonspeaking EOs, voice and travel language translators, handheld PDAs, and software bundles for Pocket PCs, Windows, Palm OS, and Cell phones.

Although some online dictionaries charge fees, a majority are now available for free use. Most of these are now organized at the author's www.CALL4ALL.us site, under Dictionaries Galore! http://www.call4all.us///home/_all.php?fi=d. Many examples of excellent translation software programs and portable, software, and online dictionaries can be seen and even ordered from these sites directly, or from those shown in Table 1.

1. http://www.ectaco.co.uk/how-find/ (Ectaco).
2. http://www.call4all.us///prod/_order.php?pp=2 (For language learning software, http://www. call4all.us///home/_all. php?fi=d links to most web dictionaries).
3. http://www.wor.com/shopping/ (World of Reading Language Learning Software).
4. http://speedanki.com/ (Speedanki.com offers Kanji Level Tests and flash cards to help one learn and review for national Japanese Proficiency Tests).
5. http://quinlanfaris.com/?cat=3 (Compares technical functions and differences between Seiko and Canon Wordtanks and the Seiko SR-E9000 PEDs).
6. http://flrc.mitre.org/Tools/reports/products_list.pl?LID=199# (Translation software and professional tools used for customized and specialized dictionary creations. Completeness of report is dependent on the completeness of the data entries and is expected to improve rapidly over time. Information is provided by each developer or vendor).
7. http://flrc.mitre.org/Tools/internetMT.pl * (These translation programs are intended for giving a general gist of meaning, not as a substitute for human translation. However, this site is the best quick view of machine translation options online, covering 13 online translation engines).

Computerized Dictionaries and Translation Software Programs Available

The most detailed and extensive table of translation software and computerized dictionary products may be found at the Foreign Language Resource Center's http://flrc.mitre.org/Tools/reports/products_list.pl?LID=202. Information provided by each developer or vendor at that site includes company, product names and version, and descriptions of languages and functions included. As about 75 companies are listed, only the list of companies providing these kinds of products will be listed here to make online searches possible. Computerized translation software companies include the following: ABLE Innovations, Alis Technologies; Acapela Group; Agfa Monotype Corporation; Al-Buraq; Arabeyes; Arabic OCR; arabsun.de; ARABVISTA; AramediA; Arava Institute for Environmental Studies; ATA Software Technology Limited; Alchemy Software Development; Abbyy Software House; Applications Technology; Ascender Corporation; Atril UK, Ltd.; Attensity Corporation; Basic Language Systems Corporation; Basis Technology; CACI, Inc.; Ciyasoft Corporation; CIMOS; Automatic Vocalization for Arabic; Automatic-Topic–Detection/ Abstract of Document; Compure, Computer & Language Technology; Ectaco; Galtech Soft, Ltd.; GlobalSight Corporation; International Systems Consultancy; IBM; Ice-LC Software; Idiom Technologies, Inc.; Jubilant Technologies, Inc.; Language Analysis Systems; Language Engineering Company; Language Weaver, Inc., LLC; Lingua; Linguist's Software; Lockheed-Martin; Marine Acoustics, Inc.–VoxTec; Paragon Software GmbH piXlogic; Postchi.com; Melingo, Ltd.; MetaTexis Software and Services; Microsoft Corporation; MultiCorpora R&D, Inc.; Nattiq Technologies; Nisus Software; NovoDynamics.com (Detects new application programming interface, API); Paragon Software; Sakhr Software Company; SDL International; SIL International Publishing Services; Smart Link Corporation; Tavultesoft Pty, Ltd.; Telelingua; THUNDERSTONE SOFTWARE; TM SYSTEMS; TRADOS Corporation; Transclick, Inc.; Translation Experts; translation.net; United Nations Educational, Scientific and Cultural Organization (UNESCO); United Nations; University of California, Davis; University of Maryland; U.S. Army Intel Center; Verity; WORDFAST; World Health Organization; WorldLanguage Resources; and Xerox–The Document Company.

Among the various types of advanced applications provided by innumerable types of software from these companies are multilingual translation; dictionaries; language learning applications and toolkits; speech recognition; information retrieval; multilingual word processing, spelling, and grammar; optical character recognition with easy insertion into Windows word processing; and web development and browsing.

Discussion and Pedagogical Implications

Common findings can now be summarized about electronic lexicons from a broad reading of research in the field by Kobayashi (33), Laufer and Hill (44), and Hill and Laufer (45), combined with the author's findings as follows:

1. PEDs facilitate L2 learning rather than hindering it. Regardless of whether they are using electronic or print dictionaries, successful students use effective lexical processing strategies. Moreover, PEDs facilitate dictionary use. Therefore, the use of PEDs should not be discouraged.
2. Rather than discouraging the use of PEDs, teachers could advise students to use a PED and a PD for different purposes.
3. Dictionary use and contextual guessing are not mutually exclusive. Successful learners use both dictionaries and contextual guessing more often than less successful learners. Dictionary use should not be frowned on for the reason that it hinders contextual guessing.
4. Many LPSs involving dictionary use and guessing are helpful for both vocabulary learning and reading. These strategies should be taught to students.
   a. Teachers should give students instruction in how to use a dictionary effectively, particularly how to look for a variety of information and what dictionaries are available.
   b. Guessing is also important for vocabulary learning and reading. Teachers should give students instruction in how to guess at word meaning using wider and immediate contexts.
   c. The ability to use a dictionary selectively is also important. Teachers should instruct students when to use a dictionary and when to turn to other LPSs.
5. Some strategies are more important for vocabulary learning than reading comprehension, and some strategies are more important for reading comprehension than for vocabulary learning. These strategies should be taught considering the desired skills and purposes of a reader or language learner (29,33).
6. Successful language learners tend to use a much wider variety of effective lexical and text processing strategies than do less proficient, unsuccessful learners, regardless of whether they use electronic or print dictionaries.
7. Teachers often observe that the more frequently EDs are used in a consistent manner with regular archiving and activation of new word information, and the more systematically new vocabulary is used and reviewed, that retention results are better.

Quality and amount of review techniques or media functions used by a learner largely determine both their *degree of retention* and *speed and percentage of retrieval* of new target terms and language forms. Reaction and retrieval times can be improved by giving *more recent and frequent encounters* with target terms, helping to reactivate them by building further memory traces. Along with recycling and review techniques to improve recognition and prediction skills, *reassessing of learning must be done regularly with frequent individual feedback to maximize motivation and acquisition*. CALL should capitalize on these language learning insights to design maximally efficient vocabulary learning programs for use both online and with portable devices.

When constructing or using online vocabulary learning programs, these same crucial vocabulary learning steps and strategies need to be encouraged by specific questions in text and functions used by the programs. There should also be a tracking or feedback mechanism to help teachers monitor learning, and to guide and prompt learners not to forget to do any of these essential phases of lexical processing.

GENERAL TRENDS AND FUTURE FRUITFUL RESEARCH AREAS

Major benefits of using portable devices include their mobility and instant archiving or storage in history memos for future useful quick review. Web dictionaries like those organized at the author's site, however, provide much more potential, as one can copy and paste between any of over 2000 online lexicons organized there for over 500 language pairs. www.CALL4ALL.us provides a "Virtual Rosetta Stone," not only of the full range of monolingual and multilingual web dictionaries, but also a vast language education links library for studying most of these languages as well.

Another main advantage of modern translation technology is that it is much more efficient. One saves a lot of time, as there is no more turning of book pages and searching for words endlessly. Words you are looking for are at your fingertips, just one click away. Each online dictionary has 400,000 entries, for example, in the case of Ectaco programs, and far more are freely available from web dictionaries organized at www.CALL4ALL.us's dictionaries page at http://www.call4all.us///home/_all.php?fi=d. Recommendations for integrating the use of web dictionaries with language learning programs online are given in Loucky (32). The 10 types of sites are organized to help teachers and students more efficiently combine the benefits of electronic and online dictionaries with CALL websites to produce more effective and enjoyable content and language learning lessons.

The general trends over the past 10 years have been for PEDs to become more prevalent because of their speedy access to language meanings, grammar data, collocations/ corpus examples, compact size, improved features, and convenience of use as well as economical pricing. Some feature as many as 32 lexicons or more, pronunciation support, Internet connectivity, review games, automatic history of searches for review, and so on. Translation software and CD-ROM dictionaries, being more expensive and limited to the location of one's PC, have not become as popular. Web and phone dictionaries appear to be the "tool of choice" of most students, as these functions are often provided at their schools or included in their cell phone services at little or no extra charge. Assistive reading pens made by *Quickionary* also offer promise to those who can afford them. They also seem to enhance learners' interest and motivation levels, and thus help to contribute to higher levels of vocabulary retention, although how to best do so online is a major question in need of further study. Some of the most promising online glossing programs being tested now can be recommended for further research in this area: 1) Wordchamp.com, 2) Rikai.com, 3) Wordsurfing.-com, and 4) Babelfish.com.

CONCLUSIONS AND RECOMMENDATIONS

To conclude, CALL and website e-learning developers need to remember that teachers need to be able to scale their language and vocabulary learning activities from those that require simpler and easier processing for lower level students, to activities that require deeper and more complex lexical processing for more advanced language learners using various kinds of EDs, both online and offline, whether stationary or mobile. It is also important for teachers to give more clear guidance about particular kinds of EDs, especially including good online programs for learning, to help maximize the use of their functions for education. We can only help maximize each program's effectiveness if students learn how to use their various functions as efficiently as possible to help them at each stage of processing new words outlined above. Further helpful guidelines and goals to examine when seeking to integrate new insights and innovations from CALL into the field of foreign language reading and vocabulary development are given by Sokmen (46). In her words, among the many areas in need of further systematic research in this field, "we need to take advantage of the possibilities inherent in computer-assisted learning, especially hypertext linking, and create software which is based on sound principles of vocabulary acquisition theory . . . programs which specialize on a useful corpus. . . provide. . .[for] expanded rehearsal, and engage the learner on deeper levels and in a variety of ways as they practice vocabulary. There is also the fairly unchartered world of the Internet as a source for meaningful activities for the classroom and for the independent learner" (p. 257).

In this way, using proven portable devices, multimedia translation software, and well-designed, interactive websites as much as possible, language learning can be made much more interesting and effective as these CALL resources are all used as tools for developing more balanced communication skills, which emphasize blending active production and interactive, content-based learning with authentic tasks and materials made much more accessible, comprehensible, and memorable with the help of modern technology. All in all, we can be quite optimistic about the future of EDs, as de Schryver (25) is. Listing 118 "lexicographers' dreams" in summarized tables, he masterfully "incorporates almost every speculation ever made about electronic dictionaries (EDs)" (p. 61) in Roby's terms (47).

Roby (47) further notes that not only technical hardware, but also human "fleshware" is the most crucial element when designing EDs, otherwise users may drown in a sea of data. One cannot drink efficiently from a fire hose. As he states, "Sophisticated software and huge hardware cannot guarantee the quality of an electronic dictionary. . . Good online dictionaries will be equipped with 'spigots' that allow users to draw manageable amounts of information. . . Information must be internalized for it to be considered knowledge." In the vast reaches of virtual e-learning cyberspace, one does indeed require a common gold standard compass, or better yet, a virtual Rosetta Stone for language learning, such as those helpful sites provided here.

As second language learners venture into "terra incognita" they do need clear maps and strategies to improve their navigation on various WebQuests for knowledge. Roby (47, p. 63) correctly asserts that "Dictionaries can be guides because they 'potentially intersect with every text of the language: in a sense all texts lead to the dictionary' (quoting Nathan). . . Learners can make forays into cyberspace with an electronic dictionary as a navigational [tool]. And in a real sense, one can expect to see portable, wireless dictionaries that will both allow physical mobility and afford Internet access." (In fact, most mobile phones and WiFi laptops already do).

Tailoring computerized dictionaries to effectively support learners' needs will require specific attention to their types, functions, and uses to best guide learners and teachers to most effective integration of these portable and online tools into language and science education. Research is showing us that all future EDs would do well to include preorganized categories of terms, searchable by topic and semantic field. Five examples of these already found online include: 1) UCREL's Semantic Analysis System located at http://www.comp.lancs.ac.uk/ucrel/usas/ with 21 major A–Z discourse fields; 2) Variation in English Words and Phrases (VIEW) at http://view.byu.edu/; 3) this writer's bilingualized Semantic Field Keyword Approach covering about 2000 intermediate to advanced terms in nine academic disciplines found at: http://www.call4all.us///misc/sfka.php; 4) ThinkMap's Visual Thesaurus at http://www.visualthesaurus.com/index.jsp?vt ; and 5) Wordnet found at http://wordnet.princeton.edu/. This writer's www.CALL4ALL.us site helps to integrate essential, common core vocabulary in many of these academic disciplines with most web dictionaries for 500 major world language pairs. For an overview, see its site map at (http://www.call4all.us///home/_all.php?fi=0) or see Loucky (32,48,49).

In the final analysis, probably what learners are guided to do with new terms will prove to be a more important learning factor than multimedia glossing and text concordancer options alone can provide. New technologies do indeed offer more powerful resources than ever before for independent or classroom study of languages. Word learning options will probably be best maximized when computing power is used to enhance learners' access to various types of EDs of high quality simultaneously in all fields, while likewise providing them with the means to auto-archive and organize new target vocabulary as they are shown how to actively use these new terms productively as soon as possible.

APPENDIX

Survey of Computerized Bilingual Dictionaries (27)

Name your Book Dictionary or Electronic/Computerized Bilingual Dictionary:

Model #: Cost:

NAME: ID/YEAR: Reading Level:

a. Grade:

b. Headwords:

c. %VLS Used:

d. DLP Level:

e. AVQ/IP:

Accessing & Archiving
Time: ___________minutes
(for 15 Laufer & Hadar terms)

1. **Assessing Vocabulary Size:**
   Check your manual to see how many words it has for
   a. English:
   b. Japanese—(or other L1):
   c. Kanji Study—
   d. How many words do you think you know in English?

2. **Accessing—Frequency of Use—How many times do you use it each day?**
   a. For English to Japanese what % of the time?
   b. For Japanese to English, what % of the time?
   c. To check unknown Kanji, what % of the time?

3. **Archiving—How do you record new words found?**
   a. In my textbook in the margins
   b. On paper or in a Vocabulary Notebook
   c. I don't record new words
   d. My CBD can record and save new words I've looked up. If so, tell how:
   e. Can it do Automatic Recording and Review (of last 1–20 words) (called a History Search)
   f. Can you save and store new words manually?
   g. Can you Save and Print Text Files or Notes on new words?

4. **Analyzing Special Functions or Features**—Does your CBD have any Special Functions or Features which help you to break up new words into parts to better understand their grammar, origins or meaning?
   If so, please try to explain how to use them and tell how often you do so. (Use Manual)
   Does it give special information about word parts, grammar, or the origin of words?
   Does it give any common phrases? _____Yes ______No ____Not Sure
   Does it give any sentence examples? ____Yes ____No ____Not Sure

5. **Anchoring New Words in Memory**—Does your Electronic Dictionary have any special Visual Images or Auditory Sounds or other special functions to help illustrate new word meanings, forms or use to help you better remember them? ___Yes _____No
   If so, tell what these special functions are and try to explain how they work to help you fix new words in your memory.

6. **Associating Functions—Does your Electronic Dictionary help you to organize your vocabulary learning in any way?**
   For example, can you put words into Study Groups?
   Do you organize your vocabulary learning or notebook in any special order or way to help you remember new words? Do you group any words together to better remember or learn them? If so, please tell how you do so.

If your computerized dictionary, translation website, or software helps you to do this in any way, please tell how:

7. **Activating Functions—Does your Electronic Dictionary give you any ways to USE new words right away?** ____Yes ____No If so, how?

Can you think of some ways ON YOUR OWN that you could USE new words you have looked up more actively or creatively? If so, tell how:

8. **Review: Do you review any new words after finding their meanings?**

____No ____Sometimes ____Yes, usually If so, tell how does your Electronic Dictionary help you to review or retest new words? Does your ED/CBD have any Vocabulary Practice Games that you can use for review and practice? If so describe. If it had, what level would you start to study at?

Does your CBD have any Special Functions or Features which help you study new words, such as challenge games, memos, word search history, and so on to help you learn, analyze, review or remember new words? ____Yes _____No _____Not Sure If so, please explain how to use them:

ELECTRONIC WARFARE

INTRODUCTION

Over the last century, there has been a burgeoning use of the electromagnetic (EM) spectrum for military purposes, including those related to communications, navigation, and targeting.

This dependence is embedded in many modern warfare doctrines and technologies, such as:

- Revolution in military affairs;
- Network-centric warfare;
- Information warfare;
- Rapid decisive operations;
- Intelligence, surveillance, target acquisition, and reconnaissance;
- Precision guided weapons.

Given the importance of the EM environment to military operations, there is obvious reason for safeguarding its use by friendly forces, denying its use by enemy forces, and defeating enemy efforts to achieve the same objectives. Electronic warfare (EW) encompasses the broad and somewhat ill-defined mix of military tactics, techniques, procedures, technology, and organizational structures that address these concerns (1, 2). It is also related to some civilian technologies and applications, which include spectrum monitoring and radio astronomy.

Historical experience has repeatedly demonstrated the importance of EW as highlighted by an extensive body of declassified information that pertains to operations by both sides in World War II (WW2)(3–5), and by more recent accounts concerning the Korean, Vietnam, Six-Day and Yom Kippur Wars, and the campaigns in the Falklands, Lebanon, Kosovo, Chechnya, and Iraq (6–11).

EW continues to be widely recognized as a powerful force multiplier, and the development and application of EW concepts and technologies consequently remains a high priority (12,13). For the greatest effect, its use is regulated by planning structures that tailor it to situational requirements and procedures intended to deny the enemy as much knowledge as possible relating to its specific capabilities and deployment structures. For this reason, many aspects of EW are highly classified.

Formally, the roles of EW are subdivided into:

1. Electronic support (ES) - taking advantage of signals emitted by an opponent's systems;
2. Electronic attack (EA) - degrading the ability of an opponent to use his systems;
3. Electronic protection (EP) - safeguarding the effective operation of friendly force electronic systems against enemy EA and ES activities.

The following article presents a breakdown of EW in this order, with attention given to both technical system concepts and relevant operational doctrine.

ELECTRONIC SUPPORT

ES, which is also known as electronic support measures, concerns the sensing of communication, radar, and other electromagnetic signals of potential interest. ES sensors perform the following technical functions:

1. Signal detection - determining the presence of a signal;
2. Signal classification - associating the signal with a type of modulation or function;
3. Signal parameter and feature extraction - measuring various signal parameters; such as carrier frequency, power, transmission start and end times, and bandwidth;
4. Emitter identification - determining the type of system that the signal is associated with;
5. Signal intercept - recovering the message content from communication signals;
6. EW analysis - inferring the organization and structure of enemy networks, dispositions of forces and operational intent from communications traffic patterns and message content;
7. Geo-location - determining the positions of signal emitters.

Several points concerning ES deserve emphasis. First, its passive nature has the great advantage that valuable intelligence can be produced without an adversary being aware. Second, the mere suspicion of its use can cause an adversary to restrict its use of communication systems and active sensors, which thereby reduces their operational value. Finally, radar ES systems often can detect a radar transmitter at ranges considerably in excess of the useful range of the radar (14).

The organization and processing of information provided by ES sensors is a complex problem. Much value of ES sensor outputs can be lost if information does not reach the appropriate commanders and other potential users in a timely way. Complicating factors include the volume of information, the difficulty of interpreting it, and the need to protect sensitive information concerning ES capabilities. The last point is a very real concern. During WW2, the decryption of German communication signals coded with the Enigma cipher provided immensely valuable intelligence to the British. Accordingly, every effort was made to avoid arousing suspicions that the Enigma cipher was anything other than unbreakable. For example, reconnaissance aircraft would be dispatched to "find" an important convoy whose orders had in fact been revealed by the

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

decryption of Enigma messages, which thereby gave the impression that the attack that followed was the direct result of routine aerial reconnaissance (5).

The diversity of the roles performed by ES systems has resulted in a significant degree of specialization in the design of the systems themselves and their organization and control.

Tactical ES

Tactical ES is the deployment of an ES capability in direct support of field operations. It typically resides within some form of dedicated EW unit that may be either part of the maneuver force's echelon or assigned to support it under an operational (OPCON) or tactical (TACON) command and control relationship. Examples of tactical ES are found in land, air, and sea operational environments, where objectives include:

1. The intercept, direction finding, and analysis of battlefield communications signals by ground-based assets to determine the composition and geographical distribution of enemy forces and the immediate intentions of its elements, from fighter to commander. When ES is performed by an EW unit native to the maneuver force, "intentions and warnings" tip-offs are reported directly to field unit commanders and their staff. The unit may also acquire and disseminate intelligence for consumption strictly within Signals Intelligence (SIGINT) channels (see below) and generate technical information for internal process refinement;
2. The detection and direction finding of battlefield surveillance radars by ground-based radar ES;
3. The detection and analysis by a radar warning receiver (RWR) of radar signals associated with enemy target acquisition, tracking, and fire control systems, to provide aircraft pilots with situational awareness and warnings of threats. This information is essential for the timely initiation of suitable countermeasures, which may include a combination of EA and evasive maneuvers;
4. A general surveillance capability by a warship's radar ES systems to track military, merchant, or clandestine ships and fishing vessels using the signals received from their navigation radars. These systems also support self-protection functions against radars associated with threat weapon systems. On larger platforms, there are usually more provisions for analyzing ES information, fusing it with other intelligence, and distributing it to other platforms, channels and organizations (including SIGINT).

The capability to geo-locate transmitters associated with communication, navigation, and radar systems is particularly important; even approximate indications of the direction of an enemy position or platform provided by direction finding (DF) are valuable from a situational-awareness perspective. Estimates of the positions of individual emitters can be determined by obtaining lines-of-bearing from spatially separated sites and solving for the positions where they intersect. Geo-location is particularly important for communication signals when the message content cannot be extracted because of encryption or other techniques. Appendix 1 provides an overview of various DF techniques that can be used for the geo-location of signal sources by ES systems.

An additional EW analysis (EWA) capability is often associated with units that deploy ES assets. EWA is a military intelligence function that specializes in drawing operational inferences from EW data. Its main purpose is to determine the enemy's "electronic order of battle," which is a comprehensive representation of its electronics systems, including their identification, geographical disposition, and where possible the association of this equipment with specific units within a command-control structure. An EWA cell may also be responsible for maintaining communication target lists and selecting information for dissemination to Intelligence organizations.

Tactical communications ES is a particularly challenging problem in urban environments. Multipath propagation effects can be expected to degrade the accuracy of radio-frequency direction-finding systems. Furthermore, opposition forces can be expected to make use of the civilian communications infrastructure, which results in a requirement to sift rapidly through a large amount of communications traffic to find the signals of interest.

Signals Intelligence

SIGINT is the strategic application of ES performed under the control of national intelligence organizations, such as the National Security Agency in the U.S., and the Government Communication Headquarters in the U.K. The term relates variously to the type of information produced, the systems used to produce it, and to the community that controls the ES systems and the analysis and distribution of their products. SIGINT "products" are disseminated via highly classified channels and, except in exceptional circumstances, are released only for use in the wider national or Military Intelligence communities after being "sanitized" of any distinguishing elements that could reveal the source. On the battlefield, there may be some overlap between SIGINT and tactical ES activities and platforms, with EW units sometimes tasked to serve both functions simultaneously.

SIGINT comprises communications intelligence (COMINT) and electronic intelligence (ELINT). COMINT is concerned with the message content of communication signals, information about communication traffic patterns, and the locations of the associated transmitters, with a strong emphasis on determining higher-level or "strategic" command and control structures. ELINT is the collection of technical or "parametric" information about the radar and other noncommunications equipment (15).

ELINT has several important uses. First, theoretical analysis of the signal parameters allows inferences to be drawn about the functions, capabilities, and limitations of the systems associated with the signals, and hence, more broadly, about enemy early warning or targeting capabilities. Second, ELINT data are used to construct emitter libraries or databases that are fundamental to EA and EP operations. For each known type of radar, information is collected on the signal parameters for the various operating modes, the estimated radar performance, its intended function(s), and the platforms the radar is known to be installed on. An ES system on a ship or tactical aircraft correlates the parameters of observed signals with the database entries to identify the radar systems that transmitted them, and, if an observed signal is associated with a threat, it provides the information needed to select and execute the most appropriate countermeasures.

SIGINT operations often involve the use of specialized equipment deployed on either dedicated or multiuse platforms, which include satellites, ships, and aircraft. During the Cold War, suitable types of aircraft were extensively modified to perform SIGINT. By operating at altitudes of 10 km or higher, useful ranges could be extended to hundreds of km for the intercept of microwave radar signals. Consequently, intelligence could be acquired from aircraft flying at the periphery of the Soviet defense perimeter. For a period, specialized high-altitude aircraft could even conduct operations over Soviet territory by flying above the effective ceiling of interceptor aircraft and ground based antiaircraft weapons. After improved Soviet antiaircraft defenses made overflights impractical, the West hurriedly deployed satellite-based systems (16).

In recent years, much interest has been aroused by the idea of integrating ES information derived at different levels (tactical, operational, and strategic) by EW and SIGINT units with similar objectives, but possibly different reporting mechanisms. For instance, modern strategies for Netcentric Warfare involve the accumulation of various kinds of data and intelligence at a central point where it can be fused to produce more complete assessments. However, many practical challenges exist in reconciling technical possibilities with doctrine. Complicating factors and risks involved with centralized analysis schemes include:

1. The quantity of data generated by advanced ES systems may tax the analysis systems that must sort through it;
2. Delays in the reporting chain, where key information may take longer to reach its ultimate destination after passing through a central accumulation point;
3. The expense and complexity of deploying communication systems with adequate bandwidth;
4. Standardization issues for technical interfaces, and the complexity of both designing and maintaining interfaces for systems that were originally designed for different purposes and may be based on widely differing technologies;
5. Complications that affect the handling and distribution of information resulting from classification issues and, in the case of multinational environments, the willingness of individual nations to declare and release their information to others;
6. The risks of commanders relying too heavily on the formation of a “complete intelligence picture” in lieu of trusting their judgment and intuition, which can lead to decision paralysis.

ES System Technologies and Implementation

ES systems are typically comprised of antenna, receiver, and processing sub-systems. Early ES systems were often improvisations based on civilian equipment. For example, receivers developed for radio amateurs had relatively good sensitivity and frequency coverage and were widely used by the Allies during WW2. The National HRO, which had excellent frequency resolution, was used to intercept communication signals in the medium and high frequency bands. The Hallicrafters S-27, which provided contiguous coverage in the lower portion of the very high frequency (VHF) band, was widely used to receive signals associated with German VHF radar, air-to-air communication, and bombing navigation systems. These receivers, although useful, had significant limitations. Their frequency coverage was limited, and their effectiveness was heavily dependent on the training and skill of the operators.

The continued evolution of the technologies used by communication and radar systems has contributed to the development of specialized ES receivers. A fundamental issue concerns the differences in the waveforms used by communication and radar signals.

Most communication systems transmit a continuous or near-continuous narrow bandwidth signal during the transmission of a message. A primary goal is to make efficient use of bandwidth to transmit information, which thereby allows the available radio frequency bands to be divided between many users. Communication signals have continued to evolve:

1. The bandwidth and channel spacing associated with conventional narrowband signals has decreased because of developments in more efficient modulation formats and accurate frequency references and synthesizers;
2. Digital modulation techniques are being increasingly used to transmit information in the form of binary data;
3. Time division multiplexing access techniques are being used by some systems, such as those based on the GSM cell phone standard, to provide a way of time sharing bandwidth between multiple users;
4. Classes of spread-spectrum techniques are being used in some military and civilian communication systems. Frequency hopping (FH) systems superpose periodic changes on the center frequency of a transmitted signal following a predetermined sequence. These changes typically occur at rates that are tens or hundreds of times per second. The portion of a transmission that corresponds to a dwell at a single frequency is often referred to as a hop. To minimize interference between FH communication systems, careful coordination is needed in the assignment of hop frequencies and/or the codes that define the hop sequences. Direct sequence spread spectrum (DSSS) uses a different approach. In the basic form, a pseudo-random number (PRN) sequence is used by the transmitter to spread the narrowband information content over a much larger bandwidth. The receiver uses the same PRN sequence to recover the information. Multiple systems

can share the same bandwidth without seriously interfering with each other if they are assigned different PRN sequences. Code division multiple access (CDMA) cell phone systems are a major application of DSSS techniques. Because the detection of spread-spectrum signals often requires special techniques (17), these signals are sometimes referred to as low probability of intercept signals.

5. Mobile communication systems and networks have proliferated and are widely used. These systems are based on the idea of dividing a geographical area into cells. Each cell has a base station that performs the functions of relaying messages between the short-range handset radios within the cell and a communication network interface to other carriers, such as the public telephone system network. Cellular telephone systems usually operate in the ultra high frequency band.

The classic pulsed-radar concept, however, involves the transmission of short duration pulses with relatively large time intervals between successive pulses. This method sidesteps the difficult problem of detecting the relatively weak signals reflected from the target during the simultaneous transmission of a high power signal. Requirements for range resolution often dictate the use of pulse widths on the order of a microsecond or less, which thereby results in relatively large bandwidths on the order of MHz. The waveforms used by advanced radars have increased in sophistication:

1. Coherent radars transmit signals whose waveforms are precisely defined;
2. Frequency or phase modulation may be used to increase range resolution;
3. The time intervals between successive pulses (pulse repetition interval) may be varied in a periodic or random sequence (pulse repetition interval stagger);
4. Multifunction radars select between different waveforms depending on the functionality that is required[1];

Application requirements for high angular resolution and compact antenna dimensions have motivated the extensive use of frequencies above 8 GHz.

The differences between radar and communication signals have motivated the development of specialized ES equipment:

1. Communication ES receivers feature extended frequency coverage to reduce the need to use different receivers, selective filters for separating signals that are closely spaced in frequency, comprehensive capabilities for demodulating the signal message content, and provisions for the measurement of signal parameters;
2. Radar ES receivers emphasize microwave frequency coverage and are optimized for the reception of pulse signals;
3. Specialized radar ES receivers have been developed for strategic and tactical applications. For example, electronic intelligence receivers are designed for the precision measurement of signal parameters, whereas radar warning receivers are designed to provide warnings of threat signals, be simple to use, and satisfy size and cost constraints;
4. Multichannel receivers have been developed to process multiple signals from antenna arrays with the accurate phase and amplitude matching needed for applications such as direction finding.

General trends in all systems include the use of precision frequency references and synthesizers to permit accurate and repeatable tuning, progressive reductions in size, and the use of form factors that permit the convenient installation of multiple receivers in standardized rack configurations.

Communication ES Signal Processing. The classic communication ES receiver implementation is basically a high-quality manually controlled superheterodyne receiver. Signal search was performed by the operator manually tuning the receiver through the frequency range known to be used by the adversary's radios and listening to the outputs of the available demodulator(s) for signals of interest. When such a signal was found, the operator would listen to the demodulated signal and record the observations. If available, a DF system would be tuned to the frequency and measurements obtained for the signal angle of arrival. This process required the attention of a skilled operator and had the additional weakness that short duration transmissions on new frequencies could be missed, particularly if the frequency ranges to be covered could not be divided up among multiple systems and operators. Another weakness concerned the size, weight, and power consumption of the equipment.

Modern purpose-designed communication EW receivers provide significant enhancements:

1. Computer controlled operation via standard digital interfaces;
2. Accurate high-speed tuning and reduced phase noise that results from the use of high-quality crystal oscillators as frequency references and sophisticated frequency synthesis techniques;
3. Provisions for phase coherent operation of multiple receivers to allow commonality of hardware between systems used for signal search and DF;
4. Built-in-test functionality;
5. Reduced size, weight, and power consumption.

Digital signal processing techniques are being adopted for advanced ES systems. Digital filter bank concepts based on the Fast Fourier Transform algorithm allow a single wideband receiver to process and detect the individual

[1] For example, the optimal waveforms for discriminating between a moving target on the ground and the surrounding terrain would be unsuitable for providing extreme range resolution.

signals present within a large instantaneous bandwidth. Also, if the system dwells on a fixed center frequency, digital downconverters can be used to extract the narrowband signals within the receiver bandwidth and software demodulators used to recover the message content from each signal.

Advanced wideband communication ES sensors based on digital filter bank techniques have some very desirable advantages:

1. A large frequency range can be scanned quickly; the tuning frequency step size can be orders of magnitude larger than the required frequency resolution. This method substantially reduces or eliminates the likelihood that a short duration transmission will be missed and can provide some capability for detecting at least some hops transmitted by a frequency hopping radio;
2. The use of Constant False Alarm Rate techniques allows the system detection processing parameters to be adjusted automatically to achieve the best possible sensitivity without incurring erroneous signal detections at a rate that exceeds a set value, even if the environmental noise is frequency dependent and time variant (18);
3. Algorithms can be implemented to determine the type of modulation used by a signal and the modulation parameters;
4. Raw signal data can be acquired and stored for off-line analysis;
5. Demodulators implemented in software can accommodate a wide range of modulation types;
6. DF functionality can be integrated into the system to provide a measurement of the angle of arrival for each signal that is detected;
7. Reports of signal detections and the measured signal parameters can be automatically stored in a database and transferred to EW analysis and intelligence systems for subsequent processing;
8. Remote controlled or autonomous operation of ES systems is feasible.

However, wideband signal processing techniques also incur disadvantages. Early implementations tended to be expensive and have significant performance limitations. A major problem concerns dynamic range, which is a measure of the ability of a system to process strong and weak signals simultaneously. This issue is of considerable importance for wideband communications ES systems because weak signals of interest and strong signals will often coexist in the same frequency range. The dynamic range of a practical system is dependent on the noise and spurious signals, which are generated in the system by various mechanisms. One of the most important of these mechanisms is third order intermodulation distortion. This occurs when two or more signals present within the system bandwidth interact because of nonlinearities in the system signal processing. The spurious signals that result remain within the system bandwidth and, depending on the size of the input signals and the nature of the system nonlinearities, can be large enough to be detected and interpreted as actual signals in subsequent processing. To avoid this undesirable result, the detection processing must be adjusted to reduce the effective system sensitivity. Thus, the presence of strong input signals tends to degrade the ability of the system to detect and process weak signals usefully. The problem is aggravated as the system bandwidth is increased because the number of strong signals within the system bandwidth can also be expected to increase. Fortunately, progressive advances in radio frequency components, analog-to-digital converters, and digital processor hardware have substantially resolved these issues, particularly when careful system design choices and tradeoffs are made. Nevertheless, a well-designed narrowband receiver may still offer advantages with respect to usable sensitivity and selectivity in a dense signal environment that includes strong signals.

In addition to its message content, a communication signal contains information that can be used to classify the type of signal, and, with some limitations, to identify individual emitters.

The measurement of the modulation type and parameters is an important topic for communications ES systems. Conventional communication systems use modulation techniques to embed information on a sinusoidal carrier signal. The choice of modulation type and implementation parameters is dependent on application requirements and various factors, such as the need for interoperability with other radio systems as well as technology and cost constraints. Advances in communication theory coupled with the availability of low-cost digital signal processing hardware have motivated the use of sophisticated digital modulation techniques to provide favorable trade-offs between bandwidth efficiency, sensitivity to propagation effects, and hardware implementation costs. At the same time, simple, classic modulation techniques, such as analog frequency modulation, remain in widespread use, in part to maintain interoperability with older systems.

Knowledge of the modulation type and parameters associated with a signal is of considerable practical value. Requirements for interoperability have led to the standardization of the modulation types used by military radios. For example, the tactical VHF radios used in ground operations typically support analog FM and digital FSK modulations in accordance with standards such as MIL-STD-188-242. If a signal has a modulation type and parameters associated with a communication system known to be used by an adversary, then it can be flagged as a potential signal of interest and prioritized to receive attention. Also, because emitters that are communicating with each other will generally use the same modulation type, this knowledge can be used to support or reject hypotheses that concern the membership of a given emitter in a network. Finally, knowledge of the modulation type and parameters facilitates the selection of an appropriate demodulation technique to recover the message content.

Because of the diversity of modulation standards and the effects of multipath propagation and nonideal radio system implementations, the modulation recognition problem is nontrivial. Algorithms for modulation recognition have been described in various papers, of which Refs. 19–22 are representative examples.

A related idea is based on the observation that the signal waveforms generated by practical radio transmitters will differ in subtle ways depending on implementation details and component tolerances, and that these differences can be sufficient to distinguish between transmitters that are very similar or even nominally identical. Various techniques have also been proposed to extract and measure appropriately selected features from a signal and use statistical tests to determine whether the feature measurements match those of previously observed signals (23, 24).

Radar ES Signal Processing. Various analog and digital approaches have been used in radar ES receivers to detect signals and measure their parameters. Descriptions and performance analyses of the more common ones have been published 25–27. The radar ES receivers used for current radar ES systems deployed for the self-protection of platforms such as aircraft and surface ships generate pulse descriptor words (PDWs) for each radar pulse that is received. Each PDW consists of digital data that represents the principal signal parameters, typically frequency, power, time of arrival, pulse duration, and if available, angle of arrival and modulation type (phase or frequency). Early implementations made extensive use of analog techniques to generate PDWs, but more recent implementations are making increasingly extensive use of digital techniques.

Pulse train deinterleaving is required because the pulses that are received from the various radars in the signal environment will be interleaved in time (i.e., in a sequence of received radar pulses there is no certainty that for a given pulse in the sequence, the previous or next pulses in the sequence will be from the same radar). Deinterleaving is typically performed in a two-stage process. First, clustering is performed as pulses are received to form clusters or groups of pulses having similar characteristics. A subset of the signal parameters contained in the PDWs, typically frequency, angle of arrival, and pulse duration, are used in this stage. The second stage involves analyzing the time relationships [Pulse Repetition Interval (PRI) deinterleaving] between the pulses collected in each cluster to identify patterns that are consistent with the hypothesis that they were transmitted by a single radar. In addition to the radar PRI behavior, the radar scan pattern can be inferred by examining the time history of the measured power of received pulses in a deinterleaved pulse train. For example, a radar that is performing a circular scan will illuminate the platform carrying the ES system with its main beam response at uniform intervals in time.

Emitter identification involves comparing the various parameters that have been measured for each of the resultant deinterleaved pulse trains with those in an EW library and identifying the best match.

In practice, many potential difficulties may occur. The PDWs generated by the receiver will contain errors that result from various sources. At least some clusters formed in the first stage will have broad ranges. For example, a large frequency range may be needed to accommodate a frequency agile radar. Consequently, some clusters may overlap. Accurate PRI deinterleaving can be very difficult to perform with limited signal data sets; many modern radars have complex PRI staggers (i.e., the time intervals between successive pulses transmitted by a radar vary randomly or follow patterns that repeat only over a long period). Deinterleaving errors can result in the pulse train transmitted by such a radar being fragmented into two or more partial pulse trains. Finally, EW databases can have errors, be incomplete, or as a result of ambiguities, may be unable to provide a unique identification.

More sophisticated approaches are being investigated for the extraction of features that can be used to provide additional information for the classification and identification of radar signals. For radars that use frequency or phase modulation to improve range resolution, knowledge of the type of modulation waveform and its parameters is useful for classification purposes. Also, the waveforms transmitted by radar systems often have distinctive features, which are sometimes referred to as unintentional modulation on pulse (UMOP). Various techniques have been proposed for the extraction and processing of waveform features for signal identification.

ELECTRONIC ATTACK

EA, which is also known as Electronic Countermeasures, involves actions intended to degrade the ability of an adversary to make use of the electromagnetic spectrum. It may be active or passive in nature.

EA Against Communication Signals

EA against communication signals can be carried out as deception operations or jamming.

Deception operations involve the transmission of signals to mislead the enemy intentionally. For example, after a ground formation has been redeployed for operations elsewhere, simulated radio traffic may be maintained to give the impression that the formation is still in its original location. Another technique involves the transmission of messages that contain misleading information in the expectation that the message content will be recovered and used by the adversary. Deception operations must be carefully designed and organized to be convincing; the information provided should be consistent with other information that the intended recipient believes to be true. Large-scale deception operations that involve carefully coordinated activities can influence an adversary's strategic planning with decisive effect. Several accounts of highly successful Allied deception operations in WW2 have been published (5, 28).

Jamming is intended to prevent an adversary from reliably receiving his communication signals by the transmission of signals that interfere with their reception. In the simplest form, a jammer consists of an antenna, power amplifier, and signal generator programmed to produce a signal with an appropriately chosen waveform. It is also possible to use a conventional transmitter or radio as an improvised jammer. Jamming systems are often deployed with an adjunct ES capability to ascertain the frequencies of signals worth jamming and to assess the effects of the jamming operation.

To be effective, jamming requires that the ratio of jammer and communication signal powers (J/S ratio) at the victim radio receiver be sufficient to degrade communication activity adequately. High-power transmitters may be used in combination with directional antennas and the judicious positioning of the jammer near the area where jamming coverage is desired.

Several distinct types of communication jamming techniques are as follows:

Narrowband Jamming. Individual communication signals can be attacked by transmitting an appropriately designed narrowband-jamming signal on the frequency used by the target signal. To determine whether the target signal is still being transmitted, the jamming may be periodically stopped and an ES capability used to check for the presence of the signal. This method of attack has several advantages. First, the jamming range is maximized because the full jamming power is focused on a single signal. Second, the likelihood of interference with own side communication is minimized because only a small part of the radio spectrum is affected. If the jamming signal can be switched rapidly between frequencies, then a single transmitter may be able to jam two or more narrowband signals on a time shared basis.

A follower jammer is a special case of narrowband jammer used to jam a FH signal. The practical implementation of the concept is challenging; each hop transmission must be detected, its frequency measured by the ES functionality integrated with the jammer and, before more than a fraction of the hop is transmitted, the jamming transmitter must be tuned to the hop frequency (29). One difficulty is that the jammer must discriminate reliably between the hops from the target transmitter and any other frequency hopping communication systems that may be operating in the environment. A more fundamental issue concerns the propagation delays associated with, first, the path from the transmitter to the jammer, and, second, the path from the jammer to the victim receiver. If the end result is that the overall delay, including the jammer response time, approaches the hop duration, then the effectiveness of the jamming will be degraded.[2]

Barrage Jamming. A wideband jamming signal is used to degrade communication activities over a relatively wide range of frequencies. A high-power jammer may be needed to provide a useful range. A partial-band jammer is a variation on the barrage jammer concept. The aim is to jam a bandwidth that is sufficiently large enough to include a sufficient proportion of the hops transmitted by a FH radio to make it unusable. The idea is that, by not attempting to jam the full bandwidth used by the frequency hopping radio, the jammer power within the hop bandwidth can be kept higher and can provide an increase in the effective range of the jammer.

Many issues must be considered with respect to communication jamming:

1. Jamming often interferes with own side communication;
2. The value of information that is obtained by ES may be considered to be of greater military value than the effect of disrupting communication;
3. An adversary can infer the presence of enemy forces with EW capabilities from the observation of jamming signals and, if given time, may find ways of countering its effects.

Consequently, aside from some specialized applications, the decision to carry out communication jamming is usually made at a relatively high level and is closely coordinated with operational plans.

The deployment of communications jammers on aircraft provides several advantages. The jammer is mobile and can be positioned quickly to affect the desired area while minimizing the effect on friendly forces. Also, the required transmitter power can be reduced because, for a given range, the propagation losses are normally much lower than they would be for the signals from a ground based jammer. Recently, serious interest has been expressed in the idea of using low-power communications jammers on small unmanned air vehicles (UAVs) to provide localized jamming coverage in the direct support of small-unit operations (30).

EA Against Radar Signals

EA against radar signals is often concerned with degrading the performance of surveillance, target acquisition, and target tracking radars to protect platforms such as aircraft and surface ships. The value of these platforms and the potential effectiveness of radar-guided weapons has led to much emphasis being placed on EA.

Active EA techniques are used to create false targets or otherwise degrade the operation of the victim radar:

1. A noise jammer transmits wideband noise in the frequency ranges used by radar systems of potential concern, which makes it difficult for the radar to detect the target and get a range measurement;
2. A range gate pull-off jammer attempts to create a false target that seems to move away from the jammer platform. The jammer first creates a false target at the jammer platform by transmitting a pulse timed to coincide with the arrival of each pulse transmitted by the victim radar. The timing of successive pulses is gradually shifted so that the jammer pulses received by the victim radar correspond to a target that is moving away from the jammer platform. The digital radio frequency memory (DRFM) improves the technique by storing and transmitting a replica of the radar-pulse waveform. This method makes it more difficult for the radar to discriminate against the jammer signal.

[2] This problem can be avoided if the hop frequency sequence can be predicted using observations of the hop frequencies and *a priori* knowledge of the algorithm used to generate the hop sequence.

Several practical problems are noted in the deployment of jammers. The operation of jammers used for the self-protection of platforms, such as aircraft, is usually restricted to the jamming of threat signals as required. This method minimizes several risks, which include the possibility of interference with other systems on the platform, and that the presence of the platform can be inferred by the detection and direction finding of signals transmitted by the jammer. In this situation, an integrated ES capability for performing the detection, characterization, and assessment of threat signals is required to provide information needed for the control of the jammer. One way of sidestepping this issue is to deploy jammers on specialized platforms, and if possible to perform the jamming outside the defended air space. Other solutions include the towing of jammers behind the platform to be protected, or deploying jammers on UAVs.

Passive EA techniques attempt to degrade the effectiveness of enemy radars without transmitting signals. A widely used idea is to create false targets by dropping chaff (typically metal coated plastic strips) from aircraft to confuse tracking radars associated with antiaircraft defense systems. Chaff can also be dispersed via rockets or shells fired from platforms such as ships as a countermeasure to radar-guided missiles. Another approach is to tow decoys behind an aircraft or ship. The use of passive EA to confuse the guidance systems of antiaircraft or antiship missiles is often combined with maneuvers designed to position the platform to minimize the likelihood that the missile-guidance system will reacquire its target or that the missile will fortuitously pass near its target. Another form of passive EA concerns the use of stealth techniques to reduce the reflected energy returned to a radar transmitter by a platform (i.e., reduce the apparent radar cross section of the platform). The effectiveness of this technique is increased if combined with active EA from other platforms.

Other forms of EA are also important. Radar systems can be destroyed by missiles designed to home in on the signals transmitted by the radar. Conventional military operations against deployed systems identified by EW sensors or other intelligence are also possible. Recently, the concept of using directed energy or electromagnetic pulse (EMP) to damage or disrupt the operation of electronic equipment has received attention.

ELECTRONIC PROTECTION

Electronic protection, also known as electronic-counter-counter measures, concerns techniques and technologies intended to preserve the ability of defense electronic systems to operate in hostile electromagnetic environments.

Active EP includes measures taken to enhance the ability of defense electronic equipment to operate without hindrance by enemy EW.

Protection against intercept and jamming of communication signals can be provided in various ways:

1. Equipment can be designed to operate over wide frequency ranges, which offers improved opportunities for a system to switch to quieter frequencies if interference or jamming is encountered;
2. Directional antennas can be employed to make the interception of a signal difficult for a receiver outside the main beam response of the transmitting antenna. Jamming resistance can be achieved if the direction that the jamming signal is coming from corresponds to a null in the receiving antenna directional response.
3. Careful choices of sites may be able to take advantage of terrain masking of areas potentially usable by jammers or ES systems;
4. Power management allows the transmitter power to be set at the minimum level required for reliable communication. Low-power operation is desirable for short-range communication because the range at which the signal can be detected and intercepted is reduced. High power levels can be used to provide reliable operation over longer ranges and/or to overcome jamming;
5. Low probability of intercept techniques can be used to render DF and intercept difficult. FH techniques are widely used by modern tactical radios;
6. Redundancy can be achieved by design and/or tactical procedures to limit the damage caused by the effects of enemy EA; for example, different types of communication systems can be networked and managed to ensure that the disruption of one system does not prevent the communication of important information.

Similar techniques are applicable to radar systems with several differences:

1. A radar system may be able to search over a restricted range of angles and still perform its mission requirements. An ES system outside the search area will not be illuminated by the mainbeam of the radar antenna and may have difficulty detecting the signals;
2. Radar antennas are generally designed to be highly directive to provide angle resolution. However, antenna designs that also achieve low sidelobe levels are desirable for several reasons. First, sensitive ES systems can usefully detect pulses that correspond to the antenna sidelobes if these are sufficiently large. Second, some jamming techniques make use of signals that are received through sidelobes in the radar antenna response and therefore confuse the radar into showing a target at an angle offset from the jammer;
3. Frequency agility involves changing the transmitter frequency pulse to pulse or between groups of pulses. It has some similarities to the use of FH by communication systems, although the primary ideas are to complicate the task of an ES system in interpreting whether the received pulses are from one or more radars, and to reduce the effectiveness of single frequency jammers.

4. LPI radars tend to use continuous wave signals with frequency or phase modulation to provide the desired range resolution. Technical considerations generally restrict the average transmitter power with the result that they are most suited to applications in which long range is not required. Against these signals, conventional radar ES systems are usually limited to very short detection ranges because of the low transmitter power and the effect of receiver optimizations for the processing of short duration pulse signals.[3]

Passive EP generally places considerable emphasis on training and operational procedures. Some of the most spectacular EW successes, such as the decryption of messages ciphered by the German Enigma machine in WW2, resulted, at least in part, from the failure of radio operators to follow correct procedures. The security of communication systems can be compromised in many possible ways. Examples include the transmission of unimportant or unnecessarily long messages; the repeated transmission of the same message with and without encryption; the failure to use code words and available EP capabilities, such as power management, FH, and encryption; and the failure to safeguard encryption equipment and keys. The likelihood of such lapses can be reduced substantially by the institution of suitable procedures followed by training under realistic conditions.

Emission Security policy includes defining procedures and techniques for minimizing the possibility of sensitive information being obtained from the intercept of RF signals that are generated unintentionally in the operation of computer or other electronic systems.

In field or operational environments, tactical EP strategy is set by Emission Control (EMCON) orders, which define specific rules for the management of electromagnetic emissions (12) during a military operation. These rules attempt to strike a balance between various requirements:

1. Maintaining command and control capabilities;
2. Limiting mutual interference between friendly systems;
3. Limiting the useful information that enemy ES can provide;
4. The execution of deception operations.

EMCON rules include the following:

1. Restrictions on transmit power times and use of radio black-out policy;
2. Guidelines, such as frequency allocations and approved system configurations;
3. Restrictions on the type of information that can be transmitted (and thus denied to the enemy);

ADDITIONAL TOPICS

EW and Navigation Systems

Before WW2, specialized direction-finding systems were developed for navigation purposes. From measurements of the angles to radio stations or beacons at known locations, position estimates could be computed. Although there were limitations on the achievable accuracy, this capability was extremely important, particularly at night and in bad weather. During WW2, more sophisticated systems were developed and deployed. Examples include Knickebein, X-Gerat, Y-Gerat, Decca Navigator, GEE, G-H, and Oboe.

Various efforts were made to jam the signals associated with these systems, particularly those used for bombing navigation.[4] Luftwaffe attempts to use the Knickebein, X-Great, and Y-Gerat navigation systems to guide bombers to targets in the U.K. were successfully countered by jamming, although a series of damaging raids was conducted using the X-Gerat system before effective jamming techniques were devised (5). German attempts to jam allied systems, such as GEE and Oboe, were generally less successful.

For example, by the time successful jamming was initiated against Oboe signals at 200 MHz, the Mark III version had moved to 3 GHz. At this frequency, the technical capabilities of the Germans were inadequate for the implementation of effective countermeasures.

In addition, both sides made efforts to interfere with enemy radio beacons, sometimes with the result that aircraft got lost or were even captured after landing in unfriendly territory.

After WW2, various navigation systems were developed and deployed. More recently, the global positioning system (GPS) has become very important, particularly in Western countries, because of the availability of worldwide coverage and the high accuracy that can be achieved. This availability has led to the widespread use of GPS for guiding precision weapons and defining target locations. The military importance of GPS has motivated the development and marketing of GPS jammers. At the same time, recognition of the potential impact of GPS jamming has resulted in serious efforts to develop and implement anti-jam features in military GPSs (31).

EW and IFF Systems

Identification friend foe (IFF) systems are used to provide a means of quickly and positively identifying friendly aircraft. When an unknown aircraft is observed, the IFF system transmits a specially coded signal and looks for the transmission of an appropriate signal in response from the IFF system in the unknown aircraft.

After early IFF systems were deployed in British bombers during WW2, the Germans discovered that the bombers could be tracked by transmitting signals to trigger their IFF systems and observing the IFF signals trans-

[3] An interesting idea is to use commercial FM radio stations as a transmitter in a bistatic radar system. The receivers are located some distance from the transmitter, and the signal processing is designed to measure the relative time shifts between the signal that propagates directly from the transmitter to the receiver and the signal that arrives via a reflection from the target.

[4] Investigations in the UK revealed that bombing attacks carried out at night were often ineffective without the use of electronic navigation aides (5).

mitted in response. Significant losses of aircraft resulted until it was realized that the IFF signals were being exploited, and the systems were removed from the aircraft (5). Since then, significant efforts have been made to reduce the vulnerability of modern IFF systems to EW.

Countermeasures Against IR Sensors

Passive infrared (IR) sensors have important military applications (32). Antiaircraft missiles using IR guidance systems have proven to be very effective in the absence of effective countermeasures, particularly for low-altitude air defense. Other important applications include ground-to-air and air-to-ground target acquisition, fire control, and night vision. In ground combat, the use of IR sensor technology has greatly increased the effectiveness of operations at night and under conditions of bad weather and haze. The usefulness of IR sensors has been enhanced progressively by technical advances in IR detectors and the processing of their outputs. IR sensors have been evolved to operate in both the long-wave infrared and mid-wave infrared bands. These dualband sensors can provide robust performance over a wide range of environmental conditions.

The importance of IR sensors has motivated the expenditure of considerable effort on the development of technology and techniques designed to reduce the effectiveness of IR sensors and their associated weapon systems. This work is very comprehensive and includes modeling and experimental measurements of the IR radiation emitted by platforms, such as ships and aircraft, and the behavior of threat IR sensors.

Flares have been widely used as decoys to distract the IR sensor-based missile guidance systems for the protection of aircraft. The use of flares is often combined with evasive action to ensure that the missile-guidance system continues to track the flare and that the missile's path toward the flare does not take it near the aircraft. Infrared counter measure (IRCM) systems generate an IR signature whose power is modulated in a way that is intended to confuse the tracking system associated with typical IR sensor-based guidance systems. Directional infrared counter measures systems extend the IRCM concept by directing the modulated IR energy toward the threat sensor. Another idea is to use a laser to blind the IR sensor.

IR deception techniques for aircraft have achieved significant successes against more basic IR sensors. However, the development of increasingly sophisticated IR sensors has necessitated continued work on the development of IR countermeasures.

Improvised IR deception measures have been used with some success to simulate ground targets.

The reduction of IR signatures associated with platforms, such as surface ships and aircraft, can significantly improve their survivability. Various measures have been used:

- Cooling visible exhaust duct metal surfaces with air or water;
- Shrouding visible exhaust duct metal surfaces;
- Cooling engine exhaust plumes by mixing them with cool ambient air;
- Cooling exposed surfaces heated by the sun with water;
- Coating exposed surfaces with low-emittance materials;
- Covering ground-based assets with IR camouflage netting.

FUTURE TRENDS IN EW TECHNOLOGY

The evolution of EW technology and concepts is driven by various factors, which include changing operational requirements and technology advances. Future systems will provide significant capability enhancements and other benefits:

1. The development and widespread deployment of capable cell phone networks and their adoption for military purposes means that ES, even at the tactical level, cannot be limited to explicitly military communication systems;
2. Requirements to shorten development cycles and reduce cost will favor increasing use of commercial-off-the-shelf technology and open standards. The implementation of digital signal processing algorithms in software running on general purpose processors and hardware based on field-programmable gate array technology provides a combination of flexibility and performance;
3. Specialized systems will tend to be replaced by multifunction systems. The concept of integrating ES and EA functionality with communication and radar systems will receive increasing attention (33);
4. Networking of EW assets and technical advances will tend to blur the distinction between tactical and strategic EW;
5. Simulators and other aids are being developed to provide realistic scenarios for EW training without requiring large-scale exercises and/or expensive equipment;
6. Models and simulations will be increasingly used to assess EW effectiveness with the aim of determining appropriate system design trade-offs and contributing to the development of EW doctrine;
7. Automated ES and EA systems will be added to the sensors carried by UAVs and platforms such as reconnaissance vehicles;
8. Smart antennas will improve the robustness of communication systems in a jamming environment;
9. The future development of aircraft and naval platforms will place increasing emphasis on signature management;
10. Decoys will be increasingly used for platform protection.

In practice, the application of technical advances will be moderated by various practical issues: There are always competing priorities for personnel and funding. Sophisticated

EW systems are often very expensive to develop and deploy and can be quickly rendered obsolescent by technology advances and changing application requirements. The development of sophisticated defense electronics systems presents formidable challenges. Many systems fall far short of initial expectations for various reasons, which range from faulty technology or trade-off analyses, the failure of anticipated technical advances to materialize, and changing application requirements. The problems involved with the introduction of advanced technology systems into service are considerable:

- Integration into platforms;
- Integration with other systems;
- Provisions made for maintenance;
- Development of suitable doctrine;
- Provisions for interoperability with allied forces;
- Training of users.

It is very easy to underestimate some of these issues. An otherwise capable system may be completely unsuitable for service use if the user interface is poorly thought out. A system may work well in the hands of skilled engineers who have an intimate understanding of its operation, but, in an operational environment, it may be virtually unusable by service personnel, even if they have substantial training and experience. Another common problem is that communications capacity required for the networking of battlefield sensors may not be available, or, if provided by communication satellites, may be prohibitively expensive.

APPENDIX 1 - GEO-LOCATION OF SIGNAL SOURCES FOR COMMUNICATIONS AND RADAR ES

GENERAL CONCEPTS

Several fundamental properties of electromagnetic waves can be used for the geo-location of signal sources:

- the signal propagates at a constant known velocity;
- the phase surfaces are perpendicular to the direction of propagation;
- the electric and magnetic field vectors are perpendicular to the direction of propagation.

In free space, the signal seems to spread out radially from a source and arrive at a receiver via a line-of-sight path. Various techniques have been developed to exploit these properties to obtain lines of position for the transmitters associated with radio, radar, and navigation systems. Using measurements from a sufficient number of sites, the locus of positions for an emitter can be uniquely solved. In practice, the problem can often be usefully simplified by the assumption that the source and sensor sites are located on a plane. If errors can be neglected, then the resulting lines of position (LOPs) pass through the position of the signal source, which thereby results in an unambiguous position estimate. The process of solving the location of a signal source from the LOPs is known as triangulation. In practice, various error sources will affect the estimated LOPs and, with multiple lines of position, the intersections of the LOPs will occur at multiple points or, in some cases, will fail to occur. Many sources of error are present in practice:

1. Environmental noise and interfering signals;
2. Thermal noise and spurious signals generated within the sensor;
3. Mutual coupling between the pairs of elements in an antenna array;
4. Gain and phase mismatches in cables and receivers used in systems that use multiple receivers to measure gain or phase differences;
5. Uncertainties in the positions of the sensors;
6. Propagation effects;
7. Geometric factors caused by the relative location of the emitter and sensors.

In a ground-based environment, propagation effects are very important. The received signal will usually arrive at the sensor via multiple paths (multipath propagation) caused by reflections from terrain features and man-made structures. Many of these error mechanisms will result in systematic bias errors that cannot be removed by averaging. However, various possibilities exist for minimizing the effects of error sources:

1. Careful positioning of sensor sites to minimize terrain masking of areas of interest and local reflections, and provide favorable source-sensor geometries;
2. The elevation of the sensor antenna on a suitable mast;
3. Increasing the number of sensors.

The statistical behavior of errors that develop in estimating the position of a source, and their sensitivity to measurement errors, has been analyzed extensively for various geo-location techniques (34–36). Algorithms for making the best use of available information from sensor arrays have been developed (37,38).

DIRECTION-FINDING TECHNIQUES

Direction finding (DF) is based on the idea of directly measuring the direction that the signal wave front is propagating. Extensive research has been applied to the development of DF techniques. Moreover, many design variables and implementation technologies are possible. Consequently, the design of practical DF systems reflects the trade-offs that are relevant to the specific application requirements. The most common ideas (37, 39, 40) are summarized in the following sections.

DF TECHNIQUES BASED ON AMPLITUDE MEASUREMENTS

The most basic form of DF is to perform an angular search using a directional antenna whose directional characteristics are known and find the angle at which the received power is either a maximum or a minimum. The choice depends on whether a well-defined maxima or null in the directional response exists. The antenna can be continuously rotated and a suitable electro-mechanical system used to display the angle that corresponds to the minimum (or maximum) received signal power. One limitation of this scheme concerns the difficulty of measuring the DF of a signal that is present for a short duration. Nevertheless, some DF systems for radar ES are based on the use of a rotating parabolic reflector antenna. The relative simplicity, coupled with the capability against weak signals provided by the high antenna gain, partly compensates for the other limitations.

Amplitude comparison DF is a more sophisticated idea. The desired angular coverage is divided into sectors, and each sector is associated with a directional antenna having a beam width comparable with the angular width of the sector and a receiver that is designed to measure the amplitude of an observed signal. The angle of arrival is determined in two stages. First, the pair of receivers associated with the largest signal power measurements is found. A coarse estimate of the angle of arrival is defined as the mid-angle between the angles that each of the antennas is pointed. Second, the angle of arrival estimate is refined by computing the ratio of the amplitudes, and using a look-up table, or a calculation based on a model of the directional gain of the antennas, to produce a fine-angle estimate. A trade-off occurs between the number of antennas and the achievable accuracy. This technique is often used in radar ES systems; it is relatively straightforward to implement, and, for microwave frequencies, the antennas are relatively compact. RWRs used in fighter aircraft often use four antennas to provide 360° angular coverage, whereas ES systems for naval craft often use six or eight antennas.

Many communications ES systems use amplitude-comparison DF techniques based on the Adcock pair antenna. This technique is based on the idea of taking the vector difference of the output signals from two closely spaced vertical monopole or dipole antenna elements. The result is a figure-8 gain pattern with the null occurring for signals that propagate across the baseline of the antenna elements. The separation of the antenna elements involves a compromise depending on the frequency range to be covered. Too close a spacing reduces the sensitivity whereas too large a spacing results in a distorted gain pattern. The Watson-Watt DF system, in its simplest form, consists of two Adcock pairs oriented at right angles. The angle of arrival of a received signal can be directly determined from the ratios of the signal powers measured from the two Adcock antenna pairs. With some additional processing, an unambiguous DF measurement can be obtained. At the cost of increased size and complexity, improved performance and frequency coverage can be obtained by using four Adcock pairs.

Interferometric DF Systems

The basic interferometric DF system consists of a pair of monopole or dipole antenna elements that are separated by less than half a signal wavelength and the means for measuring the phase difference between their output signals. Using the measured signal frequency, the known signal propagation velocity, and the antenna separation, the signal angle of arrival with respect to the antenna baseline can be computed. The angle of arrival measured for this arrangement is ambiguous; the signal can arrive from either side of the baseline. This limitation can be resolved by adding one or more antenna elements to form a two-dimensional array for each pair of antenna elements, an angle of arrival estimate relative to the baseline of the antenna pair is obtained. By solving for the result that is most consistent with these measurements, an unambiguous estimate for the angle of arrival is obtained. One implementation uses an array of 5 antennas positioned in a regular pentagon to form 10 antenna pairs, five of which correspond to the faces of the pentagon and the other five to the diagonals (41).

The interferometric DF technique is expensive in hardware. Each antenna in the array requires a dedicated channel from a multichannel receiver that has accurate phase-matching between the channels. Digital signal processing techniques facilitate the implementation of such systems, one point being that phase-matching errors can be corrected by measuring them with a suitable calibration signal, storing their values in a table, and using the stored calibration data to correct subsequent measurements. The correlative DF techniques used by some systems are another development of this concept. Well-designed interferometric DF systems have a relatively good reputation for accuracy, particularly when a large antenna array is used.

Single-Channel DF Systems

To minimize size, cost, weight, and power consumption, several DF system implementations have been developed that require only a single-channel receiver. The pseudo-doppler DF technique is distinguished by the use of a circular array of uniformly spaced antennas with a commutator switch that sequentially connects one antenna in the the array at a time to the receiver. The effect is analogous to moving a single antenna element on a circular track and contributes a sinusoidal phase modulation to the received signal. An estimate of the angle of arrival is obtained by measuring the relative phase shift of this modulation component. The Watson-Watt technique has also been applied successfully to single-channel DF systems.

Single-channel DF techniques are widely used for low-cost portable systems. However, a relatively long observation time is needed compared with the conventional Watson-Watt and interferometric techniques.

Other DF Techniques

Other DF techniques are possible and have some advantages. Circular antenna arrays using the Butler matrix network can provide unambiguous DF with a receiver having as few as two channels. A theoretical comparison of their performance with other techniques is given in Ref. 42. Super-resolution techniques, such as the multiple-signal classification (MUSIC) algorithm (43), have the ability to resolve multiple signal sources in angle, even when their signals overlap in frequency. However, the large antenna arrays and the cost of the associated receiver and processing hardware are difficult to justify for most applications.

Attempts have been made to use power measurements to provide an indication of range. This method presents some difficulties. The actual power radiated by a transmitter is dependent on various factors that include the antenna configuration, height, and the selected transmitter output power (if this functionality is available). Furthermore, in a ground environment, propagation losses depend on the nature of the terrain. The usefulness of power measurements increases if measurements are available from multiple sites.

TIME DIFFERENCE OF ARRIVAL AND FREQUENCY DIFFERENCE OF ARRIVAL GEO-LOCATION TECHNIQUES

The basic concept of geo-location using time difference of arrival (TDOA) measurements can be illustrated by considering a pair of spatially separated receivers and a signal source at an unknown location. Given the assumptions of line of sight propagation paths and fixed-signal propagation velocity, the signals observed at the receivers arrive with delays proportional to the distances from the signal source to the receivers. The difference in delays corresponds to the TDOA.

Given a TDOA measurement and knowledge of the signal-propagation velocity and the receiver locations, the locus of possible transmitter positions can be solved. If the problem is simplified to two dimensions by assuming the signal source and receivers lie on a plane, then the resulting line of position is a hyperbola. Given three or more receivers, the hyperbolic lines of position obtained for the different pairs of receivers will intersect at the signal source location if sources of error can be neglected.

Two basic approaches are used for measuring TDOAs. The first is applicable if a time domain feature of the signal waveform can be easily identified. For example, the time of arrival (TOA) of a pulse modulated signal can be measured by performing amplitude demodulation to obtain the pulse waveform and measuring the absolute time that corresponds to a suitable reference point on the leading edge of the pulse waveform, such as the point where the pulse reaches a fixed fraction of the peak power level. The TDOA can then be obtained by taking the difference between the corresponding TOAs observed at two locations. The second requires that the signals from the receiver sites be relayed to a single site where the relative time differences are measured using signal processing techniques, such as cross-correlation.

TDOA based geo-location techniques involve several complications. The requirement for the accurate measurement of very small relative time delays necessitates carefully designed and engineered systems. If the signals received at the separate sites must be relayed to a common site for processing, then the requirements for suitable data links may involve issues of cost and practicality. Nevertheless, TDOA geo-location techniques have some attractive advantages:

- specialized receiving antennas are not required;
- the orientation of the receiving antenna is not critical;
- several methods can be used to confirm that a signal received at different sites is from the same transmitter;
- the accuracy is relatively unaffected by multipath propagation that occurs in the immediate vicinity of the receiver sites.

The differential frequency shifts that result from relative motions of the transmitters and receivers complicates the signal processing needed for TDOA estimation. With suitable processing, these frequency differences can be estimated and used to define lines or surfaces on which the signal source lies. FDOA based techniques are primarily applicable to airborne or satellite platforms and can be combined with geo-location based techniques based on TDOA measurements.

MINIMIZATION OF ERROR SOURCES

The performance of practical geo-location systems can be improved in several ways.

DF Techniques

The performance of DF systems can vary widely, depending on the implementation and choice of deployment sites:

1. System design choices and trade-offs need to be considered carefully. Antenna arrays with large baselines tend to have performance advantages, but they are generally undesirable for tactical applications. Conversely, attempts to cover a large frequency range with a single antenna array involve significant challenges;
2. Gain and phase mismatches contributed by the receiver hardware and the cables between the antenna and receiver can be corrected by measuring the errors and subtracting them from future measurements. The errors can be measured by using a suitable signal source and radio frequency switch to apply a calibration signal at the point where the cables connect to the antenna. Measurements obtained at suitably chosen test frequencies can be used to construct a calibration table containing the amplitude and phase-correction factors required at each of the test frequencies;
3. Systematic errors contributed by the antenna can be corrected using a calibration table to provide correction values to be subtracted from the measurements. A one-dimensional calibration table can be constructed by carrying out controlled tests using signals transmitted from a fixed angle at frequencies spaced through the frequency range covered by the system and measuring the discrepancy between the actual and observed angles. Because the errors generally must be angle dependent, the use of a two-dimensional calibration table is desirable. This table can be constructed by the repeating the procedure for angles

distributed around the full 360° interval. Interpolation can be used to generate calibration values for intermediate frequencies and angles.

4. The choice of sites for the deployment of DF systems is critical. Ideally, the site should be free of features that contribute to multipath propagation, and line-of-sight propagation should be possible over the area of interest. In these respects, the elevation of the antenna is an important factor. Another consideration is that the sites should be selected to provide favorable sensor-target geometries for geo-location via triangulation.
5. Geo-location performance improves as the number of sites from which DF information is available increases.

TDOA and FDOA Techniques

The performance of TDOA and FDOA geo-location systems is sensitive to system-implementation choices, the nature of the signals of interest, and various aspects of the system deployment:

1. If the system operation is dependent on the relaying of signals received at the sensor sites to a common site for processing, the system must be able to perform this function without significantly degrading the quality of the signals.
2. Provisions must be made to account for the delays contributed by the relaying of the signals observed at the sensor sites to a common site; these delays must be removed or accounted for.
3. The performance of TDOA estimation processing depends on the signal-to-noise ratio and the presence of suitable information contained in the signal modulation. Narrowband signals may require higher signal-to-noise ratios and/or longer observation times to achieve the desired accuracy;
4. Frequency shifts that result from relative motions of the receivers and transmitter affect TDOA measurement processing. If, for scenarios of interest, they are sufficiently important, then provisions must be made in the TDOA estimation processing to remove them. If FDOA information is used for geo-location, then the most favorable results will be obtained when the sensors move rapidly, because this action increases the relative frequency shifts, and a given error in frequency measurement becomes less significant. Also, uncertainties contributed by the movement of the signal source are reduced.

ENVIRONMENTAL SCIENCE COMPUTING

ENVIRONMENT AND SOCIETY

The environmental problems are becoming more and more important for the modern society, and their importance will certainly be increased in the near future. High pollution levels (high concentrations and/or high depositions of certain harmful chemical species) may cause damage to plants, animals, and humans. Moreover, some ecosystems can also be damaged (or even destroyed) when the pollution levels become very high. This explains why the pollution levels must be studied carefully in the efforts

- to predict the appearance of high pollution levels, which may cause different damages in our environment and/or
- to decide what must be done to keep the harmful concentrations and/or depositions under prescribed acceptable limits.

The control of the pollution levels in highly developed and densely populated regions in the world is an important task that has to be handled systematically. This statement is true for many regions in Europe and North America but also other parts of the world are under economic development currently and urgent solutions of certain environmental problems either are already necessary or will soon become necessary. The importance of this task has been increasing steadily in the beginning of the new millennium. The need to develop reliable and easily applicable control strategies for keeping harmful pollution levels under prescribed limits will become even more important in the next decades.

Climate changes are causing another challenging problem for the modern society. The quick changes have many different consequences. The impact of the climatic changes on the pollution levels is one of the consequences, and this consequence must be investigated carefully by studying the relationship between climatic changes and high pollution levels. It should also be mentioned here that there is a feedback: The pollution levels influence the climatic changes. It is necessary to couple environmental models with climatic models to study fully the interrelations between climatic changes and pollution levels. This task is very challenging.

Mathematical models are powerful tools when the trends in the development of the pollution levels and the measures which the society must take to ensure a sustainable development are studied. These models are often very complex and lead to huge computational tasks. Some tasks cannot be treated even if powerful modern computers are used.

IMPORTANT TASKS TREATED BY THE ENVIRONMENTAL MODELS

Advanced mathematical models for studying environmental phenomena can be used successfully to design control strategies for keeping the pollution under critical levels under the assumption that these models produce reliable results. The application of comprehensive environmental models in sensitivity tests is important in the efforts

- to understand better the physical and chemical processes involved in the environmental phenomena or to treat efficiently the tasks proposed by policy makers and
- to ensure that the control strategies for keeping the pollution under the prescribed acceptable limits are reliable.

Sensitivity tests can be applied to resolve these two tasks. It is important to study the sensitivity of concentrations and deposition of harmful pollutants caused by variations of:

- anthropogenic emissions,
- biogenic emissions,
- meteorological conditions,
- velocity rates of chemical reactions,
- boundary conditions,
- initial conditions, and
- numerical algorithms.

This list is certainly not complete and can be continued. It is even more important to emphasize the fact that this list tells us that the task of performing complete sensitivity analysis by applying large-scale environmental models is extremely large and very difficult. Finally, many terms, in which the parameters from the above list are involved, are nonlinear. The nonlinearity causes great difficulties, which can be resolved only by conducting many experiments with different scenarios and studying carefully the results to find typical trends and relationships.

The difficulties are increased because there are interconnections of the effects because of variation of different parameters. For example, the variation of both the anthropogenic emissions and the biogenic emissions may lead to some effects, which are not observed when only the anthropogenic emissions or only the biogenic emissions are varied. The effects caused by simultaneous variations of several key parameters can only be studied by increasing the number of scenarios used in the experiments. Thus, the tasks become larger and more difficult.

The necessity of validating the results is an additional source for difficulties. The problem of designing a completely reliable routine for validating the results of the sensitivity tests is still open. Two approaches can be used (and, in fact, are commonly used) in the attempts to validate the results from sensitivity analysis tests:

- comparisons with measurements and
- comparisons with results obtained by other models.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

The objections, which can be raised against the complete reliability of the comparisons with measurements for the validation of the model results, are many and serious. The most important objection is the well-known fact that two different quantities are compared when such a procedure is used. The measurement is a quantity, either concentration or deposition, which is obtained at a given geographical point (the location of the measurement station). The corresponding quantity, which is the quantity calculated by the model, is a representative mean value averaged in some surrounding (determined by the spatial discretization chosen) of the point in which the measurement station is located. This fact implies that even if both the measurement and the corresponding calculated result are exact (which will never happen in practice), they will in general be different. Another implication, which is even more important from a practical point of view, is the following: We should expect to improve the possibility (the potential possibility, at least) of getting better validation results by using comparisons with measurements when we increase the spatial resolution of the model, but the computational tasks become larger and much more difficult when the spatial resolution is increased. It may become necessary to replace some physical and chemical mechanisms used in the model with coarse resolution with more accurate mechanisms when the resolution is refined. Finally, the need for accurate input data for large-scale models defined on refined grids also causes great difficulties.

The objections, which can be made in the case where the results obtained by two or more models are compared, are also both many and serious. It is extremely difficult to determine in a reliable manner the precise reason for differences of results produced by different models. The answer of the following question is interesting when a long sequence of sensitivity tests is run: *What is the relationship between the parameter that is varied and the studied quantity (the concentration or the deposition of a certain harmful pollutant)?* If two models are run with the same sequence of sensitivity tests and if the relationship between the parameter that is varied and the model results is different for the two models, then the difference may, partially or totally, be caused by several reasons. The differences may, for example, be caused (or, at least, be influenced to some degree) by the use of different projections and/or resolutions in the different models, by the application of different sets of input data, by the fact that the numerical methods used are different, by the fact that the chemical schemes are not the same, and so on. It is not clear how these unwanted reasons for differences of the results from two or more models can be eliminated to study only the relationship between the parameter we are varying and the studied quantity.

It should be emphasized here that the objections against the two commonly used procedures for validating results from sensitivity tests indicate that it is necessary to be cautious. It should also be emphasized, however, that it is absolutely necessary to do such comparisons. Many sound conclusions can be drawn after such comparisons, but one should not fully rely on the results of the comparisons. One should continue the search for better and more reliable validation tests.

MATHEMATICAL DESCTIPTION OF ENVIRONMENTAL MODELS

The environmental models are normally described by systems of partial differential equations (PDEs). The number of equations is equal to the number of chemical species studied by the modes and the unknown functions are concentrations of these species. Five basic stages are described in the development of a large environmental model:

- one has to select the physical and chemical processes that are to be taken into account during the development of the model,
- the selected processes must be described mathematically,
- the resulting system of PDEs must be treated by numerical methods,
- the reliability of the obtained results must be evaluated and
- conclusions should be drawn.

It is important to take into account *all* relevant physical and chemical processes during the development of the models. If more physical and chemical processes are included in the model, then one should expect that more accurate and more reliable results can be calculated. However, two difficulties are related to the attempt to include as many as possible physical and chemical processes in the model:

- The complexity of the model is increased when more processes are included in it. The treatment of the model on the available computers might become very difficult, and even impossible, when too many processes are taken into account.
- Some physical and chemical processes are still not well understood, which means that such processes must either be neglected or some simplified mechanisms, based on uncertain assumptions and/or on experimental data, must be developed.

It is necessary to find a reasonable compromise related to the number of processes that are to be taken into account when a large environmental model is developed. This reasoning explains also why it is necessary to validate the model results.

The selected physical and chemical processes have to be described by mathematical terms. Some more- or less-standard rules exist that can be used for the mathematical description of different processes. Several examples, which are related to air pollution modes, are listed below:

- The transport caused by the wind (called advection) is described by using terms that contain first-order spatial derivatives of the unknown functions (the concentrations of the studied pollutants) multiplied by the wind velocities.
- The diffusion of the concentrations is expressed by second-order spatial derivatives multiplied by the diffusivity coefficients.

- The chemical reactions are represented by nonlinear mathematical terms.
- The change of the concentrations in time is given by first-order derivatives of the concentrations of the pollutants with respect to time.

It should be stressed here that the above rules are applicable not only to air pollution models but also to many other environmental models.

When all selected physical and chemical processes are expressed by some mathematical terms, then these terms have to be combined in a system of PDEs. For example, when long-range transport air pollution is studied, the system of PDEs, which represents the mathematical model, can be written as follows (it should be mentioned that similar systems are used in other environmental models):

$$\begin{aligned}
\frac{\partial c_i}{\partial t} &= -u\frac{\partial c_i}{\partial x} - v\frac{\partial c_i}{\partial y} && \text{horizontal advection}\\
&\quad -\frac{\partial}{\partial x}\left(K_x\frac{\partial c_i}{\partial x}\right) + \frac{\partial}{\partial y}\left(K_y\frac{\partial c_i}{\partial y}\right) && \text{horizontal diffusion}\\
&\quad +Q_i(t,x,y,z,c_1,c_2,\ldots,c_q) && \text{chemical reactions}\\
&\quad +E_i(t,x,y,z) && \text{emissions}\\
&\quad +(k_{1i}+k_{2i})c_i && \text{dry and wet deposition}\\
&\quad -w\frac{\partial c_i}{\partial z} + \frac{\partial}{\partial z}\left(K_z\frac{\partial c_i}{\partial z}\right) && \text{vertical exchange}\\
i &= 1,2,\ldots,q && q-\text{number of chemical species} \qquad (1)
\end{aligned}$$

where

- $c_i = c_i(t,x,y,z)$ is the concentration of the chemical species i at point (x,y,z) of the space domain and at time t of the time interval,
- $u = u(t,x,y,z)$, $v = v(t,x,y,z)$ and $w = w(t,x,y,z)$ are wind velocities along the Ox, Oy and Oz directions respectively at point (x,y,z) and time t,
- $K_x = K_x(t,x,y,z)$, $K_y = K_y(t,x,y,z)$ and $K_z = K_z(t,x,y,z)$ are diffusivity coefficients at point (x,y,z) and time t (it is often assumed that K_x and K_y are nonnegative constants, whereas the calculation of K_z is normally rather complicated),
- $k_{1i} = k_{1i}(t,x,y,z)$ and $k_{2i} = k_{2i}(t,x,y,z)$ are deposition coefficients (dry and wet deposition, respectively) of chemical species i at point (x,y,z) and time t of the time interval (for some species these coefficients are nonnegative constants; the wet deposition coefficients k_{2i} are equal to zero when it is not raining).

Normally, it is not possible to solve exactly the systems of PDEs by which the large environmental models are described mathematically. Therefore, the continuous systems of the type in Equation (1) are to be *discretized*. Assume that the space domain, on which Equation (1) is defined, is a parallelepiped (this is as a rule the case when environmental models are to be handled) and that $x \in [a_1, b_1]$, $y \in [a_2, b_2]$, $z \in [a_3, b_3]$ and $t \in [a, b]$. Consider the grid-points (t_n, x_j, y_k, z_m) where $x_j = a_1 + j\Delta x$, $j = 0,1,2,\ldots,N_x$, $y_k = a_2 + k\Delta y$, $k = 0,1,2,\ldots,N_y$, $z_m = a_3 + m\Delta z$, $m = 0,1,2,\ldots,N_z$ and $t_n = a_3 + n\Delta t$, $n = 0,1,2,\ldots,N_t$. Assume also that the initial values $c_i(a,x,y,z)$ are given. Then, the task of finding the exact solution of the unknown functions c_i at all points (t,x,y,z) of the domain (infinite number of points) is reduced to the task of finding approximations of the values of the functions c_i at the points (t_n, x_j, y_k, z_m); the number of these points can be very large (up to many millions), but it is finite. The original task is relaxed in two ways. First, the number of points at which the problem is treated is reduced to the number of grid-points, and then it is required to find approximate solutions instead of the exact solution.

In the example given above, equidistant grids are introduced (i.e., Δx, Δy, Δz, and Δt are constants). Nonequidistant grids can also be used. The vertical grids are normally not equidistant.

It is assumed here that Cartesian coordinates have been chosen. Other coordinates, for example, spherical coordinates, can also be used.

The above two remarks illustrate the fact that the discretization can be performed in different ways. The important thing is that the main idea remains the same: One considers *approximate* values of the unknown functions at a *finite* number of grid-points, which are defined by the discretization chosen, instead of the exact solution of Equation (1) on the whole continuous space domain.

Numerical methods must be used to find approximate values of the solution at the grid-points. It is also appropriate to split the model, the system of PDEs of the type in Equation (1), into several submodels (subsystems), which are in some sense simpler. Another advantage when some splitting procedure is applied is that the different subsystems have different properties, and one can try to select the best numerical method for each subsystem.

It is clear that if some splitting procedure and appropriate numerical methods are already chosen, then any continuous system of the type in Equation (1), which represents an environmental model, is replaced by several *discrete* submodels that have to be treated on the available computers.

As mentioned above, the model described by Equation (1) is an air pollution model. However, it must be emphasized, once again, that many environmental models are also described by systems of partial differential equations and, thus, can be treated similarly.

NEED FOR EFFICIENT ORGANIZATION OF THE COMPUTATIONAL PROCESS

The discretization of the system of PDEs by which the environmental models are described mathematically leads to huge computational tasks. The following example illustrates clearly the size of these tasks. Assume that

- $N_x = N_y = 480$ (when a 4800 km × 4800 km-domain covering Europe is considered, then this choice of the discretization parameters leads to 10 km × 10 km-horizontal cells),

- $N_z = 10$ (i.e., 10 layers in the vertical direction are introduced) and
- $N_s = q = 56$ (the chemical scheme contains 56 species).

Then, the number of equations that are to be handled at each time-step is $(N_x + 1)(N_y + 1)(N_z + 1)N_s = 142,518,376$. A run over a time-period of one year with a time stepsize $\Delta t = 2.5$ seconds will result in $N_t = 213,120$ time-steps. When studies related to climatic changes are to be carried out, it is necessary to run the models over a time period of many years. When the sensitivity of the model to the variation of some parameters is studied, many scenarios (up to several hundreds) are to be run. This short analysis demonstrates the fact that the computational tasks that occurs when environmental studies are to be carried out by using large-scale models are enormous. Therefore, it is necessary:

- to select fast but sufficiently accurate numerical methods and/or splitting procedures,
- to exploit efficiently the cash memories of the available computer,
- to parallelize the code

in the efforts to make a large environmental model tractable on the available computers. It should be mentioned that it may be impossible to handle some very large environmental models on the computers currently available even when the above three conditions are satisfied.

SOME APPLICATIONS

Results from two important applications,

(1) the impact of biogenic emissions on pollution levels and
(2) the influence of the climatic changes on pollution levels in Europe,

will be given to illustrate the usefulness of models when some environmental phenomena are studied.

Bad Days

High ozone concentrations can cause damage to human health. Therefore, critical levels for ozone have been established in the European Union (EU) as well as in other parts of the world. Some of these critical levels are legislated in the EU Ozone Directive. Assume that $c_{\max}$ is the maximum of the 8-hour averages of the ozone concentrations in a given day at site **A**. If the condition $c_{\max} > 60$ ppb is satisfied, then the day under consideration is declared as a “bad day” for site **A**. “Bad days” have damaging effects on some groups of human beings (for example people who suffer from asthmatic diseases). Therefore, the number of such days should be reduced as much as possible. Two aims are stated in the Ozone Directive issued by the EU Parliament in year 2002:

- **Target aim**. The number of “bad days” in the European Union should not exceed 25 days after year 2010.
- **Long-term aim**. No “bad day” should occur in the European Union (the year after which the long-term aim has to be satisfied is not specified in the EU Ozone Directive).

Biogenic Emissions and “Bad Days”

The distribution of the “bad days” in different parts of Europe is shown in the two upper plots of Fig. 1: (a) in left-hand-side plot for year 1989 and (b) in the right-hand-side plot for year 2003. The numbers of the “bad days” in Europe is in general reduced considerably in the period from 1989 to 2003. The significant reduction of the human-made (anthropogenic) emissions in Europe is the reason for these reductions. The reductions of the human-made (anthropogenic) emissions in Europe are shown in Fig. 2. The reduction of the emissions of nitrogen oxides (NOx emissions) and volatile organic compounds (VOC emissions) is most important for the changes of the numbers of “bad days.”

The results presented in the two upper plots are obtained by using “normal biogenic emissions.” Increased biogenic emissions (“high biogenic emissions”) were also used. The changes of the “bad days” when high biogenic emissions are used instead of the normal biogenic emissions are shown on the two lower plots in Fig. 1 (for year 1989 in the left-hand-side plot, and for year 2003 in the right-hand-side plot). A great difference can be observed: The largest increases of the “bad days” in year 1989 are in Eastern and South-Eastern Europe, whereas the largest increases in year 2003 occur in Germany and some surrounding countries. It is not very clear what the reason for the different behavior is. Some possible explanations are given below.

Consider the NOx and VOC emissions, which contribute to the formation and destruction of ozone (and, thus, these emissions play an important role when the numbers of “bad days” are to be studied). Consider also the two major countries, Germany and Ukraine, where the differences are largest. Comparing the changes of the emissions for years 1989 and 2003, it is observed (Table 1) that whereas the reductions of the VOC emissions are nearly the same (60.3% for Germany and 53.4% for Ukraine), the reduction of the NOx emissions of nitrogen oxides in Germany (46.3%) is nearly four times larger than the corresponding reduction in Ukraine (12.1%). This disparity might be one reason for the different patterns in the lower plots of Fig. 1.

Some combinations of NOx and VOC emissions imply dominance of the formation of ozone, whereas other combinations increase the destruction rate. Assume that the biogenic emissions are kept fixed (the normal biogenic emissions). The results indicate that the combinations of these two types of emissions in Eastern Europe increase the formation rate of ozone (in the transition from year 1989 to year 2003), whereas the opposite situation is observed in Central Europe. This result could also be observed by comparing the upper two plots in Fig. 1: The numbers of “bad days” in the region around Moscow is increased in 2003 despite the fact that the both the NOx and VOC

emissions were decreased (the biogenic emissions in the upper two plots are the same).

Other reasons can explain the different patterns in the two lower plots of Fig. 1. For example, the meteorological conditions may also play some role. More scenarios are needed to find the right answer of the question about the differences of the numbers of "bad days" in different parts of Europe. However, it is important to emphasize that the biogenic emissions:

- play an important role when the numbers of "bad days" are studied,
- must be studied more carefully (some scientists claim that these are underestimated). and
- requires much more scenarios, which have to be run over long time periods (many years). These scenerios are needed in the efforts to answer the questions that originated during the experiments.

The last requirement leads to huge computational tasks and great storage requirements.

Climatic Changes and "Bad Days"

Many programs are designed to predict the future state of the world's climate and to explore the effects of such changes on a variety of policy sectors (e.g., food, water, energy, socioeconomic development, and regional security). The major efforts in this direction are coordinated by the Intergovernmental Panel on Climate Change (IPCC). Environmental degradation is also of concern in future climate scenarios, and much effort has been dedicated to understand changing pressures on an already stressed system. Here, the attention will be focused on pollution in the future climate. Within many regions on planet Earth, air pollution policy has been regionalized to achieve two major aims: (*1*) to control and reduce transboundary pollution and (*2*) to meet policy objectives to limit air pollution impacts on human health and sensitive ecosystems. The effort to achieve these two aims has been a daunting task. Within Europe, the Convention on Long Range Transport of Air Pollution has been dedicated to establishing a legal framework for reducing air pollution and assuring the safety of humans and ecosystems within prescribed limits. Limit values for a variety of pollutants have also been established, as mentioned above, in the EU. However, in reaching compliance to the air quality directives, very few studies have considered the possibility that climate change *may induce* an additional controlling factor. Therefore, it is desirable to answer the question:

- *Will climate change add to the rate of reaching compliance to air quality policy objectives, or will it make the process of reaching compliance more difficult?*

This question can be considered in two aspects: qualitative and quantitative. If only a qualitative answer is needed, then the task becomes easy. The answer is obviously yes, because both the chemical reactions and the biogenic emissions depend on the temperature. Thus, the warming effect will certainly have some impact on the pollution levels. The second aspect is much more interesting, because it is important to produce some quantitative evaluation of the impact of the climate changes on the pollution levels. The predictions about the increase of the annual temperatures in Europe according to the IPCC SRES A2 Scenario as well as several other conclusions, which are related to the climatic changes in Europe and are discussed in the reports prepared by the scientists from IPCC, can be used to prepare three climatic scenarios related to pollution studies. These scenarios can also be used to obtain quantitative evaluation of the impact of future climatic changes on certain pollution levels.

Climate Scenario 1

The predicted, by the IPCC SRES A2 Scenario, annual changes of the temperature were used to produce this climatic scenario. Resulting from this scenario changes of the temperature in Europe are shown in Fig. 3. Consider any cell of the grid used to create the plot shown in Fig. 3

Table 1. Changes of Anthropogenic Emissions Participating in the Formation and Destruction of Ozone in Germany and Ukraine

	Emissions of nitrogen oxides			Emissions of volatile organic compounds		
Country	1989	2003	Reduction	1989	2003	Reduction
Germany	2989	1605	46.3%	3202	1272	60.3%
Ukraine	1065	936	12.1%	1512	704	53.4%

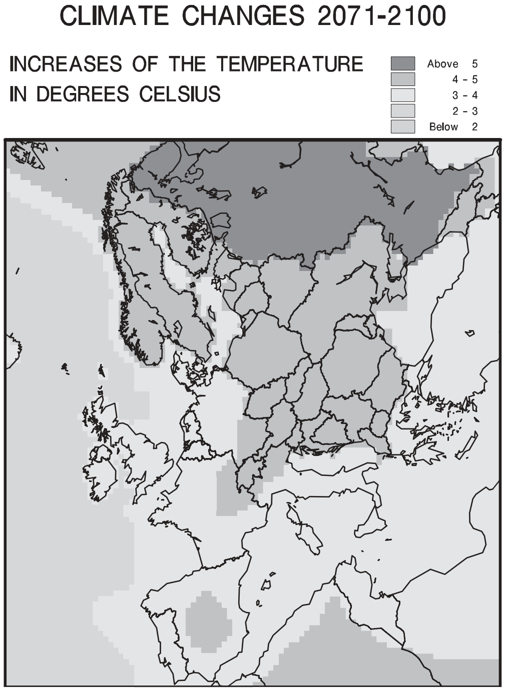

Figure 3. Future changes of the temperatures in Europe according to the IPCC SRES A2 Scenario.

and assume that this cell is located in a region where the increase of the temperature is in the interval [a,b]. The temperature at the chosen cell at hour n (where n is in the interval from 1989 to 2004) is increased by an amount $a + c(n)$, where $c(n)$ is randomly generated in the interval $[0, b - a]$. The mathematical expectation can increase the annual mean of the temperature at any cell of the space domain, where it is predicted that the increase of the temperature is in the interval [a,b], $(b - a)/2$. Only temperatures are varied in this scenario and the mean value of the annual change of the temperature at a given point will tend to be $(b - a)/2$ for each year of the chosen interval (from 1989 to 2004).

Climate Scenario 2

The extreme meteorological events will become even stronger in the future climate. It is also expected that: (*1*) higher maximum temperatures and more hot days will be observed in the land areas; (*2*) higher minimum temperatures, fewer cold days, and fewer frost days will be observed in nearly all land areas; and (*3*) the diurnal temperature range will be reduced over land areas. The temperatures during the night were increased with a factor larger than the factor by which the daytime temperatures were increased. In this way, the second and the third requirements are satisfied. The first requirement is satisfied as follows. During the summer periods, the daytime temperatures are increased by a larger amount in hot days. All these changes are observed only over land. Furthermore, the temperatures were varied in such a way that their annual means remained the same, at all cells, as those in the first climatic scenario. The cloud covers over land during the summer periods were also reduced.

Climate Scenario 3

It is also expected that there will be (*1*) more intense precipitation events and (*2*) increased summer drying and associated risk of drought. The precipitation events during winter were increased both over land and over water. The precipitation events in the continental parts of Europe were reduced during summer. Similar changes in the humidity data were made. The cloud covers during winter had increased, whereas the same cloud covers as in the second climatic scenario were applied during summer. As in the previous two climatic scenarios, the mathematical expectation of the annual means of the temperatures is the same as the predictions made in the IPCC SRES A2 Scenario.

Computational Difficulties. The computational requirements are enormous when the influence of the climatic changes on pollution levels is studied. The difficulties develop because:

- the models are to be run over a long time period (the time period was 16 years in the particular study discussed here, but it is perhaps more appropriate to use a longer period, say, 25 or even 50 years),
- many scenarios are to be used (14 scenarios were actually used, but again more scenarios will give better information about the studied phenomena),
- it is highly desirable to use fine resolution (the domain under consideration, containing the whole of Europe and its surroundings, was discretized by using a 480 × 480 × 10 grid).

The task of running 14 scenarios over a time period of 16 years on a fine grid (480 × 480 × 10 cells) is extremely time consuming. The storage requirements are also enormous. Therefore, the task of running so many scenarios over a long time period could be solved successfully only if several requirements are simultaneously satisfied: (*1*) fast but also sufficiently accurate numerical methods are to be implemented in the model, (*2*) the cache memories of the available computers have to be used efficiently, (*3*) codes that can be run in parallel have to be developed and used, and (*4*) reliable and robust splitting procedures have to be implemented. It must be emphasized that it is *impossible* to handle the 14 scenarios over a time period of 16 years on the available supercomputers if the subtasks (*1*)–(*4*) are not solved efficiently. Even when it was done, it took more than 2 years to compute data from all 2688 runs (14 scenarios × 16 years × 12 months) carried out in this particular study. This fact illustrates the great computational difficulties that are related to the investigation of impact of climatic changes on pollution levels.

Model Results

Some results related to the numbers of "bad days" are given in Fig. 4. Several conclusions can be drawn by investigating

Figure 4. Distributions of the "bad days" in different parts of Europe when Climate Scenario 3 is used (the two upper plots) and changes of the numbers of bad days (in percent) when Scenario Climate 3 is applied instead of the Basic Scenario (the lower two plots). Plots obtained by using meteorological data for 1989 are given on the left-hand side, whereas plots for 2003 are on the right-hand-side.

the results in Fig. 4 and comparing some of them with results from Fig. 1:

- Comparing the results shown in the upper plots of Fig. 4 (obtained by using Scenario Climate 3) with the corresponding plots in Fig. 1 (obtained with the Basic Scenario), it is observed that some regions where the limit of 25 "bad days" is exceeded when the Basic Scenario is used are enlarged when Scenario Climate 3 is applied.
- The previous conclusion was qualitative. Quantitative results can be obtained by taking the ratios of the results obtained by Climatic Scenario 3 and the Basic Scenario (multiplied by 100 in order to get the changes in percent). Results are shown in the lower plots of Fig. 4. It is observed that the climatic changes can cause significant increases of the "bad days" (in some areas of Europe by more than 30%). Therefore, the climatic changes must be taken into account in investigations carried out to define some measures that are to be taken to keep the pollution levels under prescribed acceptable levels.
- Many questions still must be answered. For example, it is not clear (as in the case where the relationship

between biogenic emissions and "bad days" was studied) why the biggest changes in year 1989 are mainly in Eastern Europe, whereas the changes are big also in Central and Western Europe in year 2003. Some reasons, similar to those given when the results in Fig. 1, can also be given here. However, it is more important to emphasize that it is necessary to carry out much more experiments with (*1*) more scenarios, (*2*) finer discretizations, (*3*) better input data, and (*4*) careful and detailed examination of the meteorological conditions in the studied period.

Much more results and conclusions, including results related to the first two climatic scenarios, are given at: http://www2.dmu.dk/atmosphericenvironment/Climate-%20and%20Pollution.

COMBINING THE ENVIRONMENTAL MODELS WITH OTHER LARGE-SCALE MODELS

The environmental phenomena are closely related to other phenomena. Therefore, the environmental models have to be considered together with other models. Several examples are given below to illustrate this statement.

Relationship Between Climatic Changes and Pollution Levels

Some results related to the impact of the climate changes on the "bad days" have been presented in one of the previous sections. It must also be mentioned here that the climate changes have significant influence also on other quantities related to damaging pollutants. Therefore, the climate changes must be considered as an important factor when decisions about measures, which will lead to reductions of harmful pollution levels, are to be taken. Furthermore, the increased pollution levels will cause some feedback effects on the climate. This finding implies that it is desirable to combine high-resolution climatic models with environmental models to study in detail the interrelations between these two processes.

Preparation of Pollution Forecasts on Different Scales

This task involves running several weakly connected large-scale models in order to handle a set of complex problems:

- weather forecasts on different regional scales (starting with results obtained on a global scale),
- weather forecasts on an urban scale (perhaps in parallel for several urban areas),
- pollution forecasts on different regional scales,
- pollution forecasts on an urban scale (perhaps in parallel for several urban areas),
- treatment of the output results in order to prepare them for the people who will use them (data mining algorithms and high-speed visualization tools must be applied at this stage),
- sending the relevant data to appropriate media (television stations, radio stations, Internet sites, GMSs, etc.).

It is clear that computer grids will be very powerful tools in the solution of the very challenging task related to the possibility to treat efficiently the set of problems described above. Currently, such sets of problems are solved only by imposing many simplifying (and very often not physical) assumptions. At the same time, it is also clear that a lot of difficulties must be overcome in the efforts to run such complex tasks efficiently on a computer grid. The greatest difficulties are the tasks of

- achieving reliable and robust transition from one scale to another,
- communicating relevant data from one part of the computational grid to another, and
- preparing the final results, which should be easily understandable by the recipients.

Coupling of Environmental Models with Economical Models

If some critical pollution levels are exceeded, then some measures are to be taken in an attempt to avoid damaging effects. The measures are normally related to some reductions of the human-made (anthropogenic) emissions. The emission reductions can be performed either directly (by using new technologies, filters, etc.) or indirectly (by introducing higher "green" taxes). It is clear, however, that the reductions of the emissions will as a rule cause economical problems; in the worst case, economical crises may be caused by putting too-heavy requirements on emission reductions. Therefore, it is necessary to combine the need to keep the pollution under the critical levels with the need to preserve the rates of the economical development of the region under consideration. It is worthwhile to combine the environmental models with economical models in the effort to achieve both lower pollution levels and sustainable development of the economy. The aim should be to optimize the process by finding out

- where to reduce the emissions and
- by how much to reduce them (the emissions should be reduced as much as needed, but no more than what is absolutely necessary)

to keep the balance between safe environment and sustainable development. The proper treatment of the task of searching an optimal solution with a combination of large-scale environmental and advanced economical models is both very time consuming, and the storage requirements are extremely high. The efficient solution of this task is a very challenging problem.

Formation and Transportation of Aerosol Particles

Aerosol particles are dangerous for health, modifying radiative fluxes, modifying cloud formation, and changing the chemical composition. Therefore, they have been recognized for their potentially negative impact on human health and ecosystems. This finding implied regulatory legislation regarding emissions and concentration levels of particulate matter all over the world. It was also acknowledged that particles play an important role in the global climate by their influence on earth's radiative balance.

The goal of aerosol modeling is to establish a detailed description of the aerosol particle concentrations, their composition, and size distribution. This model requires advanced modeling techniques and innovation as well as reliable validation data of particle characteristics.

Aerosol models may provide a predictive capability for future projections of the outcome of policy strategies on emissions. Consequently, aerosol models are needed that properly describe the cycle of formation, dispersion, and removal of particles. Such validated models can be used as cost-effective tools for reliable studies of the current status and predictions for various environmental and health impacts in the future.

Some extra mathematical terms, which described the transport and the transportation of aerosol particles, have to be added to the model described by Equation (1) when it has to be used in aerosol studies. Moreover, it is necessary to add some equations in Equation (1).

Studying Persistent Organic Pollutants

The persistent organic pollutants (POPs) are chemical compounds with different origins but common characteristics, such as semi-volatility, hydro-phobicity, bioaccumulation, toxicity, potential for long-range transport, and a tendency to accumulate in cold regions ("cold condensation"). POPs may have adverse health effects on humans and wildlife as well as harmful effects on the immune and reproductive systems. Several POPs currently are either banned or regulated through international treaties, but they are still found in the Arctic environment. Models similar to the model described by Equation (1) can be used to study POPs. The treatment of such models leads to huge computational tasks because (*1*) the spatial domains are normally very large (hemi-spherical models and, even better, global models are to be used) and (*2*) fine resolution of the systems of PDEs is highly desirable.

Implementation of Variational Data Assimilation in Environmental Models

Many uncertainties are related to large environmental models. The lack of reliable knowledge for some underlying physical and chemical processes is introducing great uncertainties, but also other reasons are for uncertainties suggested such as, inaccurate input data. Observations can be used to reduce the influence of the uncertainties. The variational data assimilation approach is becoming more and more popular. This approach could be viewed as an attempt to adjust globally the results obtained by a given model to a set of available observations. This approach has the theoretical advantage of providing consistency between the dynamics of the model and the final results of the assimilation. Variational data-assimilation procedures are based on the minimization of certain functional. Assume that (*1*) an improved initial concentration field must be found (it is important when pollution forecasts are to be computed) and (*2*) observations are available at time-points t_p, where $\mathrm{p} \in \{0, 1, 2, \ldots, \mathrm{P}\}$. These observations can be taken into account in an attempt to improve the results obtained by a given model. This effect can be achieved by minimizing the value of the following functional:

$$\mathrm{J}\{\mathrm{c}_0\} = \frac{1}{2}\sum_{\mathrm{p}=0}^{\mathrm{P}} \langle \mathrm{W}(\mathrm{t_p})(\bar{\mathrm{c}}_\mathrm{p} - \bar{\mathrm{c}}_\mathrm{p}^{\mathrm{obs}}),\, \bar{\mathrm{c}}_\mathrm{p} - \bar{\mathrm{c}}_\mathrm{p}^{\mathrm{obs}} \rangle \qquad (2)$$

where $\mathrm{J}\{\bar{\mathrm{c}}_0\}$ depends on the initial value $\bar{\mathrm{c}}_0$ of the vector of the concentrations, $\mathrm{W}(\mathrm{t_p})$ is a matrix containing some weights and $\langle , \rangle$ is an inner product in an appropriately defined Hilbert space (the usual vector space is normally used, i.e., $\bar{c} \in \mathcal{R}^q$ where q is the number of chemical species). The functional $\mathrm{J}\{\bar{\mathrm{c}}_0\}$ depends on both the weights and the differences between calculated by the model concentrations $\bar{c}_p$ and observations $\bar{c}_p^{\mathrm{obs}}$ at the time levels $\{0, 1, \ldots, P\}$ at which observations are available.

Data assimilation can be used not only to improve the initial values (as in the above example) but also in many other tasks (improving the emissions, boundary conditions, the calculated concentrations, etc.). The variational data-assimilation technique should not be considered as a universal tool that can be used in all situations. No measurements are available when different scenarios are used to study the response of the model to the variation of different parameters (emissions, meteorological conditions, climatic changes, etc). We have to rely only on the model in such studies. Therefore, it is absolutely necessary to use data-assimilation techniques not only to improve the model results but also to improve some physical and chemical mechanisms implemented in the model. The hope is that the improved model will provide more reliable results in situations where no measurements are available.

Using Ensembles

Ensembles (based on using results from several different models or results from the same model run by using different parameters, say, different initial values) can be applied in an attempt to improve the reliability of the model. The results are normally averaged. One should expect that the averaged results are better in some sense. This conclusion is based on an assumption (very often not explicitly stated) that no bias is observed in the errors of the results. If, for example, all the models participating in the ensemble procedure strongly overestimate the concentrations of some chemical species, then the results of the ensemble will not be much better because they will also overestimate the species under consideration. Similar conclusions can also be drawn in the case where one model is run with many values of a selected parameter (in this case the set of the values should be carefully chosen). Another problem may develop if one model produces very different results (say, 100 times higher than the other models). In such a case, the "bad" model will spoil the results of the ensemble (it should be eliminated, before the preparation of the ensemble). These examples are provided to show that one must be careful: It is necessary (*1*) to analyze somehow the properties of the models participating in the ensemble procedure or (*2*) to select a good set of values of the parameter which is varied.

The application of ensembles (for different purposes) requires increased computer power. Indeed, the performance of 50–100 runs and preparing an ensemble on the basis of all these runs is a challenging task even for the best high-performance computers currently available. However, the results obtained by using ensembles normally are more reliable than the results obtained in a single run.

EXPERT DECISION SYSTEM FOR ROBOT SELECTION

INTRODUCTION

Over the past two decades, an upward trend has been observed in the use of industrial robots because of quality, productivity, flexibility, health, and safety reasons. Robots can help manufacturers in virtually every industry to stay globally competitive. Robots can be programmed to keep a constant speed and a predetermined quality when performing a task repetitively. Robots can manage to work under conditions hazardous to human health, such as excessive heat or noise, heavy load, and toxic gases. Therefore, manufacturers prefer to use robots in many industrial applications in which repetitive, difficult, or hazardous tasks need to be performed, such as spot welding, arc welding, machine loading, die casting, forging, plastic molding, spray painting, materials handling, assembly, and inspection. However, a wide selection of robot alternatives and the large number of performance attributes result in a major problem for potential robot users when deciding which robot to purchase.

In the absence of a robust decision aid, the robot selection decisions can be based on the recommendations of robot vendors, the recommendations of an expert hired for performing the evaluation task, or the user's own experience. The recommendations of robot vendors may be biased because they have an inherent interest in selling their product. Basing robot selection decisions on expert advice may be highly costly because experts usually charge considerable amounts for their valuations. Relying on personal experience generally results in selecting a robot with which the user is most familiar, ignoring other crucial factors.

A robot that has the capability of affording heavy load at high speed, as well as good repeatability and accuracy, will contribute positively to the productivity and flexibility of the manufacturing process, which are of high importance when competitive market forces require the introduction of new products into the market. When product design changes need to be made repeatedly, owning a high performing robot will avoid replacement or modification. Many studies reported in the literature address the development of a robust decision tool that enables the potential robot user to select a high-performing robot.

Although it is usually assumed that the specified performance parameters are mutually independent, in general performance parameters provided by robot vendors are not achievable simultaneously. For instance, Offodile and Ugwu (1) reported that for a Unimation PUMA 560 robot manufacturer-specified repeatability deteriorated as the speed increased beyond 50% of the status speed and the weight increased beyond 0.91 kg. Furthermore, it is very difficult to determine the functional relationship between these parameters; thus, making this assumption introduces a risk of selecting a robot that might fail to provide the required performance.

In this article, integration of an expert system and a decision-support system is proposed to enhance the quality and efficiency of the robot selection process. Rather than seeking the advice of an expert or group of experts, the user may consult an expert system to determine the key performance attributes and a short list of acceptable robot alternatives. Expert systems are used to perform a wide variety of complicated tasks that can only be performed by highly trained human experts. Although the problem domain for robot selection may be considered as narrow, which fits the expert system structure, it is also complex and requires a multicriteria decision making (MCDM) procedure. An expert system needs to access the database of a decision-making system to gather factual knowledge. Furthermore, the judgmental data obtained from experts can be incorporated into a decision-making system through an expert system.

A MCDM methodology is required in the expert decision system framework because the expert system provides a subset of robot alternatives based on the technical aspects, and an appropriate MCDM technique evaluates the short list of alternatives and determines the robot that best fits the user requirements.

The proposed decision-support system that employs quality function deployment and fuzzy linear regression integrates user demands with key specifications of robots. The developed decision-making approach has advantages compared with the techniques previously proposed for robot selection. Statistical methods, such as ordinary least squares, are based on determining a meaningful statistical relationship between performance parameters, which is difficult to achieve in practice and the problem aggravates for a small number of candidate robots. Multiattribute decision-making techniques such as multiattribute utility theory (MAUT), analytic hierarchy process (AHP), technique for order preference by similarity to ideal solution (TOPSIS), assume that preferential independence of the performance parameters hold. However, that is a very critical assumption that usually fails to hold in real-world applications. Although fuzzy multiattribute decision-making techniques enable qualitative attributes to be taken into account in an effective manner, they suffer from the same shortcoming as the other multiattribute decision-making techniques. Data envelopment analysis (DEA) does not require the preferential independence assumption of performance parameters. However, DEA assumes that every characteristic defined as output is related to every input. Profiling may be considered as an alternative to tackle that problem, but gathering the efficiency scores into a single efficiency score may also be problematic (2).

INDUSTRIAL ROBOTS

The Robot Institute of America has given the definition of a robot as a reprogrammable, multifunctional manipulator

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

designed to move material, parts, tools, or specialized devices through variable programmed motions for the performance of a variety of tasks (3).

Before going any further, main parameters used for robot classification are briefly introduced, and major benefits of robot installations are addressed. *Reprogrammability* has made industrial robots a key component of flexible automation. The robot's motion is controlled by a program that can be modified to change the motion of the robot arm significantly. The programmability provides the versatility of a robot.

The basic *geometric configurations* of the robots are usually classified as Cartesian, cylindrical, spherical, and jointed arm. A robot that conforms to a Cartesian geometry can move its gripper to any position within the cube or rectangle work envelope. A robot with a cylindrical geometry can move its gripper within a volume described by a cylinder. The spherical (polar) arm geometry positions the robot through two rotations and one linear actuation. Jointed arm, which are sometimes referred to as articulated robots, have an irregular work envelope. As more flexible and specialized coordinate systems are demanded through time, other robot coordinate systems such as selective compliance assembly robot arm (SCARA), which is particularly used in electronic circuit board assembly applications, have emerged.

Each joint on a robot introduces a *degree of freedom*. In general, a robot with 6 degrees of freedom is required for positioning the tool to a point in space with any orientation. Although a robot with the highest degrees of freedom can produce the most complex movement, one shall consider other factors such as range and quality of motion corresponding to a given degree of freedom.

The *work envelope* is a boundary for the region in which the robot operates determined by the extreme positions of the robot axes. The size of the work envelope defines the limits of reach; thus, it is a key characteristic that needs to be considered in robot selection. Although the reach for a Cartesian configuration is a rectangular-type space, the reach for a cylindrical configuration is a hollow cylindrical space, and the reach for a spherical configuration is a hollow spherical space, respectively; the reach for a jointed arm configuration does not have a specific shape.

The basic types of *power sources* (*drives*) for robots can be named as hydraulic, pneumatic, and electric. The main advantage of hydraulic actuators is that they can afford large load capacity, but they also have many drawbacks, such as possibility of leaks that may be hazardous in certain applications and a high noise level. An important application of hydraulic robots is in spray painting. The pneumatic power source is relatively inexpensive; it enables short cycle times, and leaks do not contaminate the work area, but it has limited positioning capability. Pneumatic robots are frequently used in pick-and-place operations and machine loading. Electric power results in uncontaminated work space, low noise level, and better positioning accuracy and repeatability; however, along with limited load capacity compared with the hydraulic power. Nowadays, the electric drive is the most popular type for general purpose industrial robots.

The *path control* is a means for describing the method that the robot controller employs to guide the tooling through the many points in the desired arm trajectory. The types of path control can be named as point-to-point, controlled path, and continuous path.

Load capacity (*payload*), which denotes the weight-lifting capacity of a robot, is a key parameter that requires careful analysis. In general, the weights that the robots can hold vary with respect to speed. Furthermore, the shape, surface conditions, and positioning of the object held are also important in terms of load capacity. The user of the robot should pay attention to the conditions under which the load capacity is determined by the manufacturer.

Repeatability and *accuracy* are the most easily confused attributes. Repeatability is a measure of the ability of the robot to return to the same position and orientation over and over again, whereas accuracy is a measure of closeness between the robot end-effector and the target point, and it is defined as the distance between the target point and the center of all points to which the robot goes on repeated trials. It is easier to correct poor accuracy than repeatability, and thus, repeatability is generally assumed to be a more critical attribute. Repeatability is a vital feature in justification and use of robots because although the accuracy of human workers may be higher, they tend to operate with less repeatability.

Even though robots have numerous advantages compared with humans in the workplace, one shall not consider a robot as a replacement for a worker in performing all manufacturing tasks. For instance, humans are superior to robots for manufacturing tasks that require intelligence and judgment capabilities. The robots are definitely more efficient, and in certain cases essential, for performing repetitive and highly fatiguing tasks, or for performing applications in environments that are hazardous or dangerous for a human worker to operate. It is also worth noting that a robot can operate three shifts per day for seven days a week with regular maintenance, whereas this schedule would have been impossible for a human worker.

Not only are robots efficient, and in certain cases essential, replacements for humans for performing fatiguing, hazardous, or dangerous tasks, but also they are important for preserving jobs for other workers by increasing productivity.

The major benefits of industrial robots can be named as

- Increased product and market flexibility,
- Increased productivity,
- Improved product quality,
- Shorter cycle times,
- Lower operating costs,
- Higher precision,
- Reduced floor space,
- Elimination of health and safety hazards.

Within the past two decades, the number of robot installations have increased with emphasis on the integration of robots into computer-integrated manufacturing systems.

JUSTIFICATION OF ADVANCED MANUFACTURING SYSTEMS

According to Meredith and Suresh (4), investment justification methods for advanced manufacturing technologies are classified into economic analysis techniques, analytical methods, and strategic approaches. These methods deviate from each other mainly because of the treatment of nonmonetary factors. Economic justification methods for manufacturing investments have been discussed thoroughly in the past couple of decades. Economic analysis methods are the basic discounted cash flow (DCF) techniques, such as present worth, annual worth, internal rate of return, and so on, and other techniques such as payback period and return on investment. It is well known by practitioners who follow the fundamental principles of engineering economy that accounting methods, which ignore time value of money, would produce inaccurate or at best approximate results.

The conventional DCF methods do not seem to be suitable on their own for the evaluation of an advanced manufacturing technology (AMT) investment because of the nonmonetary impacts posed by the system. Sullivan (5) points out the inadequacy of traditional financial justification measures of project worth such as return on investment, payback, and net present worth in considering the strategic merits of advanced manufacturing technologies. The results of the surveys conducted by Lefley and Sarkis (6) for appraisal of AMT investments in the United Kingdom and United States indicate the support for the difficulty in assessing AMT investments because of their nonquantifiable benefits. Because of this difficulty, over 80 % of the respondents in the United States and United Kingdom point out that not all potential benefits of AMT investments are considered in the financial justification process. Improvements in product quality, reliability, productivity, precision, cycle times, and competitiveness as a result of the versatility and flexibility of the system, are the focal points in the justification stage of an AMT investment. Productivity, quality, flexibility, and other intangibles should be examined in terms of potential returns through enhancement of long-term business competitiveness as well as in terms of a comprehensive evaluation of internal costs.

When flexibility, risk, and nonmonetary benefits are expected, and in particular if the probability distributions can be estimated subjectively, analytical procedures may be used. Strategic justification methods are qualitative in nature, and they are concerned with issues such as technical importance, business objectives, and competitive advantage (4). When strategic approaches are employed, the justification is made by considering long-term intangible benefits. Hence, using these techniques with economic or analytical methods would be more appropriate. Figure 1, which is an updated version of the classification provided in Karsak and Tolga (7), resumes the justification methods for advanced manufacturing technologies. Axiomatic design approach (8,9), digraph and matrix methods (10), and QFD and fuzzy regression (2) can be listed as the major updates to the classification given in Ref. 7.

Over the past several decades, manufacturing firms have assigned an increasing importance to robot selection because improper selection of robots can adversely affect their productivity and product quality along with profitability. The increased use of robots and the complexity of the robot evaluation and selection problem have motivated the researchers to develop models and methodologies for making sound decisions.

Mathematical programming, statistical procedures, and fuzzy set theoretic methods, as well as multiattribute and multiobjective decision-making methods can be listed among analytical methods used for robot selection. More recently, axiomatic design approach, digraph and matrix methods, and quality function deployment (QFD) and fuzzy regression have also been proposed as alternative decision aids. Many classifications for models developed for robot selection are available in the literature. For instance, Khouja and Offodile (11) classified models for robot selection as multicriteria decision-making models, performance-optimization models, computer-assisted models, statistical models, and other approaches. Here, we briefly review expert system applications and the use of multicriteria decision making (MCDM) techniques, which possess the potential for considering the multiple and conflicting criteria inherent in the robot selection problem.

Relatively few studies exist regarding the use of expert systems in robot selection. Fisher and Maimon (12) developed a two-phase model for robot selection. In phase 1, an expert system is used to obtain a list of tasks' requirements. The expert system determines a set of robotics technologies and engineering specifications that meet the requirements. In phase 2, a list of candidate robots is chosen and ranked. Boubekri et al. (13) developed a computer-aided system for robot selection, which includes an expert system that considers the functional and organizational parameters specified by the user, an economic feasibility analysis module based on payback period, and a module that provides the user with a detailed description of each robot in the knowledge base. Agrawal et al. (14) employed an expert system to determine the set of important attributes for the particular application and narrow down the robot alternatives, and then used a multiattribute decision-making approach named TOPSIS, which is based on the ideal solution concept, for ranking the shortlist of robot alternatives.

Several articles have focused on the use of MCDM techniques for justification of industrial robots. Imany and Schlesinger (15) compared linear goal programming and ordinary least-squares methods via a robot selection problem in which robots are evaluated based on cost and technical performance measures, which include load capacity, velocity, and repeatability. Liang and Wang (16) presented a robot selection procedure using the concepts of fuzzy set theory. Although providing a multicriteria tool that can incorporate subjective criteria, their approach suffers from the implicit assumption of mutual independence of technical performance parameters. Khouja (17) used DEA and MAUT in a two-phase procedure for robot selection. Baker and Talluri (18) addressed some limitations of the simple radial efficiency scores used for ranking industrial robot alternatives in Khouja's study and proposed a more robust evaluation procedure based on cross-efficiency analysis, which is an extension used for improving the discriminating power of DEA. Goh (19) presented an AHP model for a group of decision makers that considered

	TECHNIQUES	ADVANTAGES	DISADVANTAGES
ECONOMIC	– Payback method – Return on investment – Discounted cash flow techniques (NPV, IRR)	– Ease in data collection – Intuitive appeal	– Do not take into account strategic and noneconomic benefits – Consider a single objective of cash flows, and ignore other benefits such as quality and flexibility
STRATEGIC	– Technical importance – Business objectives – Competitive advantage – Research and development	– Require less technical data – Use the general objectives of the firm	– Necessity to use these techniques with economic or analytic ones because they consider only long-term intangible benefits
ANALYTIC	– Scoring models (AHP, etc.) – Multi-attribute utility theory – Mathematical programming – Integer programming – Goal programming – DEA – Axiomatic design approach – Digraph and matrix methods – Stochastic methods – QFD and fuzzy regression – Expert systems – Fuzzy set theory	– Uncertainty of the future and the multiobjectivity can be incorporated – Subjective criteria can be introduced in the modeling phase	– Require more data – Usually more complex than the economic analysis

Figure 1. Classification of justification methods for advanced manufacturing technologies (7).

both subjective and objective factors for robot selection. Karsak (20) developed a two-phase decision framework that employs DEA in the initial phase to determine the technically efficient robot alternatives and a fuzzy robot selection algorithm in the second phase to rank the technically efficient robots. Parkan and Wu (21) studied the robot selection problem using operational competitiveness rating, TOPSIS, and utility function model, and proposed to rank the robot alternatives based on the averages of the rankings obtained by these three decision aids. Braglia and Petroni (22) proposed the use of DEA with restricted multiplier weights for identifying the optimal robot by considering cost as the single input and engineering attributes as the outputs, and they addressed the advantages and drawbacks of using weight-restriction constraints compared with those of cross-efficiency analysis. Talluri and Yoon (23) proposed a cone-ratio DEA approach for robot selection, which made use of weight-restriction constraints to incorporate a priori information on the priorities of factors. More recently, a practical common weight MCDM methodology with an improved discriminating power has been developed for robot selection (24). The merits of the approach proposed in the paper compared with DEA-based models can be summarized as its ability to evaluate all robot alternatives by common weights for performance attributes that overcome the unrealistic weighting scheme common to DEA resulting from the fact that each decision-making unit (DMU) selects its own factor weights to lie on the efficient frontier, and to further rank DEA-efficient DMUs with a notable saving in computations compared with cross-efficiency analysis.

EXPERT SYSTEM

An expert system is a computer information system developed to act like a human expert in a specific area of knowledge. It is an interactive computer-based decision tool that uses both facts and heuristics to solve difficult decision problems based on an expert's knowledge. Because the knowledge of an expert tends to be domain-specific rather than general, expert systems that represent this knowledge usually reflect the specialized nature of such expertise. Expert systems provide the means for overcoming the shortcomings of conventional human decision-making processes and conventional software through integrating human expertise and power of computers.

Although a generally accepted view on traditional computer program is summarized as

$$\text{Traditional computer program} = \text{Data} + \text{Algorithm},$$

the expert system can be described as

$$\text{Expert system} = \text{Knowledge base} + \text{Inference engine}$$

An expert system consists typically of the following major components:

- *Knowledge base* comprises specific knowledge about the problem domain under consideration. It differs from a database because much knowledge in the knowledge base is represented implicitly. The knowledge is most commonly represented in terms of production rules. A production rule has the following structure:

  IF *conditions*
  THEN *conclusions*

- *Knowledge-acquisition interface* helps experts to express knowledge in a form that can be incorporated in a knowledge base. Determination of the problem domain and its characteristics, identifying the concepts that are used to describe the objects and their interrelationships; acquiring the knowledge; and representing it through suitable representation technique, such as production rules, implementation, and validation, can be listed as the stages of the knowledge acquisition process.

- *Inference engine* employs general rules of inference to arrive at logical conclusions according to the knowledge base of the expert system. Two main inference approaches are used by an inference engine to exploit the knowledge base: forward chaining (data driven) and backward chaining (goal-driven reasoning). Forward chaining begins with data input by the user and scans the rules to find those whose antecedent conditions are fulfilled by the data. It then fires those rules and deduces their consequences. The consequences are added to the knowledge base, and the rules are revisited to observe which new rules may now be fired. This process is repeated until all rules which may be fired have been fired (25). As opposed to forward chaining that is data driven, backward chaining is goal driven because the inference process is guided by the final goal or objective that should be reached rather than by the available information. The process identifies rules that have the goal as a consequence.
- *User interface* is responsible for the form of communicating with the user. User interface attempts to equip the user with most capabilities of interacting with a human expert. The user interface presents the conclusions and explains the reasoning for justification purposes. Most of them may provide sensitivity analysis and what-if analysis tools to observe the changes that would have occurred if the variables had taken different values.

Figure 2 illustrates the structure of an expert system and the interrelationship between its components. Particularly for the cases in which substantial information and data processing and analysis are required, expert systems derive conclusions at a much faster rate compared with human experts. Furthermore, expert systems are apt to deal with incomplete and uncertain information. However, the knowledge acquired in the expert system depends on the expert, and thus, the conclusions obtained are prone to change with knowledge elicited from a different human expert.

MULTICRITERIA DECISION MAKING APPROACH

MCDM addresses the problem of making decisions in the presence of multiple, usually conflicting criteria. MCDM includes two main fields, namely multiattribute decision making (MADM) and multi-objective decision making (MODM). While MADM refers to making preference decisions over a finite number of alternatives, considering multiple and possibly conflicting attributes, MODM aims to design the best alternative given a set of multiple and conflicting objectives. MCDM techniques are applied when a selection/design problem with multiple and usually conflicting attributes/objectives with incommensurable units is encountered. Conflict among attributes/objectives increases in the sense that a favorable value in one may have to be obtained with a poor value in the other. Incommensurable units refer to each criterion that has different units of measurement rendering a direct comparison between different criteria impossible. The basic differences in MADM and MODM problems are provided in Table 1.

Because the decision problem addressed here considers selection among a finite number of alternatives, in the presence of multiple and conflicting attributes with each attribute having different units of measurement, a MADM approach would be required.

In this section, a decision-making approach that integrates quality function deployment and fuzzy linear regression is presented to address the robot selection problem. The delineated procedure is based on the methodology developed by Karsak (2). QFD is a customer-oriented design tool that aims to meet customer requirements in a better way and enhance organizational capabilities while maximizing company goals. A key objective of QFD is to determine directly from the customer what they would

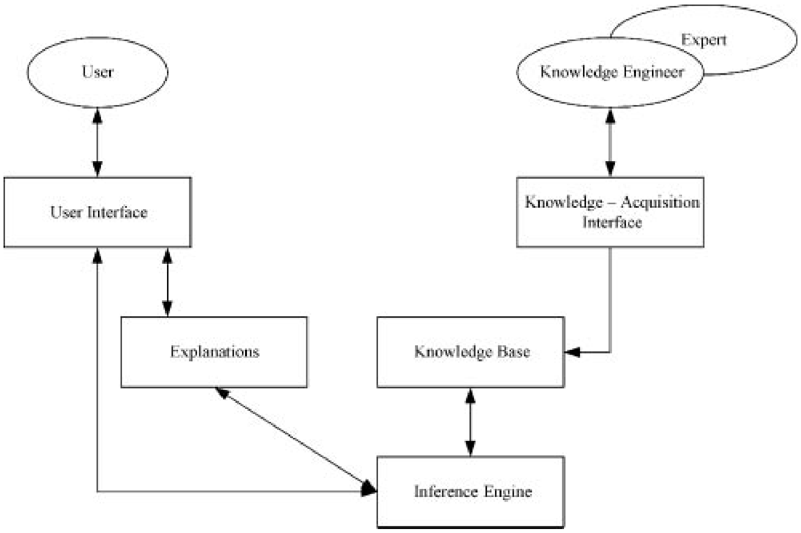

Figure 2. Structure of an expert system.

Table 1. Comparison of MADM and MODM Approaches

	MADM	MODM
Criteria defined by	Attributes	Objectives
Objectives	Implicit	Explicit
Attributes	Explicit	Implicit
Constraints	Implicit	Explicit
Number of alternatives	Finite (small)	Infinite (large)
Interaction with decision-maker	Limited	Significant
Utilization	Selection/evaluation	Design/search

expect from a specific product or service. QFD aims at delivering value by focusing on prioritized customer requirements, translating these into engineering characteristics (design requirements), and then communicating them throughout the organization in a way to assure that details can be quantified and controlled.

Relationships between customer requirements and engineering characteristics and among the engineering characteristics are defined by answering a specific question that corresponds to each cell in a matrix named the house of quality (HOQ). Hauser and Clausing (26) defined the HOQ as a kind of conceptual map that provides the means for interfunctional planning and communications.

Fuzzy linear regression was first introduced by Tanaka et al. (27). As opposed to statistical regression that is based on probability theory, fuzzy regression is founded on possibility theory and fuzzy set theory. In fuzzy regression, regression residuals that denote the deviations between observed values and estimated values are assumed to be caused by imprecise and vague nature of the system. Fuzzy regression has been reported as a more effective tool than statistical regression when the data set is insufficient to support statistical regression, human judgments are involved, and the degree of system fuzziness is high (27).

Fuzzy linear regression is selected as a decision tool for parameter estimation of functional relationships because of its aptness to deal with human expert knowledge, which is an important source in robot selection. First, the ratings for factors such as product quality, manufacturing flexibility, and vendor support that are listed among customer requirements are generally represented by expert judgment. Moreover, the fuzziness inherent in the relationships between customer requirements and robot characteristics, and the dependencies among robot's technical characteristics (i.e., the relationships between performance parameters, such as repeatability, velocity, and load capacity, which are difficult, if possible, to determine precisely) can be expressed effectively using expert judgment.

Over the past decade, some research has been performed on quantifying the planning issues in HOQ, mainly focusing on the interpretation of imprecise design information related to customer requirements and relationships between customer requirements and engineering characteristics. Many authors have used fuzzy set theory to consider the imprecision and vagueness in determining the importance of customer requirements and addressing the relationships between customer requirements and engineering characteristics (28, 29). Few researchers have addressed the development of procedures for setting target levels for engineering characteristics using fuzzy regression and fuzzy optimization (30, 31). Chan and Wu (32) presented a comprehensive review of QFD including quantitative methods applicable to it.

Similar to the process of setting target levels for engineering characteristics in QFD (30, 31), the target values for the robot characteristics can be determined by solving the following formulation:

$$\max z(y_1, y_2, \ldots, y_m) \tag{1}$$

subject to

$$\begin{aligned} y_i &= f_i(x_1, x_2, \ldots, x_n), & i &= 1, 2, \ldots, m \\ x_j &= g_j(x_1, x_2, \ldots, x_{j-1}, x_{j+1}, \ldots, x_n), & j &= 1, 2, \ldots, n \end{aligned}$$

where y_i denotes the customer perception of the degree of satisfaction of the ith customer requirement ($i = 1, 2, \ldots, m$), x_j is the normalized target value of the jth robot characteristic ($j = 1, 2, \ldots, n$), f_i represents the functional relationship between the ith customer requirement and the robot characteristics, and g_j denotes the functional relationship between the jth robot characteristic and other robot characteristics. The objective function of Equation (1) can be expressed as

$$z(y_1, y_2, \ldots, y_m) = \sum_{i=1}^{m} w_i (y_i - y_i^{\min})/(y_i^{\max} - y_i^{\min}) \tag{2}$$

where w_i is the relative importance weight of the ith customer requirement and is defined such that $0 < w_i \leq 1$ and $\sum_{i=1}^{m} w_i = 1$, and $y_i^{\min}$ and $y_i^{\max}$ denote the minimum and the maximum possible values, respectively, for the ith customer requirement. Because $(y_i - y_i^{\min})/(y_i^{\max} - y_i^{\min}) \in [0, 1]$, $z(y_1, y_2, \ldots, y_m)$ also takes values between 0 and 1, where 0 and 1 being the worst and the best values, respectively. Thus, Formulation (1) can be represented as

$$\max z(y_1, y_2, \ldots, y_m) = \sum_{i=1}^{m} w_i (y_i - y_i^{\min})/(y_i^{\max} - y_i^{\min}) \tag{3}$$

subject to

$$\begin{aligned} y_i &= f_i(x_1, x_2, \ldots, x_n), & i &= 1, 2, \ldots, m \\ x_j &= g_j(x_1, x_2, \ldots, x_{j-1}, x_{j+1}, \ldots, x_n), & j &= 1, 2, \ldots, n \\ y_i^{\min} &\leq y_i \leq y_i^{\max}, & i &= 1, 2, \ldots, m \end{aligned}$$

The information provided in the HOQ can be used to estimate the parameters of the functional relationships f_i and g_j. Because the relationships between customer requirements and robot characteristics and the interactions among robot characteristics are vague and generally difficult to define precisely, fuzzy regression seems to be a sound alternative approach for serving this purpose.

A fuzzy linear regression model is defined as follows (27):

$$\tilde{y} = \tilde{A}_0 + \tilde{A}_1 x_1 + \tilde{A}_2 x_2 + \cdots + \tilde{A}_n x_n \qquad (4)$$

where $\tilde{y}$ is the fuzzy output, x_j are the real-valued independent variables, and $\tilde{A}_j$ are the fuzzy parameters expressed as symmetrical triangular fuzzy numbers with centers α_j and spreads c_j, respectively, which have the membership function given as follows:

$$\mu_{\tilde{A}_j}(a_j) = \begin{cases} 1 - \dfrac{|\alpha_j - a_j|}{c_j}, & \alpha_j - c_j \le a_j \le \alpha_j + c_j \\ 0, & \text{otherwise} \end{cases}$$

Thus, the fuzzy linear regression model can be rewritten as

$$\tilde{y} = (\alpha_0, c_0) + (\alpha_1, c_1)x_1 + (\alpha_2, c_2)x_2 + \cdots + (\alpha_n, c_n)x_n \qquad (5)$$

Fuzzy linear regression determines the fuzzy parameters $\tilde{A}_j$ such that the estimated output has the minimum total spread while satisfying a target degree of belief H, where $0 \le H < 1$. The H value, which is selected by the decision maker, is referred to as the measure of goodness of fit of the estimated fuzzy linear regression model to the data set. To determine the fuzzy parameters $\tilde{A}_j$ the linear programming model given below is solved (33):

$$\min Z = \sum_{j=0}^{n} \left(c_j \sum_{k=1}^{s} |x_{jk}| \right) \qquad (6)$$

subject to

$$\sum_{j=0}^{n} \alpha_j x_{jk} + (1 - H) \left(\sum_{j=0}^{n} c_j |x_{jk}| \right) \ge y_k, k = 1, 2, \ldots, s$$

$$\sum_{j=0}^{n} \alpha_j x_{jk} - (1 - H) \left(\sum_{j=0}^{n} c_j |x_{jk}| \right) \le y_k, k = 1, 2, \ldots, s$$

$$x_{0k} = 1, k = 1, 2, \ldots, s$$

$$c_j \ge 0\,, j = 0, 1, \ldots, n$$

where x_{jk} is the value of the jth independent variable for the kth observation (here, the normalized value of the jth robot characteristic for the kth robot alternative), and y_k is the value of the dependent variable for the kth observation (here, the customer perception of the degree of satisfaction of the customer requirement for the kth robot alternative). The aim of Formulation (6) is to determine $\tilde{A}_j$ in a way to minimize the total fuzziness under the condition that each observation y_k has at least H degree of belonging to its fuzzy estimate [i.e., $\mu_{\tilde{y}_k}(y_k) \ge H$ for $k = 1, 2, \ldots, s$]. Here, both x_{jk} and y_k are crisp numbers for all j and k, and thus the resulting formulation is a conventional linear program. When no fuzziness is considered in the system parameters, only the center value estimates obtained from Formulation (6) are used in Formulation (3), whereas the spreads are ignored (30). Applications of fuzzy linear regression to QFD have been reported in the literature (30, 31).

INTEGRATED KNOWLEDGE-BASED DECISION FRAMEWORK FOR ROBOT SELECTION

Because of the wide selection of robot attributes and candidate robots, expert decision methods are a viable approach for robot selection. After gathering information about the robot application, an expert system is used to provide a list of pertinent attributes and their acceptable values. Based on the analysis of the entire production cell, some robot selection attributes may be ignored whereas others may be considered as critical. Through the integration of an expert system with the database of available robots, a shortlist of robots meeting the minimum acceptable values is determined. The selection of the most suitable robot cannot be accomplished through an inference procedure based on symbolic reasoning. Thus, an appropriate analytical decision making tool needs to be employed to determine the best robot, which results in moving from the expert system part to the decision model base. The basic structure of an integrated knowledge-based decision system is depicted in Fig. 3.

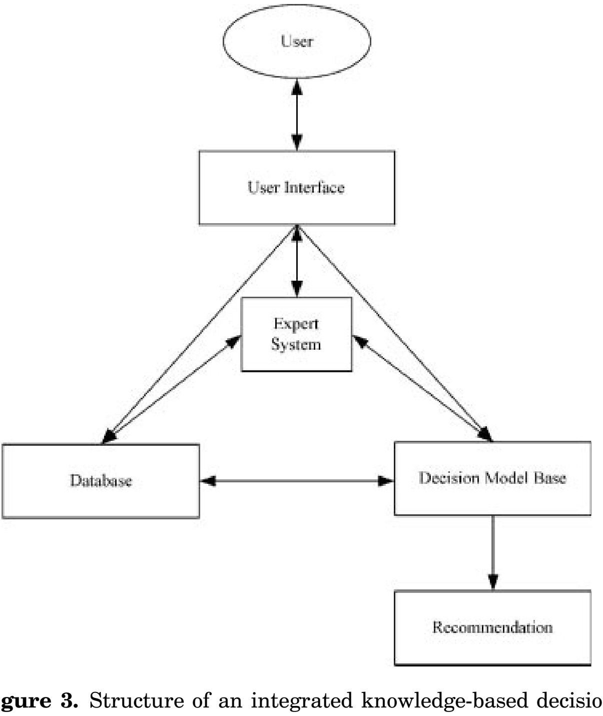

Figure 3. Structure of an integrated knowledge-based decision system.

The procedure is initiated by seeking information from the user about the application for which the robot is required. Potential applications are listed as spot welding, arc welding, machine loading, die casting, forging, plastic molding, spray painting, materials handling, assembly, and inspection. The list may be extended to cover more applications.

When the user identifies the type of application, the expert system is used to determine the set of key attributes for the particular application with their threshold values. Benefiting from the literature on robot selection (11–17) and the expert interviews, the robot parameters taken into consideration can be listed as

- Configuration
- Degrees of freedom
- Vertical reach
- Horizontal reach
- Power source (drive)
- Weight
- Control type
- Accuracy
- Repeatability
- Load capacity
- Velocity
- Programming method
- Programming language
- Memory size

The list of robot attributes given above is not meant to be comprehensive, and it can be easily expanded. Attributes with discrete states are assigned code numbers where each code number denotes the state of the attribute. For example, code numbers from 1 to 7 are used to represent degrees of freedom, where code numbers 1 to 6 denote the respective degrees of freedom, whereas code number 7 corresponds to degrees of freedom greater than or equal to 7. On the other hand, for attributes with values grouped as ranges, code numbers are assigned corresponding to the range in which the value of the respective attribute lies. For example, an attribute whose values are grouped as ranges is given in Table 2.

Table 2. Coding of the Parameter Repeatability

Repeatability (mm)	Code	Significance
Repeatability ≤ 0.025	1	Very good
$0.025 <$ Repeatability ≤ 0.050	2	Good-to-very good
$0.050 <$ Repeatability ≤ 0.100	3	Good
$0.100 <$ Repeatability ≤ 0.200	4	Average-to-good
$0.200 <$ Repeatability ≤ 0.300	5	Average
$0.300 <$ Repeatability ≤ 0.500	6	Poor-to-average
$0.500 <$ Repeatability ≤ 0.750	7	Poor
$0.750 <$ Repeatability ≤ 1.000	8	Very poor-to-poor
Repeatability > 1.000	9	Very poor

For the cases where the user does not specify a code number, the user is reminded by a prompt that an attribute value is not entered. If the user does not possess adequate information regarding the attribute value, then a default value is assigned by the expert system. An example for the list of robot parameters for the robot selection problem is depicted in Fig. 4.

For illustrative purposes, spray painting is considered as the application type. Spray painting, like many other robot applications, presents safety and health hazards while requiring precision. In general, hydraulic or pneumatic robots are employed for spray painting. Spray painting necessitates the use of continuous path control since the cavities of the painted piece-part must be reached by the robot. The expert system is employed to obtain a list of robot alternatives that meet the minimum performance requirements. If none of the robots satisfies the specified requirements, then the user is asked to revise the parameter values. Although the basic structure remains the same for all types of applications, the order of questions may vary for the considered application as key parameters for robot selection may differ according to the application type. A set of sample rules called for the spray painting application can be given as follows:

{Rule p}
IF application is spray painting
AND environment is unclean
THEN drive is hydraulic

{Rule q}
IF application is spray painting

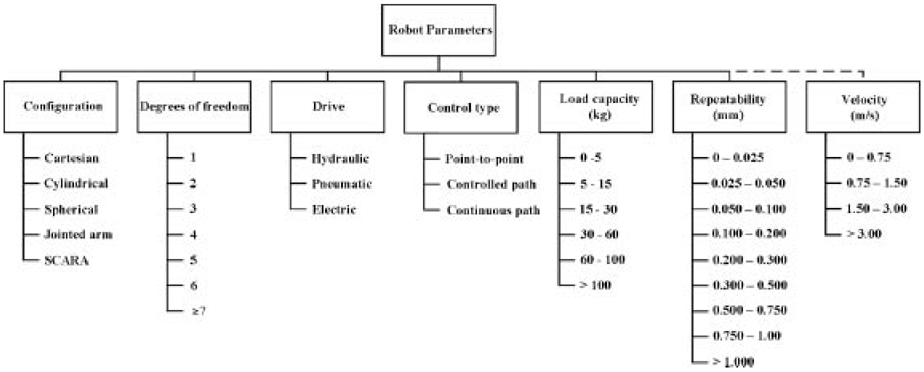

Figure 4. Example of parameters listing for the robot selection problem.

AND drive is hydraulic
THEN min number of degrees of freedom is 5

{Rule r}
IF degrees of freedom is 5
OR degrees of freedom is 6
OR degrees of freedom is ≥ 7
AND load capacity is average
AND repeatability is poor-to-average
AND velocity is average
THEN we have ROBOTS1

{Rule s}
IF we have ROBOTS1
AND configuration is jointed arm
AND control type is continuous path
AND programming is manual dry-run mode
THEN robot set is determined
AND display ROBOTS1A

The decision problem aims to determine the best robot alternative from the short-list of candidates determined using the expert system module by taking into consideration customer requirements (hereafter named as user requirements) and robot characteristics, the relationships between user requirements and robot characteristics, and the interactions between robot characteristics. The algorithm developed to rank the robot alternatives is summarized in Table 3.

Major user requirements for an industrial robot can be denoted as improved product quality, reduced cycle time, improved manufacturing flexibility, easier and standardized programming, improved precision, improved reliability and stability, improved potential to interface with existing equipment, reduced costs, and vendor support.

The prototype HOQ given in Fig. 5 illustrates the user requirements and robot characteristics, and the related data for the short list of robot alternatives. The relationship matrix in the HOQ is used to represent the relationships between the manufacturing firm's demands regarding product quality, manufacturing flexibility, vendor support, and so on, and robot characteristics such as repeatability, velocity, load capacity, and so on. The roof matrix in the HOQ is employed to denote the inner dependence among the robot characteristics. Below the relationship matrix, objective measures (i.e., data related to the abovementioned robot characteristics for each of the short-listed robot alternatives) are indicated. The rightmost part of the HOQ, which captures the user's perspective, presents the data that results from the competitive analysis of the robot alternatives with respect to user requirements. In accordance with customer requirement ratings in earlier studies, performance with respect to user requirements other than "cost" has been scaled from 1 to 5, where 1 and 5 represent the worst and the best, respectively.

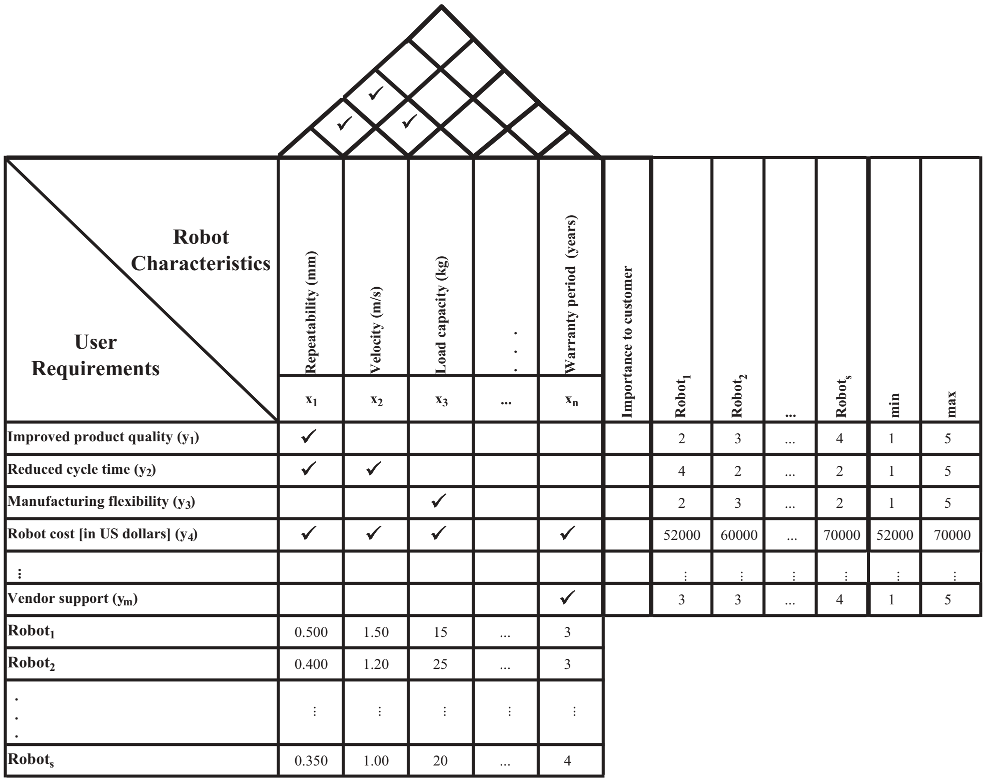
To avoid problems regarding scale differences, data concerning robot characteristics are normalized using a linear normalization procedure. It is obvious that the normalized data lie in the [0,1] interval, and the robot characteristic is more favorable as the normalized data approaches 1. To preserve conformity with other user requirements data that are denoted using a [1, 5] scale, cost data related to robot alternatives are normalized in a way to obtain a value of 5 for the lowest cost robot and a value of 1 for the robot with the highest cost.

The importance weights of the user requirements are determined using the AHP, which has been previously employed for prioritizing customer requirements within QFD framework (2). AHP is a multicriteria decision-making technique that is based on ratio scales and pairwise comparisons. In AHP, the relative importance values are determined using pairwise comparisons with a scale of 1 to 9, where a score of 1 indicates equal importance between the two elements, and 9 represents the extreme importance of one element compared to the other one. The values in between signify varying degrees of importance between these two extremes. Obviously, the weights for the user requirements may vary with respect to the application type of industrial robots.

Then, fuzzy linear regression is employed to estimate the parameters of the functional relationships between user requirements and robot characteristics, and among

Table 3. Stepwise Representation of the Algorithm Employed in the Decision Model Base to Rank the Short List of Robot Alternatives

Step 1.	Obtain the key robot attributes and their threshold values, and the shortlist of acceptable robot alternatives from the expert system module.
Step 2.	Identify the user requirements and other robot characteristics.
Step 3.	Obtain the pertinent robot attributes and other related robot characteristics data for the short list of robot alternatives.
Step 4.	Normalize the data concerning robot characteristics using a linear normalization procedure to avoid problems regarding scale differences.
Step 5.	Determine the relative importance weights of user requirements for the related application type employing the analytic hierarchy process.
Step 6.	Determine the preference ratings of robot alternatives with respect to user requirements.
Step 7.	Identify the relationships between user requirements and robot characteristics, and among the robot characteristics.
Step 8.	Estimate the parameters of the functional relationships between user requirements and robot characteristics, and of the functional relationships among robot characteristics.
Step 9.	Formulate the linear programming model to determine the target values of robot characteristics using the information obtained in previous steps.
Step 10.	Calculate the deviation of each robot alternative from the target robot possessing the optimal robot characteristic values computed in Step 9 using a distance metric based on the p-order relative lower partial moment.
Step 11.	Rank the robot alternatives according to the sum of deviations from the target robot characteristic values. Select the robot alternative that is closest to the target robot.



Robot Characteristics User Requirements	Repeatability (mm) x_1	Velocity (m/s) x_2	Load capacity (kg) x_3	. . . ...	Warranty period (years) x_n	Importance to customer	$Robot_1$	$Robot_2$	...	$Robot_s$	min	max
Improved product quality (y_1)	✓						2	3	...	4	1	5
Reduced cycle time (y_2)	✓	✓					4	2	...	2	1	5
Manufacturing flexibility (y_3)			✓				2	3	...	2	1	5
Robot cost [in US dollars] (y_4)	✓	✓	✓		✓		52000	60000	...	70000	52000	70000
⋮							⋮	⋮	⋮	⋮	⋮	⋮
Vendor support (y_m)					✓		3	3	...	4	1	5
$Robot_1$	0.500	1.50	15	...	3							
$Robot_2$	0.400	1.20	25	...	3							
. . .	⋮	⋮	⋮	⋮	⋮							
$Robot_s$	0.350	1.00	20	...	4							

Figure 5. House of quality for the robot selection problem.

robot characteristics themselves. As in several previous works on fuzzy regression, the H value can be set to 0.5 for the base case. When the data set is sufficiently large H could be set to 0, whereas a higher H value is suggested as the size of the data set becomes smaller (33).

Using the normalized data for the robot selection problem, parameter estimations are obtained by fuzzy linear regression. Because no fuzziness is considered in the system parameters, only the center value estimates obtained from fuzzy regression are employed in formulation (3) to determine the target values for robot characteristics, whereas the spread values are disregarded (31). To determine the ranking order of robot alternatives, the following distance metric is used:

$$d_k^p = \left[\sum_j (\max(0, (x_j^* - x_{jk})))^p \right]^{1/p}, \quad k = 1, 2, \ldots, s \quad (7)$$

where x_j^* is the normalized target value of the jth robot characteristic obtained by solving formulation (3), x_{jk} is the normalized value of the jth robot characteristic for the kth robot alternative, and d_k^p is the distance metric for the kth robot alternative that is based on the p-order relative lower partial moment. The robot alternative with the minimum value of the distance metric is determined as the best robot ($\min_k d_k^p$). Here, use of conventional distance metrics such as the city block distance or the Euclidean distance, which punish the desirable higher than optimal robot characteristics values of the robot alternatives as hard as the lower than optimal ones, would have been inappropriate.

CONCLUSION

An expert system can represent the logic of a human expert who possesses knowledge and experience in a specialized domain. An integrated use of MADM techniques and an expert system is deemed appropriate because the expert system framework typically results in multiple candidates, which needs to be evaluated by an appropriate decision making technique. The proposed integrated framework enables the use of structured decision modeling and techniques suitable for the complex nature of the robot selection problem by means of the decision support module.

The proposed decision framework possesses many advantages compared with the robot selection approaches developed in earlier studies. The primary advantage of expert decision models is to incorporate expert knowledge into a difficult problem. Second, by adopting the QFD principles, the decision-making system allows both user requirements that are generally qualitative and robot characteristics to be considered in the robot selection process. Third, using QFD enables incorporating not only the relationships between user requirements and robot characteristics but also the relationships between robot characteristics disregarding the unrealistic preferential independence assumption frequently encountered in earlier robot selection studies using multiattribute decision making techniques. Furthermore, the parameter estimation of the abovementioned functional relationships is performed using fuzzy regression, which is suitable for considering high system fuzziness.

Although the expert decision model is apt to take into account many robot attributes, one shall note that considering a wide selection of robot attributes results in several rules in the expert system that may prove to be devastating in application. Moreover, the expert system needs to be updated on a regular basis because of the technological changes. It is also worth noting that the expert system delineated in this manuscript illustrates the guidelines of constructing such a system for robot selection, and it by no means intends to serve as a thorough real-world application.

GEOGRAPHIC INFORMATION SYSTEMS

A geographic information system (GIS) is a set of computer-based tools to collect, store, retrieve, manipulate, visualize, and analyze geo-spatial information (information identified by its location on the surface of reference, for example, the Earth). Some definitions of GIS include institutions, people, and data, besides the computer-based tools. These definitions refer more to a total GIS implementation than to the technology. Examples of GIS definitions can be found in Maguire (1), Chrisman (2), Foote and Lynch (3) among others. Our definition is discussed next.

Computer-based tools are hardware (equipment) and software (computer programs). *Geo-spatial information* describes facts about the Earth's features, for example, the location and characteristics of rivers, lakes, buildings, and roads. *Collection* of geo-spatial information refers to the process of gathering, in computer-compatible form, facts about features of interest. Facts usually collected are the location of features given by sets of coordinate values (such as latitude, longitude, and sometimes elevation), and attributes such as feature type (e.g., highway), name (e.g., Interstate 71), and unique characteristics (e.g., the northbound lane is closed). *Storing* of geo-spatial information is the process of electronically saving the collected information in permanent computer memory (such as a computer hard disk). Information is saved in structured computer files. These files are sequences of only two characters (0 and 1) called bits, organized into bytes (8 bits) and words (16–64 bits). These bits represent information stored in the binary system. *Retrieving* geo-spatial information is the process of accessing the computer-compatible files, extracting sets of bits, and translating them into information we can understand (for example, information given in our national language). *Manipulation* of geo-spatial data is the process of modifying, copying, or removing selected sets of information bits or complete files from computer permanent memory. *Visualization* of geo-spatial information is the process of generating and displaying a graphic representation of the information, complemented with text and sometimes with audio. *Analysis* of geo-spatial information is the process of studying, computing facts from the geo-spatial information, forecasting, and asking questions (and obtaining answers from the GIS) about features and their relationships. For example, what is the shortest route from my house to my place of work?

HARDWARE AND ITS USE

Computer hardware changes at a very fast pace most all the time. Better and better computers are available every year. This evolution impacts GIS and makes this description difficult in terms of covering what is the "state-of-art" in hardware. A good introduction to GIS hardware is given by UNESCO (4). Our goal here is to overview the major hardware components of GIS without trying to discuss any one in detail. The main component is the computer (or computers) on which the GIS run. Currently, GIS systems run on desktop computers mainframes (used as a stand-alone or as part of a network), and servers connected to the Internet. In general, GIS operations require handling large amounts of information (50 megabytes or larger file sizes are not uncommon), and in many cases, GIS queries and graphic displays must be generated very quickly. Therefore, important characteristics of computers used for GIS are processing speed, quantity of random access memory (RAM), size of permanent storage devices, resolution of display devices, and speed of communication protocols.

Several peripheral hardware components may be part of the system: printers, plotters, scanners, digitizing tables, and other data collection devices. *Printers and plotters* are used to generate text reports and graphics (including maps). High-speed printers with graphics and color capabilities are commonplace today. The number and sophistication of the printers in a GIS organization depend on the amount of text reports and small size (typically 8.5" by 11") maps and graphics to be generated. Plotters allow the generation of oversized graphics. The most common graphic products of a GIS system are maps. As defined by Thompson (5), "Maps are graphic representations of the physical features (natural, artificial, or both) of a part or the whole of the Earth's surface. This representation is made by means of signs and symbols or photographic imagery, at an established scale, on a specified projection, and with the means of orientation indicated." As this definition indicates, there are two different types of maps: (1) line maps, composed of lines, the type of map we are most familiar with, in paper form, for example a road map; and (2) image maps, which are similar to a photograph. A complete discussion of maps is given by Robinson et al. (6). Plotters able to plot only line maps usually are less sophisticated (and less expensive) than those able to plot high-quality line and image maps. Plotting size and resolution are other important characteristics of plotters. With some plotters, it is possible to plot maps with a size larger than 1 m. Higher plotting resolution allows plotting a greater amount of details. Plotting resolution is very important for images. Usually, the larger the map size needed, and the higher the plotting resolution, the more expensive the plotter.

Scanners are devices that sense and decompose a hardcopy image or scene into equal-sized units called pixels and store each pixel in computer-compatible form with corresponding attributes (usually a color value per pixel). The most common use of scanning technology is in fax machines. They take a hardcopy document, sense the document, and generate a set of electric pulses. Sometimes, the fax machine stores the pulses to be transferred later; other times they are transferred right away. In the case of scanners used in GIS, these pulses are stored as bits in a computer file. The image generated is called a raster image. A raster image is composed of pixels. Generally, pixels are

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

square units. Pixel size (the scanner resolution) ranges from a few micrometers (for example, 5 microns) to hundreds of microns (for example, 100 microns). The smaller the pixel size, the better the quality of the scanned images, but the larger the size of the computer file, the higher the scanner cost. Scanners are used in GIS to convert hardcopy documents to computer-compatible form, especially paper maps. Wempen (7) gives a complete discussion of scanning technology.

Some GISs cannot use raster images to answer geospatial questions (queries). Those GISs that can are usually limited in the types of queries they can perform (they can perform queries about individual locations but not geographic features). The reason of this limitation is the lack of explicit information in raster images. Only the location of each pixel in a grid array and a value per pixel (such as color) are the explicit information of raster images. Explicit information is the information that can be expressed without vagueness, implication, or ambiguity, leaving no quetion as to meaning or intent. Computer programs can recognize explicit information. Raster images mainly carry tacit information. Tacit information is information that is difficult to express, often personal or context-speciific, hard to communicate, and even harder to represent in a formal way. In general, computer programs cannot recognize tacit information. Most queries need information in vector form (that carries a lot more explicit information). Vector information represents individual geo-spatial features (or parts of features) and is an ordered list of vertex coordinates and alphanumeric and graphic attributes. Vector information is used for representation and analysis in most GIS. Figure 1 shows the differences between raster and vector.

Digitizing tables are devices that collect vector information from hardcopy documents (especially maps), and they consist of a flat surface on which documents can be attached, and a cursor or puck with several buttons, used to locate and input coordinate values (and sometimes attributes) into the computer. Attributes are commonly input via keyboard. The result of digitizing is a computer file with a list of coordinate values and attributes per feature. This method of digitizing is called “heads-down digitizing.” Digitizing tables were the most common tools for digitizing maps, but their use has decreased in the last decade.

Currently, there is a different technique to generate vector information. This method uses a raster image as a backdrop on the computer terminal. These images are the result of scanning paper maps or derive from digital photos. Usually, the image are geo-referenced (transformed into a coordinate system related in some way to the Earth). The raster images are displayed on the computer screen, and the operator uses the computer mouse to collect the vertices of a geo-spatial feature and to attach attributes (the keyboard or audio may be also used). As in the previous case, the output is a computer file with a list of coordinate values and attributes for each feature. This method is called “heads-up digitizing.” A more in-depth discussion on geospatial data acquisition in vector or raster format is given by GEOWEB (8).

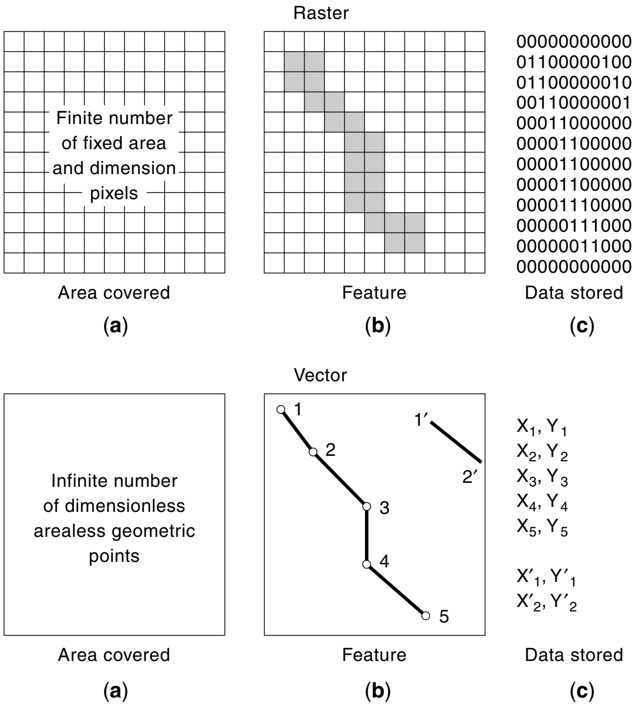

Figure 1. The different structures of raster and vector information, feature representation, and data storage.

SOFTWARE AND ITS USE

Software, as defined by the AGI dictionary (9), is the collection of computer programs, procedures, and rules for the execution of specific tasks on a computer system. A computer program is a logical set of instructions that tells a computer to perform a sequence of tasks. GIS software provides the functions to collect, store, retrieve, manipulate, query and analyze, and visualize geo-spatial information. An important component of software today is a graphical user interface (GUI). A *GUI* is set of graphic tools (icons, buttons, and dialog boxes) that can be used to communicate with a computer program to input, store, retrieve, manipulate, visualize, and analyze information and generate different types of output. Pointing with a device such as a mouse to select a particular software application operates most GUI graphic tools. Voice can also be used in a GUI to communicate with a computer program. Figure 2 shows a GUI.

GIS software can be divided into five major components (besides the GUI): input, manipulation, database management system, query and analysis, and visualization. *Input software* allows the import of geo-spatial information (location and attributes) into the appropriate computer-compatible format. Three different issues need to be considered: how to transform (convert) analog (paper-based) information into digital form, how to accept digital information collected by different devices, and how to store information in the appropriate format. Scanning, as well as heads-down and heads-up digitizing software with different levels of

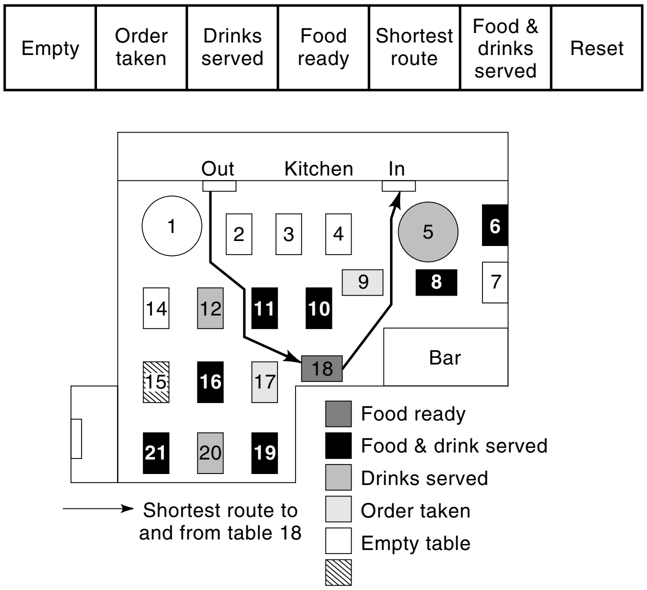

Figure 2. GUI for a GIS in a restaurant setting and the graphic answers to questions about table occupancy, service, and shortest route to Table 18.

automation, transforms paper-based information (especially graphic) into computer-compatible form. Text information (attributes) can be imported by a combination of scanning and character recognition software, or can be imported manually using keyboards or voice recognition software. In general, each commercial GIS software package has a proprietary format used to store locations and attributes. Only information in that particular format can be used in that particular GIS. When information is converted from paper into digital form using the tools from that GIS, the result is in the appropriate format. When information is collected using other devices, then a file format translation needs to be made. Translators are computer programs that take information stored in a given format and generate a new file (with the same or similar information) in a different format. In some cases, translation results in information loss.

Manipulation software allows changing the geo-spatial information by adding, removing, modifying, or duplicating pieces or complete sets of information. Many tools in manipulation software are similar to those in word processors, for example, create, open, and save a file; cut, copy, paste; and undo graphic and attribute information. Many other manipulation tools allow drafting operations of the information, such as drawing parallel lines, square, rectangles, circles, and ellipses; moving graphic elements; and changing colors, line widths, and line styles. Other tools allow the logical connection of different geo-spatial features. For example, geo-spatial features that are physically different and unconnected can be grouped as part of the same layer, level, or overlay (usually, these words have the same meaning), by which they are considered part of a common theme (for example, all rivers in a GIS can be considered part of the same layer: *hydrography*). Then, one can manipulate all features in this layer by a single command. For example, one could change the color of all rivers of the *hydrography* layer from light to dark blue by a single command.

Database management system (DBMS) is a collection of software for organizing information in a database. This software performs three fundamental operations: storage, manipulation, and retrieval of information from the database. A database is a collection of information organized according to a conceptual structure describing the characteristic of the information and the relationship among their corresponding entities (9). In a database, usually at least two computer files or tables and a set of known relationships, which allows efficient access to specific entities, exist. Entities in this concept are geo-spatial objects (such as a road, house, and tree). Multipurpose DBMS are classified into four categories: inverted list, hierarchical, network, and relational. Healy (10) indicates that there are two common approaches to DBMS for GIS: the hybrid and the integrated. The hybrid approach is a combination of a commercial DBMS (usually relational) and direct access operating system files. Positional information (coordinate values) is stored in direct access files and attributes in the commercial DBMS. This approach increases access speed to positional information and takes advantage of DBMS functions, minimizing development costs. Guptill (11) indicates that, in the integrated approach, the standard query language (SQL) used to ask questions about the database is replaced by an expanded SQL with spatial operators able to handle points, lines, polygons, and even more complex structures and graphic queries. This expanded SQL sits on top of the relational database, which simplifies geo-spatial information queries.

Query and analysis software provides new explicit information about the geo-spatial environment. The distinction between query and analysis is somewhat unclear. Maguire and Dangermond (12) indicate that the difference is a matter of emphasis: "Query functions are concerned with inventory questions such as 'Where is. . .?' Analysis functions deal with questions such as 'What if. . .?'." In general, query and analysis use the location of geo-spatial features, distances, directions, and attributes to generate results. Two characteristic operations of query and analysis are buffering and overlay. *Buffering* is the operation that finds and highlights an area of user-defined dimension (a buffer) around a geo-spatial feature (or a portion of a geo-spatial feature) and retrieves information inside the buffer or generates a new feature. *Overlay* is the operation that compares layers. Layers are compared two at a time by location or attributes. Query and analysis use mathematical or logical models to accomplish their objectives. Different GISs may use different mathematical or logical models and, therefore, the results of querying or analyzing the same geo-spatial data in two different GISs may be different.

Mathematical or logical models are of two kinds: (1) Embedded models and (2) external models. Embedded models are the kind of models that are used by any GIS user to perform query and analysis; they are an integral part of a GIS. For example, the models used to perform buffering and overlay are embedded models. Embedded

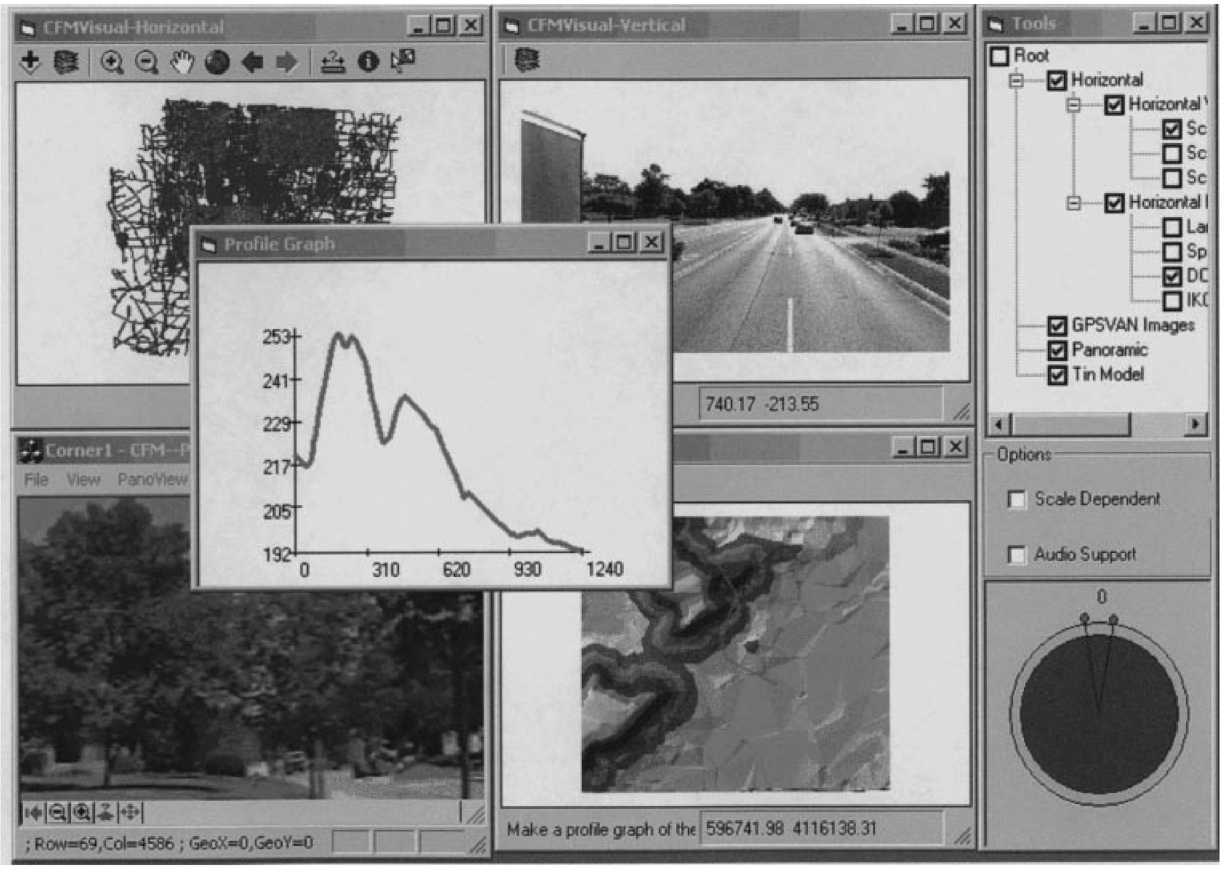

Figure 3.

models in many commercial systems are similar to black boxes: You input the data and you obtain results but, in general, you do not know how these results are generated. External models are mathematical or logical models provided by the user. In some quarters, the use of external models is known as GIS modeling.

There is not a clear distinction between the discipline of scientific modeling and GIS modeling. We would hypothesize that there are two instants of modeling in GIS: (1) when the input of scientific modeling is the outcome of GIS, and GIS is the only way to produce such outcome, and the scientific model can be programmed or interfaced with GIS; (2) When the input of scientific modeling can be collected or generated by means different than GIS, but GIS may be the simple way or the most cost-efficient way to provide the input data or the software implementation of the scientific model. In our opinion, only the first instant should be called GIS modeling. Todorov and Jeffress (13), White et al. (14), and Lauver et al. (15) present examples of GIS modeling. Wilson (16) presents an example of scientific modeling using GIS.

Query and analysis are the capabilities that differentiate GIS from other geographic data applications such as computer-aided mapping, computer-aided drafting (CAD), photogrammetry, and mobile mapping.

Visualization in this context refers to the software for visual representation of geo-spatial data and related facts, facilitating the understanding of geo-spatial phenomena, their analysis, and inter-relations. The term visualization in GIS encompasses a larger meaning. As defined by Buttenfield and Mackaness (17), "visualization is the process of representing information synoptically for the purpose of recognizing, communicating, and interpreting pattern and structure. Its domain encompasses the computational, cognitive, and mechanical aspects of generating, organizing, manipulating, and comprehending such representation. Representation may be rendered symbolically, graphically, or iconically and is most often differentiated from other forms of expression (textual, verbal, or formulaic) by virtue of its synoptic format and with qualities traditionally described by the term 'Gestalt,'" and it is the confluence of computation, cognition, and graphic design.

Traditional visualization in mapping and GIS is accomplished through maps, diagrams, and perspective views. A large amount of information is abstracted into graphic symbols. These symbols are endowed with visual variables (size, value, pattern, color, orientation, and shape) that emphasize differences and similarities among those facts represented. The joint representation of the facts shows explicit and tacit information. Explicit information can be accessed by other means such as tables and text. Tacit information requires, in some cases, performing operations with explicit information, such as computing the distance between two points on a road. In other cases, by looking at the graphic representation, we can access tacit information. For example, we can find an unexpected relationship between the relief and erosion that is not obvious from the explicit information. This example represents the power of visualization!

The most noticeable improvement in GIS recently is in visualization. Multimedia visualization that combines raster, vector, audio, panoramic views, digital video, and so on is gaining acceptance in the GIS community. Experimental systems with these capabilities are being demonstrated in university research centers and by some commercial vendors. Multimedia visualization systems offer the possibility of overcoming many of the problems of traditional visualizations. These systems allows dynamic, multisource, multisense, multiquality, representations of the environment instead of static, single-source, single-sense, single-quality representations. Figure 3 shows a prototype system developed by the Center for Mapping of The Ohio State University.

USING GIS

GIS is widely used. Users include national, state, and local agencies; private business (from delivery companies to restaurants, from engineering to law firms); educational institutions (from universities to school districts, from administrators to researchers); and private citizens. As indicated earlier, the full use of GIS requires software (that can be acquired from a commercial vendor), hardware (which allows running the GIS software), and data (with the information of interest). Partial use of GIS is possible today with access to the Internet. As indicated by Worboys (18), "data are only useful when they are part of a structure of interrelationships that form the context of the data. Such a context is provided by the *data model.*" Depending on the problem of interest, the data model maybe simple or complex. In a restaurant, information about seating arrangement, seating time, drinks, and food are well defined and easily expressed by a simple data model. Fundamentally, you have information for each table about its location, the number of people it seats, and the status of the table (empty or occupied). Once a table is occupied, additional information is recorded: How many people occupy the table? At what time was the table occupied? What drinks were ordered? What food was ordered?. What is the status of the order (drinks are being served, food is being prepared, etc.) Questions are easily answered from the above information with a simple data a model (see Fig. 2) such as follows: What table is empty? How many people can be seated at a table? What table seats seven people? Has the food ordered by table 11 been served? How long before table 11 is free again? Of course, a more sophisticated data model will be required if more complex questions are asked of the system. For example, What is the most efficient route to reach a table based on the current table occupancy? If alcoholic drinks are ordered at a table, how much longer will it be occupied than if nonalcoholic drinks are ordered? How long will it be before food is served to table 11 if the same dish has been ordered nine times in the last few minutes?

Many problems require a complex data model. A nonexhaustive list of GIS applications that require complex models is presented next. This list gives an overview of many fields and applications of GIS:

Siting of a store: Find, based on demographics, the best location in a region for a new store. Retailers collect ZIP codes information, the corresponding sale amount, and the store location for each transaction. This information can be used in a GIS to show the volume of sales coming from each ZIP code region. Using additional information for each ZIP code region, such as income, lifestyle retailers can determine how far a customer is willing to drive to go to a store. This information can be used to determine the best site for a new store.

Network analysis: Find, for a given school, the shortest bus routes to pick up students. School districts use the postal addresses of students, school locations, and student distribution to plan cost-efficient school bus routes. Some of the products of network analysis for school routing are find students homes, bus stops, and schools on maps; assigns students to closest stop; assign stops to a run and runs to a route; identify district boundaries, walk-zones, and hazardous streets; and generate stop times and driver directions for runs.

Utility services: Applications for utility services include service interruption management, emergency response, distribution, network operation, planning, research, sales, engineering, and construction. An electric company, for example, provides services to residential, commercial, government, nonprofit, and others clients. These services are location-based and require a fast response to irregular situations such as an outage. Outage are responded to by priority. Generally, an outage in a hospital requires a faster response than to a residence. Using GIS, this response is efficient and timely.

Land information system: Generate, using land parcels as the basic unit, an inventory of the natural resources of a region and the property-tax revenue. The geo-spatial description of each parcel, their attributes such as owner, area, number of rooms, value, use, and so on, together with the basic geographic features of the region, such as roads, rivers, streams, and lakes; vegetation; political boundaries; and so on, allows the study and analysis of the region.

Automated car navigation: Having a dataset with enough route information such as the geo-spatial description of roads, their speed limit, number of lanes, traffic direction, status of roads, construction projects,and so on, it is possible to use GIS for real-time car navigation. Questions such as: the recommended speeds, the path to be followed, street classification, and route restrictions to go from location A to location B can be answered during navigation.

Tourist information system: Integrating geo-spatial information describing roads and landmarks such as restaurants, hotels, motel gasoline stations, and so on, allows travelers to answer questions such as follows: What is the difference in driving time to go from location A to location B following the scenic route instead of the business route? Where, along the scenic route, are the major places of interest located? How far is the next four-star hotel? How far am I from the next gasoline station? Some systems allow to reserve a hotel room, rent a car, buy tickets to a concert or a movie, and so on, from the route.

Political campaigns: How to maximize funds and to reach the larger sympathetic audience is basic in a political campaign. Based on population information, political trends, cost, and social-economic level, it is possible, for example, to set the most time-efficient schedule to visit the largest possible number of cities where undecided voters could make the difference during the last week of a political campaign.

Marketing branch location analysis: Find, based on population density and consumer preferences, the location and major services to be offered by a new bank branch.

Terrain analysis: Find the most promising site in a region for oil exploration, based on topographic, geological, seismic, and geo-morphological information.

Driving directions: Find how to go from Point A to Point B based on the postal addresses, which is one of the most popular applications of GIS, and one that only requires access to the Internet. Most computer users are familiar with this application. You type the postal address of your departure place and the postal address of your destination. A computer program will generate a set of directions to travel. These instructions will be given by naming the major streets and highways you will drive, indicating how to connect from one to the next, and the distance to be traveled in each segment, and time of traveling (based on the legal speed limit). The program will provide you with written instructions or a map displaying the route to be traveled.

QUALITY AND ITS IMPACT IN GIS

The unique advantage of GIS is the capability to analyze and answer geo-spatial questions. If no geo-spatial data is available for a region, of course, it is not possible to use GIS. On the other hand, the validity of the analysis and quality of the answers in GIS are closely related to the quality of the geo-spatial data used and the quality of the embedded models and the external models. If poor quality or incomplete data were used, the query and analysis would provide poor or incomplete results. The same will happen if the quality of the models was poor. Therefore, it is fundamental to know the quality of the information in a GIS and the quality of the models. Generally, the quality of the embedded models in commercial GIS is unknown. In many cases, a GIS user has no way to know how good the embedded models of the system are, which is problematic in GIS because perfect geo-spatial data used with poor-quality embedded models generates poor results and the user may not be aware of that.

From the viewpoint of data, quality is defined by the U.S. National Committee Digital Cartographic Data Standard (NCDCDS)(19) as "fitness for use." This definition states that quality is a relative term: Data may be fit to use in a particular application but unfit for another. Therefore, we need to have a very good understanding of the scope of our application to judge the quality of the data to be used. The same committee identifies, in the Spatial Data Transfer Standard (SDTS), five quality components in the context of GIS: lineage, positional accuracy, attribute accuracy, logical consistency, and completeness.

SDTS is the U.S. Federal Information Processing Standard–173 and states "lineage is information about the sources and processing history of the data." Positional accuracy is "the correctness of the spatial (geographic) location of features." Attribute accuracy is "the correctness of semantic (nonpositional) information ascribed to spatial (geographic) features." Logical consistency is "the validity of relationships (especially topological ones) encoded in the data," and completeness is "the mapping and selection rules and exhaustiveness of feature representation in the data." The International Cartographic Association (ICA) has added two more quality components: semantic accuracy and temporal information. As indicated by Guptill and Morrison (20), "semantic accuracy describes the number of features, relationships, or attributes that have been correctly encoded in accordance with a set of feature representation rules." Guptill and Morrison (20) also indicate "temporal information describes the date of observation, type of update (creation, modification, deletion, unchanged), and validity periods for spatial (geographic) data records." Most of our understanding about the quality of geo-spatial information is limited to positional accuracy, specifically point positional accuracy. Schmidley (21) has conducted research in line positional accuracy. Research in attribute accuracy has been done mostly in the remote sensing area, and some in GIS (see Chapter 4 of Ref. 20). Very little research has been done in the other quality components (see Ref. 20).

To make the problem worse, because of limited digital vector geo-spatial coverage worldwide, GIS users combine, many times, different sets of geo-spatial information, each set of a different quality level. Most GIS commercial products have no tools to judge the quality of the data used; therefore, it is up to the GIS user to judge and keep track of information quality.

Another limitation of GIS technology today is the fact that GIS systems, including analysis and query tools, are sold as "black boxes." The user provides the geo-spatial data, and the GIS system provides results. In many cases, the methods, algorithms, and implementation techniques are considered proprietary and there is no way for the user to judge their quality. More and more users are starting to recognize the importance of quality GIS data. As result, many experts are conducting research into the different aspects of GIS quality.

Quality of external models usually can be evaluated. Generally, the user knows in detail the external model to be used and can derive means to evaluate its quality. Models can be evaluated by comparing their results with data of higher quality. For example, a rain prediction model can be evaluated by comparing the predicted rain with the actual rain. If this comparison is done enough times, it is possible to have a good estimator of the quality of the model.

THE FUTURE OF GIS

GIS is in its formative years. All types of users have accepted the technology, and it is a worldwide multibillion-dollar industry. This acceptance has created a great demand in digital geo-spatial information and improved technology to be satisfied in the near future. High-resolution (1 meter or less) commercial satellites and multisensor platforms (for example, global position system technology, inertial navigation systems, high-resolution digital images, laser scanners, multispectral, hyperspectral, etc.) generating high-resolution images, positions, attitude, and so on mobile mapping technology generating high-resolution images and geo-spatial positions and attitude; efficient analog-to-digital data conversion systems; and so forth are some of the promising approaches to the generation of geo-spatial data.

At the same time, the use of the Internet is creating new opportunities and new demands in GIS. Opportunities generated by the Internet include allowing access to a very large number of datasets all over the world and World Wide Web mapping. World Wide Web mapping is based on the easy-to-use browser-based format that is both simple and cost-effective to implement, which allows the common individual to use the Web to access maps and GIS-based data. Sophisticated GIS applications become usable by everyone over the Internet.

New demands in GIS generated by the Internet include better and faster analysis and query tools as well as better visualization systems; better tools to access and merge remote data without creating new datasets are needed; an integrated format for raster, vector, video, panoramic views, audio, spectral, multispectral data, and so on is fundamental, which will allow integration of multimedia data into a single format and will simplify the storage and manipulation of geo-spatial data. The Open GIS Consortium will help in satisfying some of the above demands. The Open GIS Consortium is an international industry consortium founded in 1994 by several GIS organizations. The purpose was to address the issue of incompatibility standards in GIS technology. Today, more than 220 companies, government agencies, and universities participate in a consensus process to develop publicly available specifications for interfaces and protocols that enable interoperable geo-processing services, data, and applications.

The vision of the Open GIS Consortium is a "world in which everyone benefits from geographic information and services made available across any network, application, or platform," and its mission "is to deliver spatial interface specifications that are openly available for global use" (22). The Open GIS Consortium envisions the integration of GIS data and technology into mainstream computing and the widespread use of standards-compliant GIS software throughout the information infrastructure. Current specifications from the Open GIS Consortium include (1) Reference Model; (2) Abstract Specification; (3) Implementation Specifications; (4) Recommendation Papers; (5) Discussion Papers; and (6) Conformant Products. The Open GIS Consortium is currently working on eight interoperability initiatives (22), and their effort will continue for several years to come.

GIS capabilities will improve, which is reflected in the large amount of ongoing research, published results, and products and services. This work includes visualization, user interfaces, spatial relation languages, spatial analysis methods, geo-spatial data quality, three-dimensional and spatio-temporal information systems, open GIS software design and access, and more. A search in the Internet of the topic "visualization research" produced than 300,000 hits. Noticeable among them are entries from AT&T Information Visualization Research Group (23) and the Stanford Computer Graphics Laboratory of Stanford University (24). In the field of "user interfaces," a search in the Internet found less than 200 hits. However, there are many professional associations such as the User Interface Engineering, which in 2003 had its eighth Conference. In the case of "Spatial Relation Languages, we received than 20,000 hits in our Internet search. Many interesting topics, such as visual languages for static and dynamic cases; Spatial Query Languages; Spatial reasoning; and so on are found under this topic. In the area of "Spatial Analysis Methods," we found more than 230,000 hits. Spatial analysis has been around for a long time, but GIS makes its use easy. Spatial data mining is a new topic in spatial analysis and generates a lot of interest among researchers. Data mining is discovering knowledge from large databases. As indicated by Ramirez (25), "simply put, data mining is basically a modeling activity. You need to *describe* the data, *build* a predictive model describing a situation you want to investigate based on patterns determined from known results, and *verify* the model. Once these things are done, the model is used to test the data to see what portions of the data satisfy the model. If you find that the model is satisfied, you have discovered something new about your data that is of value to you." We found more than 46,000 hits searching specifically for "Spatial Data Mining" on the Internet. This topic is of great interest that would provide a major payoff to the user of geo-spatial data. Searching for the topic "Geo-Spatial Data Quality," we found more than 2500 hits on the Internet. Many of these hits are related to metadata, but efforts in other aspects of data quality and visualization of geo-spatial quality were also found. The search of "Three-Dimensional and Spatio-Temporal Information Systems" on the Internet was conducted in two steps. We searched for "Three-Dimensional Information Systems" and received than 290,000 hits. We found a large variety of subjects such as machine vision, three-dimensional databases, and three-dimensional display systems that are more or less related to GIS. We also searched for "Spatio-Temporal Information Systems" and received than 16,000 hits. It is obvious that the subject of three-dimensional information systems is more advanced than spatio-temporal systems, but there is ongoing research in both subjects. Finally, in the topic of "Open GIS Software Design and Access," we discussed earlier the work of the Open GIS Consortium that is the best link to this topic. These research and development efforts will result in better, reliable, faster, and more powerful GIS.

Several peripheral hardware components may be part of the system: printers, plotters, scanners, digitizing tables, and other data collection devices. *Printers* and *plotters* are used to generate text reports and graphics (including maps). High-speed printers with graphics and color capabilities are commonplace today. The number and sophistication of the printers in a GIS organization depend on the amount of text reports to be generated. Plotters allow the generation of oversized graphics. The most common graphic products of a GIS system are maps. As defined by Thompson (1), "Maps are graphic representations of the physical features (natural, artificial, or both) of a part or the whole of the earth's surface. This representation is made by means of signs and symbols or photographic imagery, at an established scale, on a specified projection, and with the means of orientation indicated." As this definition indicates, there are two different types of maps: (1) line maps, composed of lines, the type of map we are most familiar with, usually in paper form, for example a road map; and (2) image maps, which are similar to a photograph. Plotters able to plot only line maps are usually less sophisticated (and less expensive) than those able to plot high-quality line and image maps. Plotting size and resolution are other important characteristics of plotters. With some plotters it is possible to plot maps with a size larger than one meter. Higher plotting resolution allows plotting a greater amount of details. Plotting resolution is very important for images. Usually, the larger the map size needed, and the higher the plotting resolution, the more expensive the plotter.

Scanners are devices that sense and decompose a hardcopy image or scene into equal-sized units called pixels and store each pixel in computer-compatible form with corresponding attributes (usually a color value per pixel). The most common use of scanning technology is in fax machines. They take a hardcopy document, sense the document, and generate a set of electric pulses. Sometimes, the fax machine stores the pulses to be transferred later; other times they are transferred right away. In the case of scanners used in GIS, these pulses are stored as bits in a computer file. The image generated is called a raster image. A raster image is composed of pixels. Generally, pixels are square units. Pixel size (the scanner resolution) ranges from a few micrometers (for example, five) to hundreds of micrometers (for example, 100 micrometers). The smaller the pixel size the better the quality of the scanned images, but the larger the size of the computer file and higher the scanner cost. Scanners are used in GIS to convert hardcopy documents to computer-compatible form, especially paper maps.

Some GIS cannot use raster images to answer geographic questions (queries). Those GIS that can are usually limited in the types of queries they can perform (they can perform queries about individual locations but not geographic features). Most queries need information in vector form. Vector information represents individual geographic features (or parts of features) and is an ordered list of vertex coordinates. Figure 1 shows the differences between raster and vector. *Digitizing tables* are devices that collect vector information from hard-copy documents (especially maps). They consist of a flat surface on which documents can be attached and a cursor or puck with several buttons, used to locate and input coordinate values (and sometimes attributes) into the computer. The result of digitizing is a computer file with a list of coordinate values and attributes per feature. This method of digitizing is called "heads-down digitizing."

Currently, there is a different technique to generate vector information. This method uses a raster image as a backdrop on the computer terminal. Usually, the image has been geo-referenced (transformed into a coordinate system related in some way to the earth). The operator uses the computer mouse to collect the vertices of a geographic feature and to attach attributes. As in the previous case, the output is a computer file with a list of coordinate values and attributes for each feature. This method is called "heads-up digitizing."

SOFTWARE AND ITS USE

Software, as defined by the AGI dictionary (2), is the collection of computer programs, procedures, and rules for the execution of specific tasks on a computer system. A computer program is a logical set of instructions, which tells a computer to perform a sequence of tasks. GIS software provides the functions to collect, store, retrieve, manipulate, query and analyze, and display geographic information. An important component of software today is a graphical user interface (GUI). A GUI is set of graphic tools (icons, buttons, and dialogue boxes) that can be used to communicate with a computer program to input, store, retrieve, manipulate, display, and analyze information and generate different types of output. Pointing with a device such as a mouse to select a particular software application operates most GUI graphic tools. Figure 2 shows a GUI.

GIS software can be divided into five major components (besides the GUI): input, manipulation, database management system, query and analysis, and visualization. *Input software* allows the import of geographic information (location and attributes) into the appropriate computer-compatible format. Two different issues need to be considered: how to transform (convert) analog (paper-based) information into digital form, and how to store information in the appropriate format. Scanning, and heads-down and heads-up digitizing software with different levels of automation, transforms paper-based information (especially graphic) into computer-compatible form. Text information (attributes) can be imported by a combination of scanning and character recognition software, and/ or by manual input using a keyboard and/or voice recognition software. In general, each commercial GIS software package has a proprietary format, used to store locations and attributes. Only information in that particular format can be used in that particular GIS. When information is converted from paper into digital form using the tools from that GIS, the result is in the appropriate format. When information is collected using other alternatives, then a file format translation needs to be made. Translators are computer programs that take information stored in a given format and generate a new file (with the same information) in a different format. In some cases, translation results in information loss.

Manipulation software allows changing the geographic information by adding, removing, modifying, or duplicating pieces or complete sets of information. Many tools in manipulation software are similar to those in word-processors: create, open, and save a file; cut, copy, paste, undo graphic and attribute information. Many other manipulation tools allow drafting operations of the information, such as: draw a parallel line, square, rectangle, circle, and ellipse; move a graphic element, change color, line width, line style. Other tools allow the logical connection of different geographic features. For example, geographic features that are physically different and unconnected, can be grouped as part of the same layer, level, or overlay (usually, these words have the same meaning). By doing this, they are considered part of a common theme (for example, all rivers in a GIS can be considered part of the same layer: *hydrography*). Then, one can manipulate all features in this layer by a single command. For example, one could change the color of all rivers of the hydrography layer from light to dark blue by a single command.

Database management system (DBMS) is a collection of software for organizing information in a database. This software performs three fundamental operations: storage, manipulation, and retrieval of information from the database. A database is a collection of information organized according to a conceptual structure describing the characteristic of the information and the relationship among their corresponding entities (2). Usually, in a database there are at least two computer files or tables and a set of known relationships, which allows efficient access to specific entities. Entities in this concept are geographic objects (such as a road, house, and tree). Multipurpose DBMS are classified into four categories: inverted list, hierarchical, network, and relational. Healy (3) indicates that for GIS, there are two common approaches to DBMS: the hybrid and the integrated. The hybrid approach is a combination of a commercial DBMS (usually, relational) and direct access operating system files. Positional information (coordinate values) is stored in direct access files and attributes, in the commercial DBMS. This approach increases access speed to positional information and takes advantage of DBMS functions, minimizing development costs. Guptill (4) indicates that in the integrated approach the Standard Query Language (SQL) used to ask questions about the database is

HOME AUTOMATION

HOME AUTOMATION

It needs to be noted that home automation systems are intended for homes, so they do not usually address the issues of working environment, multiparty cooperation, ergonomics, and floor planning that are usually the problems addressed in the intelligent building design literature.

Home developers and builders are offering community linkage and links with schools in their new construction projects. Thus, the physical community is connected to the virtual community. The creation of community centers (let them be physical or virtual) is the end result of such efforts.

Home automation systems in various forms have appeared in the market for many years. Thus, we have seen many intelligent security systems, energy management units, lighting controllers, entertainment systems, and so on. Interfacing of these products has been limited, however, and has been usually rather costly, especially in the U.S. market. Some products have received a wide market acceptance and have become de facto standards in a limited home automation market.

Home automation products can, in general, be categorized as follows:

- Interactive smart products
- Intelligent subsystems
- Central automation systems

Most of us have extensively used interactive smart systems—that is, devices that previously required manual control but now have a wide set of programmable features. The cases of programmable video cassette recorders (VCRs), automated door openers, and automated sprinkler systems fall into this category. Intelligent subsystems consist of two or more interactive smart systems that are able to exchange information to accomplish more sophisticated tasks. The interaction between a TV and a programmable VCR falls into this category, as well as an interface of a telephone answering machine with the lighting or the security system. The ultimate and most comprehensive home automation system would be one that integrates a number of smart systems or intelligent subsystems into a system that can be thoroughly and seamlessly controlled by the home owner. Such a system would provide a comprehensive system of home information, telecommunication, entertainment, and control.

Several advantages are realized through the use of such an integrated system. A smart microwave can have its cooking schedule controlled through a central database that stores all the home inhabitants' schedules and habits. A VCR can record only the satellite or cable TV programs that the users like or allow to be viewed and then selectively broadcast them to the TV sets in the house. An integrated security system can be linked with video cameras, the VCR, the telephone network, and the local police station. A smoke detector can be linked to the heating, ventilating, and air conditioning system, and to lighting controls so that, in case a fire breaks out, smoke can be cleared and hallways can be appropriately illuminated to help people move out of the house.

Having such a system with so many differing applications brings forth a wealth of problems in terms of the required integration. High-definition video requires several megahertz of bandwidth, whereas a room thermostat requires a minimum bandwidth occasionally. High-fidelity audio or video traffic requires very strict limits on delays, whereas a washing machine control signal does not have these requirements.

From Home Automation to Intelligent Buildings

Advances in hardware and software technology have affected not only the home automation market but the market of intelligent buildings as well. Intelligent buildings is a term used to describe buildings that are not passive toward their occupants and the activities that take place in them but can program their own systems and manage the consumption of energy and materials. In an intelligent building, sensors receive information on the status of the building and, through the communication system of the building, transfer it to a central controller where, after the necessary comparisons and processing, actions are taken. An intelligent building consists of the peripheral units, the units that monitor the proper functioning of the equipment and regulate it if needed, and the field elements—that is, the sensors, indicators, and activators present in the building.

APPLICATIONS

Several applications have been envisioned by designers of home automation systems and standards organizations. The following categories of applications have been presented in the literature:

- Control of homes' heating, lighting, windows, doors, screens, and major appliances via a TV or TV-like screen.
- Remote control of the house environment via a touch-tone key telephone.
- Detectors to identify rooms that have been empty for more than a specified period of time and possibly transfer this information to the security system or regulate the heating of the room.
- Help for the elderly and disabled.

In the initial phases of research and development efforts, the following applications were identified:

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

- Load management;
- Domestic appliance system;
- Environment control;
- Lighting control;
- Security;
- Safety;
- Access control;
- Voice communication;
- Data communication (including telecontrol); and
- Entertainment.

Several other applications that can make use of the communications that exist outside the home include:

- Home banking;
- Information services;
- Working from home;
- Health monitoring (health check, health security);
- Telecontrol (appliances security heating, video recording); and
- Telemetering (gas, electricity, water).

Looking at the previously presented classifications of applications, one sees that there is a big difficulty in finding and imposing the most appropriate classification and identifying non-overlapping definitions, and then identifying functional links between different applications. Entertainment applications usually receive the most attention in standardization activities and market products because a large market already exists that has been accustomed to integration and common formats. Thus, the integration of audio devices such as DAT players, record players, cassette players, CD/DVD players, radio tuners, microphones, headphones, and remote controls has seen a very large market. The same concepts apply to video equipment; that is, the integration of TV display screens, VCRs, TV tuners, video cameras, video disk players, DVD players, video printers, and satellite dish platforms through a common interface has received considerable attention.

Security applications are the most advanced applications at homes today in terms of providing an integration of controller sensors, actuators, video camera, camera platform, microphones, door phone, push buttons/key access, and timers.

A considerable number of electric utilities have been involved with using advanced techniques of home automation for load management.

PRODUCTS AND STANDARDS

As in many other industries, home automation products were first introduced before a complete set of standards was specified. So in tracing the market and product development, we see a large number of products that do not follow any standard specifications but are absolutely proprietary.

Lonworks

For designers who will be involved in home automation designs, companies like Texas Instruments, Motorola, and Toshiba have been very active in developing the tools and components that will make this process easier.

Home automation systems have borrowed extensively from the developments in the networking community. The idea of using a local area network (LAN) to control and connect devices was implemented in Echelon's Lonworks. Lonworks is based on a distributed control LAN using its local operating network (LON). Communications media, network communication protocols, and application software are integrated. The LAN implements a predictive p-persistent CSMA protocol and can handle rates up to 1.25 Mbps. In the physical layer, transceivers for a variety of media are offered. The Neuron C application language, an extension of ANSI C, adds several features that allow efficient input/output (I/O) operations and efficient network management.

International efforts have been under way to develop standards covering the communication between home automation system modules. Most of these efforts use a LAN environment and follow standard layered approaches, such as the ones advocated by OSI.

CEBus

In the United States, the Electronic Industry Association (EIA) recognized the need to develop standards covering all aspects of home automation systems communication. A committee was organized in 1983 to carry out the task. In 1988, a home automation system communication standard known as CEBus (consumer electronic bus) was made available by the EIA committee for comments. It was upgraded and re-released in December 1989 after undergoing several changes. A final document became available in 1992 (1). The CEBus document covers the electrical and procedural characteristics of systems modules communication. The CEBus powerline technology was one of the first attempts to transport messages between household devices, using the 110–I20VAC electrical wiring in U.S. households. More than 400 companies have occasionally attended the CEBus committee meetings, providing a comprehensive standard, intended for the consumer electronics industry. The main objectives of CEBus have been:

- Low-cost implementation;
- Home automation for retrofit into existing cabling networks;
- To define minimum subsets per appliance intelligence and functional requirements;
- Distributed communication and control strategy;
- Basic plug-and-play functionality allowing devices to be added or removed from the network without interrupting the communication of other subsystems; and
- To accommodate a variety of physical media.

However, CEBus faced only the home automation area and never offered truly multimedia capabilities. In late

1995, CEBus became part of an umbrella standard known as Home Plug and Play (HPnP).

Home Plug and Play

Additions to the application layer of the original CEBus standards have been made in order to create the HPnP specification, transforming standalone products into interactive network products. This specification is expected to make systems easier to install and combine in a reliable in-home network. Among the objectives to be covered by HPnP standards is transport protocol independence, so more than one networking protocol can be used in the same home.

HPnP has three object types: status, listener, and request objects, which adapt the system in which the status information is given to the other systems. By the use of these objects, products from different producers can be used without detailed knowledge of their inner workings.

An important feature of HPnP is that it enables consumers to install more complex systems incrementally without complicating their use or requiring burdensome upgrades.

X.10

Like CEBus, the X.10 specification defines a communication "language" that allows compatible home appliances to talk to each other based on assigned addresses. X.10 is a broadcasting protocol. When an X.10 transmitter sends a message, any X.10 receiver plugged into the household power line tree receives and processes the signal, and responds only if the message carries its address. X.10 enables up to 256 devices to be uniquely addressed, while more than one device can be addressed simultaneously if they are assigned the same address.

HBS

The Japanese home bus system (HBS) has been developed as the national standard in Japan for home automation after several years of research and trials. HBS uses a frequency-division-multiplexing system using coaxial cable. Three bands are used for transmission of control signals: baseband, for high-speed data terminals; subband; and, for transmission of visual information, the FM-TV band. Recent efforts have concentrated on the expansion of the traditional idea of a home automation system into one that incorporates multimedia capabilities by using standard telecommunication services, such as ISDN BRI, and controls that provide low noise and low distortion.

EHS

The European home systems (EHS) specification has been developed under European Commission funding under the ESPRIT program. Its aim was to interconnect electrical and electronic appliances into the home in an open way so that different manufacturers can offer compatible products. An EHS product consists of three parts: a modem chip, a microcontroller, and a power supply. The main power cabling is used to carry the command and control signals at a speed of 2.4 kbps. Digital information is carried by a high-frequency signal superimposed on the voltage of the main. Sensitivity to electrical noise remains a problem, and filters are necessary to eliminate unwanted interference. Other media used include coaxial cable (to carry frequency-multiplexed TV/digital audio signals and control packets, 9.6 kbps), two twisted pair cables (telephone and general purpose, 9.6 kbps and 64 kbps), radio, and infrared (1 kbps).

EIBA Technologies

The European Installation Bus Association (EIBA) has assumed the role of the integrator in the European market. The EIB system for home and building automation is another topology-free, decentralized system with distributed intelligence, based on a CSMA/CA protocol for serial communication. Currently, various EIBA bus access units for twisted pair are commercially available. The bus access unit includes a transceiver; it locally implements the operating system and caters for user RAM and EEPROM space.

EIBA's objectives include the development of a unified concept for electrical fitting and home and building management. EIBA is a multivendor body that aims to establish a standard for building system technology on the European market. It makes the EIB system know-how available to members and licensees, provides members and licensees with support and documentation, establishes standards among its members, and specifies appropriate criteria for quality and compatibility, with the help of external test institutes. It also maintains the position of the EIB Tool Environment (ETE) as an unrivaled platform for open software tool development, at the heart of which is the EIB Tool Software (ETS), offering a common tool for the configuration of EIB installations.

EIB components, actuators, and monitoring and control devices communicate via a standardized data path or bus, along which all devices communicate. Little wiring is required, which in turn results in lower fire risk and minimized installation effort. Home automation systems provided by Siemens (see www.siemens.de) follow the EIBA standards and have several desirable features. Siemens' Home Electronic System (HES) provides:

- Security due to the continuous control of active processes around the house at the homeowner's fingertips;
- Economy in the use of utilities such as water, electricity, and heating energy;
- Convenience through simplifying operation and reducing the burden of routine tasks; and
- Communication by integrating the household management system into external communications facilities.

IEEE 1394

In order to combine entertainment, communication, and computing electronics in consumer multimedia, digital interfaces have been created. Such is the case of IEEE 1394, which was conceived by Apple Computer as a desktop LAN, and then was standardized by the IEEE 1394 working group.

IEEE 1394 can be described as a low-cost digital interface with the following characteristics:

- *High speed*. It is able to achieve 100 Mbit/s, 200 Mbit/s, and 400 Mbit/s; extensions are being developed to advance speeds to 1.6 Mbit/s and 3.2 Mbit/s and beyond.
- *Isochronous support*. Bandwidth for time-sensitive applications is guaranteed by a deterministic bandwidth allocation for applications such as real-time video feeds, which otherwise could be disrupted by heavy bus traffic.
- *Flexible topology*. There is no central bus supervision; therefore, it is possible to daisy-chain devices.
- *Hot-plug capability*. There is no need for the user to configure node IDs or unique termination schemes when new nodes are added; this action is done dynamically by the bus itself.
- *Cable power*. Peripherals of low cost can be powered directly from the IEEE 1394 cable.
- *Open standard*. The IEEE is a worldwide standards organization.
- *Consolidation of ports of PCs*. SCSI, audio, serial, and parallel ports are included.
- There is no need to convert digital data into analog data, and loss of data integrity can be tolerated.
- There are no licensing problems.
- A peer-to-peer interface can be provided.

The EIA has selected IEEE 1394 as a point-to-point interface for digital TV and a multipoint interface for entertainment systems; the European Digital Video Broadcasters (DVB) have selected it as their digital television interface. These organizations proposed IEEE 1394 to the Video Experts Standards Association (VESA) as the home network media of choice. VESA adopted IEEE 1394 as the backbone for its home network standard.

PLC

At the end of 1999, the Consumer Electronics Association (CEA) formed the Data Networking Subcommittee R7.3, and began work on a High-speed PowerLine Carrier (PLC) standard. PLC technology aims to deliver burst data rates up to 20 Mbps over powerline cables. However, like CEBus and X10, PLC shares the same power network with motors, switch-mode power supplies, fluorescent ballasts, and other impairments, which generate substantial impulse and wideband noise. To face this difficult environment, different technologies take widely differing approaches depending on the applications they are pursuing. Technologies and algorithms including orthogonal frequency-division multiplexing (OFDM), rapid adaptive equalization, wideband signaling, Forward Error Correction (FEC), segmentation and reassembly (SAR), and a token-passing MAC layer are employed over the powerline physical layer technologies in order to enhance transmission robustness, increase the required bandwidth, guarantee the quality, and provide both asynchronous and isochronous transmission.

HomePlug

The HomePlug Powerline Alliance is a rather newly founded nonprofit industry association established to provide a forum for the creation of an open specification for home powcrlinc networking products and services. The HomePlug mission is to promote rapid availability, adoption, and implementation of cost-effective, interoperable, and specifications-based home power networks and products enabling the connected home. Moreover, HomePlug aims to build a worldwide standard, pursuing frequency division for coexistence with access technologies in North America, Europe, and Asia. For medium access control, Homeplug 1.0 extends the algorithm used in IEEE 802.11 to avoid collisions between frames that have been transmitted by stations (2).

HomePNA

HomePNA is defined by the Home Phoneline Networking Association in order to promote and standardize technologies for home phone line networking and to ensure compatibility between home-networking products.

HomePNA takes advantage of existing home phone wiring and enables an immediate market for products with “Networking Inside.” Based on IEEE 802.3 framing and Ethernet CSMA/CD media access control (MAC), HomePNA v 1.0 is able to provide 1 Mbps mainly for control and home automation applications, whereas HomePNA v2.0 (3), standardized in 2001, provides up to 14 Mbps. Future versions promise bandwidths up to 100 Mbp/s.

COMMUNICATIONS AND CONTROL MEDIA

Several media, individually or in combination, can be used in a home automation system. Power line carrier, twisted pair, coaxial cable, infrared, radio communications, Digital Subscriber Loop (DSL) technologies, cable modems, and fiber optics have been proposed and investigated. Each medium has a certain number of advantages and disadvantages. In this section, we will present some of the most profound features of the media.

The power line carrier (PLC) or mains has been proposed in several applications. It is the natural medium of choice in load management applications. No special cables need to be installed because the power line is the bus itself. From one side, the power line medium already has a large number of appliances connected to it, but on the other side it is not a very friendly medium for transmission of communication signals because there is a fluctuation of the power line impedance and a high noise level on the line. There is also interference with communication caused by other houses. Spread spectrum or ASK techniques have been proposed for efficient modulation of the signal in PLC.

Recent advances in twisted pair (TP) transmissions, especially in telecommunications and computer networking applications, make it very attractive for applications that use standard computer interfaces. TP can be the generic system for the home system datagram services; if new communication technologies reach the home, TP can be used for high-bandwidth applications as well. TP can be easily assembled and installed, and connectors can be easily attached to it.

Coaxial cables have not been extensively—except for the Japanese market—used in home automation systems. Their high bandwidth and the experience technical people have amassed through the cable systems make them a very attractive medium. Retrofitting them in existing houses is one of their major disadvantages.

Infrared (IR)—that is, electromagnetic radiation with frequencies between 10^{10} and 10^{24} Hz—has been used extensively in remote control applications. Its use in home automation systems will require line-of-sight—that is, detectors in every single room so that there is a full coverage.

Radio waves—that is, electromagnetic signals whose frequency covers the range of 3 kHz to 300 MHz—do not need direct vision between the transmitter and the receiver, but there is a need for a license and problems with interference. Radio-frequency technology is being used for real-time data management in LANs in order to give free access to the host system from multiple mobile data input devices. Wireless home networking technology will operate in the large-bandwidth radio-frequency ranges and will use proprietary compression techniques. In the future, consumers might receive e-mail messages wirelessly from a compliant handheld device or view enhanced Web content on their connected television sets. The use of a radio frequency of 2.4 GHz will cut down on noise within the home and provide some security.

Home networking opens up new opportunities for cost-effective phones that include Internet capabilities. By sharing resources, manufacturers should be able to reduce the cost of an Internet phone by using the processor and modem of a connected PC. Currently, a number of major manufacturers are developing their own wireless home networking products. Two major industry groups, the Home Phoneline Networking Alliance (HPNA) and the HomeRF, are attempting to develop standards for two different technology sets.

The HomeRF Working Group (HRFWG) was formed to provide the foundation for a broad range of interoperable consumer devices by establishing an open industry specification for wireless digital communication between PCs and consumer electronic devices anywhere in and around the home. HRFWG, which includes the leading companies from the PC, consumer electronics, peripherals, communications, software, and semiconductor industries, has developed a specification for wireless communications in the home called the Shared Wireless Access Protocol (SWAP).

The specification developed by the HRFWG operates in the 2.4-GHz band and uses relaxed IEEE 802.11 wireless LAN and digital European cordless telephone (DECT) protocols. It also describes wireless transmission devices and protocols for interconnecting computers, peripherals, and electronic appliances in a home environment. Some examples of what users will be able to do with products that adhere to the SWAP specification include:

- Set up a wireless home network to share voice and data among peripherals, PCs, and new devices such as portable, remote display pads.
- Review incoming voice, fax, and e-mail messages from a small cordless telephone handset.
- Intelligently forward incoming telephone calls to multiple cordless handsets, fax machines, and voice mailboxes.
- Access the Internet from anywhere in and around the home from portable display devices.
- Activate other home electronic systems by simply speaking a command into a cordless handset.
- Share an ISP connection between PCs and other new devices.
- Share files, modems, and printers in multi-PC homes.
- Accommodate multiplayer games or toys based on PC or Internet resources.

Bluetooth

The Bluetooth program, backed by Ericsson, IBM, Intel, Nokia, and Toshiba, is already demonstrating prototype devices that use a two-chip baseband and RF module and hit data rates of 730 kbit/s at 2.4 GHz. Bluetooth uses a proprietary MAC that diverges from the IEEE 802.11 standard. Bluetooth has already managed to serve as a universal low-cost, user-friendly air interface that will replace the plethora of proprietary interconnect cables between a variety of personal devices and peripherals. Bluetooth is a short-range (10 cm to 10 m) frequency-hopping wireless system. There are efforts to extend the range of Bluetooth with higher-power devices.

Bluetooth supports both point-to-point and point-to-multipoint connections. Currently, up to 7 slave devices can communicate with a master radio in one device. It also provides for several piconets to be linked together in an ad hoc networking mode, which allows for extremely flexible configurations such as might be required for meetings and conferences.

The Bluetooth protocol stack architecture is a layered stack that supports physical separation between the Link Manager and the higher layers at the Host Interface, which is common in most Bluetooth implementations.

Bluetooth is ideal for both mobile office workers and small office/home office (SOHO) environment as a flexible cable replacement that covers the last meters. For example, once a voice over internet protocol (VoIP) call is established, a Bluetooth earphone may automatically switch between cellular and fixed telephone networks, when one enters his home or office. Of course, the low-bandwidth capability permits only limited and dedicated usage and inhibits Bluetooth from in-house multimedia networking.

IEEE 802.11

IEEE 802.11 is the most mature wireless protocol for wireless LAN communications, deployed for years in corporate, enterprise, private, and public environments (e.g., hot-spot areas). The IEEE 802.11 standards support several wireless LAN technologies in the unlicensed bands of 2.4 and 5 GHz, and share use of direct-sequence spread spectrum (DSSS) and frequency hopping spread spectrum (FHSS) physical layer RF technologies.

Initially, the IEEE 802.11 standard provided up to 2 Mbps at the 2.4-GHz band, without any inherent quality of service (QoS). The wide acceptance, however, initiated new versions and enhancements of the specification. The first and most important is the IEEE 802.11b specification, which achieves data rates of 5.5 and 11 Mbps. Recently, the IEEE 802.1lg task group has formed a draft standard that achieves data rates higher than 22 Mbps. In the 5-GHz band, the IEEE 802.1la technology supports data rates up to 54 Mbps using OFDM schemes. OFDM is very efficient in time-varying environments, where the transmitted radio signals are reflected from many points, leading to different propagation times before they eventually reach the receiver. Other 802.11 task groups targeting specific areas of the protocol are 802.11d, 802.11e, 802.11f, and 802.11h.

HIPERLAN/2

HIPERLAN/2 is a broadband wireless LAN technology that operates at rates as high as 54 Mbps in the 5-GHz frequency band. HIPERLAN/2 is a European proposition supported by the European Telecommunications Standards Institute (ETSI) and developed by the Broadband Radio Access Networks (BRAN) team. HIPERLAN/2 is designed in a flexible way so as to be able to connect with 3G mobile networks, IP networks, and ATM networks. It can be also used as a private wireless LAN network. A basic characteristic of this protocol is its ability to support multimedia traffic i.e., data, voice, and video providing quality of service. The physical layer uses OFDM, a technique that is efficient in the transmission of analog signals in a noisy environment. The MAC protocol uses a dynamic TDMA/TDD scheme with centralized control.

Universal Serial Bus (USB)

As most PCs today have at least 2 USB ports, accessible from outside the case, connecting new USB devices is a very simple Plug-n-Play process. Moreover, USB is able to cover limited power requirements of the devices, in many cases eliminating the need for additional power cables. USB 1.1 provides both asynchronous data transfer and isochronous streaming channels for audio/video streams, voice telephony, and multimedia applications, and bandwidth up to 12 Mbps adequate even for compressed video distribution. USB v2.0 transfers rates up to 460–480 Mbps, about 40 times faster than vl.l, covering more demanding consumer electronic devices such as digital cameras and DVD drives. USB may not dominate in the Consumer Electronics Networks in the short term, but it will certainly be among the major players.

Universal Plug-and-Play (UPnP)

UPnP aims to extend the simplicity and auto-configuration features from device PnP to the entire network, enabling the discovery and control of networked devices and services. UPnP in supported and promoted by the UPnP forum. UPnP is led by Microsoft, while some of the major UPnP forum members are HP, Honeywell, Intel, Mitsubishi, and Philips. The scope of UPnP is large enough to encompass many existing, as well as new and exciting, consumer electronics networking and automation scenarios including home automation/security, printing and imaging, audio/video entertainment, kitchen appliances, and automobile networks.

In order to ensure interoperability between vendor implementations and gain maximum acceptance in the existing networked environment, UPnP leverages many existing, mature, standard protocols used on the Internet and on LANs like IP, HTTP, and XML.

UPnP enables a device to dynamically join a network, obtain an IP address, convey its capabilities, and be informed about the presence and capabilities of other devices. Devices can automatically communicate with each other directly without any additional configuration. UPnP can be used over most physical media including Radio Frequency (RF, wireless), phone line, power line, IrDA, Ethernet, and IEEE 1394. In other words, any medium that can be used to network devices together can enable UPnP. Moreover, other technologies (e.g., HAVi, CeBus, orXlO) could be accessed via a UPnP bridge or proxy, providing for complete coverage.

UPnP vendors, UPnP Forum Working Committees, and the UPnP Device Architecture layers define the highest-layer protocols used to implement UPnP. Based on the device architecture specification, the working committees define information global to specific device types such as VCRs, HVAC systems, dishwashers, and other appliances. UPnP device vendors define the data specific to their devices such as the model name, URL, and so on.

DSL and Cable Modems

Digital subscriber line (DSL) is a modem technology that increases the digital speed of ordinary telephone lines by a substantial factor over common V.34 (33,600 bps) modems. DSL modems may provide symmetrical or asymmetrical operation. Asymmetrical operation provides faster downstream speeds and is suited for Internet usage and video on demand, where the heaviest transmission requirement is from the provider to the customer.

DSL has taken over the home network market. Chip sets will combine home networking with V.90 and ADSL modem connectivity into one system that uses existing in-home telephone wiring to connect multiple PCs and peripherals at a speed higher than 1 Mbps.

A cable modem is another option that should be considered in home network installations. Cable modem service is more widely available and significantly less expensive than DSL in some countries. Cable modems allow much faster Internet access than dial-up connections. As coaxial cable provides much greater bandwidth than telephone lines, a cable modem allows downstream data transfer speeds up to 3 Mbps. This high speed, combined with the fact that millions of homes are already wired for cable TV, has made the cable modem one of the top broadband contenders. The advent of cable modems also promises many new digital services to the home, including video on demand, Internet telephony and videoconferencing, and interactive shopping and games.

At first glance, xDSL (i.e., DSL in one of the available varieties) appears to be the frontrunner in the race between cable modems and DSL. After all, it can use the phone wire that is already in place in almost every home and business. Cable modems require a television cable system,which is also in many homes and businesses but does not have nearly the same penetration as basic telephone service. One important advantage that cable modem providers do have is a captive audience. All cable modem subscribers go through the same machine room in their local area to get Internet access.

In contrast to cable modem service, xDSL's flexibility and multi vendor support is making it look like a better choice for IT departments that want to hook up telecommuters and home offices, as well as for extranet applications. Any ISP will be able to resell xDSL connections, and those connections are open to some competition because of the Telecommunications Act of 1996. The competitive multi-vendor environment has led to a brisk commodity market for xDSL equipment and has made it a particularly attractive and low-cost pipe. Although new services are sure to be spawned by all that bandwidth, xDSL providers are able to depend on the guaranteed captive audience of their cable modem counterparts.

Fiber Optics

Fiber optics at home have also been evaluated in the literature. The well-known advantages of fiber, such as increased bandwidth, immunity to electromagnetic noise, security from wiretaps, and ease of installation, compete with its disadvantages, such as higher cost, difficulty in splicing, and requirement of an alternate power supply. A standard for a fiber optic CEBus (FOBus) has been developed.

One of the major drives behind the use of fiber optics is the ability to carry multimedia traffic in an efficient way. As telecommunication companies are planning to bring fiber to the home, a fiber optic network in the house will make the Internet working with places outside the house cost effective and convenient. Connection with multimedia libraries or with other places offering multimedia services will be easily accomplished to the benefits of the house occupants, especially students of any age who will be able to access, and possibly download and manage, these vast pools of information.

Several minimum requirements of a FOBus are set forth. In terms of service, the FOBus should provide the following services:

- Voice, audio, interactive, bulk data, facsimile, and video;
- One-way, two-way, and broadcast connectivity;
- Transport of continuous and bursty traffic;
- Interfaces to external networks and consumer products; and
- Multiple data channels and a single, digital control channel.

The network should meet the following physical requirements:

- Low installation costs and ease of installation;
- High reliability;
- Easy attachment of new devices;
- No interruption of service while a new node is being connected; and
- Access to the network via taps in each room.

The FOBus standard should also have a layered architecture in which layers above the physical layer are identical to the corresponding CEBus layers in other media.

Some of the applications of a fiber optic network in the home that will drive the design of the fiber optic home network are: the connection to emerging all-fiber networks, which will provide high-quality, high-bandwidth audio/visual/data services for entertainment and information; fiber network connection to all-fiber telephone networks to allow extended telephone services such as ISDN, videotelephone, and telecommuting; transport of high-quality audio/video between high-bandwidth consumer devices such as TVs and VCRs; and transport of control and data signals for a high degree of home automation and integration.

SECURITY

Security (the need to prevent unauthorized nodes from reading or writing information) is an issue of concern for every networking product. Many manufacturers have decided to create a security context on their products and have the key information on them, which means that one object of one context sends a message to another context object, and thus both have to be built by the same company so that the security encoding algorithm can be exchanged between them.

Security in the home automation systems literature is seen as follows:

- Security in terms of physical access control and alarm systems.
- Security in terms of the well being of house inhabitants through systems that monitor health status and prevent health problems.
- Security of the building itself in terms of a safe construction and the subsequent monitoring of this status.
- Security in terms of confidentiality of the information exchanged.

The latter is being achieved by the use of various security techniques in use, including message authentication algorithms, which are of two main types. Two-way authentication algorithms require the nodes involved in the checking to know the encoding algorithm, and each node must have an authentication key in order to accept the command issued. A one-way authentication algorithm verifies only the transmitter and the information that goes on the APDTU (packet in the application layer); it requires only one authentication key, but the encoding algorithm must be known by the nodes. Both types of algorithm require a random number that is encoded with the authentication keys.

Encryption is also used in order to obtain greater security in the message and in the data sent on the APDU. The algorithm or technique used has to be known by the receiver and transmitter. Encryption is implemented with the help of the authentication algorithm ID in the second byte.

FUTURE DIRECTION

Home automation systems have been presented as a promising technology for bringing the computer and communications revolution that has swept the office and industrial environments in the last decade to the home environment. However, we have not seen an use of home automation systems and an increase in the market share as predicted from market analysts. This lack of acceptance can be attributed to marketing problems, costs of installation and retrofitting, slow growth of new housing, and a lack of standards that synchronize with the developments in the other technological areas.

The wide availability of powerful computers at homes and the availability of high-speed telecommunications lines (in the form of cable TV, satellite channels, and, in the near future, fiber) make a redirection of the home automation industry necessary. More emphasis should be on applications that require access to external sources of information—such as video-on-demand and the Internet—or on access from outside the home to home services—such as the load management application discussed above from utilities or individuals and remote surveillance.

User-friendly customer interfaces combined with reasonable pricing will certainly move the industry ahead. The availability of the Internet and the World Wide Web should be exploited in different ways. First, the interfaces and the click-and-drag operations could be adopted and then the high use of bandwidth could be accomplished. The above considerations should be viewed in light of cost and retrofitting issues in existing dwellings and the availability of appliances that are compatible with standards and that can be purchased from multiple vendors.

Wireless technologies seem to dominate the future of home automation systems. With regard to the future of fiber optics at home, several observations can be made. External or non premises service providing networks, and second-generation television, receivers such as high-definition television (HDTV) are two main areas in which developing technologies will impact the design of the FOBus. One external network that the FOBus will have to accommodate is the public telephone network. The current public switched network uses copper wire in its local loop to provide service to a neighborhood; but in the future, the use of fiber in the loop (FITL) will be gradually phased in. Neighborhood curbside boxes will be replaced with optical network units (ONUs) that will provide plain old telephone service (POTS) as well as extended network services. Initially, the service to the home will be provided on copper medium, but it will eventually be replaced with fiber as well. The FITL system will support broadband communications, especially interactive applications.

Another external network that will impact the FOBus design is the cable television network, which is also gradually being replaced by fiber. The FOBus specification will have to accommodate the high-bandwidth services delivered by the cable network (generally in the form of broadcast channels); it may also have to support interactive services that are envisioned for the future.

The other developing technology that will impact the design of the fiber optic CEBus is the emerging advanced television (ATV) standard, which will most likely include HDTV. In the United States, the EIA is examining digital standards for HDTV transmission. Most require bandwidth of 20 Mbps, which the proponents of the standards claim can be transmitted on a standard 6-MHz channel using modulation techniques such as quadrature amplitude multiplexing. In addition, the ATV receiver will likely have separate input ports for RF, baseband digital, and baseband analog signals. The choice of which of these ports to use for the CEBus/ATV interface has not been made. Each has its own advantages. Using the RF port would allow a very simple design for the in-home fiber distribution network, and the interface would only have to perform optical-to-electrical conversion. The digital port would remove bandwidth constrictions from the broadcast signal and also allow for interactive programming and access to programming from various sources. The ATV could become the service access point for all audio/visual services in the home.

An important issue in home automation is the integration of Internet technologies in the house. Several companies have proposed technologies to embed network connectivity. The idea is to provide more control and monitoring capability by the use of a Web browser as a user interface. In this new technology, Java and http (standard Internet technologies) are accessed through a gateway that manages the communication between the Web browser and the device.

Among the advantages of this new technology are the following:

- Manufacturers can provide their products with strong networking capabilities, and increase the power of the Internet and the available intranets.
- The use of a graphical user interface (GUI) allows a simple display of the status, presence, and absence of devices from the network.
- Java, Visual Basic, and Active X development environments reduce the development time of device networking projects.
- Interface development is easy.
- Batch processes to gather data are easy and fast.

Standard technologies to network devices via the Internet provide for the development of internetworking solutions without the added time and costs of building proprietary connections and interfaces for electronic devices.

Manufacturers of home automation systems must take into account several factors. The users are the first to be considered. Their physiological and psychological capabilities as well as their socioeconomic characteristics must be considered before a new technology is adopted.

Another issue is the added value provided by such systems in terms of the reduction of repetitive tasks and the skills and knowledge required to operate them. Health and safety considerations must be taken into account. Also, one needs to examine the current status of technologies and the dynamics of these technologies in order to offer a successful product in the market and, mainly, in order to create a new healthy market sector.

The suggested technologies should be able to enhance the life in a household but certainly not dominate it. The systems should be reliable and controllable but also adaptive to specific user needs and habits. They should also be able to adapt to changing habits.

HOME COMPUTING SERVICES

INTRODUCTION

Relevance of the Topic

The 1990s and the current decade have experienced tremendous growth in computers and telecommunications, and, for the first time, developments in technologies in the home followed in close proximity to their correlates in the corporate world. Notably, the diffusion of the Internet into the private sector has proceeded at enormous pace. Not only has the number of households with Internet access skyrocketed, but also access speed, number of users within the household, types of uses, and mobility of access have expanded.

In some cases, corporate use of technologies followed private home use (e.g., for Instant Messenger and other chat applications). Popular private applications such as music and video downloads initially required access to large corporate or academic networks because of capacity needs. Such applications encouraged the increasing diffusion of broadband into private homes.

Home and business technologies are increasingly intertwined because of the increasingly rapid pace of innovation. Also, home information technology (IT) may experience growth during times of economic slowdown because of price decline or network effects (DVD; Internet in the early 1990s; wireless today).

Although convergence is a predominant trend, a market for private IT applications separate from the corporate market is evolving as well. Price decline and miniaturization encourage the perspective of ubiquitous computing and of a networked society.

Definitions

A range of concepts have evolved that permit the conceptual separation of business/public computing services from those related to the home or private use. One definition points to *all the infrastructures and applications the private user can take advantage of for private uses*. This definition encompasses most applications discussed in this article, notably entertainment, information, communication, and shopping. Some other applications cross over into the public or business realm, in particular telework and distance learning. Although this article focuses on services in the home, more recently miniaturization and mobile technologies have blurred the line between home and other locations. Mobile phones, personal digital assistants (PDAs), personal entertainment technologies all are designed to extend applications that are conveniently available in the home to any location the user chooses.

Home computing trends revolve around various household functionalities, notably entertainment, information, purchasing, education, work, and health. During an age of networks, these applications are often no longer merely household related, but they require integration of home and business technologies. A key trend observed during the past decade has been the convergence of technologies, of content, and of applications.

Structure of this Article

Although understanding the technological advances in this area is important, much of the technology is derived from corporate computing applications and adopted for home use. Thus, this article will focus on content and usage of home computing more so than on technical details.

This article explores key issues pertaining to home computing products and services. In particular, it will discuss convergence of technology and other current technological trends related to end-user devices and networking. Selected services for the home will be addressed in light of technological changes.

As the technology becomes more available and common, concepts such as “computerized homes,” “Home-IT,” “information society,” or “networked society” are increasingly defined by the services with which they are associated.

The article concludes with future Home-IT trends.

DRIVERS OF TECHNOLOGY ADOPTION IN THE PRIVATE HOME

Convergence

Convergence of technologies has a critical impact on home computing as well as information and entertainment. Although analog technologies generally coincided with a limited one-on-one relationship of applications and appliances, digital technologies have made it possible to perform multiple functions with the same piece of equipment, which has lead to an increasing overlap between the telecommunications, television, and consumer electronics industries. For the user, it means that the same appliance can be used for work-at-home, chat, children’s entertainment, and online shopping or banking. Apart from technological innovation and cooperation among industry sectors, adoption of interactive media consumption patterns by the users is the third dimension of convergence. There is a continuing debate as to how rapidly convergence will be embraced by consumers. Although it has been technically feasible for some time, convergence is seen as limited because of demographics, lifestyle preferences, and other factors (1). For instance, the convergence of television (TV) and computers on the user side has not advanced as rapidly as expected, even though streaming video of television programming is available on the Internet, cable systems offer “Digital Cable,” and cell phones have cameras that permit instant e-mailing of pictures. Most Americans still watch television one program at a time, even though many rely increasingly on the Internet for news, weather, stock market, and other information.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

However, at least on the supply side, convergence is gradually advancing. Responding to digital satellite competition, cable companies have enhanced the existing fiber/coax physical plant of their systems with digital set-top boxes and digital distribution technology. These upgrades permit greater channel capacity, as well as interactive features. On-screen program guides, several dozen pay-pv-view (PPV) channels as well as multiplexed premium cable channels and digital music channels are common. Digital picture, flat-screen technology, surround sound, and high-definition television (HDTV) encourage the trend toward home theaters. In a typical digital cable offering interactivity is limited to two levels of information, which can be retrieved while watching a program or perusing the on-screen program guide; PPV ordering, as well as selection, programming, and recording of future programs through the on-screen guide are also interactive features. The systems are designed to allow for future expansion, especially online ordering of services as well as other purchases. Some systems offer Video on Demand (VoD), in which users can order movies and other videos from a large selection in a real-time setting. The more common "in-demand" offerings simulate a near-VoD experience, in which the most popular movies are available at half-hour starting times.

Several providers experiment with interactive applications that give the viewer options beyond simply choosing a program, including game show participation, choice of camera angles at sports games, access to background information for products advertised in commercials, and choice of plot lines and endings in movies. Other interactive uses of TV are calling up additional information on news and sports or TV/PC multitasking. Increasingly, TV and radio are supplemented by websites for information retrieval as well as audience feedback and service applications (such as buying tickets or merchandise).

In the consumer electronics sector, convergence is currently taking place both from computer companies and from home entertainment companies. Microsoft has developed a media player that allows integration of video, audio, photos, and even TV content, and Intel is making a significant investment in companies creating digital consumer products (2). On the other hand, Sharp is planning to debut liquid crystal display (LCD) TVs with PC card slots that enable the addition of "digital-video recording functions or a wireless connection to a home computer network" (3).

User Interface: TV, PC, Phone

Much discussion of Home-IT focuses on the Internet. Innovations associated with traditional media also offer considerable potential, in part because all electronic media are evolving rapidly, converging with other media, and becoming increasingly interactive. These hybrid media often reach the majority of the population (in some countries, a vast majority) that lacks regular, adequate Internet access (4, 5). Also, in spite of improvements in "user friendliness," many users see the PC as work-related, difficult to use (requires typing), and prone to breakdowns and viruses. PCs also tend to be outdated within a few years. By contrast, TV sets last for decades, they are easy to use, not prone to viruses, and are less expensive.

Worldwide, TV consumption is still the prevalent leisure activity, mainly because of its universal, low-cost accessibility and its ability to afford hours of entertainment and information with minimal effort. Although usage patterns are changing rapidly, for some time consumers may continue to choose TV for news and entertainment and PC for other sources of information and electronic commerce. Also, there seems to be a demographic pattern in that young viewers increasingly stray away from conventional TV news either to Internet news or entertainment/news programs (e.g., Comedy Central). Although it is a digital technology, the tremendously rapid adoption of the DVD player is largely a replacement for VHS home video with higher video quality.

Although the expectation was that video delivery would increasingly involve home computing devices, such as combination PC-TV or Web-TV and digital recording technology such as TiVo (5), most households invest in big-screen televisions and surround sound. TiVo was also adopted more slowly than expected.

A third popular user interface is the telephone. As a result of their rapid replacement cycle compared with regular-line phones, cellular phones in particular tend to be equipped with the latest technological gadgets. As prime value is placed on instant "24/7" communication, mobile technology epitomizes trends in personal technology. As a result of simple use, ubiquity, and compatibility with existing technology (i.e., the existing telephone network), adoption and upgrading of mobile phones are rapid. Besides regular voice use, text messaging has gained popularity among younger users, especially in Europe and Japan. Currently, web access is available via narrowband channels. However, the next generation of mobile broadband is currently being deployed. In concert with smartphones and wireless PDAs, broadband mobile networks (e.g., those based on the UMTS (Universal Mobile Telecommunications System) standard) provide multimedia services such as videophone or content streaming. The first rollout in Asia started in 2003. Pricing and compelling services are again key to success.

Interactive Entertainment

Content is the key to adoption of advanced interactive services. As a result of the high visibility of movies, the great public interest in this type of content, and their easy availability, Movies-on-Demand was the offering of choice for early interactive trials. Meanwhile, cable systems and satellite providers offer near PPV with 50–100 channels offering current movies as well as specialized (e.g., "adult") programming and sports or music events.

Music, sports, and special interest programming also have received their share of attention by the programmers of interactive cable systems. Interactive game channels are added to some systems. In-home gambling has strong economic appeal; regulatory barriers prevail, however. Anecdotal evidence suggests that participants in interactive trials enjoyed watching regular TV programs they missed during the week, newscasts tailored to individual preferences (6), as well as erotica.

Several television providers have experimented with interactive applications that give the viewer options beyond simply choosing a program, including participation in game shows such as *Wheel of Fortune* and *Jeopardy*, "pick-the-play" games for *Monday Night Football*, ordering pizza using Web-TV during a *Star Trek* marathon, access to background information for products advertised in commercials, and choice of plot lines and endings in movies.

Compared with the massive number of traditional movies available, interactive movies are few and far between. They are difficult to produce and require considerable technology. Even most sites for Internet video provide mainly repackaged conventional programming. Audience demand for interactivity is not yet understood. Many children and teens feel comfortable with it because of exposure to video and computer games; in fact, a considerable number of toys now include interactive components and interface with the world wide web (WWW) (7). Most likely the push for greater interactivity will come from advertising, which already relies on cross-promotion between different media including TV and Internet. As the marketing increasingly focuses on individualization, the ability to provide targeted advertising even within the same program is likely to have great appeal to advertisers. Also, because commercial avoidance is increasingly common, the push for product placement within programs may also lead to increasingly individualized product inserts.

Broadcast television stations are expanding their channel offerings as a result of conversion to HDTV and the resulting availability of greater channel capacity. However, the expectation is that they will, at least initially, offer greater selection and targeting rather than actual interactivity.

The Digital Home

The ultimate interactive experience may involve a home that is equipped with technology that can respond to the residents' needs. Smart house technology typically is developed for high-end or special needs homes, and these technologies filter down into existing and mid-level homes. Some smart-house solutions for the elderly use the TV set as an interface for appliance control and surveillance. A key feature of future smart-house technology is the ability of various appliances to "talk to the Internet and to each other" (8), which allows a maximum of control by the user, as well as coordination of technologies. In the long run, shifting control onto the Web could generate considerable cost savings by reducing the complexity of the technology within each device.

Especially home networking technologies such as the European EIBus or the US-led CEBus enable the interconnection of different household devices such as heating, shades, or lighting. In addition, wireless local area networks (LANs) are gaining ground in the private sphere, connecting IT devices. Eventually, audio/video, PC, and other household networks will converge (9,10) .

Although many such technologies are available, they have not been adopted on a broad scale. However, one might expect that demographic trends will drive such adoption: Aging baby boomers have an increased need for home-based conveniences and efficiencies; young home buyers have grown up with network technologies and may expect a high level of technology in their future homes. Also, elderly family members need increased attention, which may be facilitated via available technologies.

However, services to be delivered to the home not only require in-home technologies. Service providers such as banks or media firms need to prepare back-end infrastructures such as fault-tolerant servers, load-balancing access pipes, and real-time databases with information on availability or price quotes. Those out-of-home infrastructures are connected to the home via networks such as cable, telephone, powerline, or wireless connections.

SERVICES FOR THE HOME

Media attention has been focused on innovative infrastructures for the residential area such as wireless LAN in the home or broadband connections to the Internet.

However, the private household, even more than a corporate user, is interested in the application side (i.e., an easy-to-use, reasonably-priced, and fun service provision). Many applications exist in reality, yet they provide a quite unstructured picture.

Kolbe (11) proposed a classification scheme for analyzing and describing the respective classes of home applications in existence. According to Brenner and Kolbe (12), there are eight main services for the private household that can be supported by IT (see Fig. 1):

The basic services "information" and "communication" take mutual advantage of each other: There is no communication possible without at least basic information provided on one end, sometimes referred to as message or content. In turn, information needs to be conveyed in order to provide any benefit. For example, any news story posted by an Internet portal is meant as "communicating

Core services:

- Information
- Communication

Home services:

- Health
- Home services
- Travel
- Transactions
- Entertainment
- Education

Figure 1. IT-influenced services for of the private household.

information" to the (anonymous or personalized) users of that portal.

They are referred to as core *services* whereas the other ones are looked on as primary *home services* because they are based on information and communication features. Nevertheless, "communication" and "information" are described separately as some services exclusively provide bilateral or multilateral information (e.g., electronic books, news) or communication (e.g., e-mail, short message service (SMS)) benefits. Market revenues are most substantial in those basic areas.

Miles (13) and others (10) after him observed that more and more aspects of private life are affected by home services. We can differentiate three forms of usage according to the degree of networking. Prior to widespread networking, stand-alone applications such as an electronic encyclopedia or a game on a PC were common. The next step is locally interconnected applications within the confines of the private home such as entertainment networks for home cinema applications or controlling the heating via TV or PC. The third form is the out-of-the-home connected applications such as applications using the Internet for e-mail or shopping as well as remote monitoring services. All services can be structured a long these three areas.

In practice, these types of services are used in conjunction with each other, for example, during activities on the Internet the household seeks weather information (information and travel) for air travel via a portal or a price comparison for airfares (travel), then executes the purchase (transactions) using a travel portal and then pays online using a credit card (transactions), and finally gets an e-mail or mobile message confirmation of this order (communication). Another example is the 'Info- or Edutainment' area that unites information, entertainment, and education aspects (e.g., in interactive multimedia encyclopedias or electronic learning toys for children).

Work, transaction, and private aspects of life are converging as are technologies and applications. In some instances, private and business usage is almost indistinguishable (e.g., the use of an Internet portal or some smart phone features). Therefore, some of the services described below may also provide business value as selective business applications benefit the private user, especially in a home office environment.

Core Services

Information. *Information* is offered by all services in which the dissemination of information to the private household is central. Information provides the basis for more complex service types to be discussed later.

The following residential applications fall into this category:

- News portals providing up-to-date coverage such as news or weather information. Together with search capabilities, they provide access to the vast resources of the Internet to the private user. Interactive TV and multimedia broadband networks are prerequisites for customized individual news services that compile one's own newspaper on personal preferences and interests like sports or stock exchange news as examined by MIT's Media Lab.
- Electronic books and newspapers such as the electronic version of the *New York, Times*, which is available online for a fraction of the newsstand price. Electronic books with portable e-book players are one of the most notable examples for pure information. Encyclopedias, magazines, dictionaries, or special topics are available on different formats for proprietary players. Hyperlink functionality, connectivity to video printers, and find-and-select algorithms are advantages that traditional books do not share.
- Push services of events and product news: Mobile marketing is gaining ground fast. The latest research in Finland shows that 23% of all mobile-phone-using Finns (80% of all Finns) have received SMS push marketing (14).
- Information kiosks, which provide basic information for travelers or shoppers.

Communication. *Communication* enables the private household to establish bilateral or multilateral contact with the immediate or extended environment. This core service provides information as the basis for a variety of further services. However, communication as a basic need of users is evident in the residential home. Traditional media like telephone and fax have been complemented by innovative media such as e-mail or mobile communications, both text and voice.

SMS has achieved near 80% usage rates in some European countries, and SMS advertising has exploded. Mobile text messages generate a substantial part of telecom operators' revenue. In Europe, SMS revenues were at 12 billion Euros for 2002 (15).

Mobile phone users in the United Kingdom sent over one billion text messages during April 2002. The Mobile Data Association predicts that the total number of text messages for 2002 will reach 16 billion by the end of the year (16).

Home Services

Health. *Health* refers to all applications concerned with making provision for, maintaining, and monitoring the health of a person or social group.

Related services in the area are:

- Telemedicine with patient monitoring (surveillance of vital signs outside the hospital setting) and monitoring of dosage (including real-time adjustment based on the patient's response). Wireless sensors can be attached to the body and send signals to measurement equipment. They are popular in countries with widely dispersed populations (e.g., Norway) and increasingly developing countries.
- Electronic fitness devices that support training and wellness of the private user.
- Health-related websites.

Health applications for today's household are very limited in its range. In some countries, smart cards carry patients' data for billing and insurance companies or health consultancy software for private diagnosis and information about certain diseases. In the future, expert systems will enable medical advice from each home without leaving the private bed.

Home Services. *Home services* consist of systems that support home security, safety, meal preparation, heating, cooling, lighting, and laundry.

Currently, home services comprise only special devices such as those in a networked kitchen. Future scenarios project comprehensive home automation with interconnected kitchen appliances, audio and video electronics, and other systems like heating or laundry. Some prototypes by the German company Miele (called Miele@home) showed early in the development of "smart homes" that the TV can control the washing machine. The interconnection to out-of-home cable TV or telephone networks leads to the remote control services (e.g., security). Much media attention was received by the Internet refrigerator by NCR, which orders needed groceries without human interaction.

Key areas comprise:

- Central control of heating or air conditioning from home computer or TV.
- Lighting, shutters, and temperature control.
- Remote monitoring of home devices for security, laundry, refrigeration, or cooking.

Intelligent clothing and wearable computing are seen as emerging areas.

Travel. *Travel* includes all applications that support the selection, preparation, and undertaking of journeys. Travel applications make the central booking information systems for hotel or flight reservation accessible to the residential user. Individual preferences provide a search pattern for finding the places of interest. Future visions includes interactive, multimedia booking from the TV chair via broadband network with instant acknowledgements.

Main focus areas are:

- Travel planning on the Internet ranges from planning the entire trip via travel portals *Travelocity* or *Expedia* to selected information on public transportation or plane departures. These travel data can also be pushed to mobile devices or delivered according to the geographic position of the user.
- Automotive services. Increasingly, the car becomes an entertainment and information center with complete audio and video system. In addition, global positioning functionality helps planning and undertaking trips.
- Ticketless travel, such as e-ticket of airlines and ticketless boarding with contactless smart cards.

Transactions. *Transactions* combine all the administrative services and transactions, such as shopping and banking, of the private household.

The main applications of administration, e-banking, and e-shopping are applications serving "traditional" functions (17). Those services help the home to fulfill necessary administrative obligations with more efficiency and ease.

Using the PC and Internet connection, the private user can perform his bank business or order certain merchandise. Today's services (e.g., management of payments) will extend to a broader range (e.g., complete investment and mortgage affairs).

Of particular importance are the following transaction-oriented services:

- Electronic execution of administrative activities such as monitoring the household's budget with spreadsheets or planning software such as Quicken.
- Using personal information management (PIM) software such as scheduling, personal address book, or task lists, often provided in combination with PDAs or smart phone software.
- Deployment of productivity tools such as word processing, presentations, or spreadsheets for private letters, invitations, or planning purposes.
- Electronic banking and investing is the main service in this category. Although the focus is still on well-structured transactions such as payments (e.g., electronic bill presentment and payment (EBPP)), more complex tasks such as investment advice and research is delivered to private banking clients.

  In Switzerland, more than 50% of all private banking clients use the Internet for banking. Overall, 13% of all brokerage transactions and 26% of all payments are done via e-banking. Financial information is also accessed by the households. The big Swiss bank, UBS, lists prices of more than 370,000 stocks. Alerts can be sent to a mobile device. Some banks offer mobile banking services that resemble the features of the Internet offering.
- Shopping on the Internet has become an important service. Although purchases focus on standardized products, everything from furniture to groceries is available. The percentage of online purchases relative to total shopping revenue remains at moderate levels but is gradually increasing. The 2003 Christmas season experienced a strong increase in Internet sales: 18 billion (out of 217.4 billion total sales), up from 13.8 billion in the last quarter of 2002. More importantly, many retailers have offered a seamless shopping experience of catalogs, Internet, and stores (18). Especially auctions like eBay have received much attention from the private user: Amazon.com, a Fortune 500 company based in Seattle, opened its virtual doors on the World Wide Web in July 1995. Amazon.com and other sellers list millions of unique new and used items in categories such as apparel and accessories, sporting goods, electronics, computers, kitchenware and housewares, books, music, DVDs, videos, cameras and photo items, toys, baby items and baby registry, software, computer and video games, cell phones and service, tools and hardware,

Type of service	***Service area***	***Status quo 2004***	***Scenario 2007***	***Scenario 2010***
CORE SERVICES	*Information*	Electronic books, news portals	Fully electronic newspaper based on personalized profile	Electronic newspaper on e-paper
	Communication	Home-fax and mobile digital telephone	E-mail from every mobile device	Worldwide multimedia video communications
HOME SERVICES	*Health*	Consultancy software	Interactive, remote health services	Medicinal diagnostics at home by expert systems
	Home services	Only special interconnected household technologies, no standards, remote monitoring	Increased home automation via standard interfaces, entertainment and home services converge	All household equipment networked to in- and out-of-home devices, the "wired" home
	Travel	Travel portals, complete journey booking from home, GPS services	Intelligent guiding services for cars, location-based services, Internet access in cars	Automatic driving services, fully telematic information for the car
	Transactions	Home shopping over the Internet Integration of 'clicks and bricks'	Multimedia home shopping also for complex products	Virtual electronic shopping mall
		Home-banking for selected transactions	Home-banking for all activities	Multimedia banking, cybercash
	Entertainment	One way pay-TV, interactivity via telephone lines	Pay-per-view, limited number of services	Fully communicative TV (personal influence on action) and Video-on-demand
	Education	Computer Based Training software or Internet offerings	Distant multimedia learning at home, public electronic libraries	Individual virtual teachers using artificial intelligence and virtual reality simulations

Figure 2. The evolution of home computing services.

travel services, magazine subscriptions, and outdoor living items.

Entertainment. *Entertainment* includes those applications that can be used for leisure activities or for the purpose of entertaining household members.

Particular areas of entertainment services are:

- Home cinema with digital surround audio and home media server that connect flat plasma or LCD-TVs, audio systems, and multimedia PC environments with the Internet. In 2003, U.S. DVD sales surpassed videotape figures for the first time.
- On-demand digital TV with hundreds of channels of audio and video content.

- Games and gambling both via the Internet and mobile networks and in electronic stand-alone devices such as game boys and gambling machines.
- Digital toys such as Sony's smart dog or Lego's *Mindstorms* programmable brick sets developed in collaboration with MIT's MediaLab. Here, a close relationship to the learning component is evident.
- Using multimedia devices such as digital video cameras or digital photography in combination with home PCs and video authoring software for creating multimedia shows at home.
- Free and premium Internet radio with endless options of genres and downloadable music on portable devices such as MP3 players or smartphones.
- Adult content.

Education. *Education* refers to all applications that train and educate members of the household in special skills or knowledge. In an increasingly dynamic private environment, this function will gain in importance.

Distance Learning (DL) is frequently a self-selected activity for students with work and family commitments. Effects of social isolation should thus be limited. For instance, DL can facilitate daycare arrangements. In some circumstances, exclusion from the social network of the face-to-face classroom can be one of the drawbacks of DL (21). The private household uses this type of "education" for the training of special skills it is interested in using off-line computer-based training (CBT) software on CD-ROM or DVD to improve, for example, on a foreign language for the next holiday abroad or naval rules in order to pass the sailing exam. In addition, electronic accessible libraries and content on the Internet open the field for self-education processes to the private area. The usage artificial intelligence will substitute human teachers as far as possible and make them more efficient for special tasks. Virtual reality will help by visualization and demonstration of complex issues. Increasingly, colleges and universities offer DL classes based on strong demand from traditional and nontraditional students. Besides the added flexibility and benefit for students who are reluctant to speak up in class, DL benefits those students living far from the place of instruction. Dholakia et al. (22) found that DL has the potential to reduce or modify student commutes.

OUTLOOK

Figure 2 summarizesthehomeservicesandshowssomeofthe expected developments for the next several years. It summarizes three possible scenarios (status quo 2004, scenario 2007, and scenario 2010) based on the assessment of past, current, and future trends, and developments of services.

REMOTE SENSING INFORMATION PROCESSING

INTRODUCTION

With the rapid advance of sensors for remote sensing, including radar, microwave, multispectral, hyperspectral, infrared sensors, and so on the amount of data available has increased dramatically from which detailed or specific information must be extracted. Information processing, which makes extensive use of powerful computers and techniques in computer science and engineering, has played a key role in remote sensing. In this article, we will review some major topics on information processing, including image processing and segmentation, pattern recognition and neural networks, data and information fusion, knowledge-based system, image mining, image compression, and so on. References (1–5) provide some useful references on information processing in remote sensing.

In remote sensing, the large amount of data makes it necessary to perform some type of transforms that preserve the essential information while considerably reducing the amount of data. In fact, most remote sensing image data are redundant, correlated, and noisy. Transform methods can help in three ways: by effective data representation, effective feature extraction, and effective image compression. Component analysis is key to transform methods. Both principal component analysis and independent component analysis will be examined for remote sensing.

IMAGE PROCESSING AND IMAGE SEGMENTATION

The motivation to enhance the noisy images sent back from satellites in the early 1960s has had significant impact on subsequent progress in digital image processing. For example, digital filtering such as Wiener filtering allows us to restore the original image from its noisy versions. Some new image processing, such as wavelet transforms and morphological methods, have been useful in remote sensing images. One important activity in remote sensing is the speckle reduction of SAR (synthetic aperture radar) images. Speckles appearing in SAR images is caused by the coherent interference of waves reflected from many elementary scatters. The statistics of SAR speckle has been well studied (6). Over a 100 articles have been published on techniques to remove the speckles. One of the most well-known techniques is the Lee's filter, which makes use of the local statistics (7). More recent studies of the subject are reported in Refs. 8 and 9.

Image restoration in remote sensing is required to remove the effects of atmospheric and other interference, as well as the noises presented by the sensors. A good example is the restoration of images from the Hubble Space Telescope.

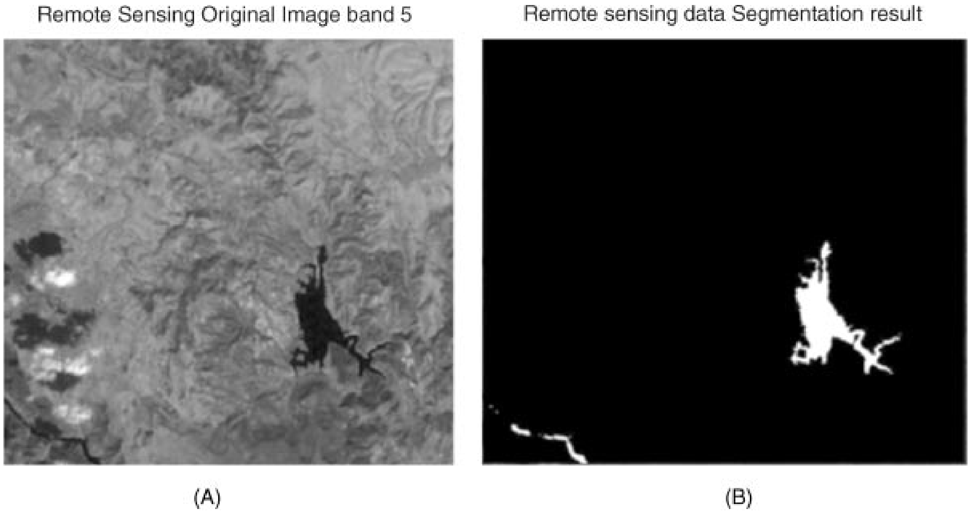
Image segmentation attempts to define the regions and boundaries of the regions. Techniques are developed that preserve the edges and smooth out the individual regions. Image segmentation may involve pixel-by-pixel classification, which often requires using pixels of known classification for training. Segmentation may also involve region growing, which is essentially unsupervised. A good example is to extract precisely the lake region of Lake Mulargias on the island of Sardinia in Italy (10). The original image is shown in Fig. 1a. The segmentation result is shown in Fig.1b, for which the exact size of the lake can be determined. For land-based remote sensing images, pixel-by-pixel classification allows us to determine precisely the area covered by each crop and to assess the changes from one month to the next during the growing season. Similarly, flood damage can be determined from the satellite images. These examples are among the many applications of image segmentation.

PATTERN RECOGNITION AND NEURAL NETWORKS

A major topic in pattern recognition is feature extraction. An excellent discussion of feature extraction and selection problem in remote sensing with multispectral and hyperspectral images is given by Landgrebe (5). In remote sensing, features are usually taken from the measurements of spectral bands, which this means 6 to 8 features in multispectral data, but a feature vector dimension of several hundred in hyperspectral image data. With a limited number of training samples, increasing the feature dimension in hyperspectral images may actually degrade the classification performance, which is referred to as the Hughes phenomenon. Reference (5) presents procedures to reduce such phenomena. Neural networks have found many uses in remote sensing, especially with pattern classification. The back-propagation trained network, the radial basis function network, and the support vector machine are the three best-performing neural networks for classification. A good discussion on statistical and neural network methods in remote sensing classification is contained in Ref. 11 as well as many other articles that appear in Refs. 3, 4, and 12. A major advantage of neural networks is that learning is from the training data only, and no assumption of the data model such as probability density is required. Also, it has been found that combining two neural network classifiers such as combining SOM, the self-organizing map, with a radial basis function network can achieve better classification than either one used alone (13).

One problem that is fairly unique and significant to remote sensing image recognition is the use of contextual information in pattern recognition. In remote sensing

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.



Remote Sensing Original Image band 5

(B)

Figure 1. Original image of Lake Mulargias region in Italy (A) and the result of region growing to extract the lake area (B).

image data, there is a large amount of contextual information that must be used to improve the classification. The usual procedure for contextual pattern recognition is to work with image models that exploit the contextual dependence. Markov random field models are the most popular, and with only a slightly increased amount of computation, classification performance can be improved with the use of such models (2,4,12).

Another pattern recognition topic is the change detection. The chapters by Serpico and Bruzzone (14) and Moser et al.(15) are recommended reading.

DATA FUSION AND KNOWLEDGE-BASED SYSTEMS

In remote sensing, there are often data from several sensors or sources. There is no optimum or well-accepted approach to the problem. Approaches can range from more theoretic, like consensus theory (16), to fuzzy logic, neural networks, multistrategy learning to fairly ad hoc techniques in some knowledge-based system to combine or merge information from different sources. In some cases, fusion at decision level can be more effective than fusion at data or feature level, but the other way can be true in other cases. Readers are referred to chapters by Solaiman (17), Benediktsson and Kanellopoulos (18), and Binaghi et al. (19) for detailed discussion.

IMAGE MINING, IMAGE COMPRESSION, AND WAVELET ANALYSIS

To extract certain desired information from a large remote sensing image database, we have the problem of data mining. For remote sensing images, Aksoy et al. (20) describe a probabilistic visual grammar to automatically analyze complex query scenarios using spatial relationships of regions, and to use it for content-based image retrieval and classification. Their hierarchical scene modeling bridges the gap between feature extraction and semantic interpretation. For image compression of hyperspectral images, Qian et al. (21) provide a survey of major approaches including vector quantization, discrete cosine transform and wavelet transform, and so on. A more comprehensive survey of remote sensing image compression is provided by Aiazzi et al.(22). Besides its important capability in image compression, wavelet transform has a major application in de-noising SAR images (23). The wavelet analysis of SAR images can also be used for near-real-time “quick look” screening of satellite data, data reduction, and edge linking (24).

COMPONENT ANALYSIS

Transform methods are often employed in remote sensing. A key to the transform methods is the component analysis, which, in general, is the subspace analysis. In remote sensing, component analysis includes the principal component analysis (PCA), curvilinear component analysis (CCA), and independent component analysis (ICA). The three component analysis methods are different conceptually. PCA is to look for the principal components according to the second-order statistics. CCA performs nonlinear feature space transformation while trying to preserve as much as possible the original data information in the lower-dimensional space see Ref. 25. ICA looks for independent components from the original data assumed to be linearly mixed from several independent sources. Nonlinear PCA that makes use of the higher-order statistical information (26) can provide an improvement over the linear PCA that employs only the second-order covariance information.

ICA is a useful extension of the traditional PCA. Whereas PCA attempts to decorrelate the components in a vector, ICA methods are to make the components as independent as possible. There are currently many approaches available for ICA (27). ICA applications in remote sensing study have become a new topic in recent years. S. Chiang et al. employed ICA in AVIRIS (airborne visible infrared imaging spectrometer) data analysis (28). T. Tu used a noise-adjusted version of fast independent component analysis (NAFICA) for unsupervised signature extraction and separation in hyperspectral images (29). With remote sensing in mind, we developed a new (ICA) method that makes use of the higher-order statistics The work is quite different from that of Cardoso (30). We name it the joint cumulant ICA (JC-ICA) algorithm (31,32). It can be implemented efficiently by a neural network. Experimental evidence (31) shows that, for the SAR image pixel classification, a small subset of ICA features perform a few percentage points better than the use of original data or PCA as features. The significant component images obtained by ICA have less speckle noise and are more informative. Furthermore, for hyperspectral images, ICA can be useful for selecting or reconfiguring spectral bands so that the desired objects in the images may be enhanced (32). Figures. 2 and 3 show, respectively, an original AVIRIS image and the enhanced image using the JC-ICA approach. The latter has more desired details.

CONCLUSION

In this article, an overview is presented of a number of topics and issues on information processing for remote sensing. One common theme is the effective use of computing power to extract the desired information from the large amount of data. The progress in computer science and engineering certainly presents many new and improved procedures for information processing in remote sensing.

ROBOT KINEMATICS

INTRODUCTION

Robot kinematics is the study of the motion (kinematics) of robots. In a kinematic analysis the position, the velocity and acceleration of all links are calculated with respect to a fixed reference coordinate system without regard to the forces or moments that cause the motion. The relationship between motion and the associated forces and torques is studied in robot dynamics. Robot kinematics mainly includes two components: forward kinematics and inverse kinematics.

Forward kinematics is also known as direct kinematics. Forward kinematics is the static geometrical problem of computing the position and orientation of the end-effector of the manipulator. Specifically, given a set of joint motion, the forward kinematics problem is to compute the position and orientation of the tool frame relative to the base frame.

In inverse kinematics, given the position and orientation of the end-effector of the manipulator, all possible sets of joint motion are calculated that could be used to attain this given position and orientation. This issue is a fundamental problem in the practical use of manipulators.

From the viewpoint of robot mechanism, robots can be divided into two types, which are called serial robots and pareller robots. Serial robots are the most widely used robots in the industry. They can be observed throughout the manufacturing industry, as well as in automotive, aerospace, and commercial use. Serial robots can be manufactured for multiple operations that range from material processing operations to assembly operations. Serial manipulators are modeled and designed as anthropomorphic mechanical arms. Depending on the application, it can be outfitted with revolute and prismatic joints. This type of robot has what is called an open kinematic, chain which can be classified as either Articulated or Cartesian robots.

The parallel manipulators have some significant advantages over the conventional serial manipulators, such as more rigidity, accuracy, and high-force/torque capacity. They also have simpler inverse kinematics, which is an advantage in real-time control. They have been used in situations in which the demand on workspace and maneuverability is low but the dynamic loading is severe, and high-speed and precision motions are of primary concern. Recently, parallel manipulators have been developed for applications in aircraft simulators (1), telescopes (2), positioning trackers (3), micro-motion devices (4), and machine tools (5–8). However, because the theories and technologies for parallel manipulators are premature, most parallel manipulators that exist today are high-cost machines that provide less accuracy than conventional machines. Therefore, additional exploration is required to make parallel manipulators more attractive to the industry (9).

In this article, the basic mathematical concepts, including translational coordinate transformation, rotational coordinate transformation, and homogeneous transformation, are introduced in the section entitled Mathematical Fundamentals. The section on solving kinematics equation presents kinematics equation of robot manipulator focusing on the solution of the posture of joints and manipulator. The case study examines the kinematics analysis of a 3DOF parallel manipulator used for machining application. The last section concludes the article.

MATHEMATICAL FUNDAMENTALS

To explain the relationship between parts, tools, and manipulators, some concepts as position vector, plane, and coordinate frame should be used (10).

Presentation of Posture

The motion of robots can be described by its position and orientation, which is called its posture. Once the reference coordinate system has been built, any point in space can be expressed by one (3×1) vector. To an orthogonal coordinate system $\{O_a - x_a y_a z_a\}$, any point p in the space can be written as follows:

$$^{a}p = \begin{bmatrix} p_x \\ p_y \\ p_z \end{bmatrix} \tag{1}$$

where $p_x,\ p_y,\ p_z$ denote the components of the vector p along the coordinate axis x_a, y_a, z_a, respectively. Here, p is called a position vector, which is shown in Fig. 1.

To research the motion and operation of robots, the expression of position and the orientation are needed. To prescribe the orientation of point b, one must assume an orthogonal coordinate system $\{O_b - x_b y_b z_b\}$ is attached to the point. Here, x_b, y_b, z_b denote the unit vectors of the coordinate axes. With respect to the reference coordinate system $\{O_a - x_a y_a z_a\}$, the orientation of point b is expressed as follows:

$$^{a}_{b}R = [\,^{a}x_b \quad ^{a}y_b \quad ^{a}z_b\,] = \begin{bmatrix} r_{11} & r_{12} & r_{13} \\ r_{21} & r_{22} & r_{23} \\ r_{31} & r_{32} & r_{33} \end{bmatrix} \tag{2}$$

where $^{a}_{b}R$ is called the rotation matrix. $^{a}_{b}R$ has nine elements in total, but only three of them are independent. The following constraint conditions should be satisfied by the nine elements:

$$^{a}x_b \cdot {^{a}x_b} = {^{a}y_b} \cdot {^{a}y_b} = {^{a}z_b} \cdot {^{a}z_b} = 1 \tag{3}$$

$$^{a}x_b \cdot {^{a}y_b} = {^{a}y_b} \cdot {^{a}z_b} = {^{a}z_b} \cdot {^{a}x_b} = 0 \tag{4}$$

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

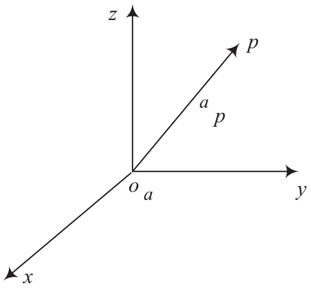

Figure 1. Presentation of position.

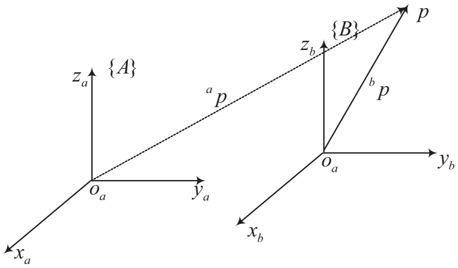

Figure 2. Translational transformation.

It can be concluded it the rotation matrix ${}^a_bR$ is orthogonal, and the following condition should be satisfied:

$$ {}^a_bR^{-1} = {}^a_bR^T; \quad |{}^a_bR| = 1 \tag{5}$$

The rotation matrix with respect to the rotation transformation by an angle θ about the axis x, y, z, respectively can be calculated as follows:

$$R(x,\theta) = \begin{bmatrix} 1 & 0 & 0 \\ 0 & c\theta & -s\theta \\ 0 & s\theta & c\theta \end{bmatrix} \tag{6}$$

$$R(y,\theta) = \begin{bmatrix} c\theta & 0 & s\theta \\ 0 & 1 & 0 \\ -s\theta & 0 & c\theta \end{bmatrix} \tag{7}$$

$$R(z,\theta) = \begin{bmatrix} c\theta & -s\theta & 0 \\ s\theta & c\theta & 0 \\ 0 & 0 & 1 \end{bmatrix} \tag{8}$$

where $s\theta = \sin\theta$ and $c\theta = \cos\theta$.

Coordinate Transformation

The description of any point p in space is different in different coordinate frames. To illustrate the relationship of the transformation from one coordinate frame to another, the mathematic expression will be used.

Translational Coordinate Transformation. Suppose that coordinate frames {B} and {A} have the same orientation. But the original points of the two coordinate frames do not overlap. The position vector $^a p_{o_b}$ is used to describe the position related to frame {A}. $^a p_{o_b}$ is called the *translational vector* of frame {B} with respect to frame {A}. If the position of point p in the coordinate frame {B} is written as $^b p$, then the position vector of p with respect to frame {A} can be written as follows:

$$^a p = {}^b p + {}^a p_{o_b} \tag{9}$$

It is called the equation of coordinate translation, which is shown in Fig. 2.

Rotational Coordinate Transformation. Suppose that coordinate frames {B} and {A} have the same original points, but their orientation is different. Using the rotation matrix ${}^a_bR$ to describe the orientation of frame {B} with respect to frame {A}, the transformation of point p in frame {A} and {B} can be deduced as:

$$^a p = {}^a_bR \cdot {}^b p \tag{10}$$

where $^a p$ denotes the position the p with the reference coordinate system {A}, and $^b p$ denotes the position the p with the reference coordinate system {B}. It is called the equation of coordinate rotation, which is shown in Fig. 3.

The following equations can be deduced:

$${}^b_aR = {}^a_bR^{-1} = {}^a_bR^T \tag{11}$$

Composite Transformation. For the common condition, neither the original points of frame {A} and {B} overlap, nor do they have the same orientation. Use the position vector $^a p_{o_b}$ to describe the original point of frame {B} with respect to frame {A}. Use the rotation matrix ${}^a_bR$ to describe the orientation of frame {B} respect to frame {A}. To any point in the space, the following transformation can be found:

$$^a p = {}^a_bR \cdot {}^b p + {}^a p_{o_b} \tag{12}$$

Homogeneous Coordinate Transformation

If the coordinates of any point in an orthogonal coordinate system are given, then the coordinates of this point in

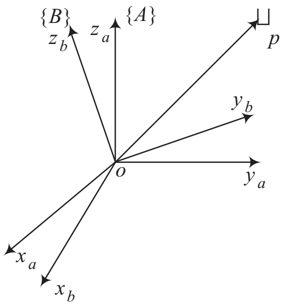

Figure 3. Rotational transformation.

another orthogonal coordinate system can be calculated by homogeneous coordinate transformation.

Homogeneous Transformation. The transformation formula in Equation (12) is unhomogeneous to point ${}^b p$, but it can be expressed by the following equivalent homogeneous transformation:

$$\begin{bmatrix} {}^a p \\ 1 \end{bmatrix} = \begin{bmatrix} {}^a_b R & {}^a p_{o_b} \\ 0_{1\times 3} & 1 \end{bmatrix} = \begin{bmatrix} {}^b p \\ 1 \end{bmatrix} \tag{13}$$

where the vector (4×1) denotes the coordinates in three-dimensional space. It still can be noted as ${}^a p$ or ${}^b p$. The above equation can be written as the form of matrix:

$${}^a p = {}^a_b T \cdot {}^b p \tag{14}$$

where the vector (4×1) of ${}^a p$ and ${}^b p$ is called a homogeneous coordinate. Here:

$${}^a_b T = \begin{bmatrix} {}^a_b R & {}^a p_{o_b} \\ 0_{1\times 3} & 1 \end{bmatrix} \tag{15}$$

In fact, the transformation formula in Equation (13) is equivalent with Equation (12). The formula in Equation (13) can be written as follows:

$${}^a p = {}^a_b R \cdot {}^b p + {}^a p_{o_b;} \quad 1 = 1 \tag{16}$$

Are position vectors ${}^a p$ and ${}^b p$ the 3×1 orthogonal coordinate or the 4×1 homogeneous coordinate? It should be decided according to the context.

Translational Homogeneous Coordinate Transformation. Suppose that the vector $ai + bj + ck$ describes one point in space, where i, j, k is the unit vector of the axes x, y, z, respectively. This point can be expressed by translational homogeneous transformation:

$$\mathrm{Trans}(a, b, c) = \begin{bmatrix} 1 & 0 & 0 & a \\ 0 & 1 & 0 & b \\ 0 & 0 & 1 & c \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{17}$$

where Trans denotes translational transformation.

Rotational Homogeneous Coordinate Transformation. Rotation about the x-axis, y-axis, and z-axis with θ, the following equations can be obtained:

$$\mathrm{Rot}(x, \theta) = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & c\theta & -s\theta & 0 \\ 0 & s\theta & c\theta & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{18}$$

$$\mathrm{Rot}(y, \theta) = \begin{bmatrix} c\theta & 0 & s\theta & 0 \\ 0 & 1 & 0 & 0 \\ -s\theta & 0 & c\theta & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{19}$$

$$\mathrm{Rot}(z, \theta) = \begin{bmatrix} c\theta & -s\theta & 0 & 0 \\ s\theta & c\theta & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{20}$$

where Rot denotes rotational transformation.

Transformation of Object

The approach used to describe the posture of any point in the space can be used to describe the position and oriention in space. For example, the following Fig. 4(a) can be expressed by the six points attached to the reference frame.

If, at first, this object rotates 90 degrees is about the y-axis of the reference frame, then it translates 4 unit lengths. This transformation can be described as follows:

$$T = \mathrm{Trans}(4, 0, 0)\mathrm{Rot}(y, 90)\mathrm{Rot}(z, 90) = \begin{bmatrix} 0 & 0 & 1 & 4 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

The above matrix shows the operations of rotation and translation about the primary reference frame. The six

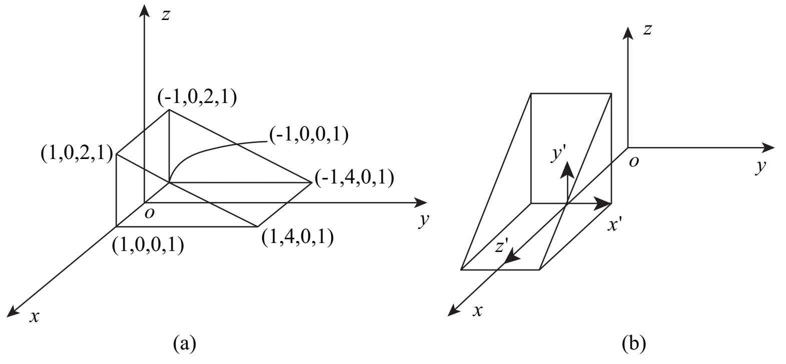

Figure 4. Transformation of wedge-shaped object.

points of the wedge-shaped object can be transformed as:

$$\begin{bmatrix} 0 & 0 & 1 & 4 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & -1 & -1 & 1 & 1 & -1 \\ 0 & 0 & 0 & 0 & 4 & 4 \\ 0 & 0 & 2 & 2 & 0 & 0 \\ 1 & 1 & 1 & 1 & 1 & 1 \end{bmatrix}$$

$$= \begin{bmatrix} 4 & 4 & 6 & 6 & 4 & 4 \\ 1 & -1 & -1 & 1 & 1 & -1 \\ 0 & 0 & 0 & 0 & 4 & 4 \\ 1 & 1 & 1 & 1 & 1 & 1 \end{bmatrix}$$

Figure 4(b) shows the result of transformation.

General Rotation Transformation

In the above sections, the rotational transformation matrix with respect to rotation about x-axis, y-axis, and z-axis have been analyzed. Next, the focus is on the rotation matrix in the common situation: rotation about any vector (axis) with θ.

The Formula of General Rotation Transformation. Assume that f is the unit vector of the z-axis in coordinate frame {C}, namely:

$$C = \begin{bmatrix} n_x & o_x & a_x & 0 \\ n_y & o_y & a_y & 0 \\ n_z & o_z & a_z & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{21}$$

$$f = a_x i + a_y j + a_z k \tag{22}$$

Therefore, rotation about vector f is equivalent to rotation about z-axis in coordinate frame {C}, thus one obtains the following:

$$\mathrm{Rot}(f, \theta) = \mathrm{Rot}(c, \theta) \tag{23}$$

If the coordinate frame $\{T\}$ is known with respect to reference coordinate frame, then another coordinate frame $\{S\}$ can be calculated with respect to frame {C}, because:

$$T = \mathrm{C}S \tag{24}$$

Where, S expresses the relative position of T with respect to C. Then:

$$S = \mathrm{C}^{-1}T \tag{25}$$

The rotation of T about f is equivalent to the rotation of S about z-axis of frame {C}:

$$\mathrm{Rot}(f, \theta)T = \mathrm{CRot}(z, \theta)S \tag{26}$$

$$\mathrm{Rot}(f, \theta)T = \mathrm{CRot}(z, \theta)\mathrm{C}^{-1}T \tag{27}$$

Then the following equation can be derived:

$$\mathrm{Rot}(f, \theta) = \mathrm{CRot}(z, \theta)\mathrm{C}^{-1} \tag{28}$$

As f is the z-axis of frame {C}, it can be found that $\mathrm{Rot}(z, \theta)\mathrm{C}^{-1}$ is just the function of f, because:

$$\mathrm{C}\,Rot(z, \theta)\mathrm{C}^{-1}$$

$$= \begin{bmatrix} n_x & o_x & a_x & 0 \\ n_y & o_y & a_y & 0 \\ n_z & o_z & a_z & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} c\theta & -s\theta & 0 & 0 \\ s\theta & c\theta & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} n_x & n_y & n_z & 0 \\ o_x & o_y & o_z & 0 \\ a_x & a_y & a_z & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

$$= \begin{bmatrix} n_x & o_x & a_x & 0 \\ n_y & o_y & a_y & 0 \\ n_z & o_z & a_z & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} n_x c\theta - o_x c\theta & n_y c\theta - a_y s\theta & n_z c\theta - o_z s\theta & 0 \\ n_x s\theta + o_x c\theta & n_y s\theta + a_y c\theta & n_z s\theta + o_z c\theta & 0 \\ a_x & a_y & a_z & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

$$= \begin{bmatrix} n_x n_x c\theta - n_x o_x s\theta + n_x o_x s\theta + o_x o_x c\theta + a_x a_x & n_x n_y c\theta - n_x o_y s\theta + n_y o_x s\theta + o_y o_x c\theta + a_x a_y & n_x n_z c\theta - n_x o_z s\theta - n_z o_x s\theta + o_z o_x c\theta + a_x a_z & 0 \\ n_y n_x c\theta - n_y o_x s\theta + n_x o_y s\theta + o_y o_x c\theta + a_y a_x & n_y n_y c\theta - n_y o_y s\theta + n_y o_y s\theta + o_y o_y c\theta + a_y a_y & n_y n_z c\theta - n_y o_z s\theta + n_z o_y s\theta + o_z o_y c\theta + a_y a_z & 0 \\ n_z n_x c\theta - n_z o_x s\theta + n_x o_z s\theta + o_z o_x c\theta + a_z a_x & n_z n_y c\theta - n_z o_y s\theta + n_y o_z s\theta + o_y o_z c\theta + a_z a_y & n_z n_z c\theta - n_z o_z s\theta + n_z o_z s\theta + o_z o_z c\theta + a_z a_z & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{29}$$

Note that $z = a, vers\theta = 1 - c\theta,\ f = z$. Equation (29) can be simplified as follows:

$$\mathrm{Rot}(f, \theta) = \begin{bmatrix} f_x f_x vers\theta + c\theta & f_y f_x vers\theta - f_z s\theta & f_z f_x vers\theta + f_y s\theta & 0 \\ f_x f_y vers\theta + f_z s\theta & f_y f_y vers\theta + c\theta & f_z f_y vers\theta - f_x s\theta & 0 \\ f_x f_z vers\theta + f_z s\theta & f_y f_z vers\theta + f_x s\theta & f_z f_z vers\theta + c\theta & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{30}$$

Each basic rotation transformation can be derived from the general rotation transformation, that is, if $f_x = 1$, $f_y = 0$ and $f_z = 0$, then $\mathrm{Rot}(f, \theta) = \mathrm{Rot}(x, \theta)$. Equation (30) yields the following:

$$\mathrm{Rot}(x, \theta) = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & c\theta & -s\theta & 0 \\ 0 & s\theta & c\theta & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{31}$$

which is identical with Equation (18)

The Equivalent Rotation Axis and Rotation Angle. Given any rotation transformationm, the equivalent rotation axis with the angle of θ can be calculated. Assume that the rotation transformationm matrix is as follows:

$$R = \begin{bmatrix} n_x & o_x & a_x & 0 \\ n_y & o_y & a_y & 0 \\ n_z & o_z & a_z & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{32}$$

If $R = \mathrm{Rot}(f, \theta)$, then

$$\begin{bmatrix} n_x & o_x & a_x & 0 \\ n_y & o_y & a_y & 0 \\ n_z & o_z & a_z & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} f_x f_x vers\theta + c\theta & f_y f_x vers\theta - f_z s\theta & f_z f_x vers\theta + f_y s\theta & 0 \\ f_x f_y vers\theta + f_z s\theta & f_y f_y vers\theta + c\theta & f_z f_y vers\theta - f_x s\theta & 0 \\ f_x f_z vers\theta + f_z s\theta & f_y f_z vers\theta + f_x s\theta & f_z f_z vers\theta + c\theta & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{33}$$

By addition of the diagonal entry in two sides of the above equation, it is derived that:

$$n_x + o_y + a_z = (f_x^2 + f_y^2 + f_z^2) vers\theta + 3c\theta = 1 + 2c\theta \tag{34}$$

$$c\theta = \frac{1}{2}(n_x + o_y + a_z - 1) \tag{35}$$

By subtraction of the undiagonal entry, it yields the following:

$$\begin{aligned} o_z - a_y &= 2 f_x s\theta \\ a_x - n_z &= 2 f_y s\theta \\ n_y - o_x &= 2 f_z s\theta \end{aligned} \tag{36}$$

The sum of the squares of the above equation is as follows:

$$(o_z - a_y)^2 + (a_x - n_z)^2 + (n_y - o_x)^2 = 4s^2\theta \tag{37}$$

$$s\theta = \pm\frac{1}{2}\sqrt{(o_z - a_y)^2 + (a_x - n_z)^2 + (n_y - o_x)^2} \tag{38}$$

Define that the rotation mentioned before is the forward rotation with respect to vector f, and $0 \leq \theta \leq 180°$. In this case, the sign of Equation (38) is positive. Then, the rotation angle θ will be uniquely confirmed, as follows:

$$\tan\theta = \frac{\sqrt{(o_z - a_y)^2 + (a_x - n_z)^2 + (n_y - o_x)^2}}{n_x + o_y + a_z - 1} \tag{39}$$

Each component of vector f can be calculated by Equation (36):

$$\begin{aligned} f_x &= (o_z - a_y)/2s\theta \\ f_y &= (a_x - n_z)/2s\theta \\ f_z &= (n_y - o_x)/2s\theta \end{aligned} \tag{40}$$

SOLVING KINEMATICS EQUATION OF ROBOT MANIPULATOR

To operate and control a robot, we must have knowledge of both its spatial arrangement and a means of reference to the environment. Kinematics is the analytical study of the geometry of motion of a robot arm with respect to a fixed reference coordinate system without regard to the forces or moments that cause the motion. The issue of solving a kinematics equation of a robot manipulator focuses on the solution about the posture of joints and manipulators (10).

Posture Description of Motion

Description of Euler Angle. The Euler angle I, shown as Fig. 5, first defines a rotation of angle ϕ around the z-axis,

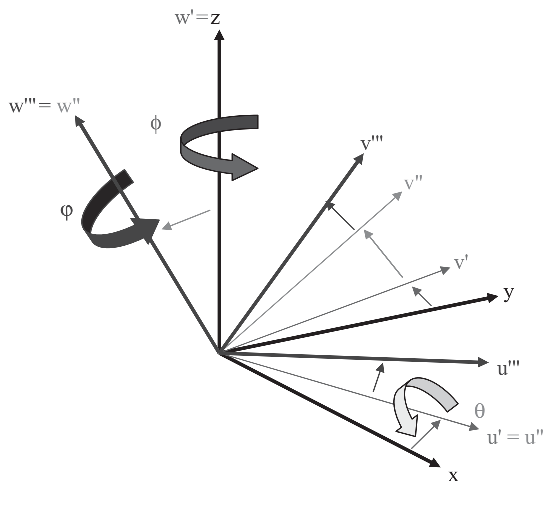

Figure 5. Euler angle I.

then a rotation of angle θ around the new x-axis, then a rotation of angle ψ around the new z-axis.

$$R_{z\phi} = \begin{pmatrix} \mathrm{c}\phi & -\mathrm{s}\phi & 0 \\ \mathrm{s}\phi & \mathrm{c}\phi & 0 \\ 0 & 0 & 1 \end{pmatrix},$$

$$R_{u'\theta} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \mathrm{c}\theta & -\mathrm{s}\theta \\ 0 & \mathrm{s}\theta & \mathrm{c}\theta \end{pmatrix},$$

$$R_{w''\varphi} = \begin{pmatrix} \mathrm{c}\varphi & -\mathrm{s}\varphi & 0 \\ \mathrm{s}\varphi & \mathrm{c}\varphi & 0 \\ 0 & 0 & 1 \end{pmatrix} \tag{41}$$

The resultant Eulerian rotation matrix generates the following:

$$R = R_{2\phi}R_{u'\theta}R_{w''\varphi}\begin{pmatrix} \mathrm{c}\phi\,\mathrm{c}\varphi & -\mathrm{c}\phi\,\mathrm{s}\varphi & \\ -\mathrm{s}\phi\,\mathrm{s}\varphi\,\mathrm{c}\theta & -\mathrm{s}\phi\,\mathrm{c}\varphi\,\mathrm{c}\theta & \mathrm{s}\varphi\,\mathrm{s}\theta \\ \mathrm{s}\phi\,\mathrm{c}\varphi & -\mathrm{s}\phi\,\mathrm{s}\varphi & -\mathrm{c}\phi\,\mathrm{s}\theta \\ +\mathrm{c}\phi\,\mathrm{s}\varphi\,\mathrm{c}\theta & +\mathrm{c}\phi\,\mathrm{c}\varphi\,\mathrm{c}\theta & \\ \mathrm{s}\varphi\,\mathrm{s}\theta & \mathrm{c}\varphi\,\mathrm{s}\theta & \mathrm{c}\theta \end{pmatrix} \tag{42}$$

The Euler angle II, which is shown as Fig. 6, first defines a rotation of angle ϕ around the z-axis, then a rotation of angle θ around the new y-axis, then a rotation of angle ψ around the new z-axis.

Note the opposite (clockwise) sense of the third rotation, ϕ. The matrix with Euler angle II generates the following:

$$\begin{pmatrix} -\mathrm{s}\phi\,\mathrm{s}\varphi & -\mathrm{s}\phi\,\mathrm{c}\varphi & \\ +\mathrm{c}\phi\,\mathrm{c}\varphi\,\mathrm{c}\theta & -\mathrm{s}\phi\,\mathrm{c}\varphi\,\mathrm{c}\theta & \mathrm{c}\phi\,\mathrm{s}\theta \\ \mathrm{c}\phi\,\mathrm{s}\varphi & \mathrm{c}\phi\,\mathrm{c}\varphi & \mathrm{s}\varphi\,\mathrm{s}\theta \\ +\mathrm{s}\phi\,\mathrm{c}\varphi\,\mathrm{c}\theta & -\mathrm{s}\phi\,\mathrm{c}\varphi\,\mathrm{c}\theta & \\ -\mathrm{c}\varphi\,\mathrm{s}\theta & \mathrm{s}\varphi\,\mathrm{s}\theta & \mathrm{c}\theta \end{pmatrix} \tag{43}$$

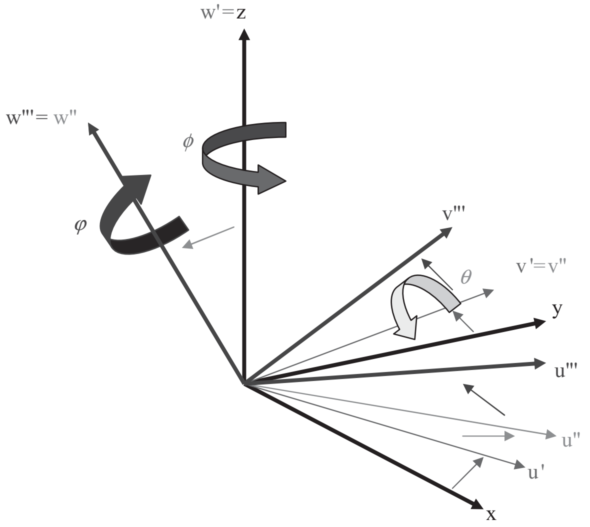

Figure 6. Euler angle II.

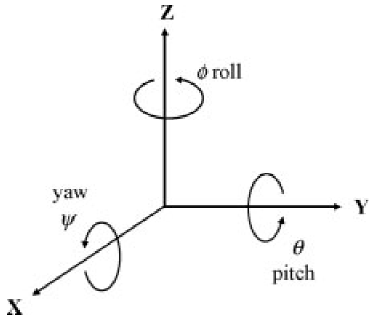

Figure 7. Rotation of raw, pitch and roll.

Description of Roll Pitch Yaw. Another common group of rotations is yaw, pitch, and roll, which are shown in Fig. 7. A rotation of ψ about the x-axis ($R_{x,\psi}$) is called yaw. A rotation of θ about the y-axis ($R_{y,\theta}$) is called pitch. A rotation of ϕ about the z-axis ($R_{z,\phi}$) is called roll.

$$\begin{aligned} &RPY(\phi,\theta,\psi) \\ &= \begin{bmatrix} c\phi & -s\phi & 0 & 0 \\ s\phi & c\phi & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}\begin{bmatrix} c\theta & 0 & s\theta & 0 \\ 0 & 1 & 0 & 0 \\ -s\theta & 0 & c\theta & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}\begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & c\psi & -s\psi & 0 \\ 0 & s\psi & c\psi & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \\ &= \begin{bmatrix} c\phi c\theta & c\phi s\theta s\psi - s\phi c\psi & c\phi s\theta c\psi + s\phi s\psi & 0 \\ s\phi c\theta & s\phi s\theta s\psi + c\phi c\psi & s\phi s\theta c\psi - c\phi s\psi & 0 \\ -s\phi & c\theta s\psi & c\theta c\psi & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \end{aligned} \tag{44}$$

Link and Joint Parameters

The Denavit-Hartenberg representation is adopted to describe the motion parameters of link and joint. The following steps are used to confirm the parameters of link and joint:

- Number the joints from 1 to n starting with the base and ending with the end-effector.
- Establish the base coordinate system. Establish a right-handed orthonormal coordinate system (X_0, Y_0, Z_0) at the supporting base with the Z_0 axis lying along the axis of motion of joint 1.
- Establish joint axis. Align the Z_i with the axis of motion (rotary or sliding) of joint $i+1$.
- Establish the origin of the ith coordinate system. Locate the origin of the ith coordinate at the intersection of

the Z_i and Z_{i-1} or at the intersection of common normal between the Z_i and Z_{i-1} axes and the Z_i axis.

- Establish the X_i axis. Establish $X_i = \pm(Z_{i-1} \times Z_i)/\|Z_{i-1} \times Z_i\|$ or along the common normal between the Z_{i-1} and Z_i axes when they are parallel.
- Establish the Y_i axis. Assign $Y_i = +(Z_i \times X_i)/\|Z_i \times X_i\|$ to complete the right-handed coordinate system.
- Find the link and joint parameters.

Jacobian of Robot Manipulator

Different Motion of Robot. To describe the micromotion of a robot, differential coefficient is used for coordinate transformation. Given the coordinate frame {T},

$$T + \mathrm{d}T = \mathrm{Trans}(dx, dy, dz)\mathrm{Rot}(f, d\theta)T \tag{45}$$

where $\mathrm{Trans}(dx, dy, dz)$ denotes the differential translation of d_x, d_y, d_z, and $\mathrm{Rot}(f, d\theta)$ denotes the differential rotation about the vector f. Then dT can be calculated as follows:

$$dT = [\mathrm{Trans}(dx, dy, dz)\mathrm{Rot}(f, d\theta) - I]T \tag{46}$$

The homogeneous transformation that expresses differential translation is

$$\mathrm{Trans}(\mathrm{d}x, \mathrm{d}y, \mathrm{d}z) = \begin{bmatrix} 1 & 0 & 0 & \mathrm{d}x \\ 0 & 1 & 0 & \mathrm{d}y \\ 0 & 0 & 1 & \mathrm{d}z \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{47}$$

For the formula of general rotation transformation

$$\mathrm{Rot}(f, \theta) = \begin{bmatrix} f_x\, f_x vers\theta + c\theta & f_y\, f_x vers\theta - f_z s\theta & f_z\, f_x vers\theta + f_y s\theta & 0 \\ f_x\, f_y vers\theta + f_z s\theta & f_y\, f_y vers\theta + c\theta & f_z\, f_y vers\theta - f_x s\theta & 0 \\ f_x\, f_z vers\theta + f_z s\theta & f_y\, f_z vers\theta + f_x s\theta & f_z\, f_z vers\theta + c\theta & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{48}$$

Because $\lim_{\theta\to 0}\mathrm{Sin}\,\theta = d\theta, \lim_{\theta\to 0}\cos\theta = 1, \lim_{\theta\to 0} vers\theta = 0$, the differential rotational homogeneous transformation can be expressed as follows:

$$\mathrm{Rot}(f, d\theta) = \begin{bmatrix} 1 & -fzd\theta & fyd\theta & 0 \\ fzd\theta & 1 & -fxd\theta & 0 \\ -fzd\theta & fxd\theta & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{49}$$

Because $\Delta = \mathrm{Trans}(dx, dy, dz)\mathrm{Rot}(f, d\theta)$, it yields the following:

$$\Delta = \begin{bmatrix} 1 & 0 & 0 & dx \\ 0 & 1 & 0 & dy \\ 0 & 0 & 1 & dz \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & -f_z d\theta & f_y d\theta & 0 \\ f_z d\theta & 1 & -f_x d\theta & 0 \\ -f_y d\theta & f_x d\theta & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} - \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} 0 & -f_z d\theta & f_y d\theta & dx \\ f_z d\theta & 0 & -f_x d\theta & dy \\ -f_y d\theta & f_x d\theta & 0 & dz \\ 0 & 0 & 0 & 0 \end{bmatrix} \tag{50}$$

The differential rotation $\mathrm{d}\theta$ about vector f is equivalent to the differential rotation with respect to the x-axis, y-axis and z-axis, namely δ_x, δ_y, and δ_z, respectively. Then $f_x\mathrm{d}\theta = \delta_x$, $f_y\mathrm{d}\theta = \delta_y$, $f_z\mathrm{d}\theta = \delta_z$. Displace the above results into Equation (50), which yields the following:

$$\Delta = \begin{bmatrix} 0 & -\delta z & \delta y & dx \\ \delta z & 0 & -\delta x & dy \\ -\delta y & \delta x & 0 & dz \\ 0 & 0 & 0 & 0 \end{bmatrix} \tag{51}$$

If $d = d_x i + d_y j + d_z k, \delta = \delta_x i + \delta_y j + \delta_z k$, then the differential motion vector of rigid body or coordinate frame can be expressed as follows:

$$D = [dx \quad dy \quad dz \quad \delta x \quad \delta y \quad \delta z]^T = \begin{bmatrix} d \\ \delta \end{bmatrix} \tag{52}$$

Jacobian Matrix of Robot. The linear transformation between the motion speed of the manipulator and each joint can be defined as the Jacobian matrix of the robot. This Jacobian matrix indicates the drive ratio of motion velocity from the space of joints to the space of end-effector. Assume that the motion equation of the manipulator

$$x = x(q) \tag{53}$$

represents the displacement relationship between the space of the operation (end-effector) and the space of the joints. Differentiating Equation (53) with respect to time yields the following:

$$\dot{x} = J(q)\dot{q} \tag{54}$$

where $\dot{x}$ is the generalized velocity of end-effector in operating space. $\dot{q}$ is the joint velocity. $J(q)$ is $6 \times n$ partial derivative matrix, which is called the Jacobian Matrix. The component in line i and column j is as follows:

$$J_{ij}(q) = \frac{\partial x_i(q)}{\partial q_j}, i = 1, 2, \cdots, 6; j = 1, 2, \cdots, n \tag{55}$$

From Equation (55), it can be known that the Jacobian Matrix $J(q)$ is the linear transformation from the velocity of joint space and the velocity of operating space.

The generalized velocity $\dot{x}$ of a rigid board or a coordinate frame is a six-dimensional column vector composed of linear velocity v and angular velocity w.

$$\dot{x} = \begin{bmatrix} v \\ w \end{bmatrix} = \lim_{\Delta t \to 0} \frac{1}{\Delta t} \begin{bmatrix} d \\ \delta \end{bmatrix} \tag{56}$$

Equation (56) yields:

$$D = \begin{bmatrix} d \\ \delta \end{bmatrix} = \lim_{\Delta t \to 0} \dot{x} \Delta t \tag{57}$$

Displace Equation (54) into the above equation, and the following is obtained:

$$D = \lim_{\Delta t \to 0} J(q)\dot{q}\Delta t \tag{58}$$

$$D = J(q)\mathrm{d}q \tag{59}$$

For a robot with n joints, its Jacobian matrix is a $6 \times n$ matrix, in which the first three lines denote the transferring rate of end-effector's linear velocity, and the last three lines denote the transferring rate of end-effector's angular effector velocity. The Jacobian matrix can be expressed as follows:

$$\begin{bmatrix} v \\ w \end{bmatrix} = \begin{bmatrix} J_{l1} & J_{l2} & \cdots & J_{ln} \\ J_{a1} & J_{a2} & \cdots & J_{an} \end{bmatrix} \begin{bmatrix} \dot{q}_1 \\ \dot{q}_2 \\ \vdots \\ \dot{q}_n \end{bmatrix} \tag{60}$$

The linear velocity and angular velocity of end-effector can be expressed as the linear function of each joint velocity q

$$\left. \begin{aligned} v &= J_{l1}\dot{q}_1 + J_{l2}\dot{q}_2 + \cdots + J_{ln}\dot{q}_n \\ w &= J_{a1}\dot{q}_1 + J_{a2}\dot{q}_2 + \cdots + J_{an}\dot{q}_n \end{aligned} \right\} \tag{61}$$

where J_{li} and J_{ai} means the linear velocity and angular velocity of end-effector that results in joint i.

CASE STUDY: KINEMATIC ANALYSIS OF A PARALLEL MANIPULATOR

This example studies the kinematics analysis of a 3DOF parallel manipulator used for a machining application. The new design of this manipulator aims to achieve higher stiffness and to implement pure 3DOF motions (i.e., all side-effect motions can be eliminated). The manipulator consists of three identical legs with active ball screw actuators, and a passive leg is installed between the base and the moving platform. Each actuated leg is connected with the moving platform by a spherical joint, and the passive link is fixed on the ground and connected to the moving platform by a universal joint. Thus, the side-effect motions can be eliminated by the u-joint.

Description of the 3DOF Parallel Manipulator

Different from most existing 3DOF parallel manipulators, this design has a hybrid and uncoupled motion. The objective of the new design is to improve the system stiffness as well as to eliminate the coupled motions at the reference point to simplify the kinematic model and the control.

In Fig. 8, the novelty of the manipulator is as follows: (*1*) the universal joint of the passive link is located on the moving platform rather than on the base platform; thus, the motion along x and y translations and z rotation is eliminated; and (*2*) the reference point on the moving platform has a hybrid and uncoupled motion with x and y rotations and z translation.

The proposed manipulator has three platforms: base platform $B_1B_2B_3$, middle platform $M_1M_2M_3$, and moving platform $E_1E_2E_3$. The base platform is fixed on the ground. The middle platform is used to support the guideway B_iM_i of actuated links D_iE_i. The moving platform is used to mount a machine tool. The passive link is installed between the middle platform and the moving platform. Actuated link D_iE_i is connected to the moving platform by a spherical joint at E_i and to a slider connected to the active ball screw by a universal joint at D_i. The passive link is fixed on the

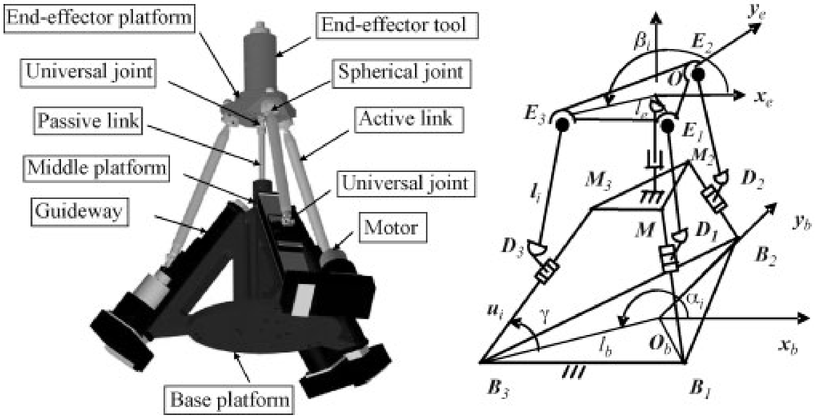

Figure 8. The CAD and Schematic model of 3DOF parallel manipulator.

middle platform at one end, and it is connected to the end-effector platform by a universal joint at the other end.

The following parameters are required for its description:

- the angle $\alpha_i (i = 1, 2, 3)$ between O_bB_i and x_b
- the angle $\beta_i (i = 1, 2, 3)$ between O_eE_i and x_e
- the size of the base platform l_b,
- the size of the end-effector platform l_e,
- the direction of a guideway γ,
- the length of an active link l_i, and
- the offset of the spherical joints on the platform z_0.

Inverse Kinematics

To describe the structure of the tripod system, two coordinate systems $\{\boldsymbol{O}_e - x_e y_e z_e\}$ and $\{\boldsymbol{O}_b - x_b y_b z_b\}$ are established, which are attached to the end-effector and base platforms, respectively. The following physical parameters are identified:

i) the angle α_i between $\boldsymbol{O}_b\boldsymbol{B}_i$ and $\boldsymbol{x}_b$,
ii) the angle β_i between $\boldsymbol{O}_e\boldsymbol{E}_i$ and $\boldsymbol{x}_e$,
iii) the dimension of the base platform l_b,
iv) the dimension of the end-effector platform l_e,
v) the direction of a guild bar γ, and
vi) the length of a support bar l_i.

For the original $\boldsymbol{O}_e$ of the end-effector, its translational motions along $\boldsymbol{x}_e$ and $\boldsymbol{y}_e$, and rotational motion along $\boldsymbol{z}_e$, are eliminated because of the usage of the passive leg, that is,

$$\left.\begin{aligned} x_e = y_e = 0 \\ z_\theta = 0 \end{aligned}\right\} \tag{62}$$

Therefore, the motions of $\boldsymbol{O}_e$ can be denoted by $(\theta_x, \theta_y, z_\theta)$, where θ_x and θ_y are the rotational motions along $\boldsymbol{x}_e$ and $\boldsymbol{y}_e$, and $\boldsymbol{z}_e$ is the translational motion along $\boldsymbol{z}_e$. The posture of the end-effector with respect to the coordinate system $\{\boldsymbol{O}_b - \boldsymbol{x}_b\boldsymbol{y}_b\boldsymbol{z}_b\}$ can be represented as follows:

$$T_e^b = \begin{bmatrix} \boldsymbol{R}_e & \boldsymbol{P}_e \\ 0 & 1 \end{bmatrix} = \begin{bmatrix} c\theta_y & 0 & s\theta_y & 0 \\ s\theta_x s\theta_y & c\theta_x & -s\theta_x c\theta_y & 0 \\ -c\theta_x s\theta_y & s\theta_x & c\theta_x c\theta_y & z_e \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{63}$$

where

c, s denote the cosine and sine functions, respectively.
T_e^b is the posture of the end-effector with respect to the coordinate system $\{\boldsymbol{O}_b – \boldsymbol{x}_b\boldsymbol{y}_b\boldsymbol{z}_b\}$.
$\boldsymbol{R}_e$ is the 3×3 orientation matrix of the end-effector.
$\boldsymbol{P}_e$ is the location of $\boldsymbol{O_e}$.

Inverse kinematics are used to find the joint motions when the posture of the end-effector T_e^b is known. The joint motions are denoted by u_i, and the posture of the end-effector T_e^b is totally determined by the motions of $\boldsymbol{O_e}(\theta_x, \theta_y, z_\theta)$. To solve the inverse kinematic problem, one can simply apply the condition that the length of a support bar is constant.

The location of the connection between the end-effector platform and an active link is

$$\begin{aligned} \mathrm{p}_{e_i}^b &= \mathrm{R}_e \mathrm{p}_{e_i}^e + \mathrm{p}_e^b \\ &= \begin{bmatrix} l_e c\beta_i c\theta_y + z_0 s\theta_y \\ l_e c\beta_i s\theta_x s\theta_y + l_e s\beta_i c\theta_x - z_0 s\theta_x c\theta_y \\ -l_e c\beta_i c\theta_x s\theta_y + l_e s\beta_i s\theta_x + z_e + z_0 c\theta_x c\theta_y \end{bmatrix} \end{aligned} \tag{64}$$

where

$$\mathrm{p}_{e_i}^b = \begin{bmatrix} x_{e_i}^b \\ y_{e_i}^b \\ z_{e_i}^b \end{bmatrix} \quad \text{and} \quad \mathrm{p}_{e_i}^e = \begin{bmatrix} l_e c\beta_i \\ l_e s\beta_i \\ z_0 \end{bmatrix}$$

z_0 is the offset of the spherical joint with respect to O_e.

The derivative of Equation (64) with the time yields

$$\begin{bmatrix} \delta x_{e_i}^b \\ \delta y_{e_i}^b \\ \delta z_{e_i}^b \end{bmatrix} = [\mathrm{J}_i]_{3\times 3} \begin{bmatrix} \delta\theta_x \\ \delta\theta_y \\ \delta z_e \end{bmatrix} \tag{65}$$

where

$$\mathrm{J}_i = \begin{bmatrix} 0 & -l_e c\beta_i s\theta_y + z_0 c\theta_y & 0 \\ (l_e c\beta_i s\theta_y - z_0 c\theta_y)c\theta_x - l_e s\beta_i s\theta_x & (l_e c\beta_i c\theta_y + z_0 s\theta_y)s\theta_x & 0 \\ (l_e c\beta_i s\theta_y - z_0 c\theta_y)s\theta_x + l_e s\beta_i c\theta_x & -(l_e c\beta_i c\theta_y + z_0 s\theta_y)c\theta_x & 1 \end{bmatrix}$$

Because the active links have a fixed length, one has

$$|\mathrm{O}_b\mathrm{E}_i - \mathrm{O}_b\mathrm{B}_i - \mathrm{B}_i\mathrm{D}_i| = |\mathrm{D}_i\mathrm{E}_i| \quad (i = 1, 2, 3) \tag{66}$$

Equation (66) yields

$$k_{i1}^2 + k_{i2}^2 + k_{i3}^2 = l_i^2 \tag{67}$$

where

$$\begin{aligned} k_{i1} &= x_{e_i}^b - (l_b - u_i c\gamma)c\alpha_i \\ k_{i2} &= y_{e_i}^b - (l_b - u_i c\gamma)s\alpha_i \\ k_{i3} &= z_{e_i}^b - u_i s\gamma \end{aligned}$$

Assuming only torsion is in the linear actuator of each active link, the derivation of Equation (67) with respect to the time is then

$$\delta u_i = \begin{bmatrix} -\dfrac{k_{i1}}{k_{i4}} & -\dfrac{k_{i2}}{k_{i4}} & -\dfrac{k_{i3}}{k_{i4}} \end{bmatrix} \cdot \begin{bmatrix} \delta x_{e_i}^b \\ \delta y_{e_i}^b \\ \delta z_{e_i}^b \end{bmatrix} \quad (i = 1, 2, 3) \tag{68}$$

where

$$k_{i4} = k_{i1}c\gamma c\alpha_i + k_{i2}c\gamma s\alpha_i - k_{i3}s\gamma$$

Substituting Equation (65) into Equation (68), one has

$$\begin{bmatrix} \delta u_1 \\ \delta u_2 \\ \delta u_3 \end{bmatrix} = (\mathrm{J}_t)_{3\times 3} \begin{bmatrix} \delta\theta_x \\ \delta\theta_y \\ \delta z_e \end{bmatrix} = \begin{bmatrix} (\mathrm{J}_{t,1})_{1\times 3} \\ (\mathrm{J}_{t,2})_{1\times 3} \\ (\mathrm{J}_{t,3})_{1\times 3} \end{bmatrix} \begin{bmatrix} \delta\theta_x \\ \delta\theta_y \\ \delta z_e \end{bmatrix} \tag{69}$$

where

$$\mathrm{J}_{t,i} = \begin{bmatrix} -\dfrac{k_{i1}}{k_{i4}} & -\dfrac{k_{i2}}{k_{i4}} & -\dfrac{k_{i3}}{k_{i4}} \end{bmatrix} \cdot J_i$$

The active link is a two-force component; therefore, only axial deformation occurs. Differentiating Equation (67) with respect to time yields the following:

$$\delta l_i = \begin{bmatrix} \dfrac{k_{i1}}{l_i} & \dfrac{k_{i2}}{l_i} & \dfrac{k_{i3}}{l_i} \end{bmatrix} \cdot \begin{bmatrix} \delta x^b_{e_i} \\ \delta y^b_{e_i} \\ \delta z^b_{e_i} \end{bmatrix} (i = 1, 2, 3) \tag{70}$$

Substituting Equation (65) into (70)

$$\dot{\boldsymbol{\rho}} = \mathbf{Jt} \tag{71}$$

where vectors $\dot{\boldsymbol{\rho}}$ and $\mathbf{t}$ are the joint velocity and the twist of the platform defined as follows:

$$\dot{\boldsymbol{\rho}} = [\,\delta l_1 \quad \delta l_2 \quad \delta l_3\,]^T$$

$$\mathbf{t} = [\,\boldsymbol{\omega}^T \quad \dot{\mathbf{p}}^T\,]^T = [\,\delta\theta_x \quad \delta\theta_y \quad \delta z_e\,]$$

that is,

$$\begin{bmatrix} \delta l_1 \\ \delta l_2 \\ \delta l_3 \end{bmatrix} = (\mathrm{J}_a)_{3\times 3} \begin{bmatrix} \delta\theta_x \\ \delta\theta_y \\ \delta z_e \end{bmatrix} = \begin{bmatrix} (\mathrm{J}_{a,1})_{1\times 3} \\ (\mathrm{J}_{a,2})_{1\times 3} \\ (\mathrm{J}_{a,3})_{1\times 3} \end{bmatrix} \begin{bmatrix} \delta\theta_x \\ \delta\theta_y \\ \delta z_e \end{bmatrix}$$

where

$$\mathrm{J}_{a,i} = \begin{bmatrix} \dfrac{k_{i1}}{l_i} & \dfrac{k_{i2}}{l_i} & \dfrac{k_{i3}}{l_i} \end{bmatrix} \cdot \mathrm{J}_i$$

Direct Kinematics

The direct kinematics is to solve the posture of the end-effector T^b_e when the joint motion u_i ($i = 1$, 2, 3) is known. The solution of a direct kinematic problem can also be derived from Equation (65). At this moment, the motions of the end-effector $(\theta_x, \theta_y, z_\theta)$ are unknown, and the joint motion u_i ($i = 1$, 2, 3) is given. To solve direct kinematic problem, z_e and θ_y could be represented by θ_x, therefore, Equation (65) can be rewritten as

$$\left.\begin{aligned} z_e^2 + (A_i s\theta_y + B_i)z_e + (C_i c\theta_y + D_i s\theta_y + E_i) = 0 \\ (i = 1, 2, 3) \end{aligned}\right\} \tag{72}$$

where the coefficients $A_i \sim E_i$ are the functions of θ_x, they are

$$\begin{aligned} A_i &= -2l_e c\beta_i c\theta_x \\ B_i &= 2(l_e s\beta_i s\theta_x - u_i s\gamma) \\ C_i &= -2(l_b - u_i c\gamma)l_e c\alpha_i c\beta_i \\ D_i &= 2l_e c\beta_i(u_i s\gamma c\theta_x - (l_b - u_i c\gamma)s\alpha_i s\theta_x) \\ E_i &= l_e^2 + l_b^2 + u_i^2 - l_i^2 - 2(l_e s\beta_i(u_i s\gamma s\theta_x \\ &\quad + (l_b - u_i c\gamma)s\alpha_i c\theta_x) + l_b u_i c\gamma) \end{aligned}$$

From Equation (67), one has

$$c\theta_y = -\frac{Fz_e^2 + Gz_e + H}{Kz_e + L} \tag{73}$$

$$s\theta_y = -\frac{Iz_e + J}{Kz_e + L} \tag{74}$$

where the coefficients F–L are the functions of θ_x, and expressed by

$$\begin{aligned} F &= B_{12}A_{13} - B_{13}A_{12} \\ G &= E_{12}A_{13} + B_{12}D_{13} - E_{13}A_{12} - B_{13}D_{12} \\ H &= E_{12}D_{13} - E_{13}D_{12} \\ I &= C_{12}B_{13} - C_{13}B_{12} \\ J &= C_{12}E_{13} - C_{13}E_{12} \\ K &= C_{12}A_{13} - C_{13}A_{12} \\ L &= C_{12}D_{13} - C_{13}D_{12} \end{aligned}$$

and

$$\begin{aligned} &A_{ij} = A_i - A_j, B_{ij} = B_i - B_j, C_{ij} = C_i - C_j \\ &D_{ij} = D_i - D_j, E_{ij} = E_i - E_j \end{aligned}$$

Because $c^2\theta_y + s^2\theta_y = 1$, substituting Equation (68) and (69) into this expression generates

$$M_4 z_e^4 + M_3 z_e^3 + M_2 z_e^2 + M_1 z_e + M_0 = 0 \tag{75}$$

where

$$\begin{aligned} M_4 &= F^2 \\ M_3 &= 2FG \\ M_2 &= G^2 + I^2 + K^2 + 2FH \\ M_1 &= z_e^2 + 2(GH + IJ + KL) \\ M_0 &= H^2 + J^2 + L^2 \end{aligned}$$

One can observe that Equation (67) includes three independent equations, and two independent equations have been derived [Equations (68) and (69)]. Another equation can be derived by substituting Equations (68) and (69) into any one of the equations in Equation (67), for example, the equation when $i = 1$. Thus one obtains

$$N_3 z_e^3 + N_2 z_e^2 + N_1 z_e + N_0 = 0 \tag{76}$$

where

$$\begin{aligned} N_3 &= K \\ N_2 &= B_1 K + L - A_1 I - C_1 F \\ N_1 &= E_1 K + B_1 L - A_1 J - D_1 I - C_1 G \\ N_0 &= E_1 L - D_1 J - C_1 H \end{aligned}$$

If the direct kinematic problem is solvable for the given design, then Equations (70) and (71) should possess a common solution of z_e. Based on Bezout's method, the following condition should be satisfied:

$$\begin{vmatrix} M_4 & M_3 & M_2 & M_1 & M_0 & 0 & 0 \\ 0 & M_4 & M_3 & M_2 & M_1 & M_0 & 0 \\ 0 & 0 & M_4 & M_3 & M_2 & M_1 & M_0 \\ N_3 & N_2 & N_1 & N_0 & 0 & 0 & 0 \\ 0 & N_3 & N_2 & N_1 & N_0 & 0 & 0 \\ 0 & 0 & N_3 & N_2 & N_1 & N_0 & 0 \\ 0 & 0 & 0 & N_3 & N_2 & N_1 & N_0 \end{vmatrix} = 0 \tag{77}$$

Equation (72) becomes an equation about θ_x when the joint motion u_i is given. Equation (72) is converted using the standard transformation formulas

$$c\theta_x = (1 - t^2)/(1 + t^2), s\theta_x = 2t/(1 + t^2), (t = \tan(\theta_x/2))$$

It is a polynomial equation with the order of 40.

After θ_x is obtained from Equation (72), z_e and θ_y can be calculated sequentially from Equations (70) and (71), and Equations (68) and (69).

Velocity Analysis

Suppose that the velocities of the end-effector are $(\dot{\theta}_x, \dot{\theta}_y, \dot{z}_e)$. Differentiating Equation (66) with respect to time, one has the velocity of an active joint as

$$\dot{\boldsymbol{u}}_i = -\frac{\dot{k}_b u_i + \dot{k}_c}{2u_i + k_b} \cdot z_{d_i} \tag{78}$$

where

$\dot{\boldsymbol{u}}_i$ is the velocity of joint i, and

$$z_{d_i} = (c\gamma c\alpha_i, c\gamma s\alpha_i, s\gamma)^T$$

$$\begin{aligned} \dot{k}_b &= 2(c\gamma(\dot{x}^b_{e_i} c\alpha_i + \dot{y}^b_{e_i} s\alpha_i) - \dot{z}^b_{e_i} s\gamma) \\ \dot{k}_c &= 2(x^b_{e_i}\dot{x}^b_{e_i} + y^b_{e_i}\dot{y}^b_{e_i} + z^b_{e_i}\dot{z}^b_{e_i}) - 2l_b(\dot{x}^b_{e_i} c\alpha_i + \dot{y}^b_{e_i} s\alpha_i) \end{aligned}$$

$$(\dot{x}_{e_o}, \dot{y}_{e_o}, \dot{z}_{e_o})^T = (0_x, 0_y, \dot{z}_e)^T + \boldsymbol{\omega}_e \times (\boldsymbol{R}_e \cdot \boldsymbol{r}^T_{ei})$$

$$\boldsymbol{\omega}_e = (\dot{\theta}_x, \dot{\theta}_y, 0)^T$$

$$\boldsymbol{r}_{ei} = (x^b_{e_i}, y^b_{e_i}, z^b_{e_i})$$

To determine the kinematic behavior of the rigid body of a support bar, its angular velocity should be known, which can be determined from

$$\boldsymbol{v}_{e_i} = \boldsymbol{v}_{d_i} + \omega_{d_i e_i} \times \boldsymbol{r}_{d_i e_i} \tag{79}$$

Therefore

$$\boldsymbol{\omega}_{d_i e_i} = \frac{\boldsymbol{r}_{d_i e_i} \times (\boldsymbol{v}_{e_i} - \boldsymbol{v}_{d_i})}{l_i^2} \tag{80}$$

where

$\boldsymbol{\omega}_{d_i e_i}$ is the angular velocity of support bar i, and

$$\begin{aligned} \boldsymbol{v}_{e_i} &= (\dot{x}^b_{e_i}, \dot{y}^b_{e_i}, \dot{z}^b_{e_i})^T \\ \boldsymbol{v}_{d_i} &= \dot{\boldsymbol{u}}_i \\ \boldsymbol{r}_{d_i e_i} &= (x^b_{e_i} - (l_b - u_i c\gamma)c\alpha_i, y^b_{e_i} - (l_b - u_i c\gamma)s\alpha, z^b_{e_i} - u_i s\gamma)^T \end{aligned}$$

Acceleration Analysis

Assume the accelerations of the end-effector are $(\ddot{\theta}_x, \ddot{\theta}_y, \ddot{z}_e)$. Differentiating Equation (73) with respect to time, one has the acceleration of an active joint as follows:

$$\ddot{\boldsymbol{u}}_i = -\frac{2\dot{u}_i^2 + 2\dot{k}_b \dot{u}_i + \ddot{k}_b u_i + \ddot{k}_c}{2u_i + k_b} z_{d_i} \tag{81}$$

where $\ddot{\boldsymbol{u}}_i$ is the acceleration of joint i, and

$$\begin{aligned} \ddot{k}_b &= 2(c\gamma(\ddot{x}^b_{e_i} c\alpha_i + \ddot{y}^b_{e_i} s\alpha_i) - \ddot{z}^b_{e_i} s\gamma) \\ \ddot{k}_c &= 2(x^b_{e_i}\ddot{x}^b_{e_i} + y^b_{e_i}\ddot{y}^b_{e_i} + z^b_{e_i}\ddot{z}^b_{e_i} + (\dot{x}^b_{e_i})^2 + (\dot{y}^b_{e_i})^2 + (\dot{z}^b_{e_i})^2) \\ &\quad -2l_b(\ddot{x}^b_{e_i} c\alpha_i + \ddot{y}^b_{e_i} s\alpha_i) \\ (\ddot{x}_{e_o}, \ddot{y}_{e_o}, \ddot{z}_{e_o})^T &= (0, 0, \ddot{z}_e)^T + (\ddot{\theta}_x, \ddot{\theta}_y, 0)^T \times (\boldsymbol{R}_e \boldsymbol{r}_{ei}) + \boldsymbol{\omega}_e \\ &\quad \times (\boldsymbol{\omega}_e \times (\boldsymbol{R}_e \boldsymbol{r}_{ei})) \end{aligned}$$

Similar to Equation (73), to obtain the angular acceleration of a support bar, the following relationship can be applied:

$$\boldsymbol{a}_{e_i} = \boldsymbol{a}_{d_i} + \boldsymbol{\omega}_{d_i e_i} \times (\boldsymbol{\omega}_{d_i e_i} \times \boldsymbol{r}_{d_i e_i}) + \varepsilon_{d_i e_i} \times \boldsymbol{r}_{d_i e_i} \tag{82}$$

Therefore,

$$\boldsymbol{\varepsilon}_{d_ie_i} = \boldsymbol{r}_{d_ie_i} \times (\boldsymbol{a}_{e_i} - \boldsymbol{a}_{d_i} - \boldsymbol{\omega}_{d_ie_i} \times (\boldsymbol{\omega}_{d_ie_i} \times \boldsymbol{r}_{d_ie_i}))/l_i^2 \tag{83}$$

where

$\boldsymbol{\varepsilon}_{d_ie_i}$ is the angular acceleration of support bar i,
$\boldsymbol{\omega}_{d_ie_i}$ is calculated from Equation (75)

$$\boldsymbol{a}_{d_i} = \ddot{\boldsymbol{u}}_i \boldsymbol{z}_d$$

CONCLUSIONS

In this article, the kinematics of robot manipulators is introduced, which includes the conceptions of reference coordinate frame, translational transformation, rotational transformation, and homogeneous transformation as well as the preliminary knowledges in robot kinematics, such as Euler angle, Denavit-Hartenberg representation and Jacobian matrix of robot. An example is given. Both direct and inverse kinematics are conducted.

ROBOT MOTION PLANNING

INTRODUCTION

The aim in robot motion planning is to be able to specify a task in a high-level, expressive language and have the robot(s) automatically convert the specification into a set of low-level primitives, such as feedback controllers and communication protocols, to accomplish the task (1,2). The robots can vary from manipulator arms used in manufacturing or surgery, to autonomous vehicles used in search and rescue or in planetary exploration, and to smart wheelchairs for disabled people. They are subject to mechanical constraints (e.g., a car-like robot cannot move sideways and an airplane cannot stop in place) and have limited computation, sensing, and communication capabilities. The environments can be cluttered with possibly moving and shape-changing obstacles and can contain dynamic (moving, appearing, or disappearing) targets. The challenge in this area is the development of a computationally efficient framework accommodating both the robot constraints and the complexity of the environment, while allowing for a large spectrum of task specifications.

A robot combines moving mechanical pieces such as wheels, gears, and breaks with digital devices such as processors and sensing and communication devices, in continuous interaction with a possibly changing environment. Therefore, motion planning is a highly interdisciplinary area, combining tools from computer science, mechanics, control theory, and differential geometry. Given the variety of applications, many motion planning approaches have been developed over the years. Depending on the task they address, motion planning problems can roughly be divided into four main groups: *navigation, coverage, mapping, and localization*(3).

In *navigation,* the problem is to find a collision-free motion between two configurations of the robot. *Coverage* is the problem of moving a robot sensor or end effector in such as way that it reaches all points in a target space (e.g., painting a surface). *Mapping* involves exploring an environment with the goal of producing a representation that can be used, for example, in navigation and coverage. Finally, in *localization,* the problem is to use a map and sensor data to determine the configuration (state) of the robot. Localization and mapping are sometimes performed simultaneously, such as in simultaneous localization and mapping (SLAM)(4).

Motion planners also differ depending on the robot model they consider. For example, it is much easier to plan the motion of a robot that is free to move instantaneously in all directions of its configuration space (omnidirectional robot), rather than generating motion for a car-like or an airplane-like vehicle that cannot move sideways (i.e., nonholonomic robot; see Ref. 5 for a collection of motion planning approaches for such robots). Motion planning can be performed for kinematic robot models, which capture only the configuration and velocity of the robot, or for dynamic robot models, which capture forces and accelerations.

Motion planning approaches can also be classified depending on the properties of the underlying algorithms. A motion plan is optimal if the produced motion minimizes energy consumption, execution time, trajectory length, and so on. Computational complexity is also a determining factor. For example, in most cases, it is desired that the amount of necessary memory and running time scale polynomially with the size of the input of the planner, which can be the number of obstacles, the number of degrees of freedom of the robot, and so on. Finally, a planner is complete if it always finds a path if one exists. Others are resolution complete, if a solution is found whenever one exists at a given discretization resolution, or probabilistic complete, if the probability of finding a solution during an iterative discretization process converges to 1 when the solution exists.

WORKSPACE AND CONFIGURATION SPACE

Given a robotic system, a *configuration* is a complete description that determines the position of every point of the system uniquely. Its *configuration space,* called for simplicity C-space, is the set of all possible configurations of the system. The number of degrees of freedom of a robotic system is the dimension of its minimal configuration space or, in other words, the minimum number of parameters needed to describe the system completely. The space in which the robotic system does work is called the *workspace*, which can be seen as the Euclidean space $\mathbb{R}^2$ or $\mathbb{R}^3$, depending on whether the motion is in plane or space. Most often, however, the workspace is defined more precisely as the subset of $\mathbb{R}^2$ or $\mathbb{R}^3$ that can be reached by a point of interest on the robot, such as the end effector of a manipulator arm.

Consider, for example, a two-joint planar robot arm, where a point on the first link is pinned to the ground, and the base of the second link is pinned to the end of the first, such that the only possible motion of the second link is a rotation about the (revolute) joint [Fig. 1(a)]. If we denote by θ_1 and θ_2 the angles formed by the two links with the horizontal, then (θ_1, θ_2) can be seen as coordinates of the configuration space, which is $S^1 \times S^1 = T^2$, where S^1 and T^2 denote the unit circle and the torus, respectively [Fig. 1(c)]. The workspace of this robot, however, is an annulus, with the outer radius determined by the sum of the lengths of the two links, and the inner radius is given by the difference between their lengths [Fig. 1(b)].

The configuration space of a planar square robot (or any other rigid body) that can only translate without rotation (see Fig. 2) is $\mathbb{R}^2$. For a planar robot that can only rotate about a fixed point, the configuration space is $SO\,(2)$, called the Special Orthogonal group in the plane, which is

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

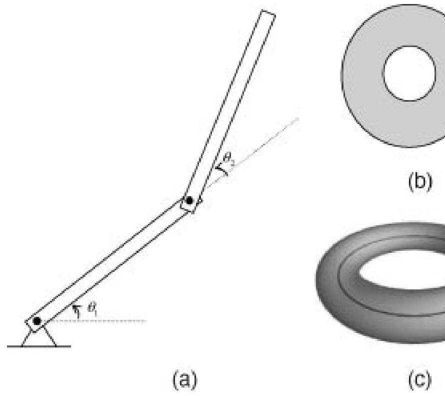

Figure 1. A two-link manipulator (a), its workspace (b), and its configuration space (c).

isomorphic to S^1. The configuration space of a robot allowed to translate and rotate in the plane is $SE(2)$, called the Special Euclidean group in the plane, and defined as $SE(2) = \mathbb{R}^2 \times SO(2)$. In space, a rotating and translating robot modeled as a rigid body evolves in $SE(3) = \mathbb{R}^3 \times SO(3)$, where $SO(3)$ is the group of rotations in space (3).

If obstacles are present in the workspace, it is useful to define explicitly the set of robot configurations for which collisions occur. For each obstacle in the workspace, the *configuration space obstacle* is defined as the set of all configurations at which the robot intersects the obstacle in the workspace. The free configuration space, also called free C-space, is the set of configurations at which the robot does not intersect any obstacle. Figure 2(b) shows the free C-space for the square robot moving in the environment shown in Fig. 2(a), if only translational motion is allowed (no rotation). The reader is referred to Ref. 3, p. 509 for an example of the free C-space construction for a polytopal robot translating and rotating in a polytopal environment with polytopal obstacles. In this setup, a navigation problem, as defined above, translates to finding a continuous curve between the initial and the final configuration in the free C-space.

RIGID BODY MOTION INTERPOLATION

A navigation problem for a robot, represented simply as a rigid body moving in space or plane with no obstacles, is also called rigid body motion interpolation. In the configuration space of the robot, which is $SE(3)$ or $SE(2)$ as defined above, this problem translates to generating a (possibly smooth) curve interpolating between two points. The problem of

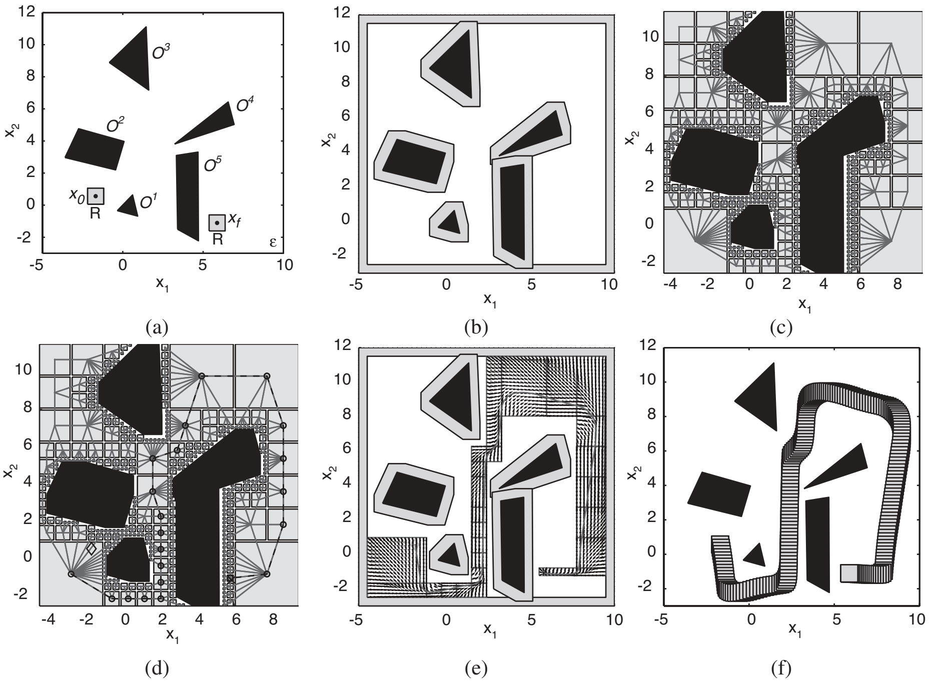

Figure 2. Cell decomposition and simultaneous planning and control for a square robot translating (no rotation) in a 2-D rectangular environment with polyhedral obstacles. The observable is the centroid of the robot: (a) initial (left) and final (right) positions of the robot. (b) The free C-space is obtained by enlarging the obstacles, shrinking the environment boundaries, and reducing the robot to its observable point. (c) Rectangular (quadtree) partition of the free C-space and the quotient graph of the partition. (d) Optimal path from initial to final node (rectangle) in the quotient graph; ◇ and × denote the initial and final position of the robot observable, respectively. (e) Vector field assignment (used in simultaneous planning and control) and the resulting trajectory of the observable. (f) Robot motion in the initial environment.

finding a smooth interpolating curve is well understood in Euclidean spaces (e.g., a line segment is a smooth interpolating curve between two points), but it is not easy to generalize such techniques to curved spaces, such as $SE(3)$ and $SE(2)$. Most work in this area proposes to generalize the notion of interpolation from the Euclidean space to a curved space. For example, in Ref. 6, Bezier curves are used for interpolating rotations based on a spherical analog of the well-known de Casteljau algorithm. Other examples include spatial rational B-splines and Hermite interpolation (see Ref. 7 for an overview).

The above methods find immediate applications in computer graphics (e.g., generate a “natural” motion for an object thrown from one place to another). However, to generate a robot motion plan, two more issues have to be taken into consideration: optimality of the trajectory and invariance with respect to the choice of a world frame. The optimality requirement is particularly relevant in applications such as deep space formations. For example, to achieve interferometry, a group of satellites is required to maintain a rigid body formation. A reconfiguration demands a fuel-optimal trajectory to preserve mission life and is constrained by the limited thrust available.

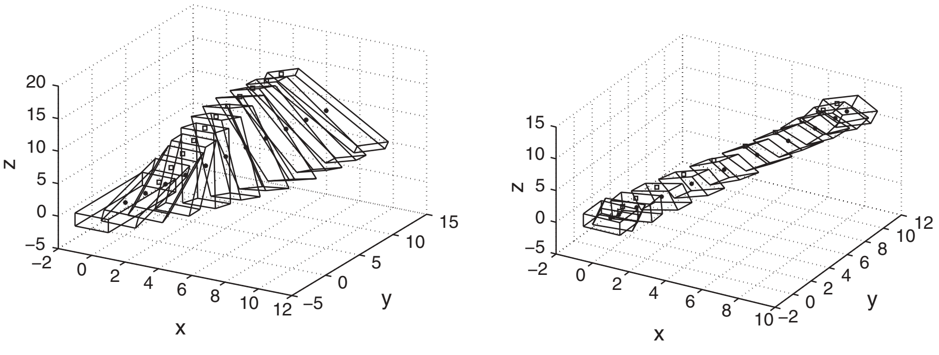
Coordinate-free approaches leading to trajectories that are invariant to reference frames exist for the generation of shortest paths and minimum acceleration trajectories on $SO(3)$ (the set of all rotations in $\mathbb{R}^3$) and $SE(3)$ (the set of all poses in $\mathbb{R}^3$) (see Ref. 8 for an overview) (see Fig. 3 for examples). However, analytical solutions are available only in the simplest cases, and the procedure for solving optimal motions, in general, is computationally intensive. A relaxation based on the generation of optimal curves in an embedding Euclidean space and subsequent projection, which leads to suboptimal solutions, is proposed in Ref. 7.

POTENTIAL-BASED PLANNERS

Potential-based motion planners are based on the idea that a robot configuration can be driven to a desired value in the same way in which a particle moves in a force field. More precisely, a potential ϕ is a differentiable, real-valued function defined on the configuration space. Its gradient $\nabla\phi$ is a vector that points in the direction of maximum (local) increase of ϕ. This gradient can be used to define a vector field, (i.e., an assignment of a vector to each point of the configuration space). Guiding a robot through an environment with obstacles toward a goal can, therefore, be achieved by constructing a potential function in the configuration space, with a minimum value at the goal and high values at the obstacles, and by setting the velocity of the robot configuration equal to the negative of the gradient of the potential. Such an approach can be used directly to accommodate kinematic robot models. However, this approach can be extended for dynamic models, by designing control laws guaranteeing the convergence of the velocities to a desired vector field (9).

The robot motion terminates at a point of zero velocity or, equivalently, at a point where the gradient of the potential function vanishes, which is a critical point for the potential function. This point can be, in general, a minimum, a maximum, or a saddle point, and it can be degenerate or nondegenerate (isolated), depending on the Hessian matrix of the potential function. Explicitly, a critical point is degenerate if and only if the Hessian i.e., the matrix of second derivatives; see Ref. 3 is singular at that point. A positive-definite Hessian indicates a local minimum, a negative-definite Hessian indicates a local maximum, and a Hessian of indefinite sign indicates a saddle point. The goal in potential-based motion planning is to have the robot stop at the minimum corresponding to the goal. Although the robot can, in theory, stop at a local maximum or at a saddle point, this is impractical, because such points are unstable, and the probability that this happens is basically zero. Other possible local minima, on the other hand, are attractive, and the robot can get “caught” into such undesirable points in its way to the goal. Most of the existing potential-based planners, where the potential function is constructed through the superposition of attractive (to the goal) functions and repulsive (from the obstacles) functions, suffer from this problem.

To address the local minima problem, two types of approaches have been developed (see Ref. 3 for a detailed overview). In the first approach, the potential field is augmented with a search-based planner. For example, the randomized path planner (RPP)(3) uses a variety of potential



(a)

(b)

Figure 3. A geodesic (minimum length, or energy) curve for a cuboid and a minimum acceleration curve for a cube.

functions, and when stuck at a local minimum, it performs a random walk, with the goal of escaping the local minimum. In the second approach, a special type of potential function, called a navigation function, is constructed. Although guaranteed to have exactly one minimum, a navigation function can only be applied to a limited class of configuration spaces, which are diffeomorphic to sphere spaces.

ROADMAPS

If several navigation tasks are expected to occur in an environment, then building a map of the environment and then performing navigation using the map can prove to be more efficient than performing navigation from scratch every time such a request occurs. The most used of such maps are topological, or graph-like, structures, where nodes correspond to "interesting features" and the edges show adjacency between nodes. For example, the nodes can be points of interest for a specific task such as targets or intersections, whereas the edges can label actions required from the robot to move from a location to another.

Roadmaps (3) are topological maps embedded in the free space. In other words, in a roadmap, the nodes correspond to physical locations in the environment, and the edges correspond to paths between different locations. A roadmap is, therefore, both a graph and a collection of one-dimensional manifolds (curves). Robots use roadmaps in the same way drivers use the interstates. Instead of planning a trip from point A to point B on small streets, a driver would plan her trip from A to a close interstate, then on the interstate for as long as possible, and then from the interstate to the destination B. Similarly, if a roadmap is available, a robot planner would find a collision-free path to the roadmap, then travel on the roadmap until close to the destination, and then find another collision-free path from the exit point on the roadmap to the destination. Most motion occurs on the roadmap, which is low dimensional, as opposed to the motion to and from the roadmap, which occurs in a possibly high-dimensional configuration space.

Several types of roadmaps have been developed over the years, which include visibility maps, deformation retracts, and silhouettes. In visibility maps, which work for polygonal environments with polygonal obstacles, the nodes are the vertices of the polygons, and an edge between two nodes means that a line of sight exists between the nodes. Deformation retracts capture the "essential" topology of an environment, and they include generalized Voronoi diagrams(3). Finally, silhouette methods are based on repeated projection of the robot-free configuration space onto lower dimensional spaces until a one dimensional representation is reached.

SAMPLING-BASED ALGORITHMS

The construction of roadmaps, as presented above, is based on an explicit representation of the free C-space. As a result, as the dimension of the configuration space increases (e.g., a manipulator arm with several joints and a gripper with fingers can have tens of degrees of freedom), motion planners based on roadmaps become computationally infeasible. In such cases, sampling-based approaches are more appropriate. In short, a sampling-based planner generates samples (i.e., collision-free configurations of the robot) and then interpolating paths for the samples. The latter process is also often achieved through sampling but at a finer rate.

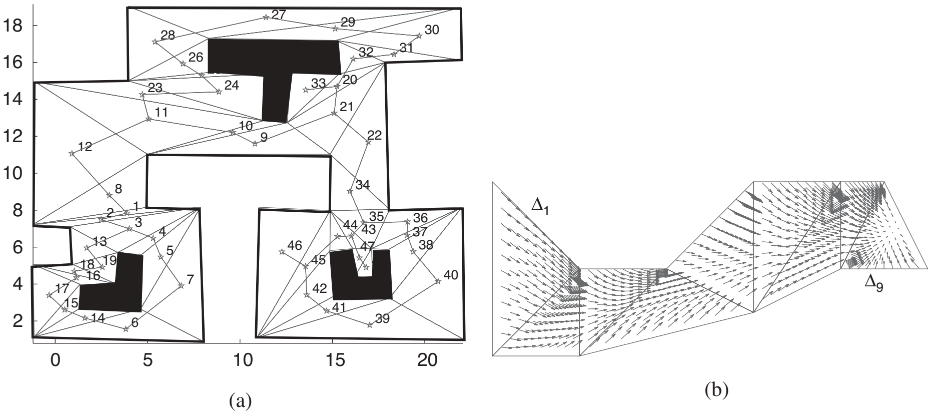
The most representative sampling-based algorithm is the Probabilistic Road Map Planner (PRM) (3). The main idea behind PRM is that it is easy (and cheap) to check for collisions with obstacles. In other words, it is easy to see whether a sample is in the free C-space. PRM uses coarse sampling to obtain the nodes of the roadmap and fine sampling to construct its edges. Once the roadmap is constructed, it is used in exactly the same way as the "classic" roadmap presented in the previous section. The existing PRMs differ by the way samples and interpolating paths are generated. The basic PRM uses uniform distribution for node sampling. Other, more sophisticated, PRMs use sampling schemes such as importance sampling in areas that are difficult to explore and deterministic sampling such as sampling on grids and quasirandom sampling.

As PRM is a roadmap planner, it is optimized for several queries. For single queries, other sampling-based algorithms are effective, such as the rapidly exploring random tree planner (RRT)(3). A combination of multiple-query and single-query methods, such as the sampling-based roadmap of trees (SRT)(3), tries to find a compromise between using a roadmap versus a large sampling tree in very difficult planning problems. Other developments in this area led to sampling-based planners that take into account kinematic and dynamic constraints, stability requirements, energy constraints, visibility constraints, and contact constraints. Sampling-based algorithms opened a new direction in robot motion planning, by making it possible to approach very high-dimensional robotic systems.

CELL DECOMPOSITIONS

Cell decompositions are among the most used techniques for robot motion planning. To illustrate the main ideas, we assume for simplicity that the motion task is a navigation task. The computation behind most of the existing approaches consists of three main steps(3). In the first step, the free configuration space is partitioned, and the quotient graph of the partition is constructed [see Fig. 2(c)]. In this graph, a node labels a free cell, and an edge between two nodes shows an adjacency relation between the corresponding cells. In the second step, the cells corresponding to the initial and the final configurations are determined, and a path is determined between the corresponding nodes in the quotient graph [see Fig. 2(d)]. This path can be optimal with respect to some cost, which in the simplest cases penalizes the distance traveled by the robot. Alternatively, the cost can prevent from generating paths "too close" to the obstacles. Finally, in the third step, a desired robot trajectory is constructed inside the configuration-space tube determined by the path in the quotient graph, and a trajectory-following controller is synthesized for the robot.

The several cell-decomposition methods can be classified according to the underlying partition scheme. The most popular cell decompositions are trapezoidal decomposi-



(a)

(b)

Figure 4. (a) A triangulation of the free space in a polygonal environment and the corresponding quotient graph. (b) A sequence of triangles (such as resulting from a path on the quotient graph of a triangulation) is executed by constructing affine vector fields in each triangle.

tions, triangulations, and rectangular grids. For example, Fig. 2(c) shows a rectangular partition, whereas Fig. 4(a) shows a triangulation of a polygonal environment cluttered with polygonal obstacles. Note that although efficient algorithms exist for planar trapezoidal partitions and triangulations, these procedures become cumbersome in higher dimensional spaces. Rectangular partitions, although not particularly efficient in plane, have the advantage of working in higher dimensions, especially when a 2^n-trees (i.e., quad-trees in plane and oct-trees in space) are used during the partition process.

The three-step, top-down process presented above has two main disadvantages. First, because no robot control and/or actuation constraints are taken into account during the decomposition, it is possible that the reference trajectory generated in the last step cannot be followed by the robot. To deal with this issue, in recent years, researchers proposed approaches for the so-called *simultaneous planning and control*. In these studies, the environment partitioning is performed at the same time with the assignment of robot-compatible controllers for each region. For example, polygonal partitions of planar environments followed by assignment of vector fields obtained as solutions of Laplaces equation in each of the regions were considered in Ref. 10. Triangular partitions and rectangular partitions can be also accompanied by the assignment of vector fields with arbitrary polyhedral bounds, if the robot dynamics are restricted to affine and multi-affine (see, for example, Ref. 11). In Figs. 2(e) and 4(b), we show how vector fields are assigned in each rectangle and triangle from a path in the quotient graph. In this setup, the "execution" of a "discrete" path is provably correct (i.e., regardless of the actual position of the robot inside each region), therefore avoiding the trajectory generation and following process.

Trapezoidal, triangular, and rectangular decompositions, as presented above, are mostly used for navigation tasks, and they are not appropriate for coverage(3). Indeed, even if coverage of cells can be efficiently achieved through coverage algorithms on graphs, covering the space inside each cell might be difficult because of the size and shape of the resulting cells. If coverage is the task at hand, then Boustrophedon decompositions and Morse Cell decompositions are more appropriate(3). Roughly put, Boustrophedon decompositions start from a trapezoidal decomposition and reorganize cells such that shorter and more efficient paths can cover the same area. Morse decompositions are based on the same idea, but they allow us to achieve coverage in non polygonal environments. Finally, for a special class of motion planning problems, called pursuit/evasion problems (games), a visibility-based cell decomposition is more appropriate. Roughly, moving from one cell to an adjacent one in this decomposition corresponds to a change in visibility (i.e., target or obstacles appear or disappear).

SYMBOLIC APPROACHES TO MOTION PLANNING AND CONTROL

The current approaches to robot motion planning and control presented above have two main limitations. First, the specification language is not rich enough for a large spectrum or robotic applications. For example, a navigation task is always formulated as "go from A to B and avoid obstacles." Nevertheless, the accomplishment of a mission might require the attainment of either A or B, convergence to a region ("reach A eventually and stay there for all future times"), visiting targets sequentially ("reach A, and then B, and then C"), surveillance ("reach A and then B infinitely often"), and so on. Second, as mentioned, some of the approaches above, such as cell decomposition, do not explicitly take into account the control, sensing, and communication constraints of the robot.

Symbolic approaches to robot motion planning and control have been developed recently to address these limitations. They draw on well-established concepts in related areas, such as behavior-based robotics and hybrid control systems. As the specification language is enriched and real-world robot control, sensing, and communication constraints are taken into account, concepts and tools from the theory of computation such as automata and languages develop naturally, hence the name "symbolic" (see Ref. 12

for a more detailed overview of these methods and the main challenges in the area).

To introduce the main ideas, note that the typical cell-decomposition approach to the navigation problem is a hierarchical, three-level process. At the first (top-most) level, the specification "go from A to B and avoid obstacles" is given, the obstacle-free configuration space of the robot is partitioned into cells, and the quotient graph is constructed (see Figs. 2(c) and 4(a) for examples). As any path connecting the cell containing A to the cell containing B in this graph satisfies the specification (i.e., it avoids obstacles), this is called the specification level. In the second step, a path on this graph is chosen, which can be seen as a "discrete" execution of the robot, hence, the name *execution level* for this step. Finally, in the third step, called the *implementation level*, a reference trajectory traversing the sequence of cells given by the path is generated, and robot controllers are constructed so that the reference trajectory is followed.

Symbolic approaches to motion planning fit into the three-level hierarchy described above, and they can be divided into two main groups: top-down approaches and bottom-up approaches. In top-down approaches (also referred to as middle-out approaches(13)), the focus is on the expressivity of the specification language, and the hope is that, while going down the three-level hierarchy presented above, implementations are possible for real-world robots. In bottom-up approaches, the starting point is a careful analysis of the control and sensing communication of the robot, possible executions are generated at the execution level, and the hope is that the set of such robot-compatible executions give rise to an expressive specification language. However, a significant gap exists between these two approaches. Bridging in this gap is one of the main challenges in the area(12).

Top-Down Symbolic Approaches

It was recently suggested that, to define a rich specification language for robot motion, inspiration can be taken from temporal logics, which are commonly used for specifying and verifying the correctness of digital circuits and computer programs. Roughly, any rich, human-like, temporal, and logic statement about the reachability of regions of interest by the robot (including the ones given as examples above) translate naturally to a formula in such a logic. Consider, for example, that a robot moves in an environment with three obstacles o_1, o_2, and o_3 and three targets r_1, r_2, and r_3 that need to be surveyed (visited infinitely many times). In other words, the task can be formulated as "*Always avoid obstacles o_1, o_2, o_3 and visit regions r_1, r_2, r_3, in this order, infinitely often.*" This specification immediately translates to the following formula of linear temporal logic (LTL) over the set of symbols o_1, o_2, o_3, r_1, r_2, r_3: $\mathbf{G}(\mathbf{F}(r_1 \wedge \mathbf{F}(r_2 \wedge \mathbf{F}r_3)) \wedge \neg(o_1 \vee o_2 \vee o_3))$, where $\neg$ and $\wedge$ stand for Boolean negation and disjunction and $\mathbf{G}$ and $\mathbf{F}$ are temporal operators that mean "always" and "eventually," respectively.

The semantics of LTL formulas are given over labeled transition graphs (also called Kripke structures or transition systems). Such a transition system can be obtained from the dual graph of the partition induced by the regions of interest, if the nodes are labeled according to their being part of obstacles or of targets, and if the edges are viewed as transitions that a robot can take. To compute a transition between two nodes (or a self-transition), one could proceed by checking for the existence of robot feedback controllers taking the robot from one region to another in finite time (or keeping the robot inside the region forever), regardless of the initial position of the robot. If this is achieved, then a certain type of equivalence relation exists between the initial control system describing the motion of the robot in the environment and the finite transition system, called bisimulation, which guarantees that the two systems satisfy the same LTL formula. Therefore, provided that the two types of controllers can be constructed, the motion planning problem is reduced to a classic model checking procedure, for which exist several off-the-shelf tools developed by the formal verification community(14).

Currently, two classes of systems are available for which such quotients can be efficiently constructed: affine systems with polyhedral partitions, and multi-affine systems (i.e., polynomial systems where the maximum power at which a variable can occur is one) with rectangular partitions. Although these two classes of systems seem restrictive for robot dynamics, it is important to note that multi-affine dynamics capture vector cross products, and they can therefore accommodate dynamics of aircraft with gas-jet actuators and underwater vehicles. In addition, differential- drive and car-like vehicles can be easily accommodated by solving an additional input–output feedback linearization. Fully automatic computational frameworks for control of affine and multi-affine dynamics from rich specifications given as arbitrary LTL formulas over linear and rectangular predicates were developed in Ref. 15 and 16. A related approach was used in Ref. 17 to control a nonholonomic robot model. In Ref. 18, it is shown that a significant decrease in computation can be achieved if the specifications are restricted to a fragment of LTL.

Bottom-Up Symbolic Approaches

The top-down symbolic approaches presented above use environment discretization to capture the complexity of the environment. While allowing for a rich specification language over the partition regions, they are (in current form) restricted to static, *a priori* known environments and simple robot dynamics, such as fully actuated or affine dynamics with polyhedral speed constraints. As suggested, robots with more complex dynamics such as helicopter-like vehicles might not be able to implement executions strings over partition regions. In this situation, the discretization may be more appropriate at the level of controllers rather than environments. The argument behind such a control-driven discretization is that the global control task can be broken down into more easily defined behavioral building blocks, each defined with respect to a particular subtask, sensing modality, or operating point. Strings over such behaviors make up words in so-called motion description languages (MDLs)(19). An example of such a string is $(k_{i_1}, \xi_{i_1}), \ldots, (k_{i_q}, \xi_{i_q})$, where $k_{i_j} : \mathcal{R}^+ \times X \rightarrow U$ are feedback control laws and $\xi_{i_j} : \mathcal{R}^+ \times X \rightarrow \{0, 1\}$ are temporal or environmentally driven interrupt conditions, $j = 1, \ldots, q$. The robot "parses" such words as $\dot{x} = f(x, k_{i_1}(t,x))$ until $\xi_{i_1}(t,x) = 1$, at which point the timer t is reset to 0, and $\dot{x} = f(x, k_{i_2}(t,x))$ until $\xi_{i_2}(t,x) = 1$, and so on.

An attractive alternative to MDL is to use motion primitives. The idea is that, instead of using controllers chosen from a collection of controls, one could think of simplifying a robot control problem by piecing together, in an appropriate way, a set of elementary trajectories chosen from a small "library"—that are themselves guaranteed to satisfy the constraints. Such feasible trajectories that can be combined sequentially to produce more complicated trajectories are called "motion primitives"(20). The compatibility rules between such primitives can be, as above, modeled as finite-state machines, called Maneuver Automata. Motion primitives can be generated in several ways, for example, by recording the actions of a human pilot; if an accurate model of the robot' s dynamics is available, model-based approaches are also possible (e.g., to design optimal maneuvers).

Although the symbolic approaches to motion planning described in this section have been applied successfully to challenging problems in autonomous mobile robotics, including acrobatic aircraft, and off-road races, several challenges still need to be addressed. For example, the problem of choosing the control modes (quanta) or motion primitives for achieving a given task is not at all obvious. One way of addressing it is by letting the control mode selection be driven by experimental data. For instance, one can envision a scenario in which a human operator is controlling a mobile platform and then, through an analysis of the input–output sample paths, construct motion description languages that reproduce the human-driven robot behavior.

TRANSACTION PROCESSING

A business transaction is an interaction in the real world, usually between an enterprise and a person, in which something, such as money, products, or information, is exchanged (1). It is often called a computer-based transaction, or simply a transaction, when some or the whole of the work is done by computers. Similar to the traditional computer programs, a transaction program includes functions of input and output and routines for performing requested work. A transaction can be issued interactively by users through a Structured Query Language (SQL) or some sort of forms. A transaction can also be embedded in the application program written in a high-level language such as C, Pascal, or COBOL.

A transaction processing (TP) system is a computer system that processes the transaction programs. A collection of such transaction programs designed to perform the functions necessary to automate given business activities is often called an application program (application software). Figure 1 shows a transaction processing system. The transaction programs are submitted to clients, and the requests will be scheduled by the transaction processing monitor and then processed by the servers. A TP monitor is a piece of software that connects multiple clients to multiple servers to access multiple data resources (databases) in TP systems. One objective of the TP monitor is to optimize the use of system and network resources when clients and servers execute on different processors.

TP is closely associated with database systems. In fact, most earlier TP systems, such as banking and airlines reservation systems, are database systems, in which data resources are organized into databases and TP is supported by database management systems (DBMSs). In traditional database systems, transactions are usually simple and independent, and they are characterized as short duration in that they will be finished within minutes (probably seconds). Traditional transaction systems have some limitations for many advanced applications such as cooperative work, in which transactions need to cooperate with each other. For example, in cooperative environments, several designers might work on the same project. Each designer starts up a cooperative transaction. Those cooperative transactions jointly form a transaction group. Cooperative transactions in the same transaction group may read or update each other's uncommitted (unfinished) data. Therefore, cooperative transactions may be interdependent. Currently, some research work on advanced TP has been conducted in several related areas such as computer-supported cooperative work (CSCW) and groupware, workflow, and advanced transaction models (2–6). In this article, we will first discuss traditional transaction concepts and then examine some advanced transaction models.

Because of recent developments in laptop or notebook computers and low-cost wireless digital communication, mobile computing began to emerge in many applications. As wireless computing leads to situations where machines and data no longer have fixed locations in the network, distributed transactions will be difficult to coordinate, and data consistency will be difficult to maintain. In this article, we will also briefly discuss the problems and possible solutions in mobile transaction processing.

This paper is organized as follows. First, we will introduce traditional database TP, including concurrency control and recovery in centralized database TP. The next section covers the topics on distributed TP. Then, we discuss advanced TP and define an advanced transaction model and a correctness criterion. Mobile TP is also presented. Finally, future research directions are included.

DATABASE TRANSACTION PROCESSING

As database systems are the earlier form of TP systems, we will start with database TP.

Databases Transactions

A database system refers to a database and the access facilities (DBMS) to the database. One important job of DBMSs is to control and coordinate the execution of concurrent database transactions.

A database is a collection of related data items that satisfy a set of integrity constraints. The database should reflect the relevant state as a snapshot of the part of the real world it models. It is natural to assume that the states of the database are constrained to represent the legal (permissible) states of the world. The set of *intintegrity constraints* such as functional dependencies, referential integrity, inclusion, exclusion constraints, and some other user-defined constraints are identified in the process of information analysis of the application domain. These constraints represent real-world conditions or restrictions (7). For example, functional dependencies specify some constraints between two sets of attributes in a relation schema, whereas referential integrity constraints specify constraints between two sets of attributes from different relations. For detailed definitions and discussions on various constraints, we refer readers to Refs. 7 and 8. Here, we illustrate only a few constraints with a simple example.

Suppose that a relational database schema has the following two table structures for Employee and Department with attributes like Name and SSN:

Employee (Name, SSN, Bdate, Address, Dnumber)
Department (Dname, Dnumber, Dlocation).

Name = employee name
SSN = social security number
Bdate = birth date
Address = living address
Dnumber = department number

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

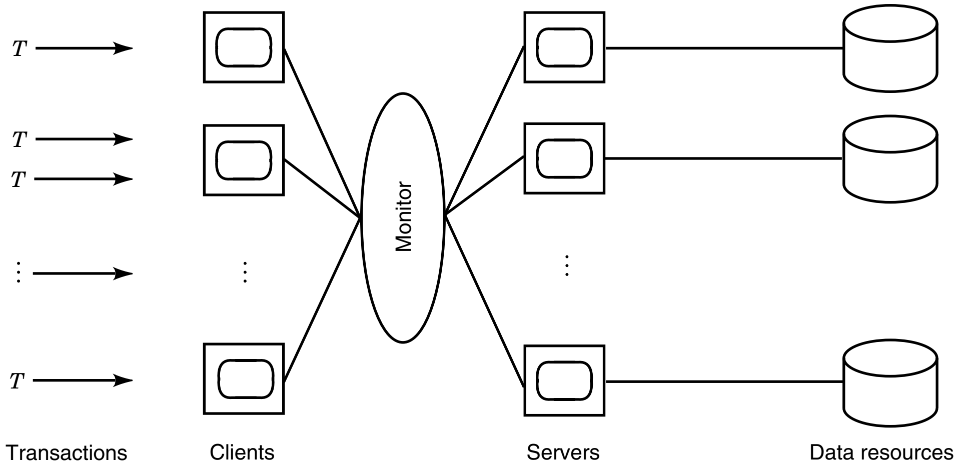

Figure 1. TP monitor between clients Data resources and data resources.

Dname = department name

Dlocation = department location

Each employee has a unique social security number (SSN) that can be used to identify the employee. For each SSN value in the Employee table, there will be only one associated value for Bdate, Address, and Dnumber in the table, respectively. In this case, there are functional dependencies from SSN to Bdate, Address, Dnumber. If any Dnumber value in the Employee relation has the same Dnumber value in the Department relation, there will be a referential integrity constraint from *Employee*'s Dnumber to *Department*'s Dnumber.

A database is said to be "consistent" if it satisfies a set of integrity constraints. It is assumed that the initial state of the database is consistent. As an empty database always satisfies all constraints, often it is assumed that the initial state is an empty database. It is obvious that a database system is not responsible for possible discrepancies between a state of the real world and the corresponding state of the database if the existing constraints were inadequately identified in the process of information analysis. The values of data items can be queried or modified by a set of application programs or transactions. As the states of the database corresponding to the states of the real world are consistent, a transaction can be regarded as a transformation of a database from one consistent state to another consistent state. Users' access to a database is facilitated by the software system called a DBMS, which provides services for maintaining consistency, integrity, and security of the database. Figure 2 illustrates a simplified database system. The transaction scheduler provides functions for transaction concurrency control, and the recovery manager is for transaction recovery in the presence of failures, which will be discussed in the next section.

The fundamental purpose of the DBMS is to carry out queries and transactions. A query is an expression, in a suitable language, that determines a portion of the data contained in the database (9). A query is considered as a read-only transaction. The goal of query processing is extracting information from a large amount of data to assist a decision-making process. A transaction is a piece of programming that manipulates the database by a sequence of read and write operations.

read(X) or R(X), which transfers the data item *X* from the database to a local buffer of the transaction

write(X) or W(X), which transfers the data item *X* from the local buffer of the transaction back to the database

In addition to *read* and *write* operations, a transaction starts with a *start* (or *begin*) operation and ends with a *commit* operation when the transaction succeeds or an *abort* when the transaction fails to finish. The following example shows a transaction transferring funds between two bank accounts (*start* and *end* operations are omitted).

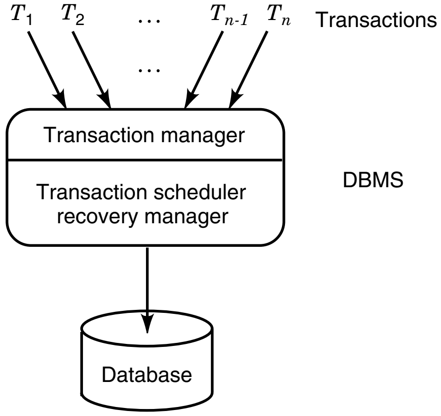

Figure 2. Database system and DBMS.

Example 1. Bank transfer transaction.

```
read($X$)
$X \rightarrow X + 100$
write($X$)
read($Y$)
$Y \rightarrow Y - 100$
write($Y$)
```

Here, X and Y stand for the balances of savings and credit accounts of a customer, respectively. This transaction transfers some money ($100) from the savings account to the credit account. It is an atomic unit of database work. That is, all these operations must be treated as a single unit.

Many database systems support multiple user accesses or transactions to the database. When multiple transactions execute concurrently, their operations are interleaved. Operations from one transaction may be executed between operations of other transactions. This interleaving may cause inconsistencies in a database, even though the individual transactions satisfy the specified integrity constraints. One such example is the *lost update* phenomenon.

Example 2. For the lost update phenomenon, assume that two transactions, crediting and debiting the same bank account, are executed at the same time without any control. The data item being modified is the account balance. The transactions read the balance, calculate a new balance based on the relevant customer operation, and write the new balance to the file. If the execution of the two transactions interleaves in the following pattern (supposing the initial balance of the account is $1500), the customer will suffer a loss:

Debit Transaction	Credit Transaction
read balance ($1500)	read balance ($1500)
withdraw ($1000)	deposit ($500)
balance := $1500 − $1000	balance := $1500 + $500
Write balance ($500)	Write balance ($2000)

The final account balance is $500 instead of $1000. Obviously, these two transactions have produced an inconsistent state of the database because they were allowed to operate on the same data item and neither of them was completed before another. In other words, neither of these transactions was treated as an atomic unit in the execution. Traditionally, transactions are expected to satisfy the following four conditions, known as ACID properties (9–11):

- *Atomicity* is also referred to as the all-or-nothing property. It requires that either all or none of the transaction's operations are performed. Atomicity requires that if a transaction fails to commit, its partial results cannot remain in the database.
- *Consistency* requires a transaction to be correct. In other words, if a transaction is executed alone, it takes the database from one consistent state to another. When all the members of a set of transactions are executed concurrently, the DBMS must ensure the consistency of the database.
- *Isolation* is the property that an incomplete transaction cannot reveal its results to other transactions before its commitment, which is the requirement for avoiding the problem of *cascading abort* (i.e., the necessity to abort all the transactions that have observed the partial results of a transaction that was later aborted).
- *Durability* means that once a transaction has been committed, all the changes made by this transaction must not be lost even in the presence of system failures.

The ACID properties are also defined in RM-ODP (Reference Model of Open Distributed Processing) (12). ODP is a standardization in a joint effort of the International Standardization Organization (ISO) and International Telecommunication Union (ITU), which describes systems that support heterogeneous distributed processing both within and between organizations through the use of a common interaction model.

Consistency and isolation properties are taken care of by the concurrency control mechanisms, whereas the maintenance of atomicity and durability are covered by the recovery services provided in transaction management. Therefore, concurrency control and recovery are the most important tasks for transaction management in a database system.

Concurrency Control and Serializability

The ACID properties can be trivially achieved by the sequential execution of transactions, which, however, is not a practical solution because it severely damages system performance. Usually, a database system is operating in a multiprogramming, multiuser environment, and the transactions are expected to be executed in the database system concurrently. In this section, the concepts of transaction concurrency control, the schedule of transactions, and the correctness criterion used in concurrency control are discussed.

A database system must monitor and control the concurrent executions of transactions so that overall correctness and database consistency are maintained. One of the primary tasks of the DBMS is to allow several users to interact with the database simultaneously, giving users the illusion that the database is exclusively for their own use (13). This feat is accomplished through a concurrency control mechanism.

Without a concurrency control mechanism, numerous problems can occur: the lost update (illustrated earlier in an example), the temporary update (or the uncommitted dependency), and the incorrect summary problems (7,14). The unwanted results may vary from annoying to disastrous in the critical applications. Example 3 shows a problem of temporary updates where a transaction T_B updates a data item f_1 but fails before completion. The value of f_1 updated by T_B has been read by another transaction T_A.

Example 3. Consider an airline reservation database system for customers booking flights. Suppose that a transaction A attempts to book a ticket on flight F_1 and on flight F_2 and that a transaction B attempts to cancel a booking on flight f_1 and to book a ticket on flight F_3.

Let f_1, f_2, and f_3 be the variables for the seat numbers that have been booked on flights F_1, F_2, and F_3, respectively. Assume that transaction B has been aborted for some reason so that the scenario of execution is as follows:

Transaction A	Transaction B
$R[f_1]$	$R[f_1]$
$f_1 = f_1 + 1$	$f_1 = f_1 - 1$
$W[f_1]$	$W[f_1]$
$R[f_2]$	$R[f_3]$
$f_2 = f_2 + 1$	$f_3 = f_3 + 1$
$W[f_2]$	$W[f_3]$
Commit transaction A	Abort transaction B

It is obvious that both transactions are individually correct if they are executed in a serial order (i.e., one commits before another). However, the interleaving of the two transactions shown here causes a serious problem in that the seat on fight F_1 canceled by transaction B may be the last seat available and transaction A books it before transaction B aborts, which results in one seat being booked by two clients.

Therefore, a database system must control the interaction among the concurrent transactions to ensure the overall consistency of the database. The execution sequence of operations from a set of transactions is called a *schedule*(15,16). A schedule indicates the interleaved order in which the operations of transactions were executed. If the operations of transactions are not interleaved (i.e., the executions of transactions are ordered one after another) in a schedule, the schedule is said to be serial. As we mentioned earlier, the serial execution of a set of correct transactions preserves the consistency of the database. As serial execution does not support concurrency, the equivalent schedule has been developed and applied for comparisons of a schedule with a serial schedule, such as view equivalence and conflict equivalence of schedules. In general, two schedules are *equivalent* if they have the same set of operations producing the same effects in the database (15).

Definition 1. Two schedules S_1, S_2 are *view equivalent* if

1. for any transaction T_i, the data items read by T_i in both schedules are the same; and
2. for each data item x, the latest value of x is written by the same transaction in both schedules S_1 and S_2.

Condition 1 ensures that each transaction reads the same values in both schedules, and

Condition 2 ensures that both schedules result in the same final systems.

In conflict equivalence, only the order of conflict operations needs to be checked. If the conflict operations follow the same order in two different schedules, the two schedules are conflict equivalent.

Definition 2. Two operations are in *conflict* if

1. they come from different transactions and
2. they both operate on the same data item and at least one of them is a write operation.

Definition 3. Two schedules S_1 and S_2 are *conflict equivalent* if for any pair of transactions T_i and T_j in both schedules and any two conflicting operations $O_{ip} \in T_i$ and $O_{jq} \in T_j$, when the execution order O_{ip} precedes O_{jq} in one schedule, say S_1, the same execution order must exist in the other schedule, S_2.

Definition 4. A schedule is *conflict serializable* if it is conflict equivalent to a serial schedule. A schedule is *view serializable* if it is view equivalent to a serial schedule.

A conflict serializable schedule is also view serializable but not vice versa because definition of view serializability accepts a schedule that may not necessarily be conflict serializable. There is no efficient mechanism to test schedules for view serializability. It was proven that checking for view serializability is an NP-complete problem (17). In practice, the conflict serializability is easier to implement in the database systems because the serialization order of a set of transactions can be determined by their conflicting operations in a serializable schedule.

The conflict serializability can be verified through a conflict graph. The conflict graph among transactions is constructed as follows: For each transaction T_i, there is a node in the graph (we also name the node T_i). For any pair of conflicting operations (o_i, o_j), where o_i from T_i and o_j from T_j, respectively, and o_i comes before o_j, add an arc from T_i to T_j in the conflict graph.

Examples 4 and 5 present schedules and their conflict graphs.

Example 4. A nonserializable schedule is shown here. Its conflict graph is shown in Fig. 3.

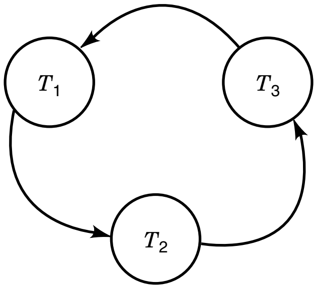

Figure 3. Conflict graph 1 (with a cycle).

Schedule	T_1	T_2	T_3
read(A)	read(A)		
read(B)		read(B)	
$A \leftarrow A + 1$	$A \leftarrow A + 1$		
read(C)			read(C)
$B \leftarrow B + 2$		$B \leftarrow B + 2$	
write(B)		write(B)	
$C \leftarrow C * 3$			$C \leftarrow C * 3$
write(C)			write(C)
write(A)	write(A)		
read(B)			read(B)
read(A)		read(A)	
$A \leftarrow A - 4$		$A \leftarrow A - 4$	
read(C)	read(C)		
write(A)		write(A)	
$C \leftarrow C - 5$	$C \leftarrow C - 5$		
write(C)	write(C)		
$B \leftarrow 6 * B$			$B \leftarrow 6 * B$
write(B)			write(B)

Example 5. A serializable schedule is shown here. Its conflict graph is shown in Fig. 4.

Schedule	T_1	T_2	T_3
read(A)	read(A)		
$A \leftarrow A + 1$	$A \leftarrow A + 1$		
read(C)	read(C)		
write(A	write(A)		
$C \leftarrow C - 5$	$C \leftarrow C - 5$		
read(B)		read(B)	
write(C)	write(C)		
read(A)		read(A)	
read(C)			read(C)
$B \leftarrow B + 2$		$B \leftarrow B + 2$	
write(B)		write(B)	
$C \leftarrow 3 * C$			$C \leftarrow 3 * C$
read(B)			read(B)
write(C)			write(C)
$A \leftarrow A - 4$		$A \leftarrow A - 4$	
write(A)		write(A)	
$B \leftarrow 6 * B$			$B \leftarrow 6 * B$
write(B)			write(B)

The following theorem shows how to check the serializability of a schedule.

Theorem 1. A schedule is conflict serializable if and only if its conflict graph is acyclic (15).

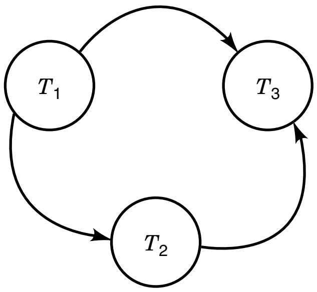

Figure 4. Conflict graph 2 (without cycle).

Intuitively, if a conflict graph is acyclic, the transactions of the corresponding schedule can be topologically sorted such that conflict operations are consistent with this order, and therefore equivalent to a serial execution in this order. A cyclic graph implies that no such order exists. The schedule in Example 4 is not serializable because there is cycle in the conflict graph; however, the schedule in Example 5 is serializable. The serialization order of a set of transactions can be determined by their conflicting operations in a serializable schedule.

In order to produce conflict serializable schedules, many concurrency control algorithms have been developed such as two-phase locking, timestamp ordering, and optimistic concurrency control.

The Common Concurrency Control Approaches

Maintaining consistent states in a database requires such techniques as semantic integrity control, transaction concurrency control, and recovery. Semantic integrity control ensures database consistency by rejecting update programs that violate the integrity constraints of the database, which is done by specifying the constraints during the database design. Then the DBMS checks the consistency during transaction executions. Transaction concurrency control monitors the concurrent executions of programs so that the interleaved changes to data items still preserve the database consistency. Recovery of a database system ensures that the system can cope with various failures in the system and recover the database to a consistent state.

A number of concurrency control algorithms have been proposed for the DBMSs. The most fundamental algorithms are two-phase locking (18,19), timestamp ordering (20,21), optimistic concurrency control (22), and serialization graph testing (23,24).

Two-phase locking (2PL) is one of the most popular concurrency control algorithms based on the locking technique. The main idea of locking is that each data item must be locked before a transaction accesses it (i.e., if conflicting operations exist, only one of them can access the data at a time, and the other must wait until the previous operation has been completed and the lock has been released). A transaction may involve accesses to many data items. The rule of 2PL states that all locks of the data items needed by a transaction should be acquired before a lock is released. In other words, a transaction should not release a lock until it is certain that it will not request any more locks. Thus, each transaction has two phases: an *expanding phase* during which new locks on data items can be acquired but none can be released and a *shrinking phase* in which the transaction releases locks and no new locks are required.

The 2PL algorithm is a very secure way to ensure that the order of any two transactions is compatible with the order of their conflicting operations. More precisely, if $o_{ip} \in T_i$ precedes $o_{jq} \in T_j$ in the schedule and o_{ip} is in conflict with o_{jq}, then all other conflicting operations of T_i, T_j must have the same order of precedence. The 2PL algorithms guarantee the conflict serializability of a schedule for concurrent transactions. However, 2PL algorithms may lead to deadlocks when a set of transactions wait for each other in a circular way. For example, two transactions T_1 and T_2 both write data items a and b. T_1 holds a lock on a and waits for a lock on b, whereas T_2 holds a lock on b and waits for a lock on a. In this case, T_1 and T_2 will be waiting for each other, and a deadlock occurs. When a deadlock occurs, some transactions need to be aborted to break the cycle.

Timestamp ordering (TO) is used to manage the order of the transactions by assigning timestamps to both transactions and data items. Each transaction in the system is associated with a unique timestamp, assigned at the start of the transaction, which is used to determine the order of conflicting operations between transactions. Each data item is associated with a read timestamp, which is the timestamp of the latest transaction that has read it, and a write timestamp, which is the timestamp of the latest transaction that has updated it. Conflicting operations must be executed in accordance with their corresponding transaction timestamps. A transaction will be aborted when it tries to read or write on a data item whose timestamp is greater than that of the transaction. The serializable order of transactions is the order of their timestamps.

Both 2PL and TO concurrency control algorithms are considered pessimistic approaches. The algorithms check every operation to determine whether the data item is available according to the locking or timestamp, even though the probability of conflicts between transactions is very small. This check represents significant overhead during transaction execution, with the effect of slowing down the TP.

Optimistic concurrency control (OCC) (22) is another approach in which no check is done while the transaction is executing. It has better performance if it is used in the environment where conflicts between transactions are rare. During transaction execution, each transaction executes three phases in its life time. The following three phases are used in the OCC protocol:

1. *Read Phase*. The values of the data items are read and stored in the local variables of the transaction. All modifications on the database are performed on temporary local storage without updating the actual database.
2. *Validation Phase*. According to the mutually exclusivity rules, a validation test is performed to determine whether the updates can be copied to the actual database.
3. *Write Phase*. If the transaction succeeds in the validation phase, the actual updates are performed to the database; otherwise, the transaction is aborted.

Optimistic approaches are generally used in conjunction with timestamps. A timestamp is assigned to a transaction at the end of its read phase or before the validation phase. The serialization order of transactions is then validated using the timestamps.

In a *serialization graph*-based concurrency control protocol, an online serialization graph (conflict graph) is explicitly maintained. The serialization graph testing (SGT) scheduler maintains a serialization graph for the history that represents the execution it controls. When a SGT scheduler receives an operation o_i of transaction T_i from the transaction manager, it first adds a node for T_i in the serialization graph (SG). The scheduler then checks whether there exists a previously scheduled operation o_k of transaction T_k conflicting with o_i. If there is one, an arc from T_k to T_i is added to the SG. The operations of transaction T_i can be executed as long as the graph is acyclic. Otherwise, the transaction, which causes a cycle in the graph, is aborted. As the acyclic serialization graph guarantees the serializability of the execution, the SGT scheduler produces the correct schedules for the concurrent transactions. However, it is not necessarily recoverable and is much less cascadeless or strict (14) as defined later.

A schedule S is said to be recoverable if, for every transaction T_i that reads data items written by another transaction T_j in S, T_i can be committed only after T_j is committed. That is, a recoverable schedule avoids the situation where a committed transaction reads the data items from an aborted transaction. A recoverable schedule may still cause cascading aborts because it allows the transactions to read from uncommitted transactions. For example, a transaction T_2 reads a data item x after x is updated by a transaction T_1, which is still active in an execution. If T_1 is aborted during the processing, T_2 must be aborted. Cascading aborts are undesirable.

To avoid cascading abortion in a schedule S, every transaction should read only those values written by committed transactions. Thus, a cascadeless schedule is also a recoverable schedule.

As a cascadeless schedule allows a transaction to write data from an uncommitted transaction, an undesirable situation may occur (14). For instance, consider the scenario of an execution

$$W_{T_1}[x,\ 2]W_{T_2}[x,\ 4].\,\mathrm{Abort}(T_1)\mathrm{Abort}(T_2)$$

where two transactions T_1 and T_2 write the same data item x, with values 2 and 4, respectively, and both are aborted later. The value of the data item x is called a before image if it will be replaced by a new value. The *before image* is saved in the log. In this case, the before image of data item x for transaction T_2 is 2 written by an aborted transaction T_1.

The term *strict schedule* was introduced in Ref. 14 to describe a very important property from a practical viewpoint. A schedule of transactions is called strict if the transactions read or write data items only from committed transactions. Strict schedules avoid cascading aborts and are recoverable. They are conservative and offer less concurrency.

The concurrency control algorithms presented above, such as 2PL, TO, and SGT, do not necessarily produce strict schedules by themselves.

If a strict schedule using 2PL algorithm is required, the locks being held by any transaction can be released only after the transaction is committed.

A TO approach with a strict schedule will not allow a transaction T to access the data items that have been updated by a previous uncommitted transaction even if transaction T holds a greater timestamp.

SGT can produce a strict schedule in such a way that each transaction cannot be committed until it is a source node of the serialization testing graph. That is, a transaction T could not be involved in a cycle of the serializable testing graph if previous transactions that T reads or writes from have all been committed.

Recoverability of Transactions

In addition to concurrency control, another important goal of transaction management is to provide a reliable and consistent database in the presence of various failures. Failures may corrupt the consistency of the database because the execution of some transactions may be only partially completed in the database. In general, database systems are not failure-free systems. A number of factors cause failures in a database system (9) such as:

1. *Transaction Abortions*. The situation can be caused by the transaction itself, which is caused by some unsatisfactory conditions. Transaction abortion can also be forced by the system. These kinds of failure do not damage the information stored in memory, which is still available for recovery.
2. *System Crashes*. The typical examples of this type of failure are system crashes or power failures. These failures interrupt the execution of transactions, and the content of main memory is lost. In this case, the only available accessible information is from a stable storage, usually a disk.
3. *Media Failures*. Failures of the secondary storage devices that store the database are typical of media failure. As the content of stable storages has been lost, the system cannot be recovered by the system software only. The common technique to prevent such unrecoverable failures is to replicate the information on several disks.

The first two types of failures are considered in the recovery of transactions. Transactions represent the basic units of recovery in a database system. If the automicity and durability of the execution of each transaction have been guaranteed in the presence of failures, the database is considered to be consistent.

Typically, the piece of software responsible for recovery of transactions is called the recovery manager (RM). It is required to ensure that whenever a failure occurs, the database is brought back to the consistent state it was in before the failure occurred. In other words, the RM should guarantee that updates of the database by the committed transactions are permanent, in contrast to any partial effects of uncompleted transactions that should be aborted.

The basic technique for implementing transactions in the presence of failures is based on the use of logs. A log is a file that records all operations on the database carried out by all transactions. It is supposed that a log is accessible after the failures occur. The log is stored in *stable storage*, which is the most resilient storage medium available in the system. Stable storage is also called *secondary storage*. Typically, it is implemented by means of duplexed magnetic tapes or disks that store duplicate copies of the data. The replicated stable storage is always kept mutually consistent with the primary copy of the disk or tape. The database is stored permanently on stable storage. The updates on a database by a transaction are not directly written into the database immediately. The operations of the transactions are implemented in the *database buffer* located in main memory (also referred to as volatile storage). It is only when the contents of the database buffer have been *flushed* to stable storage that any update operation can be regarded as durable.

It is essential that the log record all the updates on the database that have been carried out by the transactions in the system before the contents of the database buffer have been written to database, which is the rule of *write-ahead log*.

A log contains the information for each transaction as follows:

- transaction identifier;
- list of update operations performed by the transaction (for each update operation, both the old value and the new value of the data items are recorded); and
- status of the transaction: tentative, committed, or aborted.

The log file records the required information for undoing or redoing the transaction if a failure occurs. As the updates were written to the log before flushing the database buffer to the database, the RM can surely preserve the consistency of the database. If a failure occurs before the commit point of a transaction is reached, the RM will abort the transaction by *undo*ing the effect of any partial results that have been flushed into the database. On the other hand, if a transaction has been committed but the results have not been written into the database at the time of failure, the RM would have to *redo* the transaction, using the information from the log, in order to ensure transaction durability.

DISTRIBUTED TRANSACTION PROCESSING

In many applications, both data and operations are often distributed. A database is considered distributed if a set of data that belongs logically to the same system is physically spread over different sites interconnected by a computer network. A site is a host computer and the network is a computer-to-computer connection via the communication system. Although the software components that are typically necessary for building a DBMS are also the principal components for a distributed DBMS (DDBMS), some additional capacities must be provided for a distributed database, such as the mechanisms of distributed concurrency control and recovery.

One of the major differences between a centralized and a distributed database system lies in the TP. In a distributed database system, a transaction might involve data residing on multiple sites (called a global transaction). A global transaction is executed on more than one site. It consists of a set of subtransactions, each subtransaction involving data residing on one site. As in centralized databases, global transactions are required to preserve the ACID properties. These properties must be maintained individually on each site and also globally. That is, the concurrent global transactions must be serializable and recoverable in the distributed database system. Consequently, each subtransaction of a global transaction must be either performed in its entirety or not performed at all.

Serializability in a Distributed Database

Global transactions perform operations at several sites in a distributed database system (DDBS). It is well understood that the maintenance of the consistency of each single database does not guarantee the consistency of the entire distributed database. It follows, for example, from the fact that serializability of executions of the subtransactions on each single site is only a necessary (but not sufficient) condition for the serializability of the global transactions. In order to ensure the serializability of distributed transactions, a condition stronger than the serializability of single schedule for individual sites is required.

In the case of distributed databases, it is relatively easy to formulate a general requirement for correctness of global transactions. The behavior of a DDBS is the same as a centralized system but with distributed resources. The execution of the distributed transactions is correct if their schedule is serializable in the whole system. The equivalent conditions are:

- Each local schedule is serializable, and
- The subtransactions of a global transaction must have a compatible serializable order at all participating sites.

The last condition means that, for any two global transactions G_i and G_j, their subtransactions must be scheduled in the same order at all the sites on which these subtransactions have conflicting operations. Precisely, if G_{ik} and G_{jk} belongs to G_i and G_j, respectively, and the local serializable order is G_{ik} precedes G_{jk} at site k, then all the subtransactions of G_i must precede the subtransactions of G_j at all sites where they are in conflict.

Various concurrency control algorithms such as 2PL and TO have been extended to DDBS. As the transaction management in a DDBS is implemented by a number of identical local transaction managers, the local transaction managers cooperate with each other for the synchronization of global transactions. If the timestamp ordering technique is used, a global timestamp is assigned to each subtransaction, and the order of timestamps is used as the serialization order of global transactions. If a two-phase locking algorithm is used in the DDBS, the locks of a global transaction cannot be released at all local sites until all the required locks are granted. In distributed systems, the data item might be replicated. The updates to replicas must be atomic (i.e., the replicas must be consistent at different sites). The following rules may be used for locking with n replicas:

1. Writers need to lock all n replicas; readers need to lock one replica.
2. Writers need to lock all m replicas ($m > n/2$); readers need to lock $n - m + 1$ replicas.
3. All updates are directed first to a primary copy replica (one copy has been selected as the primary copy for updates first and then the updates will be propagated to other copies).

Any one of these rules will guarantee consistency among the duplicates.

Atomicity of Distributed Transactions

In a centralized system, transactions can either be processed successfully or aborted with no effects left on the database in the case of failures. In a distributed system, however, additional types of failure may happen.

For example, network failures or communication failures may cause network partition, and the messages sent from one site may not reach the destination site. If there is a partial execution of a global transaction at a partitioned site in a network, it would not be easy to implement the atomicity of a distributed transaction. To achieve an atomic commitment of a global transaction, it must be ensured that all its subtransactions at different sites are capable and available to commit. Thus, an agreement protocol has to be used among the distributed sites. The most popular atomic commitment protocol is the two-phase commitment (2PC) protocol.

In the basic 2PC, there is a *coordinator* at the originating site of a global transaction. The participating sites that execute the subtransactions must commit or abort the transaction unanimously. The coordinator is responsible for making the final decision to terminate each subtransaction. The first phase of 2PC is to request from all *participants* the information on the execution state of subtransactions. The participants report to the coordinator, which collects the answers and makes the decision. In the second phase, that decision is sent to all participants. In detail, the 2PC protocol proceeds as follows for a global transaction T_i(9):

Two-Phase Commit Protocol Phase 1: Obtaining a Decision.

1. Coordinator asks all participants to prepare to commit transaction T_i:
   a. Add [prepare T_i] record to the log.
   b. Send [prepare T_i] message to each participant.
2. When a participant receives [prepare T_i] message, it determines if it can commit the transaction:
   a. If T_i has failed locally, respond with [abort T_i].
   b. If T_i can be committed, send [ready T_i] message to the coordinator.
3. Coordinator collects responses:
   a. All respond "ready"; decision is commit.
   b. At least one response is "abort"; decision is abort.
   c. At least one fails to respond within time-out period, decision is abort.

Phase 2: Recording the Decision in the Database1.

1. Coordinator adds a decision record ([abort T_i] or [commit T_i]) in its log.
2. Coordinator sends a message to each participant informing it of the decision (commit or abort).
3. Participant takes appropriate action locally and replies "done" to the coordinator.

The *first phase* is that the coordinator initiates the protocol by sending a "prepare-to-commit" request to all participating sites. The "prepare" state is recorded in the log, and the coordinator is waiting for the answers. A participant will reply with a "ready-to-commit" message and record the "ready" state at the local site if it has finished the operations of the subtransaction successfully. Otherwise, an "abort" message will be sent to the coordinator, and the subtransaction will be rolled back accordingly.

The *second phase* is that the coordinator decides whether to commit or abort the transaction based on the answers from the participants. If all sites answered "ready-to-commit," then the global transaction is to be committed. The final "decision-to-commit" is issued to all participants. If any site replies with an "abort" message to the coordinator, the global transaction must be aborted at all the sites. The final "decision-to-abort" is sent to all the participants who voted the "ready" message. The global transaction information can be removed from the log when the coordinator has received the "completed" message from all the participants.

The basic idea of 2PC is to make an agreement among all the participants with respect to committing or aborting all the subtransactions. The atomic property of global transaction is then preserved in a distributed environment.

The 2PC is subject to the blocking problem in the presence of site or communication failures. For example, suppose that a failure occurs after a site has reported "ready-to-commit" for a transaction, and a global commitment message has not yet reached this site. This site would not be able to decide whether the transaction should be committed or aborted after the site is recovered from the failure. A three-phase commitment (3PC) protocol (14) has been introduced to avoid the blocking problem. But 3PC is expensive in both time and communication cost.

Transaction Processing in Heterogeneous Systems

Traditional DDBS are often homogeneous because local database systems are the same, using the same data models, the same languages, and the same transaction managements. However, in the real world, data are often partitioned across multiple database systems, file systems, and applications, all of which may run on different machines. Users may run transactions to access several of these systems as single global transactions. A special case of such systems are multidatabase systems or federated database systems.

As the 2PC protocol is essential to support the atomicity of global transactions and, at the same time, the local systems may not provide such support, layers of software are needed to coordinate and the execution of global transactions (25) for transactional properties of concurrency and recovery. A TP monitor is a piece of software that connects multiple clients to multiple servers to access multiple databases/data resources as shown in Fig. 1. Further discussions on TP monitors can be found in Ref. 1.

ADVANCED TRANSACTION PROCESSING

In traditional database applications such as banking and airline reservation systems, transactions are short and noncooperative and usually can be finished in minutes. The serializability is a well-accepted correctness criterion for these applications. TP in advanced applications such as cooperative work will have different requirements, need different correctness criteria, and require different systems supports to coordinate the work of multiple designers/users and to maintain the consistency. Transactions are often called advanced transactions if they need nonserializable correctness criteria. Many advanced transaction models have been discussed in the literature 2–5. In this section, we will briefly examine some advanced transaction models and then present a general advanced transaction model and its correctness criterion.

Advanced Transaction Model

In addition to advanced transactions, we can also see other similar terms such as nontraditional transactions, long transactions, cooperative transactions, and interactive transactions. We will briefly list some work on advanced TP or cooperative TP in advanced database transaction models (2,3), groupware (4,26,27), and workflow systems (5,28).

Advanced Database Transaction Models (3).

1. Saga (29). A transaction in Saga is a long-lived transaction that consists of a set of relatively independent steps or subtransactions, T_1, T_2 ,..., T_n. Associated with each subtransaction T_i is a compensating transaction C_i, which will undo the effect of T_i. Saga is based on the compensation concept. Saga relaxes the property of isolation by allowing a Saga transaction to reveal its partial results to other transactions before it completes. As a Saga transaction can interleave its subtransactions with subtransactions of other sagas in any order, consistency or serializability is compromised. Saga preserves atomicity and durability of traditional transaction by using forward and backward recoveries.
2. Cooperative Transaction Hierarchy (30). This model supports cooperative applications like computer-aided design (CAD). It structures a cooperative application as a rooted tree called a cooperative transaction hierarchy. The external nodes represent the transactions associated with the individual designers. An internal node is called a transaction group. The term cooperative transaction refers to transactions with the same parent in the transaction tree. Cooperative transactions need not to be serial-

izable. Isolation is not required. Users will define correctness by a set of finite automata to specify the interaction rules between cooperative transactions.

3. Cooperative SEE Transactions (31). This model supports cooperative work in software engineering environments (SEEs). It uses nested active transactions with user-defined correctness. ACID properties are not supported.
4. DOM Transaction Model for distributed object management (32). This model uses open and closed nested transactions and compensating transactions to undo the committed transactions. It also use contingency transactions to continue the required work. It does not support ACID properties.
5. Others (3). Open nested transactions, ConTract, Flex, S, and multilevel transactions models use compensating transactions and contingency transactions. The ACID properties are compromised. The polytransaction model uses user-defined correctness. Tool Kit also uses user-defined correctness and contingency transactions to achieve the consistency.

Groupware (2,26,33). Most groupware systems synchronize cooperative access to shared data in a more or less ad hoc manner. Groupware systems involve multiple concurrent users or several team members at work on the same task. The members, or users, are often in different locations (cities or even countries). Each team member starts up a cooperative transaction, each cooperative transaction should be able to see the intermediate result of other cooperative transactions, and these cooperative transactions jointly form a cooperative transaction group. When they read or update the uncommitted data from other cooperative transactions, nonserializable synchronization and concurrency mechanisms are required to maintain consistency. A cooperative editing system is an example.

Workflow Applications (5). Workflow is used to analyze and control complicated business processes. A large application often consists of a collection of tasks. Each task can be viewed as a cooperative transaction processed by one user or designer, and these tasks are partially ordered by control and data flow dependencies. The workflow supports the task coordination specified in advance through the control flow. Serializability is not preserved either.

These applications have some common properties: (1) users are often distributed; (2) they conduct some cooperative work in an interactive fashion; and (3) this interactive cooperative work may take a long time. These applications have the following special consistency requirements:

1. A transaction may read intermediate results produced by other transactions.
2. The consistency between individual and group needs to be maintained.

Based on this summary, we give the following definition.

Definition 5. An advanced transaction (cooperative transaction group) is defined as a set (group) of cooperative transactions $T_1, T_2, \ldots, T_n$, with the following properties:

1. Each cooperative transaction is a sequence (or partial order) of read(x) and write(y) operations.
2. For the same data item, there might be more than one read(x), written as read^1(x), read^2(x), . . ., in a cooperative transaction, and each read(x) will get a different value depending on the time and interaction with other transactions.
3. Similarly, for each y, there might be more than one write(y), written as write^1(y),,write^2(Y), . . ., each of which will produce an individual version of data item y.

The first part shows that an advanced transaction is a cooperative transaction group. If the size of the group is one, it will become a single transaction. The property 1 is the same as that in traditional transactions. The second and third properties indicate some cooperative features. The first read(x) may read other transaction's committed or uncommitted data depending on the concurrency control employed. After the first read operation on x, the data item might be updated by another transaction or another cooperative transaction; then it can read the new value in the next read(x). Similarly, after the first write operation on x, because of the cooperative feature, a transaction may read some new data from other transactions and then issue another write(x) to incorporate it to the current processing. The later write(x) can undo the previous write or do a further update to show the new semantics.

To further justify the second and third properties of the definition, we discuss their compatibilities with interactive and noninteractive transactions in advanced transaction applications.

Interactive Transactions. A cooperative transaction can be formed with great flexibility because a user can dynamically issue an operation depending on the most current information. If a data item has been updated recently after the first read, the cooperative transaction may wish to read the data again because of the cooperative feature. In order to incorporate the recent changes in to its own transaction, it can perform additional operations or compensate for the previous operations, which is also the flexibility of interactive work.

Noninteractive Transactions. In some database transaction models, the transactions are not as interactive as those online transactions from groupwares and transaction workflow applications (3). To maintain system consistency and meet the application requirements, all of them use compensating transactions, contingency transactions, or triggers, where a compensating transaction is a transaction undoing the effect of a previous transaction; a contingency transaction is a transaction to continue or extend a previous transaction; and the trigger is a mechanism to invoke another transaction (if the trigger condition is true) to restore the consistency. A compensating transaction, a contingency transaction, or a trigger can be viewed as an extension of a transaction that violates the consistency requirements during the execution, and the extended part will have the read and write operations on some data items in common. They are another type of interaction. These interactions need to be programmed in advance; therefore, they are not as flexible as interactive transactions. But the interactive features are still required even for these noninteractive database transaction applications.

Similar to distributed database transactions, the advanced transaction definition could be extended to a distributed advanced transaction as follows:

Definition 6. A distributed advanced transaction (distributed cooperative transaction group) is defined as a set (group) of cooperative transactions T_1, T_2,. . ., T_n, with the following properties:

1. Each transaction T_i consists of a set of subtransactions T_i^j at site j, $j \in [1 \cdot \cdot m]$, m is the number of sites in a distributed system. Some T_i^j might be empty if T_i has no subtransaction at site j.
2. Each subtransaction is a sequence (or partial order) of read(x) and write(y) operations.
3. For the same data item x, there might be more than one read(x), denoted as read^1(x), read^2(x),. . ., in a cooperative transaction, each read(x) will get a different value depending on the time and interaction with other transactions.
4. Similarly, for each y, there might be more than one write(y), denoted as write^1(y), write^2(y),. . ., each of which will produce an individual version of data item y.

Just as the serializability theory plays an important role in the traditional transaction model in developing concurrency control and recovery algorithms, a general correctness theory for advanced transactions is also required to guide transaction management for advanced applications. In the next subsection, we will present such a correctness criterion.

f-Conflict Serializability

As in the traditional transactions, we can assume that, for write operations on x, there must be a read operation before the first write in a cooperative transaction. It is natural to read the data first before the update [i.e., one's update may depend on the read value or one may use a read operation to copy the data into the local memory, then update the data and write it back (when the transaction commits)].

In advanced transaction applications, cooperative transactions could read and write a data item more than once, which is different from traditional transactions. The reason for reading a data item more than once is to know the recent result and therefore make the current transaction more accurate, which, however, will violate the serializability, because a cooperative transaction may read a data item before another transaction starts and also read the data updated by the same transaction. If so, the schedule between these two transactions will not be serializable. However, from the semantic point of view, the most important read or write on the same data item will be the last read or write. If we give high priority to the last read or write conflicts in developing the correctness criteria, we could have an f-conflict (final conflict) graph, based on which we will present an f-conflict serializability theorem as a general correctness criterion for advanced TP.

Definition 7. The f-conflict graph among transactions is constructed as follows. For each transaction T_i, there is a node in the graph (we also name the node T_i). For any pair of final conflicting operations (O_i, O_j), where O_i from T_i and O_j from T_j, respectively, and O_i comes earlier than O_j, add an arc from T_i to T_j in the conflict graph.

Definition 8. A schedule is f-conflict serializable if and only if its f-conflict graph is acyclic. The f-conflict serialization order of a set of transactions can be determined by their f-conflicting operations in an f-conflict serializable schedule. From the definitions, we can see the relationship between conflict serializability and f-conflict serializability.

Theorem 2. If a schedule is conflict serializable, it is also f-conflict serializable; the reverse is not true.

The conflict serializability is a special case of f-conflict serializability in traditional TP.

Definition 9. A schedule of distributed advanced transactions is f-conflict serializable if and only if

1. the schedule of subtransactions at each site is f-conflict serializable, and
2. the f-conflict serialization order at all sites are the same.

Advanced transactions or cooperative transactions may have different application-dependent requirements and require different system supports to coordinate the work of multiple users and to maintain the consistency. As a result, different synchronization, coordination, and control mechanisms within a cooperative transaction group are developed. The f-conflict serializability in conjunction with application-dependent semantics could be used for designing and testing advanced TP approaches. The application-dependent requirements can be reflected in the detailed transaction structures. For example, when there are several write operations on the same x, the later write might be to undo and then redo the operation (or perform a different operation). The undo operations might be reversing operations or compensating operations, and the redo operations could be contingency operations or new operations that may need to keep the intention (user intention) of the original write (6,27) or to incorporate the new semantics.

In a recent work, we have verified a cooperative editing system, REDUCE, according to this theory, and have shown that the schedules from this system is f-conflict serializable (34).

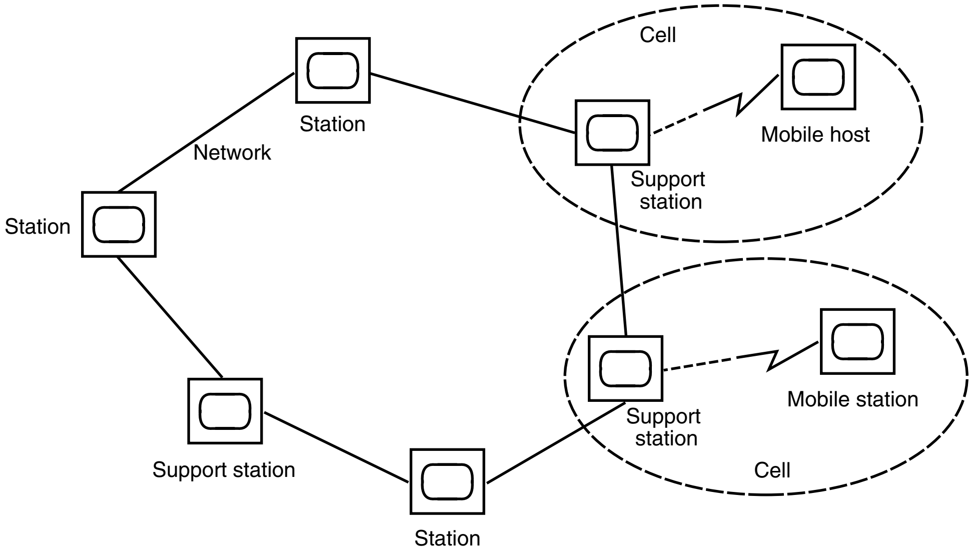

Figure 5. Wired and wireless net-working environment.

Advanced transactions are very long when compared with traditional transactions. The arbitrary abortion of such long transactions is not appropriate because aborting long transactions means increasing the processing cost and response time. In an environment with short (traditional) transactions and long/cooperative transactions, long/cooperative transactions should not be aborted because of conflict operations with short transactions. On the other hand, because the quick response is often required or preferred for short transactions, long transactions should not block the short transactions.

Based on the f-conflict serializability, a timestamp ordering concurrency control algorithm (35) is developed to support both traditional short transactions and long cooperative transactions. With this new timestamp ordering method, short transactions can be processed in the traditional way, as if there are no cooperative transactions. Therefore, they will not be blocked by long transactions; a cooperative transaction will not be aborted when there is a conflict with short transactions, rather, it will incorporate the recent updates into its own processing. The serializabilities, among short transactions, and between a cooperative transaction (group) and other short transactions, are all preserved.

Mobile Transaction Processing

In both centralized and DDBS, data and machines have fixed locations. As a result of recent advances in the development of portable computing devices and wireless communication networks, mobile computing began to emerge in many database applications. The mobile computing environment consists of mobile computers, known as mobile hosts, and a wired network of computers, some of which are mobile support stations through which mobile hosts can communicate with the wired network. Each mobile support station manages those mobile hosts within its cell, the geographical area it covers. Figure 5 shows both a wired and wireless connected networking environment.

Mobile computing systems can be viewed as an extension of distributed systems (36). However, to support TP in the mobile computing environment, physical limitations imposed by the nature of the networking environment have to be taken into consideration (37,38).

- Communication between mobile hosts and mobile support stations is asymmetric. Bandwidth in the upstream direction from mobile hosts to mobile support stations is low, resulting in excessive latency.
- Portable computing devices have a limited battery life, processing capability, and storage capacity.
- Most mobile hosts do not stay continuously connected, for a number of reasons, including reducing connection charges and saving power. Mobile hosts can also move between cells, disconnecting one cell to connect to another.

In such an environment, the characteristics of mobile transactions can differ in a number of ways from transactions in distributed systems (39,40).

- When a mobile host moves to a new cell during the execution of a transaction, it might need to continue its execution in another cell. Therefore, a mobile transaction might have to split its computation in that some parts of the computation are executed on the mobile host and others on different fixed hosts.
- A mobile transaction tends to be long-lived because of the high latency of wireless communication and long disconnection time.
- A mobile transaction tends to be prone to failure.

- A mobile transaction may be running in a distributed and heterogeneous system.

Traditional TP protocols may not address these distinctive characteristics of mobile computing systems and mobile transactions. To support TP in a mobile computing environment efficiently and effectively, a number of desirable features should be supported.

- Operations on shared data must ensure correctness of transactions executed on both mobile hosts and fixed hosts.
- Transaction aborts and blocking should be minimized to save resources and to increase concurrency. Early detection of data conflicts leading to transaction restarts is required.
- Communication between mobile hosts and support stations should be minimized and adaptable to the network connectivity.
- Autonomy for mobile transactions to be processed locally during disconnection should be supported.

A traditional distributed transaction consists of a set of subtransactions that are executed concurrently at multiple sites and there is one coordinator to coordinate the execution and commitment of these subtransactions. A mobile transaction is another kind of distributed transaction. The entire transaction can be submitted in a single request from the mobile host, or the operations of a transaction are submitted in multiple requests, possibly to different support stations in different cells. The former method involves a single coordinator for all the operations of the transaction, whereas the latter may involve multiple coordinators. For example, after submitting some operations (and getting partial results back), the mobile host might need to submit the remaining operations to another cell because it has moved to a new cell. The execution of the mobile transaction is not fully coordinated by a single coordinator because, to a certain extent, it depends on the movement of the mobile computer. The kangaroo transaction model (41) uses a split operation to create a new subtransaction when the mobile computer hops from one cell to another. A subtransaction is a global or a local transaction that can be committed independently and the failure of one may result in the entire kangaroo transaction being undone. To manage the execution of a kangaroo transaction, a data structure is maintained between the mobile support stations involved.

In typical multidatabase systems where users may simultaneously access heterogeneous data from different local databases, a global locking table can be maintained for correct execution of concurrent global and local transactions. In the mobile environment, intensive communication of locking information between the local sites and the global transaction manager is impractical because of the physical limitations of the networking environment. A hierarchical concurrency control algorithm using global locking table with semantic information contained within the hierarchy can be used to dynamically adjust the amount of communication required to detect and resolve data conflicts (42). To reduce the impact on local transactions due to the processing of the long-lived global transactions submitted by mobile users, the *Pre-Serialization* technique allows global transactions to establish their serialization order before completing execution (43). In this way, subtransactions of a global transaction can be committed independently at local sites and resources may be released in a timely manner.

Guaranteeing the consistency of data processed by mobile hosts is harder because mobile hosts are often disconnected from the rest of the network while still in operation. For instance, if a data item cached in a mobile computer is updated by another computer while the mobile computer is disconnected, the cached data will become inconsistent or out of date. If a conventional lock-based approach is adopted in the mobile computing environment to maintain data consistency, the system could suffer from significant performance degradation as the data items held by a long-lived mobile transaction could not be released until the transaction commits. To improve data availability, a transaction can *pre-commit* at the mobile host (44) so that the future value of a data object can be made visible to other transactions before the delayed final commit of the transaction at the mobile support station, which reduces the blocking of other transactions to increase concurrency and costly transaction aborts can also be avoided as a pre-committed transaction is guaranteed to commit.

During disconnection, mobile host users may issue query or update transactions on the data that reside locally. Data are often replicated or cached at mobile hosts for reasons of performance and availability. To support TP in a networking environment with intermittent links, *weak transactions*(45) let users access local data in mobile computing applications where bounded inconsistency is acceptable. In a weak transaction, weak read operations read local, potentially inconsistent copies and weak write operations perform tentative updates. Data reconciliation can be activated when the mobile computer is reconnected to the wired network.

In mobile computing systems, the number of mobile hosts is far greater than the number of support stations, and support stations have a relatively abundant downstream bandwidth. The pull-based architecture in traditional distributed systems, where data items are delivered from servers to clients on a demand basis, is no longer a good match in mobile computing systems. In contrast, push-based data delivery fits well the inherent communication asymmetry to exploit the abundant downstream bandwidth in mobile computing systems. In the push-based architecture called *Broadcast Disks*(46), data items are continuously and repetitively broadcast to mobile hosts without any specific request, and the mobile hosts listen to the broadcast channel and retrieve data of their interest. Data dissemination can be found in many applications, including stock trading and electronic auctions. In these applications, data updates must be disseminated promptly and consistently to a large community of mobile users.

In the broadcast environment, data items may be updated by transactions executed at the server while they are being broadcast. To ensure the consistency of mobile transactions, the broadcast channel can be used to transmit concurrency control-related information to the mobile hosts to perform all or part of the transaction validation function (47–49). In this way, data conflicts can be detected earlier at the mobile hosts to avoid any computing and communication resources being wasted, as well as helping to improve the performance of mobile transactions. In addition, transaction restarts are more costly in the mobile environment. Excessive transaction aborts because of ineffectiveness of the concurrency control mechanisms or unnecessary restrictive correctness criteria should be avoided (50).

To increase the concurrency of mobile transactions, multiple versions of data items can be broadcast (51). A mobile read-only transaction can choose to read the data versions, if they exist, that correspond to a single database state. With multiversioning, mobile transactions can resume execution after temporary disconnection, as long as the required versions are still on the broadcast. To provide better currency, additional information in the form of an invalidation report consisting of a list of data items that have been updated can periodically be broadcast to the mobile hosts.

Mobile transactions also introduce some other new problems, such as awareness of location. In wired DDBSs, location transparency is an important feature. However, mobile applications may be location-dependent, for instance, the current position of a mobile host may be accessed by a mobile transaction. Moreover, failures occur more often in mobile computing because of the frequent switching on and off of mobile computers and the frequent handoff when mobile computers move across the boundary of cells. Another new challenge in the mobile computing environment is failure handling and recovery.

FUTURE RESEARCH DIRECTIONS

The future work on TP will continue in the direction on new transaction models. Although the advanced transaction model and f-conflict serializability provide a guideline for advanced application, many particular applications still need user-defined correctness and often employ the semantic information for semantic serializability and semantic atomicity.

In advanced database applications such as CAD and cooperative work, the transactions are often cooperative or interactive or online analysis processing. We need to design mechanisms for advanced models to support partial rollbacks, reread, and rewrite operations to reflect the cooperative features.

As database systems are being deployed in more and more complex applications, the traditional data model (e.g., the relational model) has been found to be inadequate and has been extended (or replaced) by object-oriented data models. Related to this extension is another research direction: TP in object-oriented databases, including semantic-based concurrency control and recovery in object-oriented databases. Ref. 52 presents a brief introduction and some future research topics on this area as well as a comprehensive list of references on advanced TP.

ACTIVE CONTOURS: SNAKES

The shape of a real-world object can be represented by its outline in the image plane. In computer vision, the outline of the object is referred to as the *object contour*. A fundamental approach to finding automatically the object contour is the “snakes framework,” which was introduced by the seminal work of Kass et al. in 1987 (1). For the last two decades, snakes have been used successfully in the context of facial animation, visual speech analysis, traffic monitoring, surveillance, medical imaging (tracking and segmentation of organs), and blue screening in Hollywood movies.

A snake is an elastic model of a continuous and flexible curve that is fitted on the boundary between the object and the rest of the image by analyzing the visual image content. The process of fitting iteratively an initial snake to the object, such that the snake encloses the object tightly, is called “snake evolution.” During its evolution, the snake imposes continuity and smoothness constraints on the evolved contour, which relax the requirement of a noise-free image. In addition to the continuity and smoothness constraints, snake have the capability to be attracted to certain shape configurations known a priori. The evolution of a snake from one configuration to another in consecutive frames of a video clip attributes a dynamic behavior to the contour and provides object-tracking capabilities. The snake performing object tracking is considered a *dynamic contour* moving from frame to frame.

THE SNAKE FORMULATION

The snake is composed of a set of control points marked in the spatial image coordinates (x,y). The control points initially can reside inside or outside the object region. From its initial configuration, the snake evolves by changing the positions of the control points while minimizing an associated cost (energy) function evaluated on the contour:

$$E_{\text{snake}} = \int_0^1 (\alpha E_{\text{image}} + \beta E_{\text{internal}} + \gamma E_{\text{external}})ds \qquad (1)$$

Where E denotes energy, s denotes the contour arc-length and α, β, and γ are the control parameters (1). The final position of the control points provides the final configuration of the snake which is obtained by the equilibrium of all three terms, E_{image}, E_{internal}, and E_{external}, in the snake energy [Equation (1)] (2). In particular, the image energy term, E_{image}, attracts the snake to a desired configuration by evaluating the visual features in the image. During its evolution, the internal energy term, E_{internal}, imposes a regularity constraint to enforce the contour continuity and smoothness. The last term in the energy function, E_{external}, accounts for the user-defined constraints. Traditionally, researchers define E_{external} in terms of a known set of shapes the object can have.

VISUAL CUES

The snake’s attraction to distinctive local features on the object boundary signifies the role of feature extraction in the snake framework. Traditionally, feature extraction is achieved by convolving an image with a mask. In its simplest form, the convolution mask H can be considered a small image, usually an $n \times n$ matrix, and the convolution operation $*$ between the image I and the mask H is performed by

$$I(x,y) * H = \sum_{i=1}^{n}\sum_{j=1}^{n} I(x + i/2, y + j/2)H(i,j) \qquad (2)$$

The convolution of the image with a filter generates a feature image in which the boundaries are expected to be highlighted while the other regions are suppressed. For instance, convolving an image shown in Fig. 1(c) using the vertical and horizontal edge filters shown in Fig. 1(a) and Fig. 1(b) produces the edge responses shown in Fig. 1(d) and Fig. 1(e). The gradient magnitude feature computed from these edge responses emphasizes the object boundary to which the snake will be attracted.

The convolution operation is a local operation, which does not guarantee the generation of expressive features. This operation can be exemplified as shown in Fig. 2(a) where the background clutter and the object texture generate ambiguous edges, causing the snake to get attracted to the wrong configurations. A solution to this problem is to use global features computed in the regions defined by the inside and the outside of the object contour (4). The similarity between the colors observed inside and outside the object is a common measure used by researchers (see Fig. 2(b) for the definition of the snake inside and outside). This similarity measure can be computed by means of the distance between the probability distribution functions (pdf) associated with the inside and outside regions. Based on this distance, the snake evolves by moving the control points inward or outward.

CURVE SMOOTHNESS

In the case when the object is not distinctive from its background or when the image contains noise, the snake may not converge to a final configuration, which represents the object shape. To overcome this problem, it is necessary to stabilize the contour evolution to keep the shape of the snake intact and to not resonate from one configuration to another. Stabilization of the contour is achieved by the internal energy term, E_{internal}, given in Equation (1).

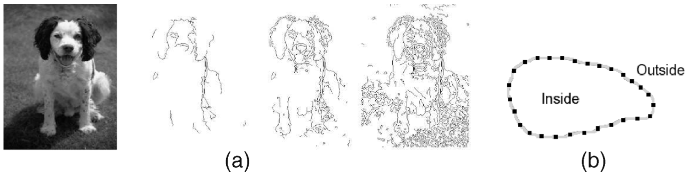

Figure 2. (a) The edges obtained by applying the Canny edge detector (3) with different thresholds. Note the ambiguity of the features that will guide the snake evolution. (b) The inside and outside regions defined by the snake.

This term includes a weighted combination of a membrane function and a thin plate function shown in Fig. 3:

$$E_{\text{internal}} = w_1 \underbrace{\Gamma(s)\left|\frac{\partial\Gamma(s)}{\partial s}\right|^2}_{\text{membrane}} + w_2 \underbrace{\Gamma(s)\left|\frac{\partial^2\Gamma(s)}{\partial s^2}\right|^2}_{\text{thin plate}} \tag{3}$$

where $\Gamma(s)$ denotes the curve and w_1 and w_2 are the weights. Practically, when $w_1 \gg w_2$, the curve is allowed to kink, whereas $w_1 \ll w_2$ forces the curve to bend slowly. A common practice is to use different weights for each control point, so that both w_1 and w_2 become functions of s. This approach allows parts of the snake to have corners and allows the others parts to be smooth.

SNAKE EVOLUTION

The motion of each control point, which is governed by Equation (1), evolves the underlying curve to new a con-

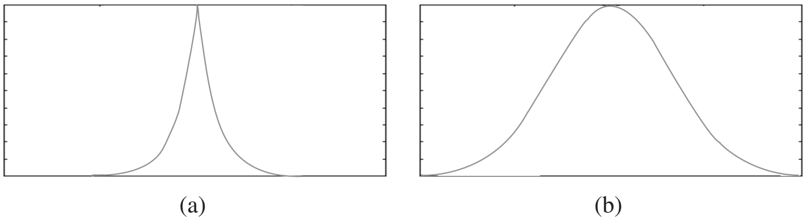

Figure 3. (a) The membrane function and (b) the thin plate function, which are a regularization filter of order 1 and 2, respectively.

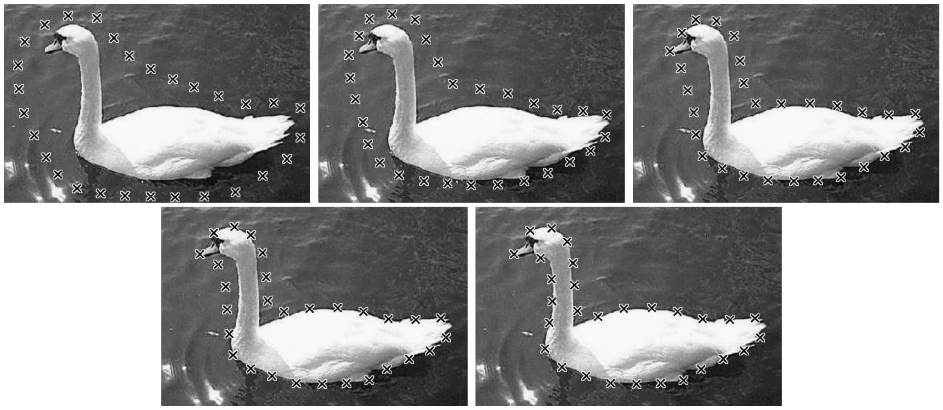

Figure 4. The evolution of an initial snake using the gradient magnitude image shown in Fig. 1(f) as its feature.

figuration. This process is shown in Fig. 4. Computing the motion of a control point s_i requires the evaluation of the first- and the second- order curve derivatives in a neighborhood $\Gamma(s_i)$. An intuitive approach to evaluate the curve derivatives is to use the finite difference approximation:

$$\frac{\partial\Gamma(s_i)}{\partial s} = \frac{\Gamma(s_i) - \Gamma(s_{i-1})}{d} \tag{4}$$

$$\frac{\partial^2\Gamma(s_i)}{\partial s^2} = \frac{\Gamma(s_{i+1}) - 2\Gamma(s_i) + \Gamma(s_{i-1})}{d^2} \tag{5}$$

The finite difference approximation, however, is not applicable in regions where two control points overlap, resulting in zero Euclidean distance between the neighboring control points: $d = 0$. Hence, a special handling of the displacement between the control points is required, so they do not overlap during their motion. Another approach to compute the derivatives is to fit a set of polynomial functions to neighboring control points and to compute the derivatives from these continuous functions. In the snake literature, the parametric spline curve is the most common polynomial approximation to define the contour from a set of control points. As shown in Fig. 5, the spline curve provides naturally a smooth and continuous approximation of the object contour. This property waives the requirement to include regularization terms in the energy function. Hence, the complexity of the snake energy formulation is simplified.

The complexity of the snake formulation can also be reduced by using a greedy algorithm (4,5). The greedy algorithms move the control points on an individual basis by finding a set of local solutions to the regular snake energy Equation (1). computing locally the energy at each control point requires analytical equations to evaluate the snake regularity and curvature (5). An alternative greedy formulation is to move each control point individually based on similarity in appearance between local regions defined inside and outside of the curve (4). Practically, if the appearance of the outside is similar to that of the inside, the control point is moved inside; if not, it is moved outside. In either approach, the assumption is that each local solution around a control point is correct and contributes to the global solution defined by the object boundary.

DISCUSSION

The snakes framework has been very useful to overcome the limitations of the segmentation and tracking methods for cases when the features generated from the image are not distinctive. In addition, its parametric form results in a compact curve representation that provides a simple technique to compute geometric features of the curve, such as the curvature, and the moments of the object region, such as the object area.

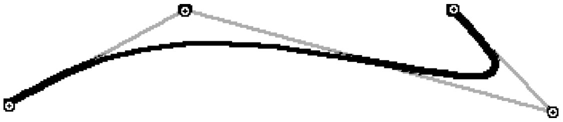

Figure 5. Spline function estimated from four control points. The gray lines denote the control polygons connecting the control points.

The algorithms developed for the snake framework perform near real time when the initial snake is placed close to the objects of interest. Their performance, however, degrades in the presence of background clutter. To overcome this limitation, researchers have proposed various shape models to be included in the external energy term.

One of the main concerns about the snakes is the amount of control points chosen initially to represent the object shape. Selection of a few control points may not define the object, whereas selecting too many control points may not converge to a solution. For instance, if the object circumference is 50 pixels and the snake is initialized with 100 control points, snake iterations will enter a resonant state caused by the regularity constraint, which prevents the control points from overlapping. A heuristic solution to this problem would be to add or remove control points when such cases are observed during the snake evolution.

Images composed of multiple objects require initialization of several independent snakes surrounding each object. Multiple snakes are required because both the finite difference approximation and the splines prevents the snake from changing its topology by splitting of one curve into two or merging of two curves into one. For topology changing curves, we refer the reader to the article on the "Level Set Methods."

COLOR: COLOR MODELS

INTRODUCTION

With the widespread use of color-imaging and display systems, the ability to describe and specify color has become increasingly important. These models are used primarily to understand or characterize the behavior of color stimuli or abstract signals that are representative of color. In general, color models may be divided into four families as follows:

- Physics-based models,
- Models based on human perception,
- Models used for imaging devices, and
- Hybrid models that are used in imaging devices but are loosely based on human perception.

PHYSICS-BASED MODELS

Sources of light have a spectral power distribution that may be represented by $i(\lambda)$, where λ denotes wavelength (with units of say, nanometers). Light interacts with an inhomogeneous surface of an object (see Fig. 1) and undergoes two distinct processes, which are described by the dichromatic reflection model (1). The first process occurs at the interface between the medium in which the incident light is traveling and the surface of the object, which causes some reflection and refraction. The refracted light passes through the interface and interacts with the particles in the medium. It is then scattered repeatedly and absorbed selectively by the pigments or colorants in the medium and is in part transmitted through the transparent surface with its spectral composition altered by the colorants. This model pertains to dielectrics, not metals. The *dichromatic reflection model* states that each of the two components—the first denoted the "interface" reflection and the second denoted the "body" reflection—may be factored into the product of the spectral composition (c), depending on wavelength only and a geometric factor (m) that depends on the angular arrangement of the illumination and viewing geometry. This model may be represented as

$$\begin{aligned} i_r(\lambda, \theta) &= i_{\text{interface}}(\lambda, \theta) + i_{\text{body}}(\lambda, \theta) && (1) \\ &= m_{\text{interface}}(\theta) c_{\text{interface}}(\lambda) + m_{\text{body}}(\theta) c_{\text{body}}(\lambda) && (2) \end{aligned}$$

The wavelength-related terms depend in turn on both the spectral composition of the illuminant and on the object. This color formation model is used in machine vision-related works and has found wide acceptance.

In a somewhat simplified framework in which viewing geometry is not of much concern—especially when the surface is Lambertian (reflects light equally in all directions, independent of viewing angle)—the viewing geometry is constant. This model may then be restated as: The light that reaches a surface gets spectrally selectively absorbed/transmitted/reflected by the surface depending on the colorants that are in the body. The energy exiting the surface may now be represented by

$$i_r(\lambda) = i(\lambda) r(\lambda) \tag{3}$$

Here, $r(\lambda)$ denotes the spectral reflectance function of the surface (note that the interface and the body are treated as one). This simplistic model discounts viewing geometry, that is, the relative position of the source of light and its direction, the surface orientation, and also the position of the observer relative to each of these.

MODELS BASED ON HUMAN PERCEPTION

A copublished article titled "Color Perception" gives a brief description of the mechanisms of color perception. In that article, we introduced the following equation regarding formation of color stimuli in the retina-based cone functions, which is represented as functions of wavelength by $l(\lambda)$, $m(\lambda)$, and $s(\lambda)$: These symbols give the spectral sensitivities of the three different cones in the human retina, denoting long, medium, and short human cone sensors (i.e., roughly red, green, and blue). In the presence of a light source (illuminant) represented by $i(\lambda)$, the reflectance function of a surface (described by $r(\lambda)$ in [0..1]) is modified in a wavelength-selective fashion to create a stimulus $i_r(\lambda)$ to the eye given by Equation (3). Let us denote the cone functions as a vector given by

$$\mathbf{lms}(\lambda) = [l(\lambda), m(\lambda), s(\lambda)] \tag{4}$$

The signals measured in the cones of the eye are then a three-vector $\mathbf{c} = [c_l, c_m, c_s]$, given by:

$$\mathbf{c} = \int_{\lambda=380\,\text{nm}}^{\lambda=830\,\text{nm}} \mathbf{lms}(\lambda) i_r(\lambda) d\lambda \tag{5}$$

In the case of emissive sources of light, $i(\lambda)$ in Equation 3 is replaced by the spectral content of the light itself. In the case of transmission through translucent materials, $r(\lambda)$ is replaced by the transmission function with respect to wavelength. These equations are founded on Grassmann's laws (2), which state that a color (**C**) that is matched with a weighted combination of three independent primaries (**R, G, B**) will maintain the laws of linearity. In other words, consider two colors **C1** and **C2**, each created with two different weightings of the primaries, given by

$$\begin{aligned} \mathbf{C1} &= \alpha_1 \mathbf{R} + \alpha_2 \mathbf{G} + \alpha_3 \mathbf{B} \\ \mathbf{C2} &= \beta_1 \mathbf{R} + \beta_2 \mathbf{G} + \beta_3 \mathbf{B} \end{aligned} \tag{6}$$

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

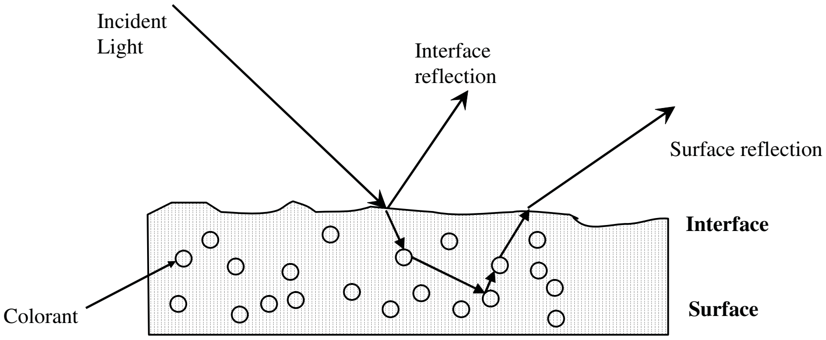

Figure 1. Dichromatic reflection model.

A combination of these two stimuli will result in a color given by

$$\mathbf{C1} + \mathbf{C2} = (\alpha_1 + \beta_1)\mathbf{R} + (\alpha_2 + \beta_2)\mathbf{G} + (\alpha_3 + \beta_3)\mathbf{B} \qquad (7)$$

Hence, with knowledge of the trichromacies of the three primaries at every wavelength, the net result of a linear combination of these primaries as they vary in their spectral content is given by Equation 2. (In computer computations as opposed to nature, integrals are actually replaced by summations based on samplings of continuous functions.) Of course, knowledge of the weights is needed and in the case of Equation 2, the various weights are given by the cone functions.

The ability to measure directly the cone functions of an observer is only a recent development. However, researchers had inferred the cone functions based on what are known as *color matching functions* and the International Commission on Illumination [Commission International de L'Eclairage, (CIE)] had standardized them long before the cone functions could be measured directly. The color-matching functions are determined by a process that involves an observer viewing a bipartite field, one half of which uses a reference color and another uses a color made by adjusting the strengths of three independent sources of illumination until a perfect match is made (illustrated in Reference 3). This model suggests that it is possible to plot the individual weights of the three primaries on a wavelength scale, which in turn gives us the weight our visual system applies to a given set of spectral stimuli to match a particular color. These weights, the color-matching functions, were determined by two independent researchers (John Guild and William D. Wright) in the 1920s. In a document published in 1931, the CIE combined these results to publish a set of RGB color-matching functions with RGB primaries standardized to those at 700 nm, 546.1 nm and 435.8 nm, respectively (4). These are shown in Fig. 2. These color-matching functions have negative excursions because some colors reside outside the triangle formed by these three primaries, and a negative excursion in the primaries' weights is the only way to represent a color outside a triangle. To address this, the CIE also published a set of color-matching-functions with non-negative values, which are known as $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ (note that these are now imaginary, nonphysical primaries). In addition to being non-negative, the new-color matching functions (see Fig. 3) were created such that $\dot{y}(\lambda)$ matched the photopic luminance response that was standardized by the CIE earlier, in 1924 (5). These color-matching functions are to be used in the same manner as the cone primaries and the RGB primaries. The equations for

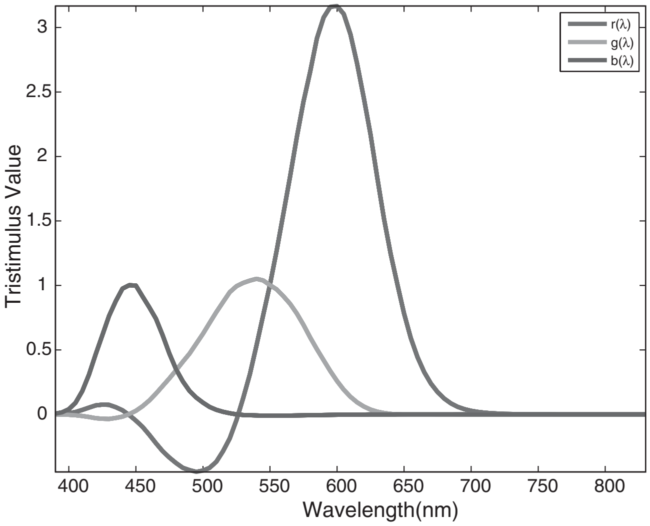

Figure 2. RGB color matching functions.

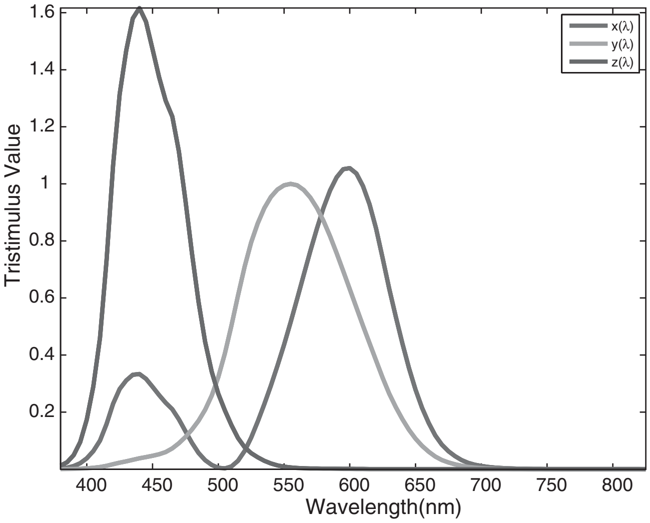

Figure 3. XYZ color matching functions with Judd-Vos modifications.

computing these special "tristimulus" values, in XYZ color space, are analogous to Equation 5 but with respect to the standardized color-matching functions as follows:

$$\begin{aligned} X &= k\int_{\lambda} \bar{x}(\lambda) i_r(\lambda) d\lambda \\ Y &= k\int_{\lambda} \bar{y}(\lambda) i_r(\lambda) d\lambda \\ Z &= k\int_{\lambda} \bar{z}(\lambda) i_r(\lambda) d\lambda \end{aligned} \tag{8}$$

In Equation 8, k denotes a normalization factor that is set to 683 lumens/Watt in the case of absolute colorimetry and to $100/\int_{\lambda} \bar{y}(\lambda) i(\lambda) d\lambda$ for relative colorimetry. In the case of relative colorimetry, this means a value of $Y = 100$ denotes the brightest color—the illuminant that reflects off a perfect-reflecting diffuser.

The first published set of color-matching functions by the CIE were originally empirically determined for a 2° field—the bipartite field used for matching subtended a 2° angle on the observers' retina. After the 1931 publication, W. S. Stiles and J. M. Burch conducted experiments (6) to measure color-matching functions for larger fields of view. This research was combined with the findings of Speranskaya (7) into the publication of a 10° observer in 1964 (8). The differences between these two standard observers is significant enough to warrant a clear specification of which observer color-matching functions are used in experimental work. More specifically, the 10° observer has noticeable shifts of the color-matching functions in the blue direction because the subtense of the stimulus encompasses a larger portion of the retina and hence, more S cones as well as increased macular pigment absorption.

In the CIE colorimetric system, an XYZ tristimulus value uniquely specifies a color. However, a convenient two-dimensional representation of the tristimulus values led to the projection of the tristimulus values by normalizing by the sum of the three values. These "chromaticity" values are given by

$$\begin{aligned} x &= \frac{X}{X+Y+Z} \\ y &= \frac{Y}{X+Y+Z} \end{aligned} \tag{9}$$

A third chromaticity value z can be analogously defined, but it is not independent because $z = 1 - x - y$. Specifying a color by its (x, y) chromaticity coordinates and its luminance Y also uniquely specifies a color, and it is often used to describe a color because the tristimulus values are straightforward to obtain from the (x, y, Y) values. The biggest advantage of the (x, y) chromaticity coordinates is that they specify a magnitude-independent hue and purity of a color. A *chromaticity diagram* (see Fig. 4) is typically used to specify a color using its chromaticity coordinates. Unique specification, however, requires the luminance to be specified as well. Figure 4 also shows the locus of illuminants standardized as daylight illuminants (per the CIE standard), specifically denoting the location D55 (standard mid-morning daylight), D65 (standard noon daylight), and also for reference, the location of illuminant A (tungsten lamps) and the equi-energy point, E ($x = y = 0.33$). Here, D65 stands for a standard daylight with a "correlated color temperature" of T = 6500 K, as the closest point on the locus of all Plankian lights, which are specified analytically as a function of T. In Fig. 4, the horseshoe-shaped locus denotes the locus of monochromatic stimuli visible to the standard 2° observer (the gamut of visible colors). Shorter wavelength stimuli (starting at 380 nm, which elicit a relatively strong blue response) reside in the lower left of this horseshoe shape, whereas the longer wavelengths (ending at 830 nm, which elicit a relatively strong red response) reside on the lower right, with the top of the horseshoe curve around 520 nm (eliciting a strong green response). The line that connects the blue and red corners is referred to as the *line of purples*. Colors on this line, although on the border of the gamut, have no counterpart in monochromatic light. The (x,y) chromaticity diagram is perceptually nonuniform: Unit vectors in the chromaticity space do not correspond to a unit change in perception even if the luminance is kept constant. In an attempt to improve the uniformity of the chromaticity diagram, in 1976 the CIE published a Uniform Chromaticity Scale (UCS) diagram that scaled and normalized the XYZ tristimulus values (9). This chromaticity diagram is denoted by u', v' axes that are related to the XYZ tristimulus values by the following equations:

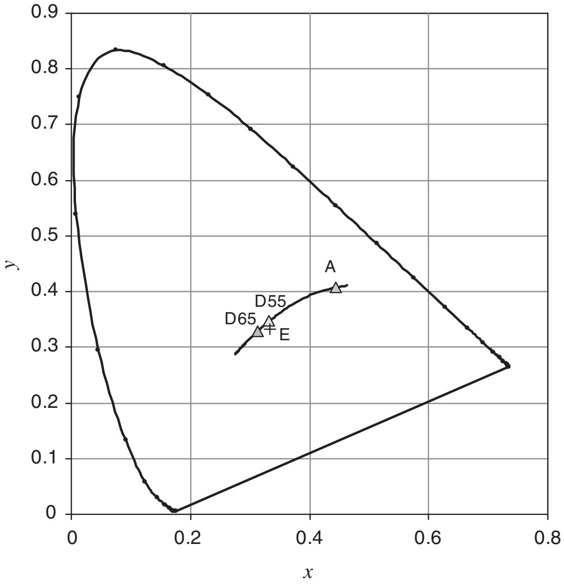

Figure 4. CIE xy chromaticity diagram that shows illuminants D55, D65, A, and E ('+', equi-energy illuminant).

$$\begin{aligned} u' &= \frac{4X}{X + 15Y + 3Z} \\ v' &= \frac{9Y}{X + 15Y + 3Z} \end{aligned} \tag{10}$$

Figure 5 shows the UCS along with the standard illuminant locations and the D-illuminant locus. As in Fig. 4, in this diagram, the horseshoe-shaped locus represents the gamut of visible colors.

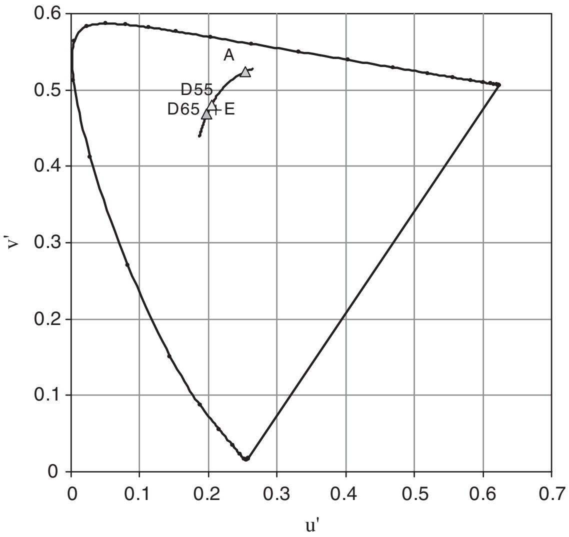

Figure 5. CIE UCS u′v′ chromaticity diagram showing illuminants D55, D65, A, and E (equi-energy illuminant).

The CIEXYZ color space, albeit powerful, does not represent colors in a perceptually uniform fashion; although the Y axis maps luminance, the X, Z axes have no perceptual correlates. To address these concerns and in turn enable a mechanism to incorporate the nonlinearity of the human visual system and furthermore provide a means of obtaining measures of differences between colors, in 1976 the CIE proposed the CIELAB and CIELUV color spaces, for subtractive and additive systems, respectively.

Lightness-Chroma-Hue Color Spaces

The CIEXYZ color space does not have perceptual correlates that would make it useful for common use. In an attempt to add perceptual behavior to color spaces, based on earlier works of many researchers, the CIE proposed a lightness scale along with two chromatic scales. In the CIELAB color space, the axes are denoted by L^* (Lightness), a^*(redness-greenness) and b*(yellowness-blueness). For a stimulus given by a tristimulus value of X, Y, and Z, the CIELAB coordinates are given by:

$$\begin{aligned} L^* &= 116\, f(Y/Y_n) - 16 \\ a^* &= 500[f(X/X_n) - f(Y/Y_n)] \\ b^* &= 200[f(Y/Y_n) - f(Z/Z_n)] \end{aligned}$$

where

$$f(t) = \begin{cases} t^{1/3}, & \text{for } t > 0.008856 \\ 7.787t + 16/116 & \text{otherwise} \end{cases} \tag{11}$$

In the above equations, the subscript n denotes the tristimulus values that correspond to the reference white—note that therefore the CIELAB color space is a relative color space. Given the CIELAB coordinates in a three–dimensional space, correlates of chroma and hue may be derived as follows:

$$C^*_{ab} = (a^{*2} + b^{*2})^{1/2} \tag{12}$$

$$h^*_{ab} = \tan^{-1}(b^*/a^*) \tag{13}$$

Under highly controlled viewing conditions, a CIELAB ΔE difference of 1 correlates with a single just noticeable difference in color. It is to be noted that the CIELAB color-difference measure was designed for color differences between uniform color patches in isolation. It has however been used for image differences measures as well. In complex imagery, difference up to 3 is not significant (10).

In a similar construct, the CIE also recommended a CIELUV color space based on the uniform chromaticity scale (UCS), which uses subtractive shift from the reference white instead of the normalization based on division that is used in the CIELAB space. The equations to transform a tristimulus value from $u\prime, v\prime$ coordinates to CIELUV are given by:

$$\begin{aligned} L^* &= 116\, f(Y/Y_n) - 16 \\ u^* &= 13\, L^*(u' - v'_u) \\ v^* &= 13\, L^*(v' - v'_n), \end{aligned}$$

where

$$f(t) = \begin{cases} t^{1/3}, & \text{for } t > 0.008856 \\ 7.787t + 16/116 & \text{otherwise} \end{cases} \tag{14}$$

The u', v' coordinates for a tristimulus value are computed using Equation 10. As in the CIELAB definitions, the subscript n denotes the u', v' coordinates of the reference white being used. For example, for viewing a computer screen, the XYZ for standard light D65 is used; for viewing hardcopy, D55 or D50 is used. The implications of the u* and v* axes are similar to those in CIELAB, which approximate redness-greenness and yellowness-blueness directions.

Based on these correlates, the CIE recommends that color-difference measures in the two uniform-perception spaces CIELAB and CIELUV be given by the Euclidean difference between the coordinates of two color samples as follows:

$$\begin{aligned} \Delta E^*_{ab} &= \left[(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2\right]^{1/2} \\ \Delta E^*_{uv} &= \left[(\Delta L^*)^2 + (\Delta u^*)^2 + (\Delta v^*)^2\right]^{1/2} \end{aligned} \tag{15}$$

where the differences are given between the corresponding color coordinates in the CIELAB and CIELUV spaces between the standard and the test samples. Many improvements to this basic color-difference measure have been proposed and adopted over the years, which involve scaling the lightness, chroma, and hue differences appropriately based on the application and the dataset of samples to which the color difference measure has been adapted or improved (11). Typically, color-difference thresholds are dependent on the application, and thresholds for perceptibility judgments are significantly lower than thresholds for acceptability judgments. Many other color-difference measures have been proposed, and more recently, the CIE DE2000 has been adopted as a measure of color difference, again for uniform color patches under highly controlled viewing conditions and is slowly gaining acceptance (11,12).

In the case of both these uniform color spaces, note that

- The color space is only a rough approximation of a color-appearance space [predictors of correlates to brightness and colorfulness attributes are better modeled with color appearance models specifically designed for this purpose (13)].
- The chroma axes do not correspond to the location of unique hues. This subject is entirely different subject and is explored by Kuehni in Reference 14.
- The color differences are not to be used for samples across different viewing conditions—reference viewing conditions need to be used.
- The lightness scale closely matches the Munsell Value scale, and the two chromatic axes are used for describing redness-greenness and yellowness-blueness perception. These color axes are clearly modeled after the human vision opponent color theory.
- These color spaces were designed for threshold color differences and their application to supra-threshold (larger than about 5 units of ΔE) color differences is to be handled with care (15).

These color spaces provide a powerful tool to model and quantify color stimuli and are used in color-difference modeling for color patches. They have more recently been used to describe color appearances (see Reference 13). Models for describing colors based on lightness, chroma, and hue are powerful in their abilities to enable communication of color stimuli as well.

MODELS USED IN IMAGING DEVICES

In linear-additive combinations of colors, a unit input of a color corresponds to a globally constant unit of the output signal, whereas in nonlinear combinations, a transfer function would determine the input–output relationship. This nonlinearity is often used in quantized systems with limited available bits and in signal compression systems to take advantage of the available output signal bit-depth by stretching small input codes over a larger range of output codes and compressing the larger input codes into a smaller output dynamic range. This model is referred to as *gamma encoding*. From an encoding perspective, in its simplest form the input–output relationship is typically given by a gain-offset-gamma model, which is given by the following:

$$y = \text{round}\left[(2^N - 1)(\alpha x + \beta)^\gamma\right] \tag{16}$$

where α denotes a scalar gain, N denotes the number of bits in a system, β is a scalar offset, γ denotes a power law with values larger than 1 (typically around 2.2), and x and y denote the normalized input and the output signals, respectively (16). In encoding systems, the three channels typically have the same parameters. Display systems based on cathode ray tubes (CRTs) have an inherent response that follows the inverse relationship—large steps in input signal at the low end of the input signal cause a small change in output, whereas at the upper end of the signal range, small steps caused large output changes. It so happens that gamma encoding (using a power-law of γ on the linear luminance input) the input prior to transmitting the data to a CRT display causes the display luminance to follow similar steps that result in a net unity transfer function. This model is also a useful means of encoding data to maximize bit-depth usage while reducing visibly apparent contouring on the output data and display (3,17). In the case of a quantized color space, for reasons of perceptual uniformity, it is preferable to establish a nonlinear relationship between color values and intensity or luminance.

RGB Color Model

The specification of a color in the RGB color space implies a linear (after gamma is removed) or nonlinear (gamma applied) combination of the red, green, and blue primaries in varying strengths. In RGB color spaces, the manner in which colors are reproduced varies from device to device. For example, a color specified as an RGB triplet is more than likely going to look different from one display device to another when the exact same RGB triplet is provided as input because of differences in the "color" of the primaries and gamma curves. This finding makes the RGB space a device-dependent color space. Specifying colors in device-dependent color spaces, although not preferred from a color-reproduction perspective, is often resorted to because of its ease in comprehension.

An RGB color model can represent any color within an RGB color cube, as shown in Fig. 6. This color model is most

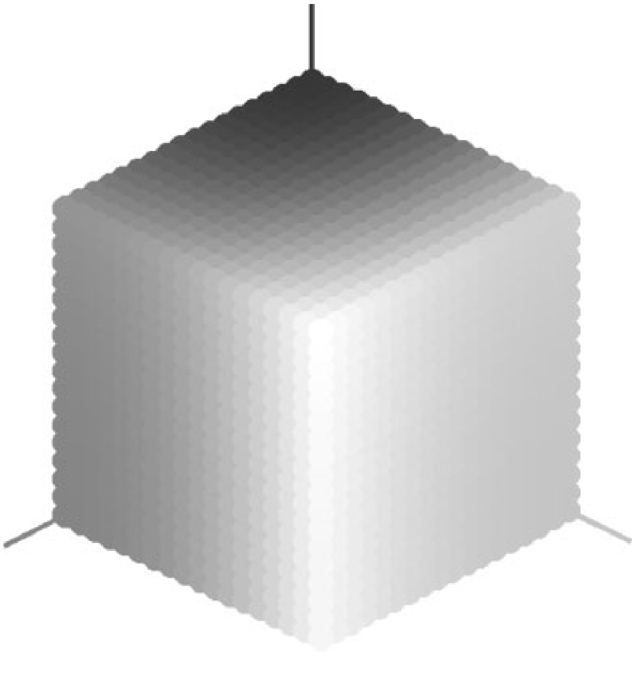

Figure 6. RGB color cube commonly used in display applications.

commonly used in display applications in which data is additive in nature. For example, a full-strength yellow color is specified by (1.0, 1.0, 0.0), denoting the use of the red and green primaries at full strength and the blue primary completely turned off. In an 8-bit system, this will correspond to a code value of (255,255,0). A three-primary display with three independent color primaries (typically denoted by their CIE x,y chromaticity values along with that of white) is specified by

$$\begin{bmatrix} x_R & x_G & x_B & x_W \\ y_R & y_G & y_B & y_W \end{bmatrix} \qquad (17)$$

From this primary set and the CIEXYZ tristimulus value of white computed as $[x_W/y_W, 1, (1-x_W-y_W)/y_W]$, a 3 × 3 system matrix **A** given by

$$\mathbf{A} = \begin{bmatrix} X_R & X_G & X_B \\ Y_R & Y_G & Y_B \\ Z_R & Z_G & Z_B \end{bmatrix} \qquad (18)$$

is computed. Using the XYZ tristimulus of white (with $\mathbf{c} = [1.0,1.0,1.0]$), **A** is computed using the following arithmetic:

$$\begin{bmatrix} x_R & x_G & x_B \\ y_R & y_G & y_B \\ z_R & z_G & z_B \end{bmatrix} \begin{bmatrix} k_R & 0 & 0 \\ 0 & k_G & 0 \\ 0 & 0 & k_B \end{bmatrix} \begin{bmatrix} 1.0 \\ 1.0 \\ 1.0 \end{bmatrix} = \begin{bmatrix} X_W \\ Y_W \\ Z_W \end{bmatrix} \qquad (19)$$

A is now given by

$$\mathbf{A} = \begin{bmatrix} x_R & x_G & x_B \\ y_R & y_G & y_B \\ z_R & z_G & z_B \end{bmatrix} \begin{bmatrix} k_R & 0 & 0 \\ 0 & k_G & 0 \\ 0 & 0 & k_B \end{bmatrix} \qquad (20)$$

Accordingly, the CIE tristimulus $\mathbf{t} = [X, Y, Z]$ that is generated from an RGB triple $\mathbf{c} = [R, G, B]$ is given by

$$\mathbf{t} = \mathbf{A}\mathbf{c}^t \qquad (21)$$

Consider for example, two displays (with the same input–output transfer functions, same absolute white luminance levels) with the following primary and white chromaticities:

$$\begin{bmatrix} 0.6400 & 0.3000 & 0.1500 & 0.3127 \\ 0.3300 & 0.6000 & 0.0600 & 0.3290 \end{bmatrix} \qquad (22)$$

and,

$$\begin{bmatrix} 0.6400 & 0.2100 & 0.1500 & 0.3127 \\ 0.3300 & 0.7100 & 0.0600 & 0.3290 \end{bmatrix} \qquad (23)$$

The system defined by Equation 22 has a system matrix given by

$$\mathbf{A}_1 = \begin{bmatrix} 0.4124 & 0.3576 & 0.1805 \\ 0.2126 & 0.7152 & 0.0722 \\ 0.0193 & 0.1192 & 0.9505 \end{bmatrix} \qquad (24)$$

and that defined by Equation 23 has a system matrix given by

$$\mathbf{A}_2 = \begin{bmatrix} 0.5767 & 0.1856 & 0.1882 \\ 0.2973 & 0.6274 & 0.0753 \\ 0.0270 & 0.0707 & 0.9913 \end{bmatrix} \qquad (25)$$

A yellow color code (1,1,0) in each case will correspond to a CIEXYZ of [0.7700,0.9278,0.1385] and [0.7622,0.9247, 0.0977], corresponding to a yellow CIE x, y coordinate of (0.4193,0.5053) and (0.4271,0.5181), respectively. The exact same representation of yellow results in different colors on screen—a consequence of using a device-dependent representation. Consequently, even though different display systems using an RGB color space define a cube in a Euclidean signal color space, their individual rendered color gamuts may very likely be significantly different. For a more rigorous comparison, the perceptual correlates (CIELAB, CIELUV or some such representation) of the colors need to also be considered.

The color-mixing matrix for additive colors mixing is shown in Table 1, which states for example that a cyan color would be created using maximum intensity of green and blue primaries and none of the red primary.

CMY/CMYK Color Model

Printers, on the other hand, create colors using inks that are deposited on paper, in which case the manner in which they create color is called subtractive color mixing. The inks selectively absorb wavelengths of incident light and reflect the remainder. As a beam of light passes through an absorbing medium, the amount of light absorbed is proportional to the intensity of the incident light times the coefficient of absorption (at a given wavelength). This model is often referred to as *Beer–Lambert–Bouguer law* and is given by the following:

$$A(\lambda) = \log_{10}\varepsilon(\lambda)c(\lambda)l(\lambda) \qquad (26)$$

Table 1. Color Mixing Matrix for Additive Primaries

	Color Displayed							
Primary Used	Red	Green	Blue	Cyan	Yellow	Magenta	White	Black
Red	1	0	0	0	1	1	1	0
Green	0	1	0	1	1	0	1	0
Blue	0	0	1	1	0	1	1	0

Table 2. Color-mixing Matrix for Subtractive Primaries

	Color Displayed							
Primary Used	Red	Green	Blue	Cyan	Yellow	Magenta	White	Black
Cyan	0	1	1	1	0	0	0	1
Yellow	1	1	0	0	1	0	0	1
Magenta	1	0	1	0	0	1	0	1

where $\varepsilon(\lambda)$ is denotes absorptivity, $c(\lambda)$ denotes the concentration, and $l(\lambda)$ denotes the path length for the beam of light. Stated differently, the higher the concentration or thickness or absorptivity of a certain absorptive material, the higher is absorption—the intensity of reflected or transmitted beam of light will be reduced (18). The simplest model for printer inks is called the *block-dye model*. In such a setup, different thicknesses of the three primary inks may be deposited on top of each other to result in a final color to the observer. The colorant amounts required to print a stimulus designated by RGB emissions is given by $Y = 1 - X$, where $Y \in \{C, M, Y\}$ and $X \in \{R, G, B\}$ all normalized to unity. Real primary inks however do not correspond to these ideal functions, and hence, more sophisticated models need to include not just the spectral absorptions/reflectances of the inks, but the density (or area) of the inks and the characteristics of the media (paper) involved. The *Kubelka-Munk equations* describe the absorption and scattering of light as it passes through layers of ink and the substrate (e.g., paper). Various extensions are used in practice that account for the shortcomings of the basic Kubelka-Munk analysis, which consider issues such as nonlinearities in ink deposition, interactions between inks, and so on (18,19). In subtractive color mixing, the primaries are typically cyan (C), yellow (Y), and magenta (M). The color-mixing matrix for subtractive color mixing is shown in Table 2.

Often, the amount of ink to be used is defined in terms of its optical density D which is given by:

$$D = -\log_{10} R \tag{27}$$

where R denotes a weighted measure of the reflectance of the ink being used. Printers commonly use halftone patterns (spatial patterns that are approximations of continuous tones of a certain color) to create shades between full-on and full-off. Consider the sample example of a black and white picture printed on the front page of a newspaper: This image may appear to be be a continuous-tone (smooth shades) grayscale picture, but a closer analysis reveals that the printer is simply a black-and-white printer with different-sized dots representing different gray shades as shown in Fig. 7. Various models are used to describe the area of a certain ink needed to create a mid-tone color (19). Digital printing uses patterns of binary dots to substitute for varying sized dots. The printing industry has long used dot-area models that describe the relationship between the area A of an ink on a medium to its reflectance function R. The simplest form is the *Murray-Davies equation* given by the following:

$$A = \frac{R_w - R}{R_w - R_s} \tag{28}$$

where R_w denotes the reflectance of the medium (unprinted), R_s denotes the reflectance of the solid ink, and R denotes the desired reflectance for which the dot-area is to be calculated. Equation 28 may also be written in terms of density using Equation 27. More complex models such as the *Yule–Nielsen model*, the *Clapper–Yule model*, the *Neugebauer model*, and its various extensions are used to better assess the amounts of the three inks (C,M,Y) needed and for the tonal response of the desired and actual ink-area, which may differ because of the characteristics of the medium being used (for example, absorption of liquid inks by paper) (20). Much like RGB color systems, in which the reference white made a difference in the appearance of a certain color, depending on the kind of paper and inks used for printing, the rendered color can be significantly different from one printer to another.

Most printers use a "K" channel, which denotes black ink, primarily because a black generated by mixing cyan, yellow, and magenta is not black enough in appearance.

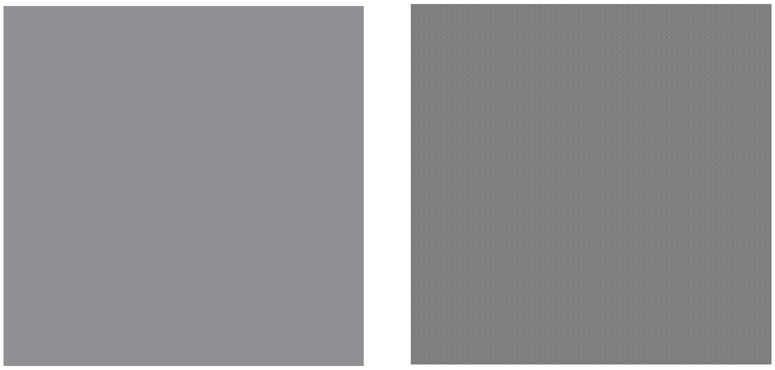

Figure 7. A continuous-tone representation of 50% gray and a halftone representation of the same code.

Additionally, to complicate matters, to print black, a printer would need to lay cyan, magenta, and yellow inks on top of each other, which makes ink drying a cause for concern and limits of ink absorption by the substrate (e.g., paper). Additionally, using one unit of black ink instead of one unit each of cyan, yellow and magenta inks can lead to significant cost savings.

HSL/HSV Color Model

To make the representation of colors intuitive, colors may be ordered along three independent dimensions that correspond to the perceptual correlates of lightness, hue, and chroma. In device-dependent color spaces, many variants of these perceptual correlates are commonly used: HSV is by far the most common. H stands for the perceptual correlate of hue; S stands for the saturation of a color, defined by the chroma of a color divided by its luminance (the more desaturated the color the closer it is to gray); and V stands for value (a perceptual correlate of lightness). This color model is commonly used in image-processing and editing software. However, the HSV color model has two visualization representations, one of which is a cylinder with black at the bottom and pure full-intensity colors on the top, and the other is representation by a cone, with black at the apex and white on the base. The equations used to convert RGB data into the HSV color space are given by the following:

$$V = \max \tag{29}$$

$$S = \begin{cases} 0 & \text{if } V = 0 \\ (V - \min)/V & \text{if } V > 0 \end{cases} \tag{30}$$

$$H = \begin{cases} 0 & \text{if } S = 0 \\ 60(G - B)/(\max - \min) & \text{if } (\max = R \text{ and } G \geq B) \\ 60(G - B)/(\max - \min) + 360 & \text{if } (\max = R \text{ and } G < B) \\ 60(B - R)/(\max - \min) + 120 & \text{if } \max = G \\ 60(R - G)/(\max - \min) + 120 & \text{if } \max = B \end{cases} \tag{31}$$

where max and min denote the maximum and minimum of the (*R,G,B*) triplet. These representations are shown in Fig. 8 on the left. From the figure, it is apparent that saturation is not dependent on the intensity of the signal. It is, however, often useful in image-processing applications to have an indicator of saturation given by a function of the intensity of the signal, which results in a conical-shaped HSV color space (Fig. 8). When the conical representation is preferred, S is given by (max—min)/(2^N−1) where 2^N−1 denotes the largest possible value for R, G, or B. Other variants of the HSV color space also exist and are used as an intuitive link to RGB color spaces (HSB, or HLS denoting various correlates of hue, saturation, and brightness/lightness).

HYBRID MODELS

Color models that are designed for imaging devices and communication needs are typically formulated such that colors are encoded/transmitted in the color space of a reference device. Colors spaces that fit such a description include the sRGB color space, the YCC, YUV, YIQ color transmission spaces, the SWOP CMYK color space, Adobe RGB (Adobe Systems, Inc., San Jose, CA), and ProPhoto RGB (Kodak, Rochester, NY), to list a few.

A popular mechanism to standardize colors across electronic devices, such as printers, monitors and the Internet, is the use of the *sRGB color space*. Originally, this was proposed by Hewlett-Packard and Microsoft and later standardized by the International Electrotechnical Commission under IEC 61966-2-1 (21). The sRGB standard has two primary parts, the viewing conditions and the necessary colorimetric definitions and transformations. The sRGB reference viewing environment corresponds to conditions typical of monitor display viewing conditions and thus may not be as well suited for print material, because of the various proprietary gamut-mapping algorithms in most printers that take advantage of each printer's color gamut. The colorimetric definitions provide the transforms necessary to convert between the sRGB color space and the CIEXYZ tristimulus color space as defined for a standard two-degree observer. More specifically, the standard is written for a standard reference monitor that has Rec. 709 primaries and a D65 white point. An overview of the technical advantages and challenges of the sRGB color space may be found in references 22 and 23. As was mentioned earlier, color spaces for video directly make use of the gamma-corrected signals, denoted as R′, G′, B′, from camcorders, without any attempt to correlate to the linear signals used in color science, such as those in Equation 5. For still imaging as well as video, this problem can be

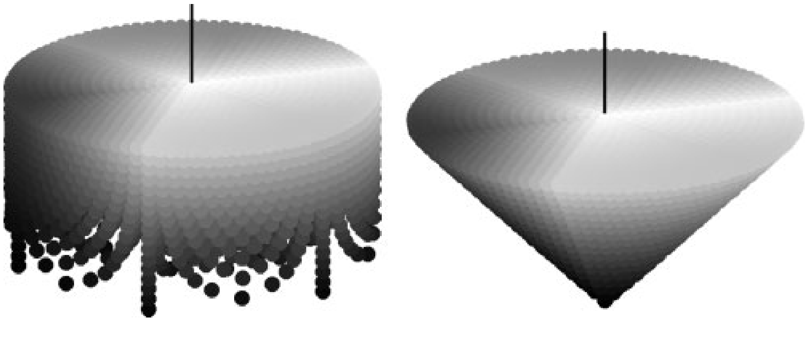

Figure 8. The HSV color model represented as a cylinder and a cone.

mitigated by the use of the transform built in to the sRGB standard, which includes a function for transforming from nonlinear signals I' to linear ones. On a scale of 0.0 to 1.0, for each of $I = R, G, B$, we apply a function

$$I = \begin{cases} I'/12.92, & \text{if } I' < 0.04045; \\ ((I' + 0.055)/1.055)^{2.4} & \text{otherwise} \end{cases} \tag{32}$$

In the video industry, a common mode of communication is the YCbCr color space (YPbPr in the analog domain) that converts RGB signal information into an opponent luma-chroma color space. A nonlinear transfer function is applied to linear-light *R, G, B* values and a weighted sum of the resulting *R′,G′,B′* values is used in the Y, Cb, and Cr signals. In the television space, these signals have dynamic ranges (on an 8-bit scale) of 16–235 for the luma signal and 16–240 in the Cb and Cr signals. This range is to allow for signal noise and potential signal processing noise, giving some head room and foot room. The weights are different depending on the color space that the data is being created for. For example, encoding $R^{'}, G^{'}, B^{'}$ signals with a 16–235 dynamic range into a color space defined by the NTSC primaries (often referred to as ITU-R BT.601), is given by the following:

$$\begin{bmatrix} Y \\ Cb \\ Cr \end{bmatrix} = \begin{bmatrix} 0.299 & 0.587 & 0.114 \\ -0.169 & -0.331 & 0.500 \\ 0.500 & -0.419 & -0.081 \end{bmatrix} \begin{bmatrix} R' \\ G' \\ B' \end{bmatrix} + \begin{bmatrix} 0 \\ 128 \\ 128 \end{bmatrix} \tag{33}$$

whereas when using HDTV (referred to as ITU-R BT.709) primaries, is given by the following:

$$\begin{bmatrix} Y \\ Cb \\ Cr \end{bmatrix} = \begin{bmatrix} 0.213 & 0.715 & 0.072 \\ -0.117 & -0.394 & 0.511 \\ 0.511 & -0.464 & -0.047 \end{bmatrix} \begin{bmatrix} R' \\ G' \\ B' \end{bmatrix} + \begin{bmatrix} 0 \\ 128 \\ 128 \end{bmatrix} \tag{34}$$

Keith Jack's book (24) is a useful reference for more details on the values of these coefficients for computer-systems that have *R′, G′, B′* data in the range of 0–255 and for details and considerations on color conversion issues. The *Y* channel typically contains most information in the image, as defined by spatial frequencies, and is hence sampled at much higher rates than the chroma signals. This information greatly helps in the ability of the transmission system to compress luma and chroma data with low overheads when compared with luma-only systems. To aid compression formats, color images in the JPEG and JPEG2000 file formats also convert the *R′, G′, B′* information into the YCbCr color space prior to compression.

In the printing industry, a commonly specified color space is the SWOP (Specifications for Web Offset Publications) CMYK color space. The SWOP CMYK (25) is a proofing specification that has a well-established relationship between the CMYK input to a standard printer and its CIELAB values (an approximation of the perceptual coordinates of a color) and for a standardized dataset. Specifying images in the SWOP CMYK color space allows the printing house and the content creator to preview images on a common baseline prior to printing. Most image-editing software available nowadays allows the user to preview images in the SWOP CMYK color space.

Depending on the application, color models have their individual uses. Device-independent color models like the CIEXYZ, CIELAB, CIELUV, and their other derivatives are used most often to communicate color either between devices or between different color processing teams across the world. The International Color Consortium (ICC) has been extremely successful in standardizing device-independent color spaces between displays, printers, and capture devices (26,27). The color profiles that are stored and communicated in ICC profiles use an intermediate profile connection space (PCS) like CIEXYZ or CIELAB. ICC profiles also store color transformation profiles to and from different color devices (say, from an input device such as a scanner to CIEXYZ, and from CIEXYZ to an output device such as a printer). For example, an sRGB ICC profile incorporates the color space transform from sRGB to the PCS, and a SWOP CMYK ICC profile would incorporate the color space transform from the PCS to the CMYK output color space for a printer. Furthermore, depending on the rendering intent (how the colors need to be represented on the output device), different transformations may be specified in the ICC profile.

CONCLUSIONS

Typically, devices that use additive color mixing are those used for display and use red, green, and blue primaries, although recently multiprimary displays (more than three) are also becoming available (28,29). The multiprimary displays allow for an improved color rendition with regard to natural colors. Recently, multiprimary acquisition systems (as opposed to three-primary acquisition systems) are gaining importance for archiving applications (30,31). The Digital Cinema Initiative (DCI), which standardizes the various aspects of digital cinema, has specified the data format for communication of digital film content to be in the CIEXYZ format, making the transmission of the information completely device independent (32). As far as subtractive color mixing devices are concerned, printers with more than three or even four inks have been available for some time now. It is fairly common for printer manufacturers to use six or seven inks—two types of cyans, magentas, and yellows, and of course a black ink. The two types of color inks allow for an increased range of ink densities to be deposited on the print media. Spectrally accurate printing is a field that is receiving attention as well and is a field of rapid advancements (30). Models of color are also becoming increasingly complex, which accounts for viewing conditions and the appearance of colors in spatial contexts of complex images as opposed to the relatively simplified constructs used in this article. All these examples are indicators that the study of color models is still a very active field.

The interested reader is referred to more detailed discussions of this subject such as the comprehensive books by Hunt (17), Berns (16), Kuehni (33), Fairchild (13), Sharma (31), and Green and MacDonald (19).

COLOR PERCEPTION

INTRODUCTION

Color as a human experience is an outcome of three contributors: light, the human eye, and the neural pathways of the human brain. Factors such as the medium through which the light is traveling, the composition of the light itself, and anomalies in the human eye/brain systems are important contributors. The human visual system, which includes the optical neural pathways and the brain, responds to an extremely limited part of the electromagnetic (EM) spectrum, approximately 380 nm to 830 nm but concentrated almost entirely on 400 nm to 700 nm. We are blind, basically, to the rest of the EM spectrum, in terms of vision. For normal observers, this wavelength range roughly corresponds to colors ranging from blue to red (as shown in Fig. 1). The red end of the spectrum is associated with long wavelengths (toward 700 nm) and the blue end with short wavelengths (400 nm).

COLOR VISION

The structure in the eye that enables color vision is the retina, which contains the necessary color sensors. Light passes through the cornea, lens, and iris; the functionality of these is roughly comparable with the similar parts of most common cameras. The pupillary opening functions in a fashion similar to the aperture in a camera and results in the formation of an upside-down image of the outside world on the back face of the eye, the retina—a dense collection of photoreceptors. Normal human color vision is enabled by four different photoreceptors in the retina. They are called the rods and the L, M, and S cones (for long, medium, and short wavelength sensitive); each has a different spectral sensitivity within the range of approximately 400 nm to 700 nm (1). Figure 2 shows the (normalized) spectral sensitivities of the cones. Note that color as we know it is specifically a human experience and that a different species of animals respond differently to spectral stimuli. In other words, a bee would see the same spectral stimulus dramatically differently than a human would. In fact, bees are known to have their spectral sensitivities shifted toward the lower wavelengths, which gives them the ability to "see" ultraviolet light. The following salient points must be considered for a holistic understanding of human color perception:

1. The rods are activated for vision at low luminance levels (about 0.1 lux) at significantly lower spatial resolution than the cones. This kind of vision is called *scotopic vision*. The corresponding spectral sensitivity function is shown in Fig. 3. At these luminances, normal humans do not have any perception of color. This lack is demonstrated easily by trying to look at a colored painting at low luminance levels. Moreover, at these luminance levels, our visual acuity is extremely poor. This specific property of the visual system is a function of the low spatial density of the rod photoreceptors in the *foveal* region of the retina.
2. The cones are activated only at significantly higher luminance levels (about 10 lux and higher), at which time, the rods are considered to be bleached. This type of vision is referred to as *photopic vision*. The corresponding sensitivity function that corresponds to luminance sensitivities is shown in Fig. 3. The green curve is called the *luminous efficiency curve*. In this article we will consider photopic vision only. Interestingly, the retinal density of the three types of cones is not uniform across the retina; the S cones are more numerous than the L or M cones. The human retina has an L, M, S cone proportion as high as 40:20:1, respectively, although some estimates (2,3) put them at 12:6:1. This proportion is used accordingly in combining the cone responses to create the luminous efficiency curve. However, the impact of these proportions to visual experiences is not considered a significant factor and is under investigation (4). What is referred to as *mesopic vision* occurs at mid-luminance levels, when the rods and cones are active simultaneously.
3. The pupillary opening, along with independently scalable gains on the three cone output, permits operation over a wide range of illuminant variations, both in relative spectral content and in magnitude.
4. Color stimuli are different from color experiences. For the purposes of computational color science, the differences between color measurements and color experiences sometimes may not be considered, but often the spatial and temporal relations among stimuli need to be taken into account.

L, M, and S cone functions may be represented as a function of wavelength as $l(\lambda)$, $m(\lambda)$, and $s(\lambda)$. In the presence of a light source (illuminant), represented by $i(\lambda)$, the reflectance function of an arbitrary surface [described by $r(\lambda)$] is modified in a wavelength-selective fashion to create a stimulus $i_r(\lambda)$ to the eye given by

$$i_r(\lambda) = i(\lambda)r(\lambda) \tag{1}$$

Let us denote the cone functions as a vector given by

$$\mathrm{lms}(\lambda) = [l(\lambda), m(\lambda), s(\lambda)] \tag{2}$$

We denote the signals measured in the cones of the eye by $\mathrm{c} = [c_l, c_m, c_s]$, given by

$$\mathrm{c} = \int_{\lambda = 380\ \mathrm{nm}}^{\lambda = 830\ \mathrm{nm}} \mathrm{lms}(\lambda) i_r(\lambda) d\lambda \tag{3}$$

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

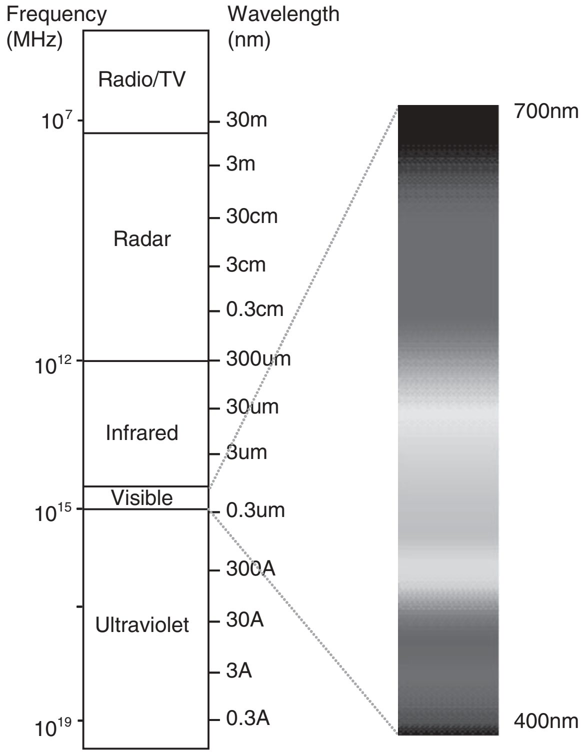

Figure 1. Electromagnetic spectrum, showing the limited range of human vision and color perception.

On an aside, although it is shown here that a color stimulus is formed by the process of reflection of the spectral energy $i(\lambda)$ of an illuminant off a surface $r(\lambda)$, it is only one manifestation of the cause of a color stimulus. The source for all colors at an elemental level may be grouped into 15 basic causes in five groups: (1) vibrations, rotations, and excitations, as in flames, neon lights, and so on; (2) ligand-field effects in transition metal compounds like turquoise, including impurities, as in rubies or emeralds; (3) molecular orbitals of organic compounds like chlorophyll and charge-transfer compounds like sapphire; (4) energy-bands in brass, gold, diamonds, and so on; and (5) geometric and physical optical effects like interference, diffraction, scattering, refraction, and so forth. The Nassau book on this topic is a thorough reference (5). In the case of emissive sources of stimuli (e.g. traffic lights, or television sets), Equation (3) is rewritten as

$$c = \int_{\lambda=380\,\mathrm{nm}}^{\lambda=830\,\mathrm{nm}} \mathrm{lms}(\lambda)e(\lambda)d\lambda \qquad (4)$$

where $e(\lambda)$ denotes the spectral stimulus that excites the cones.

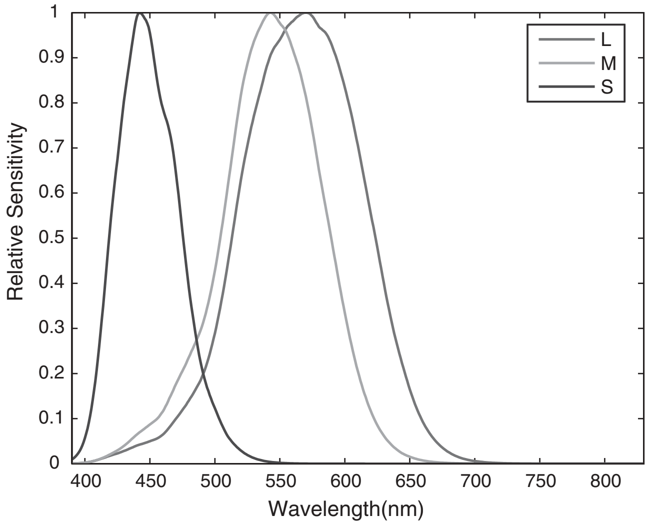

Figure 2. Cone sensitivity functions of normal human observers.

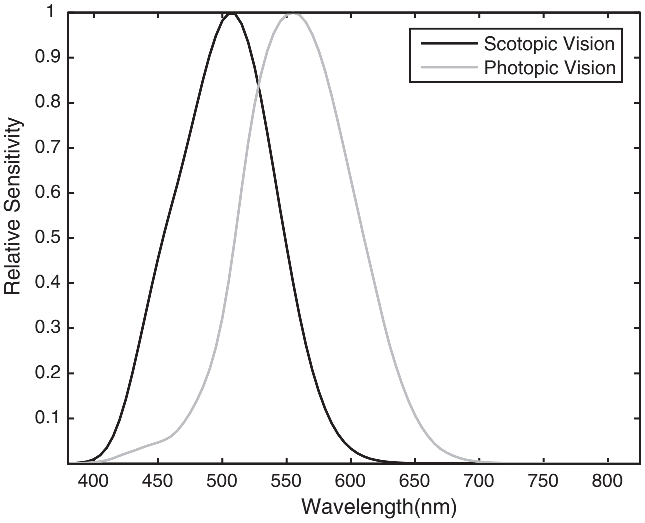

Figure 3. Sensitivity functions for photopic and scotopic vision in normal human observers.

A glance at the L, M, and S cone functions in Fig. 2 clearly highlights that the three measurements c, resulting from stimulating these cones, is not going to reside in an orthogonal three-dimensional color space—there will be correlation among L, M, and S. As a result of psychophysical testing, it is understood that human color vision operates on the basis of opponent color theory, which was first proposed by Ewald Hering in the latter half of the nineteenth century (2,6,7). Hering used a simple experiment to provide the primary proof of opponent color processes in the human visual system. An older hypothesis about the human visual system (works of Hermann von Helmholtz and James Maxwell in the mid-nineteenth century) suggested that the human visual system perceives colors in three independent dimensions (each corresponding to the three known color-sensitive pigments in the eye, roughly approximated by red, green, and blue axes). Although conceptually correct, this hypothesis could not explain some of the effects (unique hues and afterimages) that Hering observed. In a series of published works, Hering suggested that the visual system does not see colors as a combination of red and green (a reddish-green color). In fact, a combination of a red stimulus with a green stimulus produces no hue sensation at all. He suggested also that the

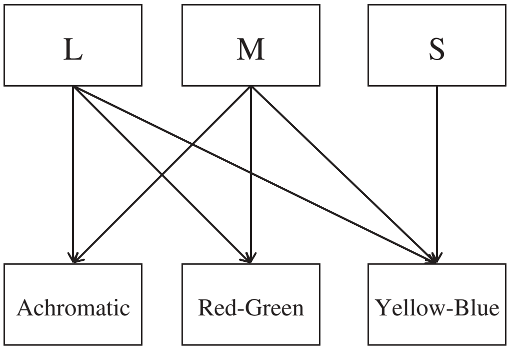

Figure 4. Weighted linear combinations of the L, M, S cone stimulations result in opponent color functions and an achromatic signal.

human visual system has two different chromatic dimensions (one corresponding to an orthogonal orientation of a red–green axis and another with a yellow–blue axis), not three. These concepts have been validated by many researchers in the decades since and form the framework of modern color theories. Similarly, staring at the bright set of headlights of an approaching car leaves a black or dark image after the car passes by, which illustrates that humans also see colors along a luminance dimension (absence or presence of white.) This finding has formed the backbone of modern color theory. Opponent color theory suggests that at least at the first stage, human color vision is based on simple linear operations on the signals measured by the L, M, and S cones. In other words, from the L, M, and S cone stimulations c, three resulting signals are computed that perform the task of reducing the interdependence between the measurements, somewhat orthogonalizing the space and hence reducing the amount of information transmitted through the neural system from the eye to the brain (see Fig. 4). This functionality is enabled by the extensive neural system in the retina of the eye. The opponent colors result in opponent cone functions (plotted in Fig. 5), which clearly suggests a fundamental conclusion of modern human color perception research: The three independent axes are luminance, redness–greenness, and yellowness–blueness (8). In other words, we have three sets of opposing color perception: black and white, red and green, and yellow and blue. In the figure, the red–green process appears as it does because colors on the ends of the spectrum appear similar (deep red is similar to purple)—the hue wraps around and often is portrayed in a circle.

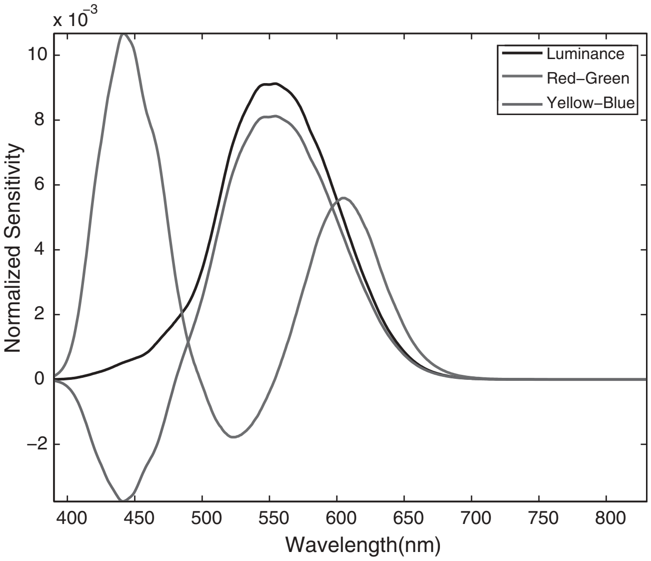

Figure 5. Normalized functions showing resultant red–green and yellow–blue sensitivities, along with the luminance channel.

Not surprisingly, much of the field of color science has been involved in trying to determine relationships between stimuli entering the eye and overall color experiences. This determination requires the ability to isolate color stimuli not just from their spatial relationships but also from the temporal relationships involved. Additionally, it requires a clear understanding of perceptual color appearance phenomena. As data have become available via a variety of experiments, the linear relationships between cone signals and color specifications has needed to be revised into a complex set of nonlinear relationships. Note that most color appearance phenomena have been developed for simplistic viewing fields, whereas all of our color experiences are based on complex images that involve complex illumination settings. It is instructive, nonetheless, to visit some common local color appearance descriptors that do not take into account spatial relationships such as the surroundings around a viewed scene. The terminology used below is used commonly in the color appearance work published by the Commission Internationale del' Eclairage in its standard documents (e.g. See Ref. 9) and in some popular textbooks on this subject (2,10). Groups involved in color ordering work and computational color technology, however, may define these terms differently based on their specific needs.

Hue

Hue is defined as the property of a color that describes it as a red, green, yellow, or blue or a combination of these unique hues. By definition, grays are not associated with any hue. A hue scale is defined typically as an angle. Figure 6 has magenta/violet hues at one end and reds at the other.

Brightness

The property of a color that makes it appear to emit more or less light.

Lightness

The property of a color that describes its brightness relative to that of the brightest white object in the visual field. A typical lightness scale is shown in Fig. 7.

Figure 6. A typical hue scale.

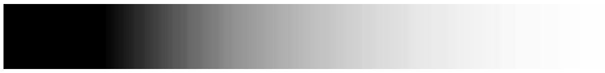

Figure 7. A typical lightness scale, with black at one end and the brightest possible white at the other.

Colorfulness

The property of a color that makes it appear more or less chromatic.

Chroma

The property of a color that describes its colorfulness relative to the brightness of the brightest white object in the visual field. In general, the relationship that exists between brightness and lightness is comparable with the relationship between colorfulness and chroma. Figure 8 shows a chroma scale for a hue of red and yellow. Note that in this example the chroma of yellows extends much farther than that of reds, as yellows appear much brighter than reds in nature and in most display systems.

Saturation

The property of a color that describes its colorfulness in proportion to its brightness. A typical saturation scale (shown here for a red and yellow hue) is displayed in Fig. 9. Note that by definition, saturation is normalized and hence unlike chroma; the same scale exists for both reds and yellows (and for other hues as well).

To aid in understanding these properties, Fig. 10 shows the locus of lines with constant hue, saturation, lightness, and chroma if we fix the brightness of white. By definition, saturation and hue are independent of the lightness of white.

Related and Unrelated Colors

In its simplest form, a color can be assumed to be independent of everything else in the viewing field. Consider, for illustrative purposes, a small patch of a color displayed in a dark room on a monitor with black background. This color is observed devoid of any relationships. This setup is typically the only one where colors are unrelated and are associated with attributes like brightness, hue, and saturation. Related colors, on the other hand, are observed in relationship with their surrounding and nearby colors. A simple example involves creating an image with a patch of brown color on a background with increasing white brightness, from black to white. The brown color is observed as a bright yellow color when on a black background but as a muddy brown on the brightest white background, which illustrates its relationship to the background (for neutral background colors). In practice, related colors are of great importance and are associated with perceptual attributes such as hue, lightness, and chroma, which are attributes that require relationships with the brightness of white. To specify a color completely, we need to define its brightness, lightness, colorfulness, chroma, and hue.

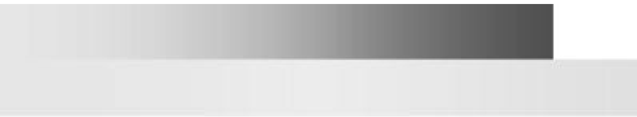

Figure 8. A typical chroma scale for red and yellow, starting with zero chroma on left and moving to maximum chroma on the right.

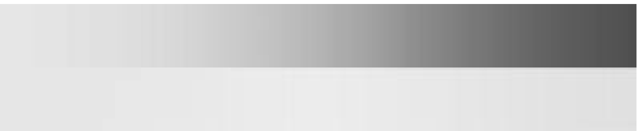

Figure 9. A typical saturation scale for red, starting with zero saturation on the left and moving to a saturation of 1 for pure color on the right.

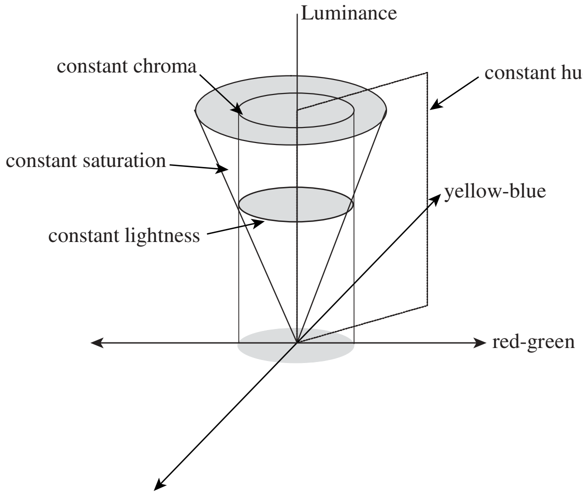

Figure 10. Loci of constant hue, saturation, lightness, and chroma shown in a perceptual color space.

Metamerism

According to Equation (3) , if we can control the stimulus that enters the eye for a given color, then to *match* two colors we merely need to match their resulting stimulus measurements c. In other words, two different spectra can be made to appear the same. Such stimuli are called *metamers*. If $c_1 = c_2$, then

$$\int_{\lambda\,=\,380\text{ nm}}^{\lambda\,=\,830\text{ nm}} \text{lms}(\lambda) i_{r_1}(\lambda) d\lambda = \int_{\lambda\,=\,380\text{ nm}}^{\lambda\,=\,830\text{ nm}} \text{lms}(\lambda) i_{r_2}(\lambda) d\lambda \tag{5}$$

Different manifestations of the above equality carry different names: “observer”, “illuminant”, and “object” metamerism, depending on whether equal stimuli c result from changing the sensor functions **lms**(λ), the light $i(\lambda)$, or the surface $r(\lambda)$. So, two completely different spectral stimuli can be made to generate the same cone stimuli for the same observer—a property that color engineers in fields ranging from textiles to televisions have considered a blessing for decades, because changes of pigments, dyes, phos-

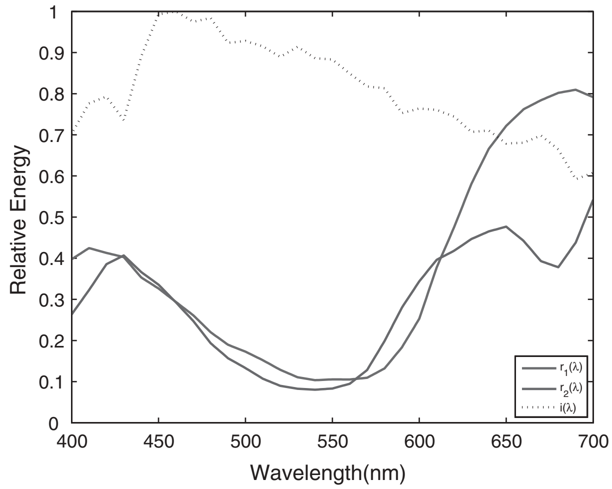

Figure 11. Metameric reflectances $r_1(\lambda)$ and $r_2(\lambda)$. Although their reflectance functions differ, under the illuminant $i(\lambda)$, their stimulation of the cones is identical and color perceived is the same.

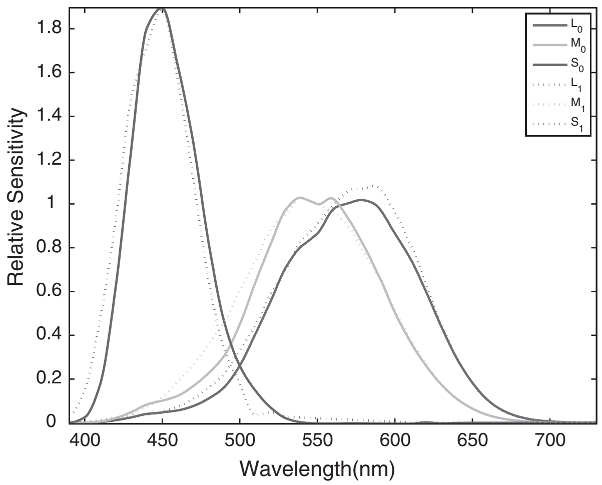

Figure 12. Different observer cone functions showing observer variances.

phors, and color filters can achieve a consistent perception of colors across various media. Equal colors are called metameric. Consider, for example, two color samples that have reflectance functions $r_1(\lambda)$ and $r_2(\lambda)$, as in Fig. 11. When plotted on a wavelength scale, it may appear that these two reflectance functions must result in completely different perceptions to the observer. However, if we were to apply the same illuminant and observer sensitivity functions to these otherwise different colors, they result in identical colors being perceived by the eye. These two colors (reflectance functions) hence are called *metamers*, and this is an example of object metamerism.

On a similar note, consider two patches of color with reflectance functions $r_3(\lambda)$ and $r_4(\lambda)$ being viewed under identical illumination conditions by two different observers (observers whose cone functions are not the same), as shown in Fig. 12. One observer would view these patches as being the same (they are metameric), whereas the other would view this exact same pair as distinctly different—resulting in observer metamerism. This kind of metamerism is relatively common, because most, if not all, concepts related to color are built around a "standard" or "average" observer, whereas in fact significant variation exists between observers. The final type of metamerism, illuminant metamerism, consists of metameric colors that arise from the same observer and reflectance but different lights.

Adaptation

Arguably, the most remarkable capability of the human visual system is its ability to adapt to changes in the illuminant. This ability may be classified broadly as lightness and chromatic adaptation. The resulting effect is that despite changes in the spectral content of the light or its absolute power, the visual system maintains quite constant overall perception. However, certain limitations apply to these abilities; these changes are limited mainly to changes in *natural* illuminants and objects. This occurance is to be expected given the types of illuminants with which humans have been most familiar.

This ability is explained best by means of an example. As one walks out of a relatively dark movie theater to bright afternoon sunlight, it takes only a few seconds for the visual system to adapt to as much as two orders of magnitude change in the intensity of the illuminant, without change in visual experience. Here, the cones are the dominant photoreceptors, and the rods have become bleached (unable to replenish their photopigments). This type of adaptation is referred to as *luminance* or *light adaptation*. Similarly, entering a dimly lit movie theater from the bright sunny outdoors again requires time to adapt to the dark conditions, after which our visual system has adapted well to the surroundings. This, however, takes slightly longer than in the former situation because now the rods need to become active, requiring them to unbleach, which is a comparatively longer process. This kind of adaptation is called *dark adaptation*. The ability to dark and light adapt gives us the ability to have reasonable visual capability in varying illuminant conditions while taking maximal advantage of the otherwise limited dynamic range of the photoreceptors themselves.

A second, and perhaps the most fascinating, mode of adaptation is called *chromatic adaptation*. This term refers to the ability of the visual system to maintain color perception under small, but significant, changes in the spectral content of the illuminant. A newspaper seems to maintain its mostly white background independent of whether we look at it outdoors under an overcast sky, indoors under a fluorescent lamp, or under an incandescent lamp. Consider looking at a bowl of fruit that contains a red apple, a yellow banana, and other fruit under an incandescent illuminant. The apple will appear red and the banana yellow. Changing the illuminant to a typical fluorescent lamp, which greatly alters the spectral content of the light, does not appear to change the color of the apple or the banana, after a few seconds of adaptation. The human visual system maintains its perception; our visual system has adapted chromatically. Interestingly, our ability to adapt to changes in spectral content of the illuminant are limited mostly to changes in natural illuminants such as sunlight.

Color Constancy

The phenomenon of objects maintaining their appearance under varying illuminants is referred to as *color constancy*. For example, the appearance of a dress that looks red in the store might look nothing like a red under street lighting (e.g., sodium-vapor lamps); the visual system cannot adapt as well to a sodium-vapor lamp as it can to a fluorescent or incandescent lamp; thus it inconsistently renders the perception of this dress fabric color. This subject is interesting given the formation model described in Equation (3). The information the eye receives from the object changes with the illuminant athough, given the premise of color constancy, the net result of the visual system needs to stay the same. This occurrence is known however, to be untrue for humans as we take informational cues from the color of the illuminant and perform some form of chromatic adaptation (11). The study of color constancy provides us with clues that describe how the human visual system operates and is used often by computational color technologists in maintaining numerical color constancy.

Color inconstancy is a battle that textile and paint manufacturers, camera and display manufacturers, and printer manufacturers regularly have to fight because significant changes may take place between illuminants in retail stores and in the home or between hardcopy and on-screen imaging. In each case, the color data reside in a different color space with its own color appearance models. Moreover, illuminants are difficult to control because we typically have mixed illuminants (not just one specific type) in whatever surrounding we are in.

After Images

When stimulated for an extended period of time by a strong stimulus, the human visual system adapts, and when the source of this stimulus is removed, a negative after image appears for a short period of time, most commonly attributed to sensor fatigue. Many forms of after images have been shown to be valid. The most commonly known type of after images is the one formed via color responses, known as chromatic after images. For example, if individuals fix their gaze on a picture of a brightly colored set of squares for some time and then a plain white stimulus is presented quickly to the eye, the individuals experience a negative image of corresponding opponent colors. Other forms of after images and visual stimulus adaptation that may be of interest to the reader have been demonstrated by Fairchild and Johnson (12).

SIMPLE COLOR APPEARANCE PHENOMENA

Specifying a color merely by its physical attributes has its advantages but has drawbacks, too, when describing the appearance of colors, especially in somewhat complex scenes. We illustrate these difficulties via some examples.

Simultaneous Lightness and Color Contrast

Consider an achromatic color placed in a relatively simple scene as shown in the upper half of Fig. 13. Both central squares seem to have the same luminance. However, if we reduce the luminance of the background in one half and increase it in the other while keeping the same central achromatic patches as shown in the lower half of the figure, one patch appears brighter than the other although in fact they have exactly the same luminance. This occurrence may be attributed to the presence of reinforcing and inhibiting ON–OFF receptive fields that work locally to enhance differences. A similar phenomenon occurs when we change the color of the background. The achromatic patches would seem to have the opponent color of the background and no longer retain their achromatic nature. In Fig. 14, all four inner squares are the same achromatic color. However, each square contrasts with its surrounding, resulting in the appearance of opponent colors. Note that the upper left square has a greenish tint, the upper right a bluish tint, the

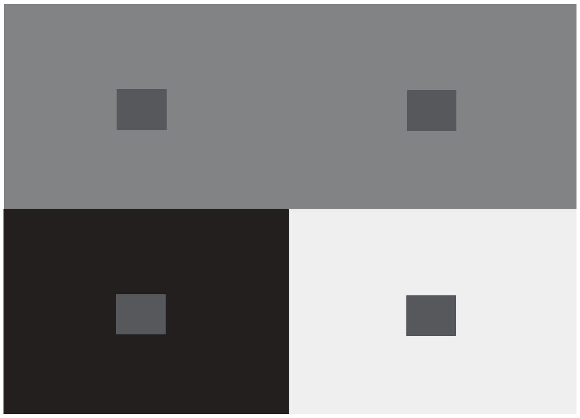

Figure 13. A simple example that demonstrates simultaneous lightness contrast. Notice that the same gray patches as in the upper half of the image seem to have different brightnesses when the background luminance is changed.

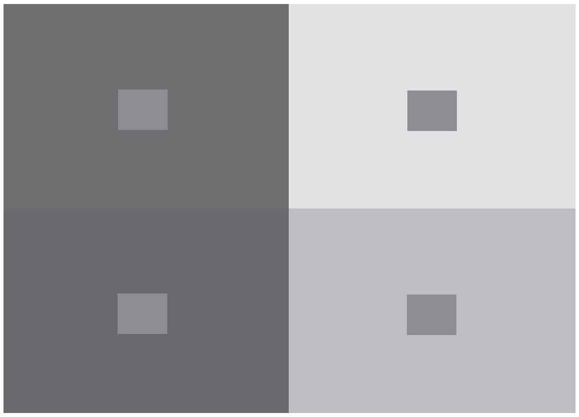

Figure 14. A simple example that demonstrates simultaneous color contrast. Notice that the same gray patches as in the upper half of the image seem to have different hues when the background luminance is changed.

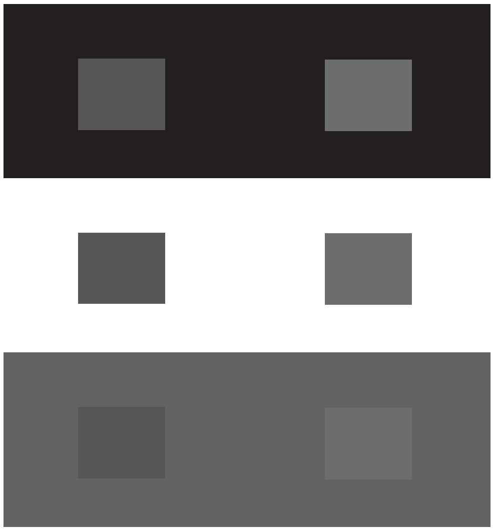

Figure 15. An example that demonstrates lightness crispening. Notice that the difference between the gray patches in the white and black backgrounds is hardly noticeable, but when the lightness of the background is in between that of the two patches the appearance of the difference is accentuated.

bottom left a yellowish tint, and the bottom right a reddish tint.

Lightness and Chromatic Crispening

The difference between two colors that are only slightly different is heightened if the color of the background that surrounds them is such that its color lies between those of the two patches. Figure 15 illustrates this phenomenon for lightness. Note that the difference between the two patches is hardly noticeable when the background is white or black, but when the luminance of the background is in between the colors of the patches, the difference is accentuated greatly.

Only a few color appearance phenomena have been addressed in this article. We have looked at some phenomena that are easy to observe and do not need in-depth study. Color appearance phenomena are the primary drivers of image quality assessments in the imaging industry. The interested reader is referred to books on this topic included in the Bibliography.

ORDER IN COLOR PERCEPTION

From the preceding sections on the various color appearance terms, one may gather that many potential candidates exist for ordering color perceptions. One means is based on the somewhat-orthogonal dimensions of redness–greenness, yellowness–blueness, and luminance. These axes may be placed along Euclidean axes, as shown in Fig. 16. Color spaces with such an ordering of axes form the basis of all computational color science.

Another method for ordering color perceptions could be based on hue, chroma, and lightness, which again could be placed along the Euclidean axes as in Fig. 17. It turns out that the two orderings are related to each other: The hue–chroma–lightness plot is simply another representation of the opponent-color plot. Such a relationship was found also by extensive studies on color orderings performed by Munsell in the early 1900s. In his publications, Munsell proposed a color ordering in which the spacing between each color and its neighbor would be perceived as equal. This resulted in a color space referred to as the Munsell color solid, which to date is the most organized, successful, and widely used color order system. Munsell proposed a notation for colors that specifies their exact location in the color solid. A vertical value (V) scale in ten steps denotes the luminance axis. Two color samples along the achromatic axis (denoted by the letter N for neutrals) are ordered such that they are spaced uniformly in terms of our perception; for example, a sample with a value of 4 would correspond to one that is half as bright as one with a value of 8. Munsell defined basic hues (H) of red (R), yellow (Y), green (G), blue (B), and purple (P) and combinations (RP for red-purples and so on) that traverse the circumference of a circle, as shown in Fig. 18. A circle of constant radius defines

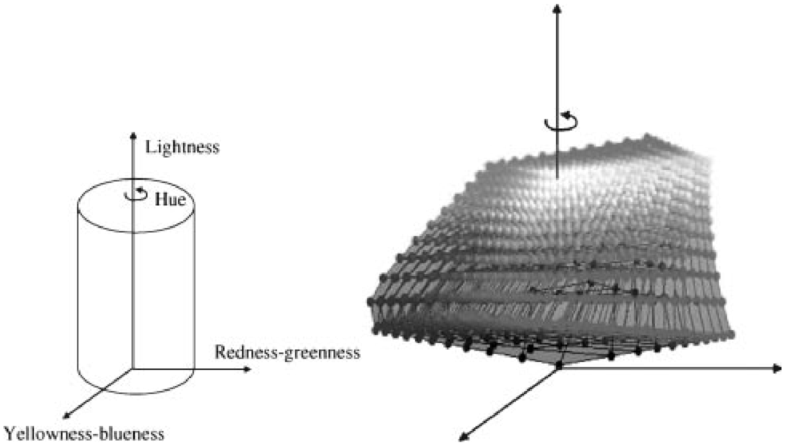

Figure 16. A plot of lightness, redness–greenness, and yellowness–blueness ordered along Euclidean axes.

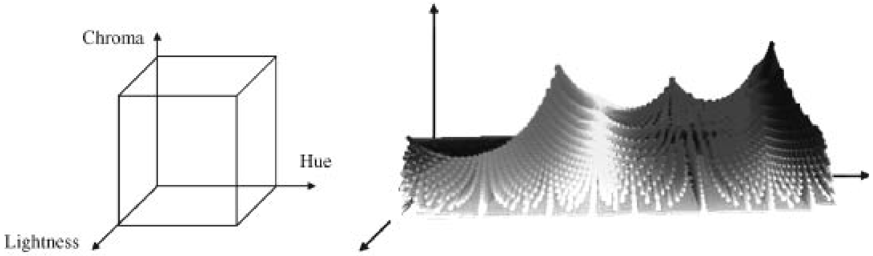

Figure 17. A plot of lightness, chroma, and hue ordered along the Euclidean axes.

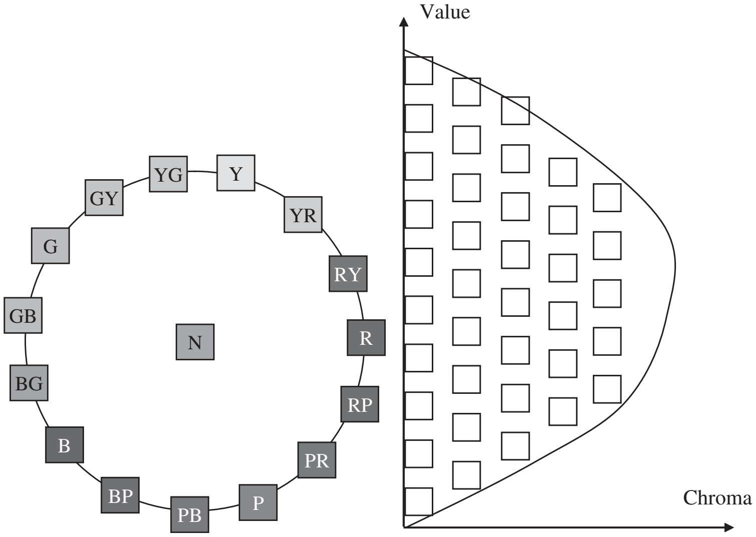

Figure 18. A plot of a constant value plane (left) that shows the various hue divisions of a constant chroma circle in the Munsell notation, alongside a constant hue plane (right).

the locus of colors with the same chroma (C) or deviations from the achromatic axis.

Increasing radii denote higher chroma colors on an open-ended scale. In this fashion, a color is denoted by H V/C (Hue Value/Chroma). For example, 5GY6/10 denotes a hue of 5GY (a green–yellow midway between a green and a yellow) at value 6 and chroma 10. Most modern computational color models and color spaces are based on the fundamentals of the Munsell color order system.

The NCS color order system is another ordering scheme, much more recent and gaining acceptance (13). The NCS color ordering system is based on the work of the Hering opponent color spaces. The perceptual axes used in the NCS are blackness–whiteness, redness–greenness, and yellowness–blueness; these colors are perceived as being "pure" (see Fig. 19). The whiteness–blackness describes the *z*-dimension, whereas the elementary colors (red, green–yellow, and blue) are arranged such that they divide the x–y plane into four quadrants. Between two unique hues, the space is divided into 100 steps. A color is identified by its blackness (s), its chromaticness (c), and its hue. For example, a color notated by 3050-Y70R denotes a color with a blackness value of 30 (on a scale of 0 to 100), a chromaticness of 50 (an open-ended scale), and a hue described as a yellow with 70% red in its mixture. A good reference that details the history and science of color order systems was published recently by Kuehni (14).

CONCLUSIONS

The multitide of effects and phenomena that need to be explored in color vision and perception is profound. One would imagine that color science, a field with such everyday impact and so interwoven with spoken and written languages, would be understood thoroughly by now and formalized. But the mechanisms of vision and the human brain are so involved that researchers only have begun unraveling the complexities involved. Starting from the works of ancient artisans and scientists and passing through the seminal works of Sir Issac Newton in the mid-1600s to the works of the most recent researchers in this field, our knowledge of the complexities of color has increased greatly, but much remains to be understood.

CONTOUR TRACKING

Object tracking is a fundamental area of research that finds application in a wide range of problem domains including object recognition, surveillance, and medical imaging. The main goal of tracking an object is to generate a trajectory from a sequence of video frames. In its simplest form, an object trajectory is constituted from the spatial positions of the object centroid and resides in a three-dimensional space defined by the image and time coordinates. In the case when the changes in the object size and orientation are tracked also, such as by a bounding box around the object, the dimensionality of the trajectory is increased by two and includes the scale and orientation, in addition to time and image dimensions.

A trajectory in a higher dimensional space provides a more descriptive representation of the object and its motion. Depending on the application domain, an increase in the trajectory dimensionality may be desirable. For instance, in the context of motion-based object recognition, a trajectory that encodes the changes in the object shape over a time period increases the recognition accuracy. The additional information encoded in the trajectory also provides a means to identify the actions performed by the objects, such as sign language recognition, where the shape of the hands and their interactions define the sign language vocabulary.

The most informative trajectory is the one that encodes the deformation in the object shape. This task requires tracking the area occupied by the object from one video frame to the next. A common approach in this regard is to track the contour of an object, which is known also as the contour evolution. The contour evolution process is achieved by minimizing a cost function that is constituted of competing forces trying to contract or expand the curve. The equilibrium of the forces in the cost function concludes the evolution process. These forces include regularization terms, image-based terms, and other terms that attract the contour to a desired configuration. The latter of these terms traditionally encodes a priori shape configurations that may be provided ahead of time.

REPRESENTING THE OBJECT AND ITS CONTOUR

The object contour is a directional curve placed on the boundary of the object silhouette [see Fig. 1(c) and (d)] . The contours are used either in a contour-based representation or in a boundary condition in a region-based representation. The region-based representation uses the distance transform, Poisson equation, of the medial axis. The distance transform assigns each silhouette pixel with its shortest distance from the object contour (1). In a similar vein, the Poisson equation assigns the mean of the distances computed by random walks reaching the object contour (2). The medial axis generates skeletal curve segments that lie on the locus of circles that are tangent to the object contour at two or more points [see in Fig. 1(c)]. Use of the contour as a boundary condition requires explicit detection of the object and prohibits defining a cost function that evolves an initial contour to its final configuration. Hence, in the remainder of the text, we will discuss the contour-based representation and related contour evolution techniques.

A contour can be represented explicitly or implicitly. Explicit representations define the underlying curve para-metrically and perform tracking by changing the parameters that, in turn, evolve the contour. Parametric representations require analytical expressions that provide a means to compute the geometric features used during the contour evolution. The most common parametric representation in the context of contour tracking uses a set of control points positioned on the object boundary. The use of different control points for different objects generates a unique coordinate system for each object, which is referred to as the Lagrangian coordinates [see Fig. 1(e)]. In the Lagrangian coordinates, the relations between the control points play an important role for computing the geometric properties of the underlying curve. These relations can be realized by either the finite difference approximation or the finite element analysis. The finite difference approximation treats each control point individually and assumes that they are connected by lines. On the contrary, the finite element analysis defines the relations by a linear combination of a set of functions referred to as the splines. The splines generate continuous curves that have parametric forms. Their parametric nature permits the computation of the geometric curve features analytically. The contour tracking in these representations is achieved by moving the control points from one place to another. For more information, we refer the reader to the article on “Snakes: Active Contours.”

Contrary to the explicit representation, the implicit contour representations for different objects lie in the same Cartesian coordinates, namely the Eulerian coordinates (grid). The contour in the Eulerian coordinates is defined based on the values for the grid positions. For instance, one common approach used in fluid dynamics research, which investigates the motion of a fluid in an environment, is to use volumetric representation. In volumetric representation, each grid is considered a unit volume that is filled with water, such that inside the contour (or surface in higher dimensions) the unit volumes are filled, whereas for outside they are empty. In the field of computer vision, the most common implicit representation is the level-set method. In the level-set method, the grid positions are assigned a signed Euclidean distance from the closest contour point. This method is similar to the distance transformation discussed for representing regions, with the difference of including a sign. The sign is used to label inside and outside the contour, such that grid positions inside the closed contour are positive, whereas the outside grid positions are negative. The signed distances uniquely

locate the contour, such that it resides on the zero-crossings in the grid. The zero-crossings are referred to as the zero level-set. The evolution of the contour is governed by changing the grid values based on the speed computed at each grid position. For more information, we refer the reader to the article on the "Level-Set Methods."

THE STATE SPACE MODELS FOR CONTOUR TRACKING

The state space models define the object contour by a set of states, $X^t : t = 1, 2 \ldots$. Tracking then is achieved by updating the contour state in every frame:

$$X^t = f^t(X^{t-1}) + W^t \tag{1}$$

where W^t is the white noise. This update eventually maximizes the posterior probability of the contour. The posterior probability depends on the prior contour state and the current likelihood, which is defined in terms of the image measurements Z^t. A common measurement used for contour tracking is the distance of the contour from the edges in the image.

The state space models-based contour tracking involve two major steps. The first step predicts the current location of the contour, such as the new position of each control point, and the second step corrects the estimated state, according to the image observations. The state prediction and correction is performed by using various statistical tools. Among others, the Kalman filtering and the particle filtering are the most common statistical tools. Computationally, the Kalman filter is more attractive because only one instance of the object state is required to perform prediction and correction. However, the Kalman filter assumes that the object state is distributed by a Gaussian, which may result in a poor estimation of the state variables that are not Gaussian distributed. The particle filtering overcomes this limitation by representing the distribution of the object state by a set of samples, referred to as the particles (3). Each particle has an associated weight that defines the importance of that particle. Keeping a set of samples for representing the current state requires maintaining and updating all the instances during the correction step, which is a computationally complex task.

Tracking the object contour using the state space methods involves careful selection of the state variables that represent the object shape and motion. For this purpose, Terzopoulos and Szeliski (4) use a spring model to govern the contour motion. In this model, the state variables include the stiffness of the spring placed at each control point. Once the object state is estimated, a correction is made by evaluating the gradient magnitude from the image. Isard and Blake (5) model the shape and rigid motion by using two state variables that correspond to the spline parameters and the affine motion. The image measurements used to correct the estimated state include the edges in the image observed in the normal direction to the contour [see Fig. 2(a)]. This approach has been extended recently to include nonrigid contour deformations that are computed after the rigid object state is recovered (6).

DIRECT MINIMIZATION OF THE COST FUNCTION

The methods falling under this category iteratively evolve the contour by minimizing an associated cost function. The cost function is constituted of the optical flow field or the appearance observed inside and outside the object and is minimized by a greedy algorithm or a gradient descent method.

The contour tracking based on the optical flow field exploits the constancy of the brightness of a pixel in time:

$$I^{t+1}(x,y) - I^t(x-u, y-v) = 0 \tag{2}$$

where I is the imaging function, t denotes the frame number, and (u,v) is the optical flow vector. The optical flow during the contour evolution can be computed by searching for similar color in a neighborhood of each pixel (7). Once the flow vectors for all the object pixels are computed, the cost of moving the contour can be evaluated by accumulating the brightness similarities using Equation (2). Tracking

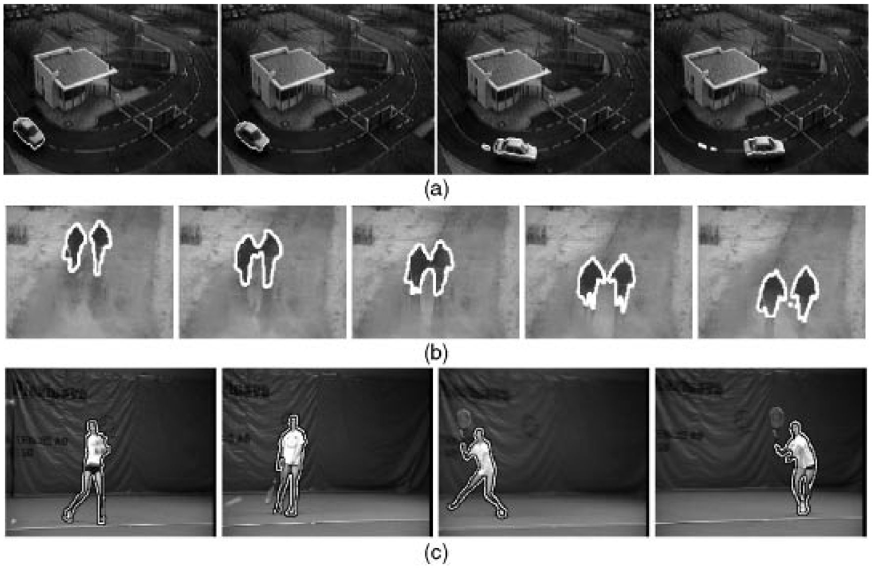

Figure 3. Tracking results of the methods proposed in (a) Ref. 7, (b) Ref. 8, and (c) Ref. 9. (Reprinted with permission from the IEEE.)

results of this approach are shown in Fig. 3(a). An alternative approach to computing the optical flow is to adopt a morphing equation that morphs the intensities in the previous frame to the intensities in the current frame (8). The intensity morphing equation, however, needs to be coupled with a contour tracking function, such that the intensities are morphed for the contour pixels in the previous and the current frame. The speed of the contour is computed according to the difference between the intensities of the corresponding pixels. For instance, if the difference is high, then the contour moves with the maximum speed in its normal direction and while the morphing function is evaluated by considering the new position of the contour. The tracking results using this approach are shown in Fig. 3(b). The cost function based on the optical flow also can be written in terms of the common motion constraint (10). The common motion constraint assumes that the motion inside the contour is homogenous, such that the contour is evolved to a new position if the difference between neighboring motion vectors is high.

In contrast to the cost functions using brightness constancy, the statistics computed inside and outside the object contour impose a less strict constraint. An important requirement of statistics-based methods is the initialization of the contour in the first frame to generate the appearance statistics. Region statistics can be computed by piecewise stationary color models generated from the subregions around each control point (11). This model can be extended to include the texture statistics generated from a band around the contour (9). Using a band around the contour combines image gradient-based and region statistics-based contour tracking methods into a single framework, such that when the width of the band is set to one, the cost function is evaluated by image gradients. The contour tracking results using region statistics is shown in Fig. 3(c).

THE SHAPE PRIORS

Including a shape model in the contour cost function improves the estimated object shape. A common approach to generate a shape model of a moving object is to estimate the shape distribution associated with the contour deformations from a set of contours extracted online or off line. The shape distribution can be in the form of a Gaussian distribution, a set of eigenvectors, or a kernel density estimate. The cost function associated with these distributions contains contour probabilities conditioned on the estimated shape distribution.

For the explicit contour representations, the shape model is generated using the spatial-position statistics of the control points. A simple shape prior in this context is to use a Gaussian distribution (10):

$$p(x_i) = \frac{1}{\sigma\sqrt{2\pi}}\exp(-\frac{(x_i - \mu_{x_i})^2}{2\sigma_{x_i}^2} - \frac{(y_i - \mu_{y_i})^2}{2\sigma_{y_i}^2}) \qquad (3)$$

where μ denotes the mean, σ denotes the standard deviation, and $\mathrm{x}_i = (x_i, y_i)$ is the position of the ith control point. Before modeling, this approach requires registration of the contours to eliminate the translational effects. Registration can be performed by mean normalization of all the contours.

An alternative shape model can be computed by applying the principal component analysis (PCA) to the vectors of the control points. The PCA generates a new coordinate system that emphasizes the differences between the contours, such that selecting a subset of principal components (eigenvectors with the highest eigenvalues) models the underlying contour distribution. Given an input contour, the distance is computed by first reconstructing the input using a linear combination of the selected principal components and then evaluating the Euclidean distance

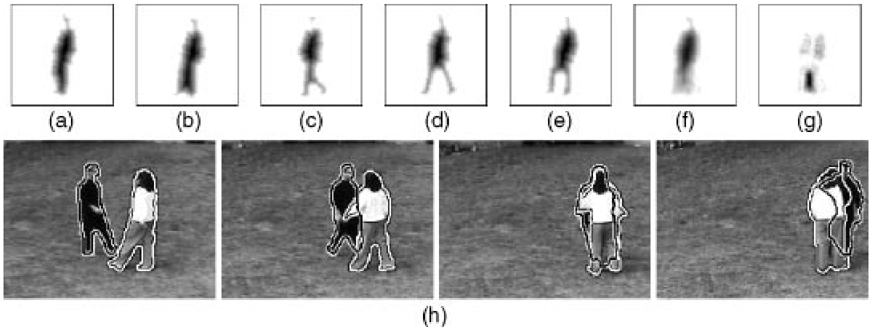

Figure 4. (a–e) A sequence of level-sets generated from walking action. (f) Mean level-set and (g) standard deviation level-set. (h) Tracking results for occluded person using the shape model given in (f) and (g). (Reprinted with permissions from the IEEE.)

between the input vector and the reconstructed contour. The weights in the linear combination are computed by projecting the input contour to the principal components.

The shape priors generated for implicit contour representations do not model explicitly the contour shape. This property provides the flexibility to model the objects with two or more split regions. Considering the level-set representation, which defines the contour by zero crossings on the level-set grid, a shape model can be generated by modeling distance values in each grid position by a Gaussian distribution (9). This modeling two level-set functions for each set of contours, as shown in Fig. 4(a–g), that correspond to the mean and the standard deviation of the distances from the object boundary.

DISCUSSION

Compared with tracking the centroid, a bounding box, or a bounding ellipse, contour tracking provides more detailed object shape and motion that is required in certain application domains. For instance, the contour trackers commonly are used in medical imaging, where a more detailed analysis of the motion of an organ, such as the heart, is required. This property, however, comes at the expense of computational cost, which is evident from the iterative updates performed on all the grid positions or the control points, depending on the contour representation chosen. In cases when the domain of tracking does not tolerate high computational costs, such as real-time surveillance, the contour trackers may be less attractive. This statement, however, will change in coming years, considering the ongoing research on developing evolution strategies that will have real-time performance (12).

The design of a contour tracker requires the selection of a contour representation. Depending on the application domain, both the implicit and explicit representations have advantages and disadvantages. For instance, although the implicit representations, such as the level-set method, inherently can handle breaking and merging of the contours, the explicit representations require including complex mechanisms to handle topology changes. In addition, the implicit representations naturally extend tracking two-dimensional contours to three or more-dimensional surfaces. The implicit representation, however, requires re-initialization of the grid at each iteration, which makes it a computationally demanding procedure compared with an explicit representation.

The choice of the cost function is another important step in the design of a contour tracker and is independent of the contour representation. The cost functions traditionally include terms related to the contour smoothness, image observations, and additional constraints. Among these three terms, recent research concentrates on developing cost functions that effectively use the image observations while adding additional constraints such as shape priors. Especially, the research on the use of innovative constraints to guide the evolution of the contour is not concluded. One such constraint is the use of shape priors, which becomes eminent in the case of an occlusion during which parts of the tracked object are not observed. Improved tracking during an occlusion is shown in Fig. 4(h) where using the shape priors successfully resolves the occlusion.

As with other object tracking approaches, in a contour tracking framework, the start or end of an object trajectory plays a critical role in its application to real-world problems. The starting of a contour trajectory requires segmentation of the object when it first is observed. The segmentation can be performed by using a contour segmentation framework, as discussed in the chapter on “Level-Set Methods”, or by using the background subtraction method, which labels the pixels as foreground or background depending on their similarity to learned background models. Most segmentation approaches, however, do not guarantee an accurate object shape and, hence, may result in poor tracking performance.

EDGE DETECTION IN GRAYSCALE, COLOR, AND RANGE IMAGES

INTRODUCTION

In digital images, edge is one of the most essential and primitive features for human and machine perception; it provides an indication of the physical extent of objects in an image. Edges are defined as significant local changes (or discontinuities) in brightness or color in an image. Edges often occur at the boundaries between two different regions. Edge detection plays an important role in compute vision and image processing. It is used widely as a fundamental preprocessing step for many computer vision applications, including robotic vision, remote sensing, fingerprint analysis, industrial inspection, motion detection, and image compression (1,2). The success of high-level computer vision processes heavily relies on the good output from the low-level processes such as edge detection. Because edge images are binary, edge pixels are marked with value equal to “1,” whereas others are “0”; edge detection sometimes is viewed as an information reduction process that provides boundary information of regions by filtering out unnecessary information for the next steps of processes in a computer vision system (3).

Many edge detection algorithms have been proposed in the last 50 years. This article presents the important edge detection techniques for grayscale, color, and range images.

EDGE AND EDGE TYPES

Several definitions of edge exist in computer vision literature. The simplest definition is that an edge is a sharp discontinuity in a gray-level image (4). Rosenfeld and Kak (5) defined an edge as an abrupt change in gray level or in texture where one region ends and another begins. An edge point is a pixel in an image where significant local intensity change takes place. An edge fragment is an edge point and its orientation. An edge detector is an algorithm that produces a set of edges from an image. The term “edge” is used for either edge points or edge fragments (6–8).

Edge types can be classified as step edge, line edge, ramp edge, and roof edge (7 –9). Step edge is an ideal type that occurs when image intensity changes significantly from one value on one side to a different value on the other. Line edges occur at the places where the image intensity changes abruptly to a different value, stays at that value for the next small number of pixels, and then returns to the original value. However, in real-world images, step edge and line edge are rare because of various lighting conditions and noise introduced by image-sensing devices. The step edges often become ramp edges, and the line edges become the roof edges in the real-world image (7,8). Figure 1(a)–(d) show one-dimensional profiles of step, line, ramp, and roof edge, respectively.

EDGE DETECTION METHODS IN GRAY-LEVEL IMAGES

Because edges are, based on the definition, image pixels that have abrupt changes (or discontinuities) in image intensity, the derivatives of the image intensity function (10) can be used to measure these abrupt changes. As shown in Fig. 2(a) and (b), the first derivative of the image intensity function has a local peak near the edge points. Therefore, edges can detect by thresholding the first derivative values of an image function or by the zero-crossings in the second derivative of the image intensity as shown in Fig. 2(c).

Edge detection schemes based on the derivatives of the image intensity function are very popular, and they can be categorized into two groups: gradient-based and zero-crossing-based (or called Laplacian) methods. The gradient-based methods find the edges by searching for the maxima (maximum or minimum) in the first derivatives of the image function. The zero-crossing (Laplacian) methods detect the edges by searching for the zero crossings in the second derivatives of the image function.

Gradient-Based Edge Detection

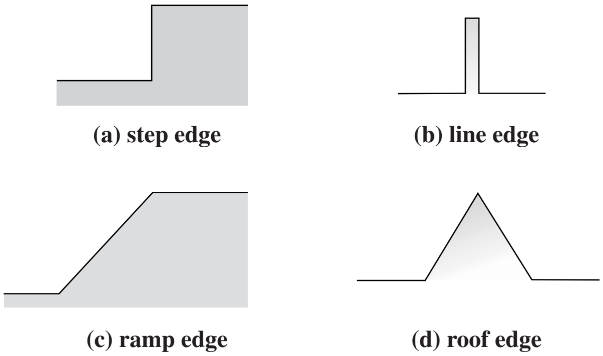
An edge is associated with a local peak in the first derivative. One way to detect edges in an image is to compute the gradient of local intensity at each point in the image. For an image, *f(x, y)* with x and y, the row and the column coordinates, respectively, its two-dimensional gradient is defined as a vector with two elements:

$$G = \begin{bmatrix} G_x \\ G_y \end{bmatrix} = \begin{bmatrix} \dfrac{\partial f(x,y)}{\partial x} \\ \dfrac{\partial f(x,y)}{\partial y} \end{bmatrix} = \begin{bmatrix} [f(x+dx, y) - f(x, y)]/dx \\ [f(x, y+dy) - f(x, y)]/dy \end{bmatrix} \tag{1}$$

where G_x and G_y measure the change of pixel values in the x- and y-directions, respectively. For digital images, dx and dy can be considered in terms of number of pixels between two points, and the derivatives are approximated by differences between neighboring pixels. Two simple approximation schemes of the gradient for $dx = dy = 1$ are

$$\begin{aligned} &G_x \approx f(x+1,y) - f(x,y)\,,\; G_y \approx f(x,y+1) - f(x,y) \\ &G_x \approx f(x+1,y) - f(x-1,y),\; G_y \approx f(x,y+1) - f(x,y-1) \end{aligned} \tag{2}$$

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.



(a) step edge

(b) line edge

(c) ramp edge

(d) roof edge

Figure 1. One-dimensional profiles of four different edge types.

These derivative approximation schemes are called the first difference and the central difference, respectively. The convolution masks for the first difference and the central difference can be represented as follows, respectively (11):

$$G_x = \begin{bmatrix} -1 & 0 \\ 1 & 0 \end{bmatrix}, \; G_y = \begin{bmatrix} -1 & 1 \\ 0 & 0 \end{bmatrix},$$

$$G_x = \begin{bmatrix} 0 & -1 & 0 \\ 0 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix}, \; G_y = \begin{bmatrix} 0 & 0 & 0 \\ -1 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix}$$

The first difference masks cause the edge location bias because the zero crossings of its vertical and horizontal masks lie at different positions. On the other hand, the central difference masks avoid this position mismatch problem because of the common center of horizontal and vertical masks (11). Many edge detectors have been designed using convolution masks using 3 × 3 mask sizes or even larger.

Two important quantities of the gradient are the magnitude and the direction of the gradient. The magnitude of the gradient G_m is calculated by

$$G_m = \sqrt{G_x^2 + G_y^2} \tag{3}$$

To avoid the square root computation, the gradient magnitude is often approximated by

$$G_m \approx |G_x| + |G_y| \text{ or} \tag{4}$$

$$G_m \approx \max(|G_x|, |G_y|) \tag{5}$$

The direction of the gradient is given by

$$\theta_g = \begin{cases} \tan^{-1}\left(\dfrac{G_y}{G_x}\right) & \text{if} \quad G_x \neq 0 \\ 0^0 & \text{if} \quad G_x = 0 \cap G_y = 0 \\ 90^0 & \text{if} \quad G_x = 0 \cap G_y \neq 0 \end{cases} \tag{6}$$

where the angle θ_g is measured with respect to the x-axis.

In general, a gradient-based edge detection procedure consists of the following three steps:

1. *Smoothing filtering:* Smoothing is used as a preprocessing step to reduce the noise or other fluctuations in the image. Gaussian filtering (10–13) is a well-known low-pass filter, and σ parameter controls the strength of the smoothing. However, smoothing filtering can also blur sharp edges, which may contain important features of objects in the image.
2. *Differentiation:* Local gradient calculation is implemented by convolving the image with two masks, G_x and G_y, which are defined by a given edge detector. Let us denote the convolution of a mask M_{kxk} and an

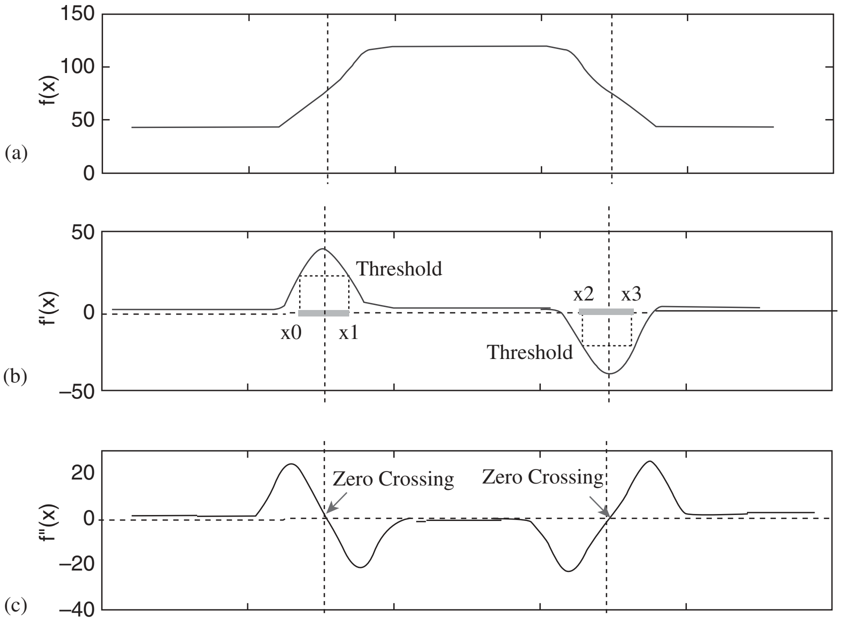


Figure 2. Edge detection by the derivative operators: (a) 1-D profile of a smoothed step edge, (b) the first derivative of a step edge, and (c) the second derivative of a step edge.

image f_{mxn} as N_{mxn}. For every pixel (i,j) in the image f, we calculate:

$$N(i,j) = M \oplus f(i,j) = \sum_{k2=-\frac{k}{2}}^{\frac{k}{2}} \sum_{k1=-\frac{k}{2}}^{\frac{k}{2}} M\,(k1,k2) \times f(i+k1, j+k2 \qquad (7)$$

for $1 \leq i \leq m,\ 1 \leq j \leq n$

3. *Detection:* Detecting edge points based on the local gradients. The most common approach is to apply a threshold to image gradients. If the magnitude of the gradient of an image pixel is above a threshold, the pixel is marked as an edge. Some techniques such as the hysteresis method by Canny (3) use multiple thresholds to find edges. The thinning algorithm is also applied to remove unnecessary edge points after thresholding as necessary (14,15).

Roberts Cross Edge Detector. The Roberts cross edge detector is the simplest edge detector. It rotated the first difference masks by an angle of 45°. Its mathematic expressions are (10,12)

$$G_x = f(x, y+1) - f(x+1, y),$$
$$G_y = f(x, y) - f(x+1, y+1) \qquad (8)$$

G_x and G_y can be represented in the following convolution masks:

$$G_x = \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix},\ G_y = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}$$

These two convolution masks respond maximally to edges in diagonal directions (45°) in the pixel grid. Each mask is simply rotated 90° from the other. The magnitude of the gradient is calculated by Equation (3). To avoid the square root computation, the computationally simple form of the Robert cross edge detector is the Robert's absolute value estimation of the gradient given by Equation (4).

The main advantage of using Roberts cross edge operator is its fast computational speed. With a 2 × 2 convolution mask, only four pixels are involved for the gradient computation. But the Roberts cross edge operator has several undesirable characteristics. Because it is based on the first difference, its 2 × 2 diagonal masks lie off grid and cause edge location bias. The other weak points are that it is sensitive to noise and that its response to the gradual(or blurry) edge is weak. Figure 3(b)–(g) show the Roberts cross edge maps with various threshold values. The experiment shows that the Roberts cross edge detector is sensitive to the noise with low threshold values. As the threshold value increases, noise pixels are removed, but also real edge pixels with weak response are removed (11).

Prewitt Edge Operator. The Prewitt edge operator uses the central difference to approximate differentiation. Two Prewitt convolution masks at x- and y-directions are shown below:

$$G_x = \frac{1}{3}\begin{bmatrix} -1 & 0 & 1 \\ -1 & 0 & 1 \\ -1 & 0 & 1 \end{bmatrix},\ G_y = \frac{1}{3}\begin{bmatrix} -1 & -1 & -1 \\ 0 & 0 & 0 \\ 1 & 1 & 1 \end{bmatrix}$$

Because it has the common center of G_x and G_y masks, the Prewitt operator has less edge-location bias compared with the first difference-based edge operators. It also accomplishes noise reduction in the orthogonal direction by means of local averaging (11).

The local gradient at pixel (x, y) can be estimated by convolving the image with two Prewitt convolution masks, G_x and $G_{y,}$ respectively. Mathematically we have

$$\begin{aligned} G_x &= \frac{1}{3}([f(x-1, y+1) + f(x, y+1) + f(x+1, y+1)] - \\ &\quad [f(x-1, y-1) + f(x, y-1) + f(x+1, y-1)]) \\ G_y &= \frac{1}{3}([f(x+1, y-1) + f(x+1, y) + f(x+1, y+1)] - \\ &\quad [f(x-1, y-1) + f(x-1, y) + f(x-1, y+1)]) \end{aligned} \qquad (9)$$

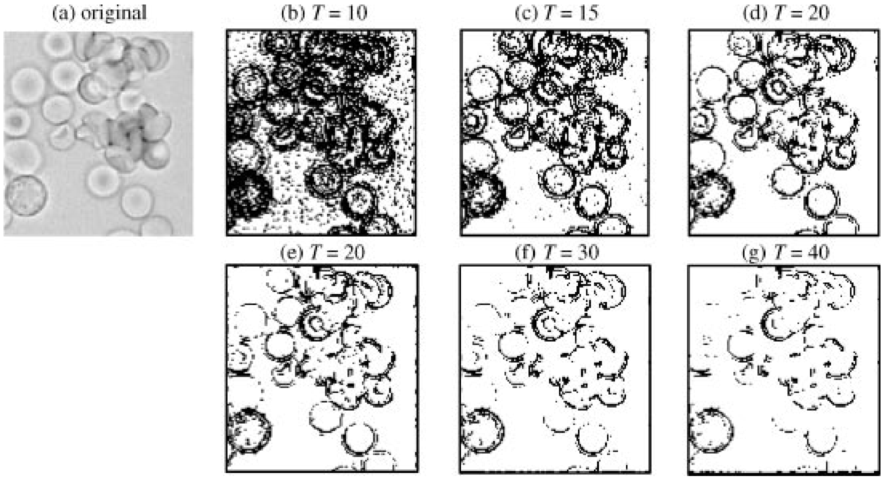

Figure 3. Roberts cross edge maps by using various threshold values: as threshold value increases, noise pixels are removed, but also real edge pixels with weak responses are removed.

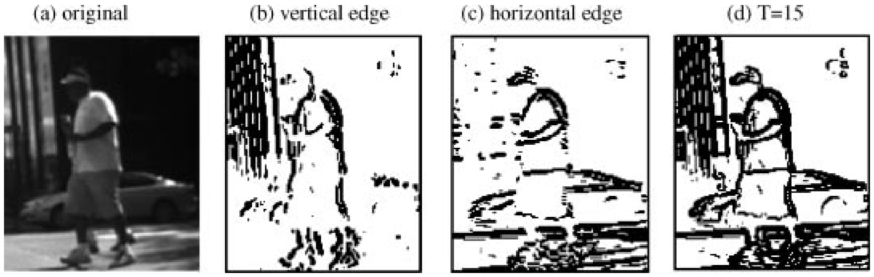

Figure 4. Prewitt edge maps: (a) original image, (b) vertical edge map generated by G_x, (c) horizontal edge map generated by G_y, and (d) complete edge map, $T = 15$.

The Prewitt operators can be extended to detect edges tilting at 45° and 135° by using the following two masks.

$$\begin{bmatrix} -1 & -1 & 0 \\ -1 & 0 & +1 \\ 0 & +1 & +1 \end{bmatrix}, \begin{bmatrix} 0 & +1 & +1 \\ -1 & 0 & +1 \\ -1 & -1 & 0 \end{bmatrix}$$

Figure 4(b) shows the vertical edge map generated by the Prewitt G_x mask, and the horizontal edge map generated by the Prewitt G_y mask is shown in Fig. 4(c). Combining these two horizontal and vertical edge maps, the complete edge map is generated as shown in Fig. 4(d).

Sobel Edge Detector. The Sobel gradient edge detector is very similar to the Prewitt edge detector except it puts emphasis on pixels close to the center of the masks. The Sobel edge detector (10,12) is one of the most widely used classic edge methods. Its x- and y-directional 3×3 convolution masks are as follows:

$$G_x = \frac{1}{4}\begin{bmatrix} -1 & 0 & 1 \\ -2 & 0 & 2 \\ -1 & 0 & 1 \end{bmatrix}, \; G_y = \frac{1}{4}\begin{bmatrix} -1 & -2 & -1 \\ 0 & 0 & 0 \\ 1 & 2 & 1 \end{bmatrix}$$

The local gradient at pixel (x,y) can be estimated by convolving the image with two Sobel convolution masks, G_x and $G_{y,}$ respectively,

$$\begin{aligned} G_x &= \frac{1}{4}([f(x-1,y+1) + 2\times f(x,y+1) + f(x+1,y+1)] - \\ &\quad [f(x-1,y-1) + 2 \times f(x,y-1) + f(x+1,y-1)]) \\ G_y &= \frac{1}{4}([f(x+1,y-1) + 2\times f(x+1,y) + f(x+1,y+1)] - \\ &\quad [f(x-1,y-1) + 2 \times f(x-1,y) + f(x-1,y+1)]) \end{aligned} \tag{10}$$

The Sobel operator puts more weights on the pixels near the center pixel of the convolution mask. Both masks are applied to every pixel in the image for the calculation of the gradient at the x- and y-directions. The gradient magnitude is calculated by Equation (3). The Sobel edge detectors can be extended to detect edges at 45° and 135° by using the two masks below:

$$\begin{bmatrix} -2 & -1 & 0 \\ -1 & 0 & +1 \\ 0 & +1 & +2 \end{bmatrix}, \begin{bmatrix} 0 & +1 & +2 \\ -1 & 0 & +1 \\ -2 & -1 & 0 \end{bmatrix}$$

Figure5(j)–(l) show the edge detection results generated by the Sobel edge detector with the threshold value, $T = 20$. Figure 5 also shows the performance analysis of each gradient-based edge detector in the presence of noises. To evaluate the noise sensitivity of each edge detector, 5% and 10% Gaussian noise are added into the original image as shown in Fig. 5(b) and (c), respectively. For fair comparisons, a fixed threshold value is used ($T = 20$) for all edge detectors. Figure 5(e) and (f) show that the Roberts cross edge detector is sensitive to noises. On the other hand, the Sobel and the Prewitt edge detectors are less sensitive to noises. The Sobel operators provide both differencing and smoothing effects at the same time. Because of these characteristics, the Sobel operators are widely used for edge extraction. The smoothing effect is achieved through the involvement of 3×3 neighbors to make the operator less sensitive to noises. The differencing effect is achieved through the higher gradient magnitude by involving more pixels in convolution in comparison with the Roberts operator. The Prewitt operator is similar to the Sobel edge detector. But the Prewitt operator's response to the diagonal edge is weak compared with the response of the Sobel edge operator. Prewitt edge operators generate slightly less edge points than do Sobel edge operators.

Non-Maximum Suppression—a Postprocessing After Gradient Operation. One difficulty in gradient edge detectors (and also in many other edge detectors) is how to select the best threshold (16) used to obtain the edge points. If the threshold is too high, real edges in the image can be missed. If the threshold is too low, nonedge points such as noise are detected as edges. The selection of the threshold critically affects the edge output of an edge operator. Another problem related with the gradient edge detectors is that edge outputs from the gradient-based method appear to be several pixels wide rather than a single pixel (see Figs. 3–5). This problem is because most edges in the real-world images are not step edges and the grayscales around the edges change gradually from low to high intensity, or vice versa. So a thinning process such as nonmaximum suppression (14,15,17–19) may be needed after the edge detection.

The method of nonmaximum suppression is used to remove weak edges by suppressing the pixels with nonmaximum magnitudes in each cross section of the edge direction (15). Here, we introduce the algorithm proposed by Rosenfeld and Thursten(14,15,17–19). Let $\theta(i)$ denote the edge direction at pixel i, and let $G_m(i)$ denote the gradient magnitude at i.

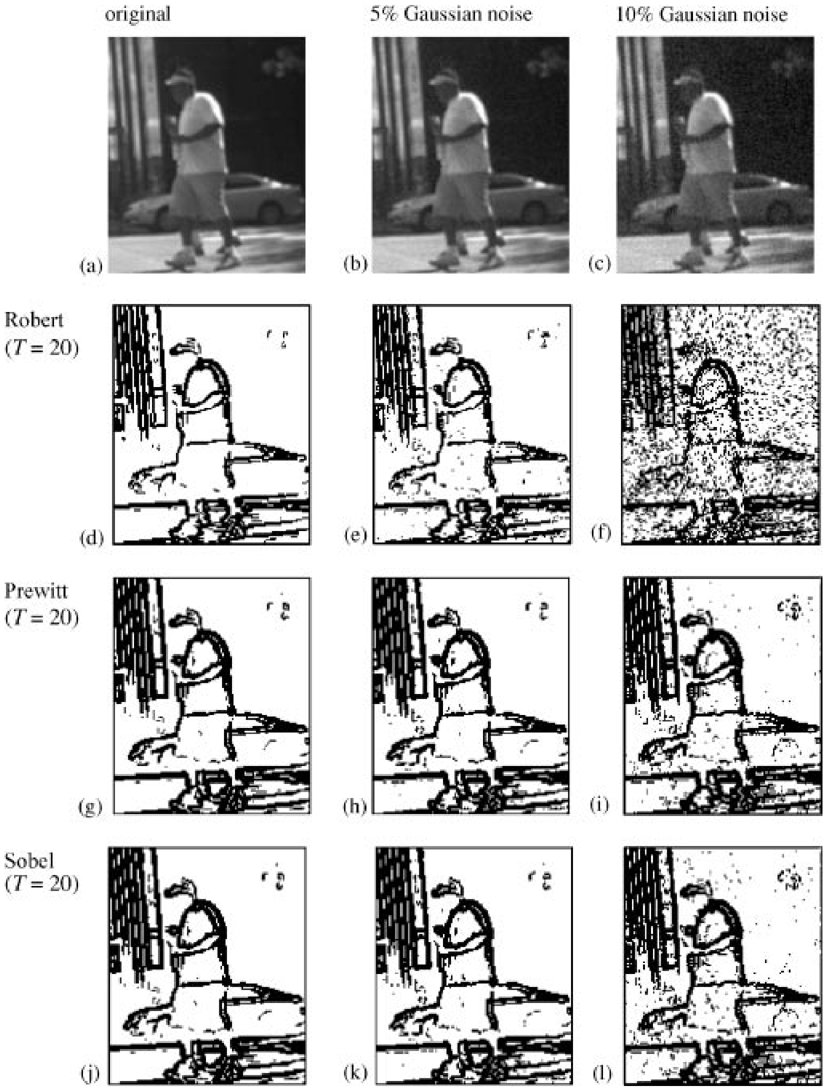

Figure 5. Performance evaluation in the presence of noises for gradient-based edge operators: (a) original image, (b) add 5% Gaussian noise, (c) add 10% Gaussian noise, (d)–(f) Roberts edge maps, (g)–(i) Prewitt edge maps, and (j)–(l) Sobel edge maps. Used the same threshold ($T = 20$) for fair comparisons.

Step 0: For every edge point, *p(x,y)*, do the following steps.

Step 1: Find two nearest neighboring pixels q_1 and q_2 that are perpendicular to the edge direction associated with the edge pixel p.

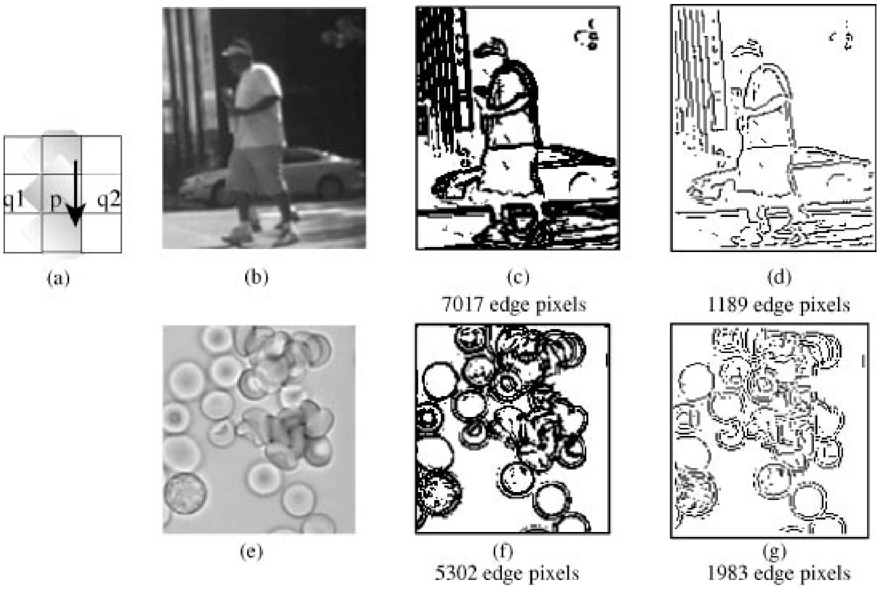
Step 2: If ($|\theta(p) - \theta(q_1)| \leq \alpha$ and $|\theta(p) - \theta(q_2)| \leq \alpha$), then go to ***Step 3*** else return to ***Step 0***.

Step 3: If ($G_m(p) \leq G_m(q_1)$ or $G_m(p) \leq G_m(q_2)$), then suppress the edge at pixel p.

Figure 6(a) shows how to choose q_1 and q_2 when edge direction at pixel p is vertical (top-to-down), which is shown in an arrow. Four edge directions are often used in the nonmaximum suppression method: 0°, 45°, 90°, and 135°, respectively, and all edge orientations are quantized to these four directions. Figure 5(d) and (g) shows the results after the nonmaximum suppression is applied to the edge images in Fig. 5(c) and (f), respectively. Figure 5(d) generated 71.6% less edge pixels compared with the edge pixels in Fig. 5(c). Figure 5(g) has 63.6% less edge pixels compared with the edge pixels in Fig. 5(f). In our experiments, more than 50% of the edge points that were generated by the gradient-based edge operator are considered as nonlocal maximal and suppressed.

Second-Derivative Operators

The gradient-based edge operators discussed above produce a large response across an area where an edge presents. We use an example to illustrate this problem. Figure 2(a) shows a cross cut of the smooth step edge, and its first derivative (or gradient) is shown in Fig. 2(b). After a threshold is applied to the magnitude of the gradient and to all pixels above the



(a) (b) (c) 7017 edge pixels (d) 1189 edge pixels

(e) (f) 5302 edge pixels (g) 1983 edge pixels

Figure 6. Experiments with nonmaximum suppression: (a) an example of how to select q_1, and q_2 when edge direction is top-to-down, (b) and (e) original input images, (c) and (f) Sobel edge maps ($T = 20$) before nonmaximum suppression, and (d) and (g) edge maps after nonmaximum suppression is applied to (c) and (f), respectively.

threshold, for example, the pixels in Fig. 2(b) between $x0 \sim x1$ and $x2 \sim x3$ are considered as edge points. As a result, too many edge points occur, which causes an edge localization problem: Where is the true location of the edge? Therefore, a good edge detector should not generate multiple responses to a single edge. To solve this problem, the second-derivative-based edge detectors have been developed.

Laplacian Edge Detector. The Laplacian of a function *f(x, y)* is given by Equation (11)

$$\nabla^2 f(x,y) = \frac{\partial^2 f(x,y)}{\partial x^2} + \frac{\partial^2 f(x,y)}{\partial y^2} \tag{11}$$

Because the Laplacian edge detector defines an edge as the zero crossing of the second derivative, a single response is generated to a single edge location as observed in Fig. 2(c). The discrete Laplacian convolution mask is constructed as follows:

For a digital image, G_x is approximated by the difference

$$\frac{\partial f(x,y)}{\partial x} = G_x \approx f(x+1,y) - f(x,y), \text{ so}$$

$$\begin{aligned}
\frac{\partial^2 f(x,y)}{\partial x^2} &= \frac{\partial}{\partial x}\left(\frac{\partial f(x,y)}{\partial x}\right) = \frac{\partial G_x}{\partial x} \approx \frac{\alpha(f(x+1,y) - f(x,y))}{\partial x} \\
&= \frac{\alpha f(x+1,y)}{\partial x} - \frac{\partial f(x,y)}{\partial x} \\
&= [f(x+2,y) - f(x+1,y)] - [f(x+1,y) - f(x,y)] \\
&= f(x+2,y) - 2f(x+1,y) + f(x,y)
\end{aligned} \tag{12}$$

This approximation is centered at the pixel $(x + 1, y)$. By replacing $x + 1$ with x, we have

$$\frac{\partial^2 f(x,y)}{\partial x^2} = f(x+1,y) - 2f(x,y) + f(x-1,y) = \begin{bmatrix} 1 \\ -2 \\ 1 \end{bmatrix}$$

Similarly,

$$\begin{aligned}
\frac{\partial^2 f(x,y)}{\partial y^2} &= f(x,y+1) - 2f(x,y) + f(x,y-1) \\
&= [1 \quad -2 \quad 1]
\end{aligned} \tag{13}$$

By combining the x and y second partial derivatives, the Laplacian convolution mask can be approximated as follows:

$$\nabla^2 f(x,y) = \begin{bmatrix} 1 \\ -2 \\ 1 \end{bmatrix} + [1 \quad -2 \quad 1] = \begin{bmatrix} 0 & 1 & 0 \\ 1 & -4 & 1 \\ 0 & 1 & 0 \end{bmatrix}$$

Other Laplacian convolution masks are constructed similarly by using the different derivative estimation and different mask size (11). Two other 3×3 Laplacian masks are

$$\begin{bmatrix} 1 & 1 & 1 \\ 1 & -8 & 1 \\ 1 & 1 & 1 \end{bmatrix} \text{ or } \begin{bmatrix} -1 & 2 & -1 \\ 2 & -4 & 2 \\ -1 & 2 & 1 \end{bmatrix}$$

After the convolution of an image with a Laplacian mask, edges are found at the places where convolved image values change sign from positive to negative (or vice versa) passing through zero. The Laplacian edge detector is omnidirectional (isotropic), and it highlights edges in all directions. Another property of the Laplacian edge detector is that it generates closed curves of the edge contours. But the Laplacian edge detector alone is seldom used in real-world computer vision applications because it is too sensitive to image noise. As shown in Fig. 7(c), the very small local peak in the first derivative has its second derivative cross through zero. The Laplacian edge detector may generate spurious edges because of image noise. To avoid the effect of noise, a Gaussian filtering is often applied to an image before the Laplacian operation.

Marr Hildreth—Laplacian of Gaussian. Marr and Hildreth (13) combined the Gaussian noise filter with the Laplacian into one edge detector called the Laplacian of Gaussian (LoG). They provided the following strong argument for the LoG:

1. Edge features in natural images can occur at various scales and different sharpness. The LoG operator can be applied to detecting multiscales of edges.
2. Some form of smoothing is essential for removing noise in many real-world images. The LoG is based on the filtering of the image with a Gaussian smoothing filter. The Gaussian filtering reduces the noise sensitivity problem when zero crossing is used for edge detection.
3. A zero crossing in the LoG is isotropic and corresponds to an extreme value in the first derivative.

Theoretically the convolution of the input image *f(x,y)* with a two-dimensional (2-D) Gaussian filter *G(x,y)* can be expressed as

$$S(x,y) = G(x,y) \times f(x,y), \text{ where } G(x,y) = \frac{1}{\sqrt{2\pi}\sigma} e^{-\frac{(x^2+y^2)}{\sigma^2}} \tag{14}$$

Then, the Laplacian (the second derivative) of the convolved image S is obtained by

$$\nabla^2 S(x,y) = \nabla^2[G(x,y) \times f(x,y)] = [\nabla^2 G(x,y)] \times f(x,y) \tag{15}$$

The computation order of Laplacian and convolution operations can be interchanged because these two operations are linear and shift invariant (11) as shown in Equation (15). Computing the Laplacian of the Gaussian filtered image $\nabla^2[G(x,y) \times f(x,y)]$ yields the same result with convolving the image with the Laplacian of the Gaussian filter ($[\nabla^2 G(x,y)] \times f(x,y)$). The Laplacian of the Gaussian filter $\nabla^2 G(x,y)$ is defined as follows:

$$\mathrm{LoG}(x,y) = \nabla^2 G(x,y) = -\frac{1}{\pi\sigma^4}\left[1 - \frac{(x^2+y^2)}{2\sigma^2}\right] e^{-\frac{x^2+y^2}{2\sigma^2}} \tag{16}$$

where σ is the standard deviation, which also determines the spatial scale of the Gaussian. Figure 8(a) shows a one-dimensional (1-D) LoG profile and (b) shows a 2-D LoG profile. A 2-D LoG operation can be approximated by a convolution kernel. The size of the kernel is determined by the scale parameter σ. A discrete kernel that approximates the LoG with $\sigma = 1.4$ is shown in Fig. 9. In summary, edge detection using the LoG consists of the following two steps:

1. Convolve the image with a 2-D LoG mask at a selected scale σ.
2. Consider as edges only those zero-crossing pixels whose corresponding first derivatives are above a threshold. To find a zero crossing, we need to check four cases for the signs of the two opposing neighboring pixels: up/down, right/left, and the two diagonals.

Note that results of edge detection depend largely on the σ value of the LoG. The convolution mask is larger for a larger σ, which is suitable for detecting large-scale edges. Figure 10 shows edge maps generated by the

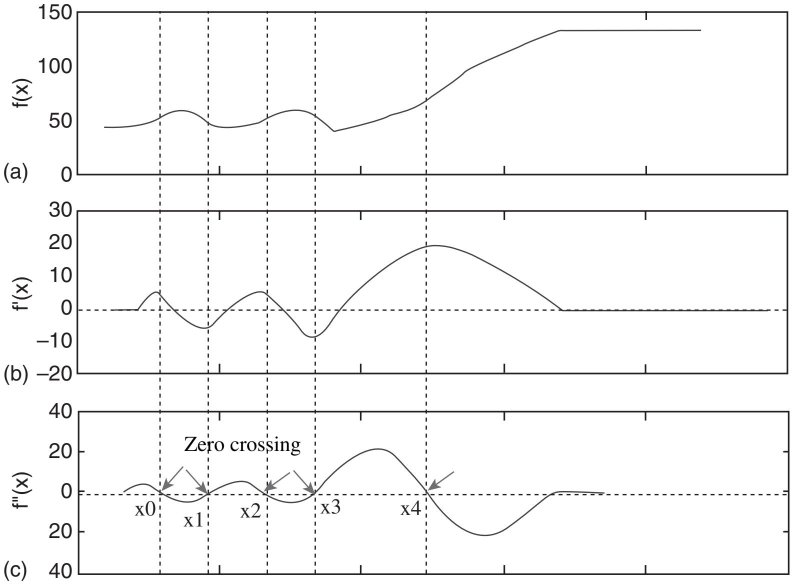


Figure 7. Illustration of spurious edges generated by zero crossing: (a) 1-D profile of a step edge with noise, (b) the first derivative of a step edge, and (c) the second derivative of a step edge. The zero crossing of *f(x)* creates several spurious edges points (x_0, x_1, x_2, and x_3).

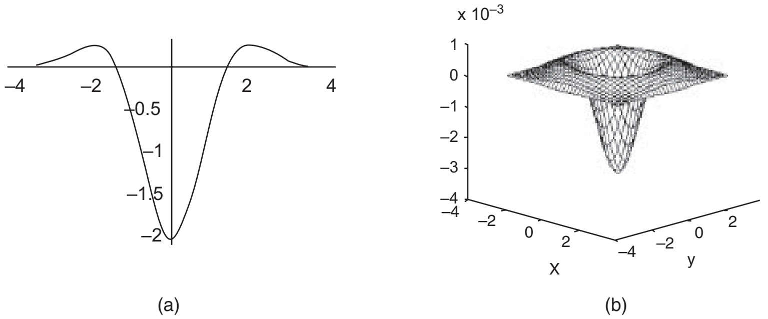

Figure 8. (a) a 1-D LoG profile and (b) a 2-D LoG profile.

LoG operator with various scales. Figure 10(b)–(e) show the LoG edge maps with $\sigma = 1.0, 1{,}5, 2.0$, and 2.5, respectively. In Fig. 10(f), two different scales $\sigma_1 = 0.7, \sigma_2 = 2.3$ are used, and the result is obtained by selecting the edge points that occurred in both scales. Figure 10(g) and (h) use the gradient magnitude threshold to reduce noise and break contours.

In comparison with the edge images based on the gradient methods in Figs. 3–5, the edge maps from the LoG is thinner than the gradient-based edge detectors. Because of the smoothing filtering in the LoG operator, its edge images (Fig. 10) are robust to noise; however, sharp corners are lost at the same time. Another interesting feature of the LoG is that it generates the closed-edge contours. However, spurious edge loops may appear in outputs and edge locations may shift at large scales (8). Both the LoG and the Laplacian edge detectors are isotropic filters, and it is not possible to extract directly the edge orientation information from these edge operators. Postprocesses such as nonmaxima suppression and hysteresis thresholding are not applicable.

Advanced Edge Detection Method—Canny Edge Detection

The Canny edge detector (3,16,20) is one of the most widely used edge detectors. In 1986, John Canny proposed the following three design criteria for an edge detector:

1. *Good localization*: Edge location founded by the edge operator should be as close to the actual location in the image as possible.
2. *Good detection with low error rate*: An optimal edge detector should respond only to true edges. In other words, no spurious edges should be found, and true edges should not be missed.
3. *Single response to a single edge*: The optimal edge detector should not respond with multiple edge pixels to the place where only a single edge exists.

Figure 9. A discrete kernel that approximates the LoG with $\sigma = 1.4$.

Following these design criteria, Canny developed an optimal edge detection algorithm based on a step edge model with white Gaussian noise. The Canny edge detector involves the first derivative of a Gaussian smoothing filter with standard deviation σ. The choice of σ for the Gaussian filter controls the filter width and the amount of smoothing (11). Steps for the Canny edge detector are described as follows:

1. *Smoothing using Gaussian filtering*: A 2-D Gaussian filter *G(x,y)* by Equation (14) is applied to the image to remove noise. The standard deviation σ of this Gaussian filter is a scale parameter in the edge detector.
2. *Differentiation*: Compute the gradient G_x in the *x*-direction and G_y in the *y*-direction using any of the gradient operators (Roberts, Sobel, Prewitt, etc.). The magnitude G_m and direction θ_g of the gradient can be calculated as

$$G_m = \sqrt{G_x^2 + G_y^2}, \ \theta_g = \tan^{-1}\left(\frac{G_y}{G_x}\right) \tag{16}$$

3. *Nonmaximum suppression:* Apply the nonmaximum suppression operation (see the section on “Nonmaximum Suppression” for details) to remove spurious edges.
4. *Hysteresis process*: The hysteresis step is the unique feature of the Canny edge operator (20). The hysteresis process uses two thresholds, a low threshold t_{low}, and a high threshold t_{high}. The high threshold is usually two or three times larger than the low threshold. If the magnitude of the edge value at the pixel *p* is lower than t_{1ow}, then the pixel *p* is marked immediately as a non-edge point. If the magnitude of the edge value at pixel *p* is greater than t_{high}, then it is immediately marked as an edge. Then any pixel that is connected to the marked edge pixel *p* and its

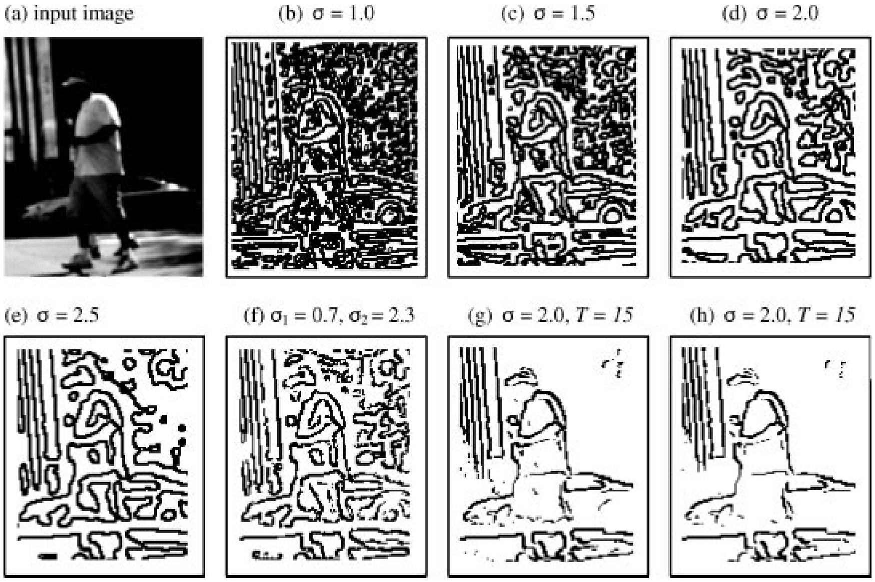

Figure 10. The LoG operator edge maps: (b) $\sigma = 1.0$, (c) $\sigma = 1.5$, (d) $\sigma = 2.0$, (e) $\sigma = 2.5$, (f) two scales used $\sigma_1 = 0.7$ and $\sigma_2 = 2.3$, (g) $\sigma = 2.0$ and $T = 15$, and (h) $\sigma = 2.0$ and $T = 20$.

magnitude of the edge value is greater than a low threshold t_{low}, it is also marked as an edge pixel. The edge marking of the hysteresis process is implemented recursively. This hysteresis producer generates the effects of reducing the broken edge contours and of removing the noise in adaptive manner (11).

The performance of the Canny operator is determined by three parameters: the standard deviation σ of the Gaussian filter and the two thresholds t_{low} and t_{high}, which are used in the hysteresis process. The noise elimination and localization error are related to the standard deviation σ of the Gaussian filter. If σ is larger, the noise elimination is increased but the localization error can also be more serious. Figures 11 and 12 illustrate the results of the Canny edge operator. Figure 11 demonstrate the effect of various σ values with the same upper and lower threshold values. As the σ value increases, noise pixels are removed but the sharp corners are lost at the same time. The effect of the hysteresis threshold is shown in Fig. 12. Figure 12(a) and (c) are edge maps with the hysteresis threshold. Edge maps with a hysteresis threshold have less broken contours than edge maps with one threshold: Compare Fig. 12(a) with Fig. 12(b). Table 1 summarized the computational cost of each edge operators used in gray images. It is noticed that the computational cost of the Canny operator is higher than those of other operators, but the Canny operator generates the more detailed edge map in comparison with the edge maps generated by other edge operators.

EDGE DETECTION IN COLOR IMAGES

What is the Color Image?

An image pixel in the color image is represented by a vector that is consisted of three components. Several different ways exist to represent a color image, such as RGB, YIQ,

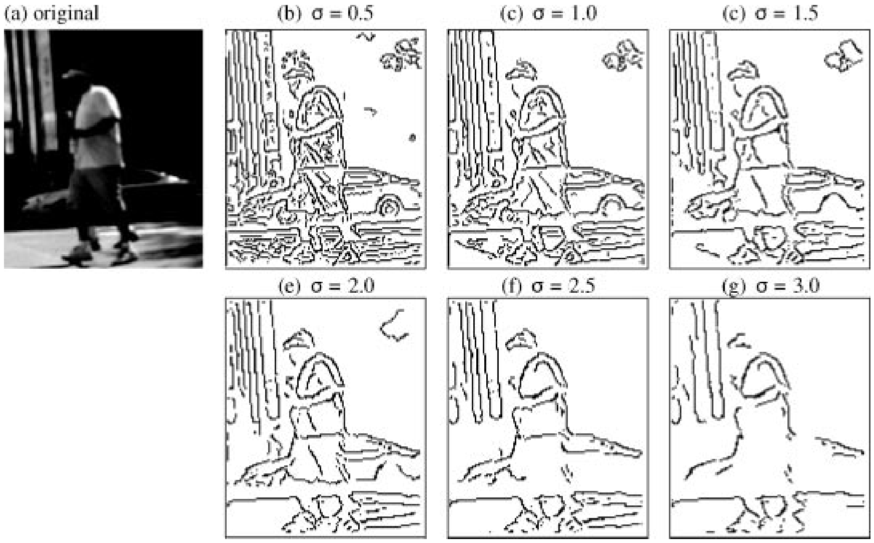

Figure 11. The effect of the standard deviation σ of the Gaussian smoothing filter in the Canny operator: (b) $\sigma = 0.5$, (c) $\sigma = 1.0$, (d) $\sigma = 1.5$, (e) $\sigma = 2.0$, (f) $\sigma = 2.5$, and (g) $\sigma = 3.0$, $T_{\mathrm{high}} = 100$, $T_{\mathrm{low}} = 40$.

HIS, and CIE L*u*v*. The RGB, the YIQ, and the HSI are the color models most often used for image processing (10).

The commonly known RGB color model consists of three colors components: Red(R), Green (G) and Blue (B). The RGB color model represents most closely to the physical sensors for colored light in most color CCD sensors (21). RGB is a commonly used color model for the digital pictures acquired by digital cameras (22). The three components in the RGB model are correlated highly, so if the light changes, all three components are changed accordingly (23).

The YIQ color space is the standard for color television broadcasts in North America. The YIQ color space is obtained from the RGB color model by linear transformation as shown below (10):

$$\begin{bmatrix} Y \\ I \\ Q \end{bmatrix} = \begin{bmatrix} 0.299 & 0.587 & 0.114 \\ 0.596 & -0.275 & -0.321 \\ 0.212 & -0.523 & 0.311 \end{bmatrix} \begin{bmatrix} R \\ G \\ B \end{bmatrix} \tag{17}$$

In the YIQ color space, Y measures the luminance of the color value and I and Q are two chromatic components called *in-phase* and *quadrature*. The main advantage of YIQ color model in image processing is that luminance (Y) and two chromatic components (I and Q) are separated (10,24).

The HSI (hue, saturation, intensity), also known as HSB (hue, saturation, brightness), and its generalized form HSV (hue, saturation, value) models are also used frequently in color image processing (24–26). The HSI model corresponds more accurately to the human perception of color qualities. In the HSI model, hue, the dominant color, is represented by an angle in a color circle where primary colors are separated by 120° with Red at 0°, Green at 120°, and Blue at 240°. Saturation is the purity of the color. The high saturated values are assigned for pure spectral colors and the low values for the mixed shades. The intensity is associated with the overall brightness of a pixel (21).

Color Edge Detection versus Gray-Level Edge Detection

The use of color in edge detection implies that more information for edges is available in the process, and the edge detection results should be better than those of the gray-level images. Novak and Shafer (27) found that 90% of edge pixels are about the same in edge images obtained from gray-level and from color images. But 10% of the edge pixels left are as undetected when gray-level information is used (28). It is because edge may not be detected in the intensity component in low contrast images, but it can be detected in the chromatic components. For some applications, these undetected edges may contain crucial information for a later processing step, such as edge-based image segmentation or matching (29). Figure 13 demonstrates the typical example of the differences between color edge detectors and gray-level edge detectors. The gray-level Sobel edge detector missed many (or all) real edge pixels because of the low contrast in the intensity component as shown in Fig. 13(c) and (d).

A color image is considered as a two-dimensional array *f(x,y)* with three components for each pixel. One major concern in color edge detection is the high computational complexity, which has increased significantly in comparison with the edge detection in gray value images (see Table 2 for the computational cost comparison between the color Sobel operator and the gray-level Sobel operator with various size of images).

Definition of Edge in Color Images

The approaches for detecting edges in color images depend on the definition of an edge. Several definitions have been

Table 1. Computational cost comparison

		Image Size		
Computational Time (Seconds)	680 by 510	1152 by 864	1760 by 1168	
	Robert	0.032	0.125	0.219
	Prewitt	0.062	0.234	0.422
	Sobel	0.047	0.187	0.343
Gray image	Robert+NMS*	0.141	0.438	0.1
Edge operator	Prewitt+NMS*	0.14	0.516	1.188
	Sobel+NMS*	0.109	0.531	1.234
	LOG	0.5	1.453	2.984
	Canny	0.469	1.531	3.172

*NMS = Nonmaximum suppression.

Table 2. Computational cost comparison: the gray-level Sobel edge detector versus the color-Sobel edge detector

	Image Size		
Computational time (Seconds)	680 by 510	1152 by 864	1760 by 1168
Gray-level Sobel operator	0.047	0.187	0.343
Color Sobel operator	0.172	0.625	1.11

proposed, but the precise definition of color edge has not been established for color images so far (30). G. S. Robinson (24) defined a color edge as the place where a discontinuity occurs in the image intensity. Under this definition, edge detection would be performed in the intensity channel of a color image in the HIS space. But this definition provides no explanation of possible discontinuities in the hue or saturation values. Another definition is that an edge in a color image is where a discontinuity occurs in one color component. This definition leads to various edge detection methods that perform edge detection in all three color components and then fuses these edges to an output edge image (30). One problem facing this type of edge detection methods is that edges in each color component may contain inaccurate localization. The third definition of color edges is based on the calculation of gradients in all three color components. This type of multidimensional gradient methods combines three gradients into one to detect edges. The sum of the absolute values of the gradients is often used to combine the gradients.

Until now, most color edge detection methods are based on differential grayscale edge detection methods, such as finding the maximum in the first derivative or zero crossing in the second derivative of the image function. One difficulty in extending these methods to the color image originates from the fact that the color image has vector values. The monochromatic-based definition lacks the consideration about the relationship among three color components. After the gradient is calculated at each component, the question of how to combine the individual results remains open (31).

Because pixels in a color image are represented by a vector-valued function, several researchers have proposed vector-based edge detection methods (32–36). Cumani (32,35) and Zenzo (36) defined edge points at the locations of directional maxima of the contrast function. Cumani suggested a method to calculate a local measure of directional contrast based on the gradients of the three color components.

Color Edge Detection Methods

Monochromatic-Based Methods. The monochromatic-based methods extend the edge detection methods developed for gray-level images to each color component. The results from all color components are then combined to generate the final edge output. The following introduces commonly used methods.

Method 1: the Sobel operator and multidimensional gradient method

(i) Apply the Sobel operator to each color component.

(ii) Calculate the mean of the gradient magnitude values in the three color components.

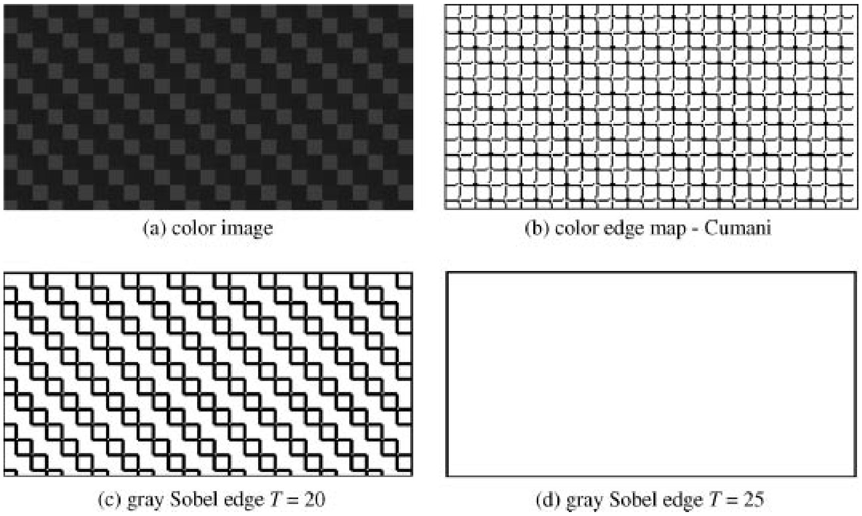
(iii) Edge exists if the mean of the gradient magnitude exceeds a given threshold (28,30).

Note the sum of the gradient magnitude in the three color components can also be used instead of the mean in Step ii).

Method 2: the Laplacian and fusion method

(i) Apply the Laplacian mask or the LoG mask to each color component.

(ii) Edge exists at a pixel if it has a zero crossing in at least one of the three color components (28,31).



(a) color image

(b) color edge map - Cumani

(c) gray Sobel edge $T = 20$

(d) gray Sobel edge $T = 25$

Figure 13. Color versus gray edge detectors: (a) color image [used with permission from John Owens at the University of California, Davis], (b) edge map generated by the color edge detector, and (c) and (d) edge map generated by the gray-level Sobel operator.

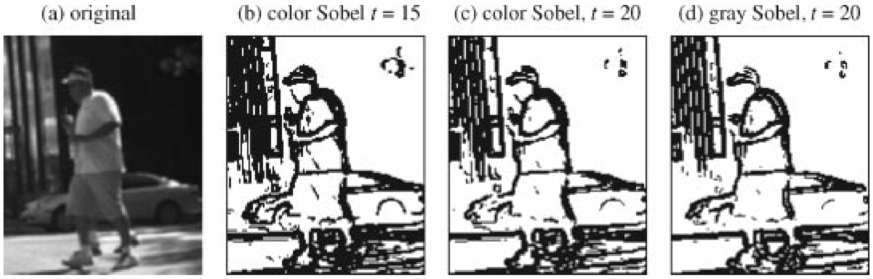


Figure 14. Experiments with the color Sobel operator: (a) color input; (b) and (c) color Sobel operator with $T = 15$, and $T = 20$, respectively; and (d) gray Sobel operator with $T = 20$.

Experimental results with multidimensional Sobel operator are shown in Fig. 14(b)–(c). The color Sobel operator generates the more detailed edge maps [Fig. 14(b) and (c)] compared with the edge map generated by the gray-level Sobel operator in Fig. 14(d). But the computational cost of the color Sobel operator increases three times more than the cost of the gray-level Sobel operator as shown in Table 2.

Vector-Based Methods. ***Color Variants of the Canny Edge Operator.*** Kanade (37) introduced an extension of the Canny edge detector (3) for edge detection in color images. Let a vector *C(r(x,y),g(x,y),b(x,y))* represent a color image in the RGB color space. The partial derivatives of the color vector can be expressed by a Jacobian matrix J as below:

$$J = \left(\frac{\partial C}{\partial x}, \frac{\partial C}{\partial y}\right) = \begin{bmatrix} \frac{\partial r}{\partial x} & \frac{\partial r}{\partial y} \\ \frac{\partial g}{\partial x} & \frac{\partial g}{\partial y} \\ \frac{\partial b}{\partial x} & \frac{\partial b}{\partial y} \end{bmatrix} = (G_x, G_y) \qquad (18)$$

The direction θ and the magnitude G_m of a color edge are given by

$$\tan(2\theta) = \frac{2 \cdot G_x \cdot G_y}{\|G_x\|^2 - \|G_y\|^2} \qquad (19)$$

$$G_m = \sqrt{\|G_x\|^2 \cos^2(\theta) + 2 \cdot G_x \cdot G_y \cdot \sin(\theta) \cdot \cos(\theta) + \|G_y\|^2 \sin^2(\theta)} \qquad (20)$$

where G_x, G_y are the partial derivatives of the three color components and $\|\cdot\|$ is a mathematical norm. Several variations exist based on different mathematical norms such as the L_1-norm (sum of the absolute value), L_2-norm (Euclidean distance), and L_∞-norm (maximum of the absolute value). Kanade (37) summarizes detailed experimental results obtained with various mathematical norms. After the edge direction and magnitude of the edge have been calculated for each pixel, the rest of the steps are the same with the Canny operator for gray-level images (see the section on the "advanced edge detection method"). Figure 15 shows edge maps generated by the color Canny operator with various scales and threshold values. The edge maps generated by the color Canny operator have the more detailed edge images compared with the edge map [Fig. 15(d)] generated by the gray- level Canny operator.

Cumani Operator. Cumani (32,35) proposed a vector-based color edge detection method that computes the zero crossings in the second directional derivatives of a color image. He defined a local measure of directional contrast based on the gradients of the image components. Then, edge points are detected by finding zero crossings of the first derivative of the contrast function in the direction of the maximal contrast.

Let a three-channel color image be represented by a two-dimensional vector field as follows:

$$f(x,y) = (\ f_1(x,y), \quad f_2(x,y), \quad f_3(x,y))$$

The squared local contrast S of *f(x,y)* at point $P = (x,y)$ in the direction of the unit vector $\vec{u} = (u_1, u_2)$ is

$$\begin{aligned} S(P,u) &= u^t J u = (u_1, u_2)\begin{pmatrix} E & F \\ F & G \end{pmatrix}\begin{pmatrix} u_1 \\ u_2 \end{pmatrix} \\ &= Eu_1^2 + 2Fu_1u_2 + Gu_2^2 \end{aligned}$$

where

$$\begin{aligned} J &= \nabla f (\nabla f)^T = \begin{pmatrix} E & F \\ F & G \end{pmatrix}, E = \sum_{i=1}^{3}\left(\frac{\partial f_i}{\partial x}\right)^2, \\ F &= \sum_{i=1}^{3}\left(\frac{\partial f_i}{\partial x}\right)\left(\frac{\partial f_i}{\partial y}\right), \text{ and } G = \sum_{i=1}^{3}\left(\frac{\partial f_i}{\partial y}\right)^2 \end{aligned} \qquad (21)$$

The maximal value λ of *S(P, u)* is

$$\lambda_{\pm} = (E + G)_z \pm \sqrt{\frac{(E - G)^2}{4} + F^2} \qquad (22)$$

This maximum λ occurs when $\vec{u}$ is the corresponding eigenvector (35)

$$\begin{aligned} \vec{u} &= \left(\sqrt{\frac{1 + C}{2}}, \sqrt{\frac{1 - C}{2}}\right), \text{ where } C \\ &= \frac{E - G}{\sqrt{(E - G)^2 + (2F)^2}} \end{aligned} \qquad (23)$$

Edge points are defined at the locations where λ has a local maximum along the direction of the unit vector $\vec{u}$. So the

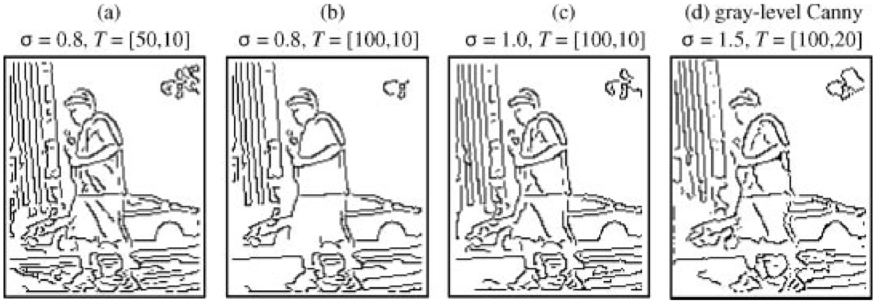

Figure 15. Experiments with the color Canny operator: color Canny edge maps (a) $\sigma = 0.8$, $t_{\text{high}} = 50$, $t_{\text{low}} = 10$; (b) $\sigma = 0.8$, $t_{\text{high}} = 100$, $t_{\text{low}} = 10$; (c) $\sigma = 1.0$, $t_{\text{high}} = 100$, $t_{\text{low}} = 10$; and (d) the edge map generated by the gray-level Canny operator $\sigma = 1.5$, $t_{\text{high}} = 100$, $t_{\text{low}} = 20$.

zero crossings of λ in the direction of $\vec{u}$ are candidates of edges (33). To find the zero crossing of λ, the directional derivative is defined as

$$\begin{aligned}\nabla\lambda_+ \cdot u_+ &= \nabla S(P, u_+) \cdot u_+ \\ &= \frac{\partial E}{\partial x} u_1^3 + \left(\frac{\partial E}{\partial y} + 2\frac{\partial F}{\partial x}\right) u_1^2 u_2 \\ &\quad + \left(2\frac{\partial F}{\partial y} + \frac{\partial G}{\partial x}\right) u_1 u_2^2 + \frac{\partial G}{\partial y} u_2^3 \qquad (24)\end{aligned}$$

where E, F, and G are defined in Equation (21). Finally, edge points are determined by computing the zero crossing of $\nabla\lambda_+ \cdot u_+$ and the sign of $\nabla\lambda_+ \cdot u_+$ along a curve tangent to u_+ at point P.

Cumani tested this edge detector with color images in the RGB space with the assumption that the Euclidean metric exists for the vector space (32). Figure 16(b), (c), and (d) show the edge detection results generated by the Cunami color edge operator at different scales. It seems that the Cunami color edge operator generated the more detailed edge images in comparison with the edge images generated by the monochromatic-based methods.

EDGE DETECTION METHOD IN RANGE IMAGES

Range images are a special class of digital images. The range images encode the distance information from the sensor to the objects. Pixel values in the range images are related to the positions of surface geometry directly. Therefore, range images provide an explicit encoding of the local structure and geometry of the objects in the scene. Edge detection methods developed for intensity images mainly focused on the detection of step edges. In the range imagers, it is possible to detect correctly both the step edges and the roof edges because of the available depth information.

Hoffman and Jain (38) described three edge types in range images: step edges, roof edges, and smooth edges. Step edges are those composed pixels in which the actual depth values are significantly discontinuous as compared with their neighboring pixels. Roof edges are where the depth values are continuous, but the directions of the surface normal change abruptly. Smooth edges are related with discontinuities in the surface curvature. But smooth edges relatively seldom occur in range images. Step edges in range images can be detected with ordinary gradient edge operators, but roof edges are difficult to be detected (39). Thus, an edge detection method for a range image must take into account these two types of edges such as discontinuities in depth and discontinuities in the direction of surface normal.

Edge Detection Using Orthogonal Polynomials

Besl and Jain (40,41) proposed a method that uses orthogonal polynomials for estimating the derivatives in range images. To estimate the derivatives, they used the locally fit discrete orthogonal polynomials with an unweighted least-squares technique. Using smooth second-order polynomials, range images were approximated locally. This method provided the smoothing effect and computational efficiency by obtaining the coefficient of the polynomials directly. But unweighted least squares could cause errors in image differentiation. To overcome this problem, a weighted least-squares approach was proposed by Baccar and Colleagues (42,43).

Extraction of Step Edges. The step edge detection method proposed by Baccar and Colleagues (42) is based on the use of locally fit discrete orthogonal polynomials with a weighted least-squares technique. For the weighted least-squares approximation *W(x)*, a one-dimensional Gaussian kernel of unit amplitude with zero mean and

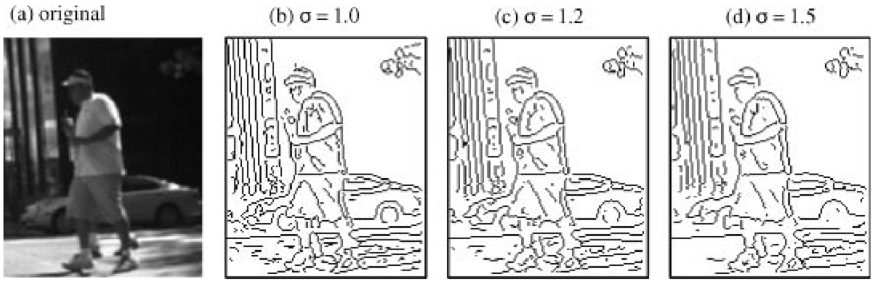

Figure 16. Experiments with the Cumani operator: (a) color input image and the Cumani edge maps (b) $\sigma = 1.0$, (c) $\sigma = 1.2$, and (d) $\sigma = 1.5$.

standard deviation σ is used. The two-dimensional Gaussian kernel at the center of the window can be represented by the product of *W(x)* and *W(y)*. Let $W(x) = e^{\frac{-x^2}{2\sigma^2}}$. Then a one-dimensional set of second-degree orthogonal polynomials φ_0, φ_1, φ_2 is defined as

$$\varphi_0(x) = 1,\ \varphi_1(x) = x,\ \varphi_2(x) = x^2 - A, \quad \text{where} \\ A = \frac{\sum xW(x)\varphi_1(x)\varphi_0(x)}{\sum W(x)\varphi_0^2(x)} \tag{25}$$

A locally approximated range image $\hat{r}(x,y)$ is calculated with a second-degree Gaussian weighted orthogonal polynomial as follows (42):

$$\begin{aligned} \hat{r}(x,y) &= \sum_{i+j\le 2} a_{ij}\varphi_i(x)\varphi_j(y) \\ &= a_{00} + a_{10}\varphi_1(x) + a_{01}\varphi_1(y) + a_{11}\varphi_1(x)\varphi_1(y) \\ &\quad + a_{20}\varphi_2(x) + a_{02}\varphi_2(y) \\ &= a_{00} + a_{10}x + a_{01}y + a_{11}xy + a_{20}(x^2 - a_{20}) \\ &\quad + a_{02}(y^2 - a_{02}) \\ &= a_{10}x + a_{01}y + a_{11}xy + a_{20}x^2 + a_{02}y^2 \\ &\quad + a_{00} - A(a_{02} + a_{20}) \end{aligned} \tag{26}$$

At a differentiable point of the surface, the quantity of the surface normal is defined as

$$a_{ij} = \frac{1}{\partial_i\partial_j}\sum_{x,y} r(x,y)W(x)W(y)\varphi_i(x)\varphi_j(y), \quad \text{where} \\ \partial_i = \sum_{x=-M}^{M} W(x)\varphi_i^2(x) \tag{27}$$

The partial derivatives of the approximated range image $\hat{r}(x,y)$ are defined by the following equations:

$$\hat{r}_x(x,y) = a_{10} + a_{11}y + 2a_{20}x, \\ \hat{r}_y(x,y) = a_{01} + a_{11}x + 2a_{02}\,y \tag{28}$$

At the center of the discrete window for $(x, y) = (0, 0)$, the partial derivatives are computed by

$$\hat{r}_x(0,0) = a_{10},\ \hat{r}_y(0,0) = a_{01} \tag{29}$$

The gradient magnitude at the center of this discrete window is $\sqrt{a_{10}^2 + a_{01}^2}$. The step edge image, $g_{step}(x,y)$, is obtained directly from the coefficients of the polynomials.

Extraction of Roof Edges. The roof edges are defined as the discontinuities in the orientation of the surface normal of objects in a range image. The quantity that defines the surface normal at a differentiable point of a surface is defined in Equation (27). The approximation to the surface normal, which is the angle between the two projections of the normal vector **n** on the (*x*, *z*)- and (*y*, *z*)-planes, is computed using

$$\gamma(x,y) = \tan^{-1}(r_y/r_x), \quad \text{where} \\ n = (-r_x, -r_y, 1)^T/(1 + r_x^2 + r_y^2)^{1/2} \tag{30}$$

The partial derivatives r_x and r_y of the function *r(x, y)* are calculated using the same Gaussian weighted least squares in Equation (28). The quantity $\gamma(x,y)$ represents the surface normal, and a 5 × 5 median filtering is applied to produce the final surface normal image. The roof edge image $g_{roof}(x,y)$ is computed from the final surface image by using the weighted Gaussian approach (42,43). The final edge map is generated after implementing a fusion step that combined step edge image $g_{step}(x,y)$ and roof edge image $g_{roof}(x,y)$ and a subsequent morphological step (42).

Edge Detection via Normal Changes

Sze et al. (44) as well as Mallet and Zhong (45) presented an edge detection method for range images based on normal changes. They pointed out that depth changes of a point in a range image with respect to its neighbors are not sufficient to detect all existent edges and that normal changes are much more significant than those of depth changes. Therefore, the step and roof edges in range images are identified by detecting significant normal changes.

Let $\vec{p}(u,v)$ be a point on a differentiable surface S and $\vec{p}(u,v) = (u, v, f(u,v))$. If we denote $\vec{p}_u$ and $\vec{p}_v$ as the partial derivatives of $\vec{p}(u,v)$ at u- and v-directions, respectively; then the partial derivatives of $\vec{p}(u,v)$ are given as follows (44):

$$\begin{aligned} \vec{p}_u &= \frac{\partial\vec{p}(u,v)}{\partial u} = (1, 0,\ f_u(u,v)) \\ \vec{p}_v &= \frac{\partial\vec{p}(u,v)}{\partial v} = (0, 1,\ f_v(u,v)) \end{aligned} \tag{31}$$

The normal of a tangent plane at $\vec{p}(u,v)$ is defined as

$$\vec{N}(u,v) = \frac{\vec{p}_u \times \vec{p}_v}{\|\vec{p}_u \times \vec{p}_v\|} \tag{32}$$

If we replace Equation (32) with Equation (31), the value of norm $\vec{N}(u,v)$ can be rewritten as below:

$$\begin{aligned} \vec{N}(u,v) &= \left(\frac{-f_u}{\sqrt{1+f_u^2+f_v^2}}, \frac{-f_v}{\sqrt{1+f_u^2+f_v^2}}, \frac{1}{\sqrt{1+f_u^2+f_v^2}}\right) \\ &= (n_1(u,v), n_2(u,v), n_3(u,v)), \end{aligned} \\ \text{where } f_u = \partial f(u,v)/\partial u \text{ and } f_v = \partial f(u,v)/\partial v \tag{33}$$

Steps for edge detection in range images via normal changes are summarized as follows (44):

1. *Calculate the normal of every point in a range image:* the partial derivatives are essential to derive the normal value at each data point as shown in Equation (33).

However, the partial derivative shown in Equation (33) cannot be computed directly because the range image data points are discrete. To calculate the normal on a set of discrete data points, the locally fit discrete orthogonal polynomials, originally proposed by Besl and Jain (40,41) and explained earlier, can be used. Other exiting methods are the orthogonal wavelet-based approach (46) and the nonorthogonal wavelet-based approach (45).

2. *Find the significant normal changes as edge point:* Using the dyadic wavelet transform proposed by Mallat and Zhong (45), the significant normal changes (or local extrema) are selected as edge points. The dyadic wavelet transform of a *f(x,y)* at scale 2^j along the x- and y-directions can be expressed by

$$\begin{aligned} W^1_{2j} f(x,y) &= f * (1/2^{2j})\varphi^1(x/2^j, y/2^j) \\ W^2_{2j} f(x,y) &= f * (1/2^{2j})\varphi^2(x/2^j, y/2^j) \end{aligned} \tag{34}$$

where $\varphi^1(x,y) = \partial\theta(x,y)/\partial x$, $\varphi^2(x,y) = \partial\theta(x,y)/\partial y$, and $\theta(x,y)$ is a smoothing function that satisfies the following conditions: Its integration over the full domain is equal to 1 and converges to 0 at infinity. The dyadic wavelet transformation of the vector of normal changes $\vec{N}(u,v)$ at scale 2^j is given by

$$W_j\vec{N}(u,v) = W^1_{2j}\vec{N}(u,v)du + W^2_{2j}\vec{N}(u,v)dv \tag{35}$$

where

$W^i_{2j}\vec{N}(u,v) = (W^i_{2j}n_1(u,v), W^i_{2j}n_2(u,v), W^i_{2j}n_3(u,v))$, $i = 1,2$.

Their associated weights can be the normal changes (or gradient) of $\vec{N}(u,v)$ along the du- and dv-directions. Two important values for edge detection can be calculated as follows: The magnitude of the dyadic wavelet transformation of $W_j\vec{N}(u,v)$ at scale 2^j is computed as

$$M_{2j}\overrightarrow{N}(u,v) = \sqrt{\|W^1_{2j}\vec{N}^{\rightarrow}(u,v)\|^2 + \|W^2_{2j}\overrightarrow{N}(u,v)\|^2} \tag{36}$$

and the angle with respect to the du-direction is

$$A_{2j}\overrightarrow{N}(u,v) = \text{argument}\left(\|W^1_{2j}\vec{N}(u,v)\| + i\|W^2_{2j}\overrightarrow{N}(u,v)\|\right) \tag{37}$$

Every point in the range image will be associated with two important values: magnitude of normal changes with respect to its certain neighbors and the direction tendency of the point (44). Edge points can be detected by thresholding the normal changes. Experimental results are provided for synthetic and real 240 × 240 range images in Ref 44. Three different methods such as quadratic surface fitting and orthogonal and nonorthogonal wavelet-based approaches are used to calculate the normal values for the comparison purpose. After the normal values are decided, the dyadic transforms proposed by Mallat and Zhong (45) are applied to detect the normal changes at every point in a range image. In their experiments, the nonorthogonal wavelet-based approach used to estimate the normal values generated the best results in comparison with the other methods.

CONCLUSION

Edge detection has been studied extensively in the last 50 years, and many algorithms have been proposed. In this article, we introduced the fundamental theories and the popular technologies for edge detection in grayscale, color, and range images. More recent edge detection work can be found in Refs.16, 30, 47 and 48. We did not touch on the topic of evaluating edge detectors. Interested readers can find such research work in Refs. 49–53.

FACE RECOGNITION TECHNIQUES

INTRODUCTION TO FACE RECOGNITION

Biometrics[1] is becoming a buzzword due to increasing demand for user-friendly systems that provide both secure and efficient services. Currently, one needs to remember numbers and/or carry IDs all the time, for example, a badge for entering an office building, a password for computer access, a password for ATM access, and a photo-ID and an airline ticket for air travel. Although very reliable methods of biometric personal identification exist, e.g., fingerprint analysis and iris scans, these methods rely on the cooperation of the participants, whereas a personal identification system based on analysis of frontal or profile images of the face is often effective without the participant's cooperation or knowledge. It is due to this important aspect, and the fact that humans carry out face recognition routinely, that researchers started an investigation into the problem of machine perception of human faces. In Fig. 1, we illustrate the face recognition task of which the important first step of detecting facial regions from a given image is shown in Fig. 2.

After 35 years of investigation by researchers from various disciplines (e.g., engineering, neuroscience, and psychology), face recognition has become one of the most successful applications of image analysis and understanding. One obvious application for face recognition technology (FRT) is law-enforcement. For example, police can set up cameras in public areas to identify suspects by matching their imagaes against a watch-list facial database. Often, low-quality video and small-size facial images pose significant challenges for these applications. Other interesting commercial applications include intelligent robots that can recognize human subjects and digital cameras that offer automatic focus/exposure based on face detection. Finally, image searching techniques, including those based on facial image analysis, have been the latest trend in the booming Internet search industry. Such a wide range of applications pose a wide range of technical challenges and require an equally wide range of techniques from image processing, analysis, and understanding.

The Problem of Face Recognition

Face perception is a routine task of human perception system, although building a similar robust computer system is still a challenging task. Human recognition processes use a broad spectrum of stimuli, obtained from many, if not all, of the senses (visual, auditory, olfactory, tactile, etc.).

In many situations, contextual knowledge is also applied (e.g., the context plays an important role in recognizing faces in relation to where they are supposed to be located). However, the human brain has its limitations in the total number of persons that it can accurately "remember." A key advantage of a computer system is its capacity to handle large numbers of facial images.

A general statement of the problem of the machine recognition of faces can be formulated as follows: Given still or video images of a scene, identify or verify one or more persons in the scene using a stored database of faces. Available collateral information, such as race, age, gender, facial expression, or speech, may be used to narrow the search (enhancing recognition). The solution to the problem involves face detection (recognition/segmentation of face regions from cluttered scenes), feature extraction from the face regions (eyes, nose, mouth, etc.), recognition, or identification (Fig. 3).

Brief Development History

The earliest work on face recognition can be traced back at least to the 1950s in psychology (4) and to the 1960s in the engineering literature (5). Some of the earliest studies include work on facial expression of emotions by Darwin (6) [see also Ekman (7) and on facial profile-based biometrics by Galton (8)]. But research on automatic machine recognition of faces really started in the 1970s after the seminal work of Kanade (9) and Kelly (10). Over the past 30 years, extensive research has been conducted by psychophysicists, neuroscientists, and engineers on various aspects of face recognition by humans and machines.

Psychophysicists and neuroscientists have been concerned with issues such as whether face perception is a dedicated process [this issue is still being debated in the psychology community(11,12)], and whether it is done holistically or by local feature analysis. With the help of powerful engineering tools such as functional MRI, new theories continue to emerge (13). Many of the hypotheses and theories put forward by researchers in these disciplines have been based on rather small sets of images. Nevertheless, many of the findings have important consequences for engineers who design algorithms and systems for the machine recognition of human faces.

Until recently, most of the existing work formulates the recognition problem as recognizing 3-D objects from 2-D images. As a result, earlier approaches treated it as a 2-D pattern recognition problem. During the early and middle 1970s, typical pattern classification techniques were used that measured attributes of features (e.g., the distances between important points) in faces or face profiles (5,9,10). During the 1980s, work on face recognition remained largely dormant. Since the early 1990s, research interest in FRT has grown significantly. One can attribute this growth to several reasons: the increase in interest in commercial opportunities, the availability of real-time hardware, and the emergence of surveillance-related applications.

[1] Biometrics: the study of automated methods for uniquely recognizing humans based on one or more intrinsic physical or behavior traits.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

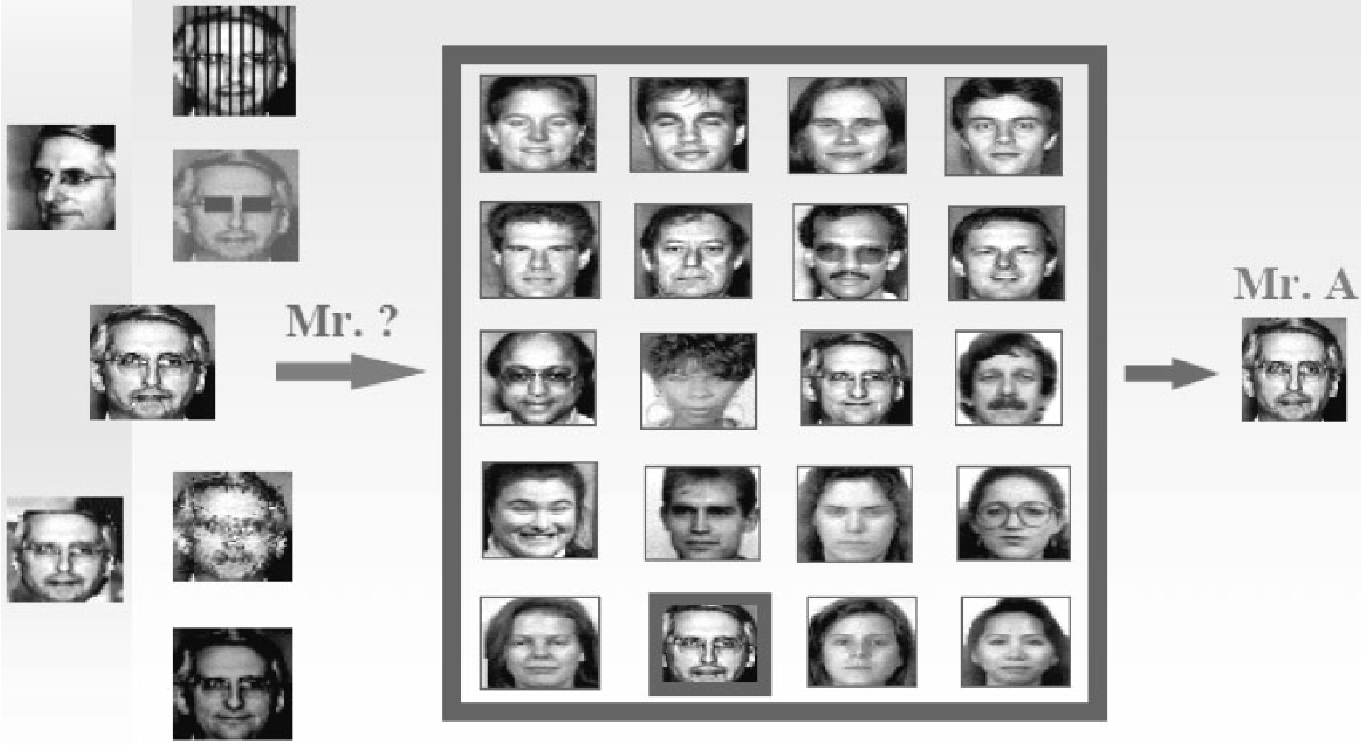

Figure 1. An illustration of the face recognition task (1): given an input facial image (left column: many variants of the facial image are used to illustrate image appearance change due to natural variations in lighting and pose, and electronic modifications that simulate more complex variations), matching it against a database of facial images (center column), and finally outputting the matched database image and/or the ID of the input image (right column).

Over the past 18 years, research has focused on how to make face recognition systems fully automatic by tackling problems such as localization of a face in a given image or a video clip and by extracting features such as eyes, mouth, and so on. Meanwhile, significant advances have been made in the design of classifiers for successful face recognition. Among appearance-based holistic approaches, eigenfaces (14,15) and Fisherfaces (16–18) have proved to be effective in experiments with large databases. Feature-based graph matching approaches (19) have also been successful. Compared with holistic approaches, feature-based methods are less sensitive to variations in illumination and viewpoint and to inaccuracy in face localization. However, the feature extraction techniques needed for this type of approach are still not sufficiently reliable or accurate (20).

During the past 8–15 years, much research has been concentrated on video-based face recognition. The still image problem has several inherent advantages and disadvantages. For applications such as airport surveillance, the automatic location and segmentation of a face could pose serious challenges to any segmentation algorithm if only a static picture of a large, crowded area is available. On the other hand, if a video sequence is available, segmentation of a moving person can be accomplished more easily using motion as a cue. In addition, a sequence of images might help to boost the recognition performance if we can use all these images effectively. But the small size and low image quality of faces captured from video can increase significantly the difficulty in recognition.

More recently, significant advances have been made on 3-D based face recognition. Although it is known that face recognition using 3-D images has many advantages than face recognition using a single or sequence of 2-D images, no serious effort was made for 3-D face recognition until recently. This delay was mainly caused by the feasibility, complexity, and computational cost to acquire 3-D data in real-time. Now, the availability of cheap, real-time 3-D sensors (21) makes it much easier to apply 3-D face recognition.

Recognizing a 3-D object from its 2-D images poses many challenges. The illumination and pose problems are two prominent issues for appearance-based or image-based approaches (22). Many approaches have been proposed to handle these issues, and the key here is to model the 3-D geometry and reflectance properties of a face. For example, 3-D textured models can be built from given 2-D images, and the images can then be used to synthesize images under various poses and illumination conditions for recognition or animation. By restricting the image-based 3-D object modeling to the domain of human faces, fairly good reconstruction results can be obtained using the state-of-the-art algorithms. Other potential applications in which modeling is crucial includes computerized aging, where an appropriate model needs to be built first and then a set of model parameters are used to create images that simulate the aging process.

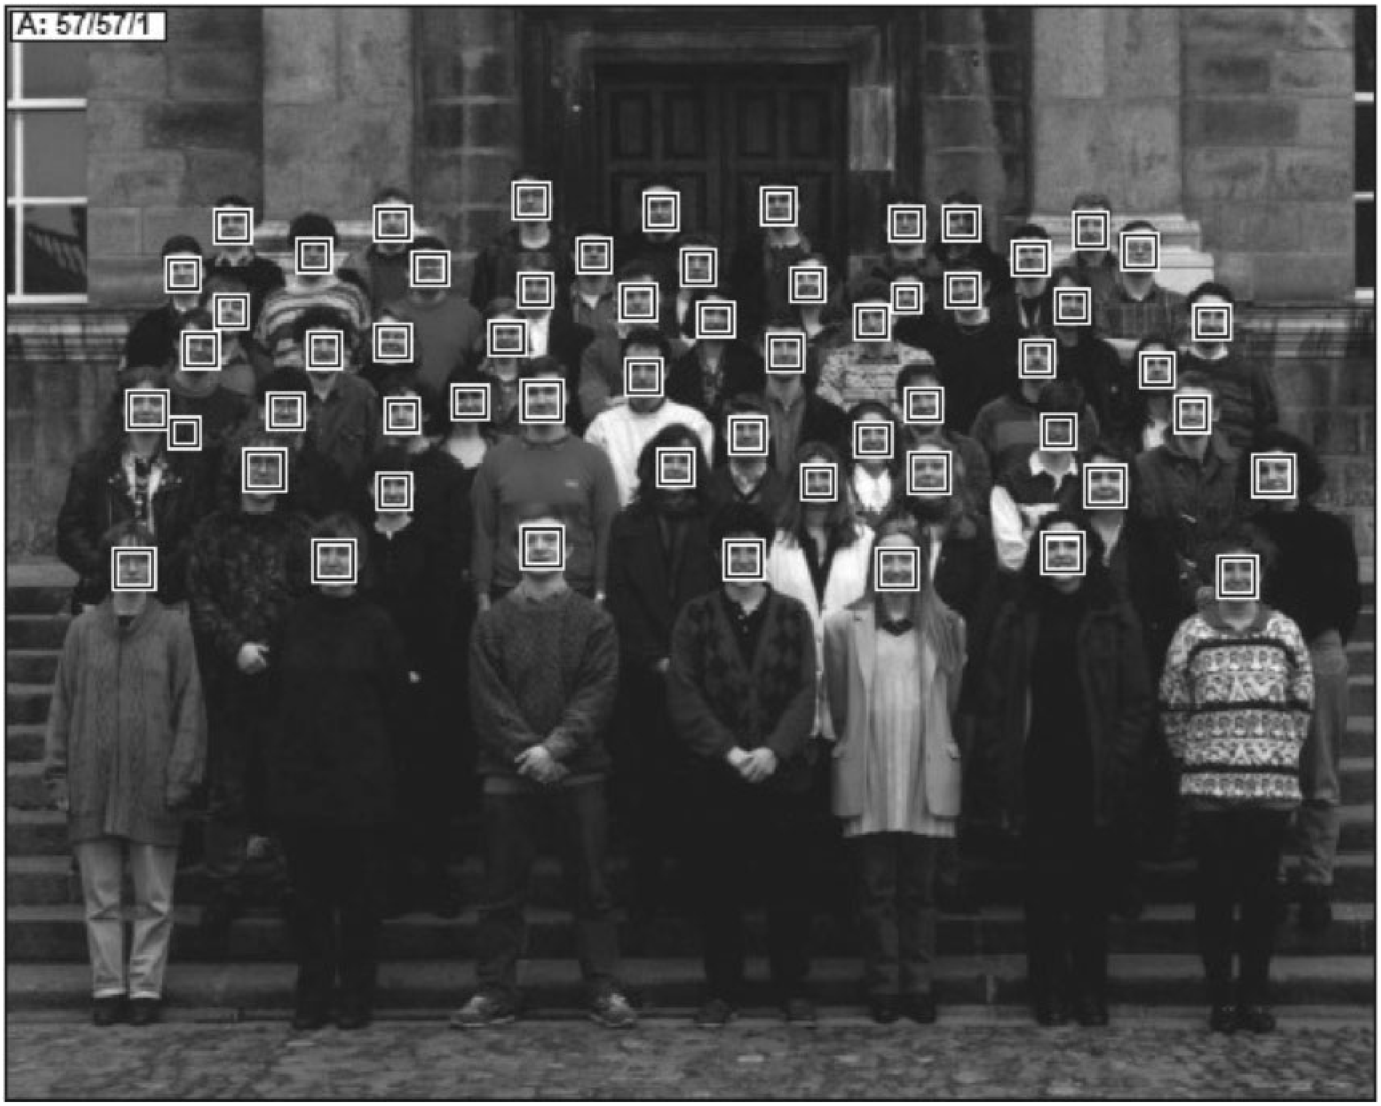

Figure 2. Detection/Segmentation/Recognition of facial regions from an image (2).

Methods for Machine Recognition of Faces

As illustrated in Fig. 4, the problem of automatic face recognition involves three key steps/subtasks:

1. Detection and coarse normalization of faces
2. Feature extraction and accurate normalization of faces
3. Identification and/or verification

Sometimes, different subtasks are not totally separated. For example, facial features (eyes, nose, mouth) are often used for both face recognition and face detection. Face detection and feature extraction can be achieved simultaneously as indicated in Fig. 4. Depending on the nature of the application, e.g., the sizes of the training and testing databases, clutter and variability of the background, noise, occlusion, and speed requirements, some subtasks can be very challenging. A fully automatic face recognition system must perform all three subtasks, and research on each subtask is critical. This is not only because the techniques used for the individual subtasks need to be improved, but also because they are critical in many different applications (Fig. 3). For example, face detection is needed to initialize face tracking, and extraction of facial features is needed for recognizing human emotion, which in turn is essential in human–computer interaction (HCI) systems. Without considering feature locations, face detection is declared as successful if the presence and rough location of a face has been correctly identified.

Face Detection and Feature Extraction

Segmentation/Detection. Up to the mid-1990s, most work on segmentation was focused on single-face segmentation from a simple or complex background. These approaches included using a whole-face template, a deformable feature-based template, skin color, and a neural network.

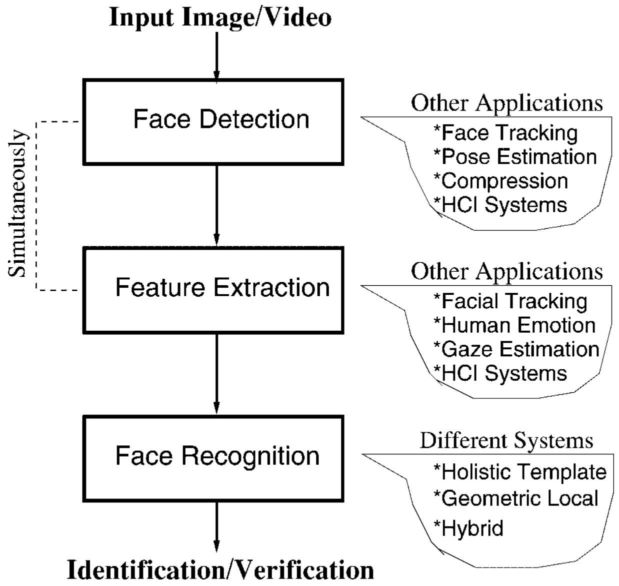

Figure 3. Configuration of a generic face recognition/processing system. We use a dotted line to indicate cases when both face detection and feature extraction work together to achieve accurate face localization and reliable feature extraction [e.g. (3)].

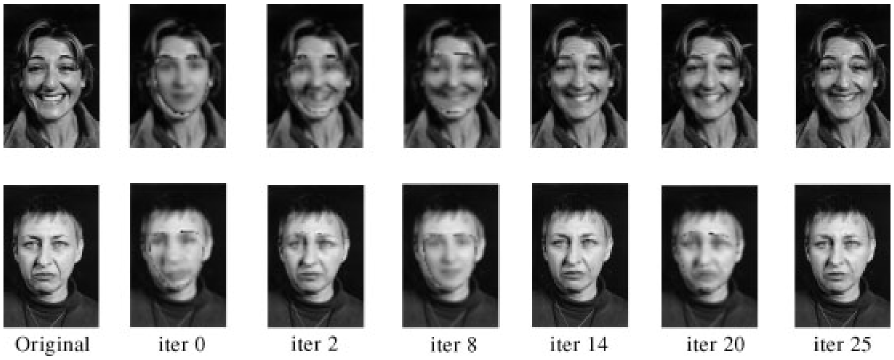

Figure 4. Mutiresolution seach from a displaced position using a face model (30).

Significant advances have been made in recent years in achieving automatic face detection under various conditions. Compared with feature-based methods and template-matching methods, appearance, or image-based methods (2, 23) that train machine systems on large numbers of samples have achieved the best results (refer to Fig. 4). This may not be surprising since complicated face objects are different from non-face objects, although they are very similar to each other. Through extensive training, computers can be good at detecting faces.

Feature Extraction. The importance of facial features for face recognition cannot be overstated. Many face recognition systems need facial features in addition to the holistic face, as suggested by studies in psychology. It is well known that even holistic matching methods, e.g., eigenfaces (15) and Fisherfaces (16), need accurate locations of key facial features such as eyes, nose, and mouth to normalize the detected face (24–26).

Three types of feature extraction methods can be distinguished:

1. Generic methods based on edges, lines, and curves
2. Feature-template-based methods that are used to detect facial features such as eyes
3. Structural matching methods that take into consideration geometrical constraints on the features

Early approaches focused on individual features; for example, a template-based approach is described in Ref. 27 to detect and recognize the human eye in a frontal face. These methods have difficulty when the appearances of the features change significantly, e.g., closed eyes, eyes with glasses, or open mouth. To detect the features more reliably, recent approaches use structural matching methods, for example, the active shape model (ASM) that represents any face shape (a set of landmark points) via a mean face shape and principle components through training (3).

Compared with earlier methods, these recent statistical methods are much more robust in terms of handling variations in image intensity and in feature shape. The advantages of using the so-called “analysis through synthesis”

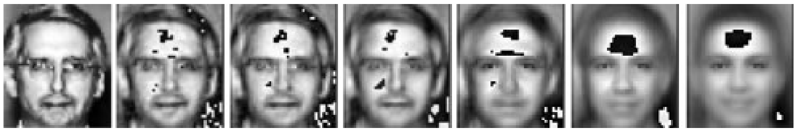

Figure 5. Original image [size 48 × 42 (i.e., 2016)] and the reconstructed image using 300, 200, 100, 50, 20, and 10 leading components, respectively (32).

approach come from the fact that the solution is *constrained* by a *flexible* statistical model. To account for texture variation, the ASM model has been expanded to statistical appearance models including a flexible appearance model (28) and an active appearance model (AAM)(29). In Ref. 29, the proposed AAM combined a model of shape variation (i.e., ASM) with a model of the appearance variation of shape-normalized (shape-free) textures. A training set of 400 images of faces, each labeled manually with 68 landmark points and approximately 10,000 intensity values sampled from facial regions were used. To match a given image with a model, an optimal vector of parameters (displacement parameters between the face region and the model, parameters for linear intensity adjustment, and the appearance parameters) are searched by minimizing the difference between the synthetic image and the given image. After matching, a best-fitting model is constructed that gives the locations of all the facial features so that the original image can be reconstructed. Figure 4 illustrates the optimization/search procedure to fit the model to the image.

Face Recognition

As suggested, three types of FRT systems have been investigated:recognition based on still images, recognition based on a sequence of images, and, more recently, recognition based on 3-D images. All types of FRT technologies have their advantages and disadvantages. For example, video-based face recognition can use temporal information to enhance recognition performance. Meanwhile, the quality of video is low and the face regions are small under typical acquisition conditions (e.g., in surveillance applications). Rather than presenting all three types of FRT systems, we focus on still-image-based FRT systems that form the foundations for machine recognition of faces. For details on all three types of FRT systems, please refer to a recent review article (the first chapter in Ref. 31).

Face recognition is such an interesting and challenging problem that it has attracted researchers from different fields: psychology, pattern recognition, neural networks, computer vision, and computer graphics. Often, a single system involves techniques motivated by different principles. To help readers that are new to this field, we present a class of linear projection/subspace algorithms based on image appearances. The implementation of these algorithms is straightforward, yet they are very effective under constrained situations. These algorithms helped to revive the research activities in the 1990s with the introduction of eigenfaces (14,15) and are still being researched actively for continuous improvements.

Eigenface and the Projection-Based Appearance Methods. The first successful demonstration of the machine recognition of faces was made by Turk and Pentland (15) using eigenpictures (also known as eigenfaces) for face detection and identification. Given the eigenfaces, every face in the database is represented as a vector of weights obtained by projecting the image into a subset of all eigenface components (i.e., a subspace) by a simple inner product operation. When a new test image whose identification is required is given, the new image is represented by its vector of weights. The test image is identified by locating the image in the database whose weights are the closest (in Euclidean distance) to the weights of the test image. By using the observation that the projection of a facial image and a nonface image are different, a method to detect the presence of a face in a given image is obtained. Turk and Pentland illustrate their method using a large database of 2500 facial images of 16 subjects, digitized at all combinations of three head orientations, three head sizes, and three lighting conditions.

In a brief summary, eigenpictures/eigenfaces are effective low-dimensional representations of facial images based on Karhunen–Loeve (KL) or principal component analysis projection (PCA)(14). Mathematically speaking, sample facial images (2-D matrix format) can be converted into vector representations (1-D format). After collecting enough sample vectors, one can perform statistical analysis (i.e., PCA) to construct new orthogonal bases and then can represent these samples in a coordinate system defined by these new bases. More specifically, mean-subtracted sample vectors x can be expressed as a linear combination of the orthogonal bases Φ_i (typically $m \ll n$):

$$\mathrm{x} = \sum_{i=1}^{n} a_i \Phi_i \approx \sum_{i=1}^{m} a_i \Phi_i \tag{1}$$

via solving an eigenproblem

$$C\Phi = \Phi\Lambda \tag{2}$$

where C is the covariance matrix for input x and Λ is a diagonal matrix consisting of eigenvalues λ_i. The main point of eigenfaces is that it is an efficient representation of the original images (i.e., from n coefficients to m coefficient). Figure 5 shows a real facial image and several reconstructed images based on several varying number of leading principal components Φ_i that correspond to the largest eigenvalues λ_i. As can be seen from the plots, 300 leading principal components are sufficient to represent the original image of size 48 × 42 (=2016).[2]

[2] Please note that the reconstructed images are obtained by converting from 1-D vector format back to 2-D matrix format and adding back the average/mean facial image.

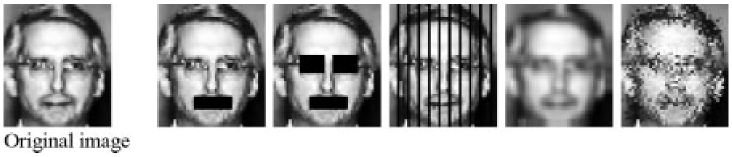

Figure 6. Electronically modified images that have been identified correctly using eigenface representation (18).

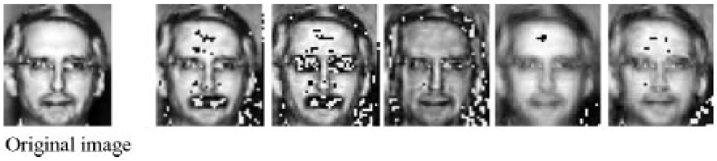

Figure 7. Reconstructed images using 300 PCA projection coefficients for electronically modified images (Fig. 7) (26).

Another advantage of using such a compact representation is the reduced sensitivity to noise. Some of the noise could be caused by small occlusions as long as the *topologic structure* does *not* change. For example, good performance against blurring, partial occlusion has been demonstrated in many eigenpicture based systems and was also reported in Ref. 18 (Fig. 6), which should not come as a surprise because the images reconstructed using PCA are much better than the original distorted images in terms of the global appearance (Fig. 7).

In addition to eigenfaces, other linear projection algorithms exist, including ICA (independent component analysis) and LDA/FLD (linear discriminant analysis/Fisher's linear discriminant analysis) to name a few. In all these projection algorithms, classification is performed 1) first by projecting the input x into a subspace via a projection/basis matrix $\mathbf{P}_{roj}$ ($\mathbf{P}_{roj}$ is Φ for eigenfaces, W for Fisherfaces with pure LDA projection, and $W\Phi$ for Fisherfaces with sequential PCA and LDA projections; these three bases are shown for visual comparison in Fig. 8),

$$\mathbf{z} = \mathbf{P}_{\mathrm{ro}j}\mathbf{x} \tag{3}$$

2) then by comparing the projection coefficient vector $\mathbf{z}$ of the input with all the pre-stored projection vectors of labeled classes to determine the input class label. The vector comparison varies in different implementations and can influence the system's performance dramatically (33).

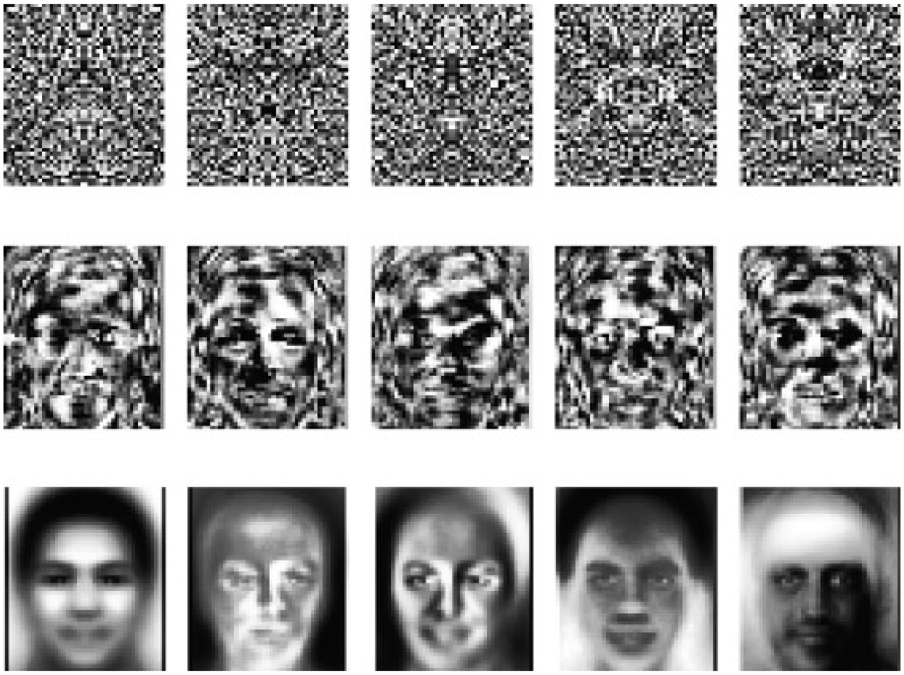

Figure 8. Different projection bases constructed from a set of 444 individuals, where the set is augmented via adding noise and mirroring. (Improved reconstruction for facial images outside the training set using an extended training set that adds mirror-imaged faces was suggested in Ref. 14.).The first row shows the first five pure LDA basis images W, the second row shows the first five subspace LDA basis images $W\Phi$, the average face and first four eigenfaces Φ are shown on the third row (18).

For example, PCA algorithms can use either the angle or the Euclidean distance (weighted or unweighted) between two projection vectors. For LDA algorithms, the distance can be unweighted or weighted.

Face recognition systems using LDA/FLD (called Fisherfaces in Ref. 16) have also been very successful (16,17,34). LDA training is carried out via scatter matrix analysis (35). For an M-class problem, the within-class and between-class scatter matrices S_w, S_b are computed as follows:

$$S_w = \sum_{i=1}^{M} Pr(w_i)C_i \tag{4}$$

$$S_b = \sum_{i=1}^{M} Pr(w_i)(\mathbf{m}_i - \mathbf{m}_0)(\mathbf{m}_i - \mathbf{m}_0)^T$$

where $Pr(\omega_i)$ is the prior class probability and usually is replaced by $1/M$ in practice with the assumption of equal priors. Here S_w is the *within-class scatter matrix*, showing the average scatter C_i of the sample vectors x of different classes ω_i around their respective means m_i: $C_i = E[(\mathrm{x}(\omega) - \mathrm{m}_i)\ (\mathrm{x}(\omega) - \mathrm{m}_i)^T|\omega = \omega_i]$. Similarly, S_b is the *between-class scatter matrix*, which represents the scatter of the conditional mean vectors m_i around the overall mean vector m_0. A commonly used measure to quantify the discriminatory power is the ratio of the determinant of the between-class scatter matrix of the projected samples to the determinant of the within-class scatter matrix: $\mathcal{J}(T) = |T^T S_b T|/|T^T S_w T|$. The optimal projection matrix W that maximizes $\mathcal{J}(T)$ can be obtained by solving a generalized eigenvalue problem:

$$S_b W = S_w W \Lambda_L \tag{5}$$

There are several ways to solve the generalized eigenproblem of Equation (5). One is to compute directly the inverse of S_w and solve a nonsymmetric (in general) eigenproblem for matrix $S_w^{-1}S_b$. But this approach is unstable numerically because it involves the direct inversion of a potentially very large matrix that probably is close to being singular. A stable method to solve this equation is to solve the eigen-problem for S_w first (32,35), [i.e., to remove the within-class variations (whitening)]. Because S_w is a real symmetric matrix, orthonormal W_w and diagonal Λ_w exist such that $S_w W_w = W_w \Lambda_w$. After whitening, the input $\mathbf{x}$ becomes $\mathbf{y}$:

$$\mathbf{y} = \Lambda_w^{-1/2}\mathbf{W}_w^T\mathbf{x} \tag{6}$$

The between-class scatter matrix for the new variable $\mathbf{y}$ can be constructed similar to Equation (5).

$$S_b^y = \sum_{i=1}^{M} Pr(\omega_i)(\mathbf{m}_i^y - \mathbf{m}_0^y)(\mathbf{m}_i^y - \mathbf{m}_0^y)^T \tag{7}$$

Now the purpose of FLD/LDA is to maximize the class separation of the now whitened samples $\mathbf{y}$, which leads to another eigenproblem: $S_b^y W_b = W_b \Lambda_b$. Finally, we apply the change of variables to $\mathbf{y}$:

$$\mathbf{z} = \mathbf{W}_b^T\mathbf{y} \tag{8}$$

Combining Equations (6) and (8), we have the following relationship: $\mathbf{z} = W_b^T \Lambda_w^{-1/2} W_w^T \mathbf{x}$ and $\mathbf{W}$ simply is

$$W = W_w \Lambda_w^{-1/2} W_b \tag{9}$$

To improve the performance of LDA-based systems, a regularized subspace LDA system that unifies PCA and LDA was proposed in Refs. 26 and 32. Good generalization capability of this system was demonstrated by experiments on new classes/individuals without retraining the PCA bases Φ, and sometimes even the LDA bases W. Although the reason for not retraining PCA is obvious, it is interesting to test the adaptive capability of the system by fixing the LDA bases when images from new classes are added.[3] The fixed PCA subspace of dimensionality 300 was trained from a large number of samples. An augmented set of 4056 mostly frontal-view images constructed from the original 1078 images of 444 individuals by adding noisy and mirrored images was used in Ref. 32. At least one of the following three characteristics separates this system from other LDA-based systems (16,34)): (1) the unique selection of the universal face subspace dimension, (2) the use of a weighted distance measure, and (3) a regularized procedure that modifies the within-class scatter matrix S_w. The authors selected the dimensionality of the universal face subspace based on the characteristics of the eigenvectors (face-like or not) instead of the eigenvalues (18), as is done commonly. Later, it was concluded in Ref. 36 that the global face subspace dimensionality is on the order of 400 for large databases of 5000 images. The modification of S_w into $S_w + \delta I$ has two motivations (1): first, to resolve the issue of small sample size (37) and second, to prevent the, significantly discriminative information[4] contained in the null space of S_w(38) from being lost.

To handle the non-linearity caused by pose, illumination, and expression variations presented in facial images, the above linear subspace methods have been extended to kernel faces (39–41) and tensorfaces (42).

Categorization of Still-Image Based FRT. Many methods of face recognition have been proposed during the past 30 years from researchers with different backgrounds. Because of this fact, the literature on face recognition is vast and diverse. To have a clear and high-level categorization, we follow a guideline suggested by the psychological study of how humans use holistic and local features. Specifically, we have the following categorization (see table 1 for more information):

[3] This makes sense because the final classification is carried out in the projection space z by comparison with pre-stored projection vectors with nearest-neighbor rule.

[4] The null space of S_w contains important discriminant information because the ratio of the determinants of the scatter matrices would be maximized in the null space.

1. **Holistic matching methods.** These methods use the whole face region as the raw input to a recognition system. One of the widely used representations of the face region is eigenpictures (14), which are based on principal component analysis.
2. **Feature-based (structural) matching methods.** Typically, in these methods, local features such as the eyes, nose, and mouth are first extracted and their locations and local statistics (geometric and/or appearance) are fed into a structural classifier.
3. **Hybrid methods.** Just as the human perception system uses both local features and the whole face region to recognize a face, a machine recognition system should use both. One can argue that these methods could offer potentially the best of the two types of methods

Within each of these categories, additional classification is possible. Using subspace analysis, many face recognition techniques have been developed: eigenfaces (15), which use a nearest-neighbor classifier; feature-line-based methods, which replace the point-to-point distance with the distance between a point and the feature line linking two stored sample points (46); Fisherfaces (16,18,34), which use Fisher's Linear Discriminant Analysis (57); Bayesian methods, which use a probabilistic distance metric (43); and SVM methods, which use a support vector machine as the classifier (44). Using higher-order statistics, independent component analysis is argued to have more representative power than PCA, and, in theory, it can provide better recognition performance than PCA (47). Being able to offer potentially greater generalization through learning, neural networks/learning methods have also been applied to face recognition. One example is the probabilistic decision-based neural network method (48) and the other is the evolution pursuit method (45).

Most earlier methods belong to the category of structural matching methods, which use the width of the head, the distances between the eyes and from the eyes to the mouth, and so on (10), or the distances and angles between eye corners, mouth extrema, nostrils, and chin top (9). Recently, a mixture-distance-based approach using manually extracted distances was reported (20). Without finding the exact locations of facial features, hidden markov model based methods use strips of pixels that cover the forehead, eye, nose, mouth, and chin (51,52). Reference 52 reported better performance than Ref. 51 by using the KL projection coefficients instead of the strips of raw pixels. One of the most successful systems in this category is the graph matching system (19), which is based on the Dynamic Link Architecture (58). Using an unsupervised learning method based on a self-organizing map, a system based on a convolutional neural network has been developed (53).

In the hybrid method category, we have the modular eigenface method (54), a hybrid representation based on PCA and local feature analysis (55), a flexible appearance model-based method (28), and a recent development (56) along this direction. In Ref. 54, the use of hybrid features by combining eigenfaces and other eigenmodules is explored: eigeneyes, eigenmouth, and eigennose. Although experiments show only slight improvements over holistic eigenfaces or eigenmodules based on structural matching, we believe that these types of methods are important and deserve further investigation. Perhaps many relevant problems need to be solved before fruitful results can be expected (e.g., how to arbitrate optimally the use of holistic and local features).

Many types of systems have been applied successfully to the task of face recognition, but they all have some advantages and disadvantages. Appropriate schemes should be chosen based on the specific requirements of a given task.

COMMERCIAL APPLICATIONS AND ADVANCED RESEARCH TOPICS

Face recognition is a fascinating research topic. On one hand, many algorithms and systems have reached a certain level of maturity after 35 years of research. On the other hand, the success of these systems is limited by the conditions imposed by many real applications. For example, automatic focus/exposure based on face detection has been built into digital cameras. However, recognition of face images acquired in an outdoor environment with changes in illumination and/or pose remains a largely unsolved problem. In other words, current systems are still far away from the capability of the human perception system.

Commercial Applications of FRT

In recent years, we have seen significant advances in automatic face detection under various conditions. Consequently, many commercial applications have emerged. For example, face detection has been employed for automatic exposure/focus in digital cameras, such as Powershot SD800 IS from Canon and FinePix F31fd from Fuji. These smart cameras can zero in automatically on faces, and photos will be properly exposed. In general, face detection technology is integrated into the camera's processor for increased speed. For example, FinePix F31fd can identify faces and can optimize image settings in as little as 0.05 seconds.

One interesting application of face detection technology is the passive driver monitor system installed on 2008 Lexus LS 600hL. The system uses a camera on the steering column to keep an eye on the driver. If he or she should be looking away from the road ahead and the pre-collision system detects something beyond the car (through stereo vision and radar), the system will sound a buzzer, flash a light, and even apply a sharp tap on the brakes.

Finally, the popular application of face detection technology is an image-based search of Internet or photo albums. Many companies (Adobe, Google, Microsoft, and many start-ups) have been working on various prototypes. Often, the bottle-neck for such commercial applications is the difficulty to recognize and to detected faces. Despite the advances, today's recognition systems have limitations. Many factors exist that could defeat these systems: facial expression, aging, glasses, and shaving.

Nevertheless, face detection/recognition has been critical for the success of intelligent robots that may provide

Table 1. Categorization of Still-Image-Based Face Recognition Techniques

Approach	Representative Work
Holistic methods	
Principal Component Analysis	
Eigenfaces	Direct application of PCA (15)
Probabilistic Eigenfaces	Two-class problem with prob. measure (43)
Fisherfaces/Subspace LDA	FLD on eigenspace (16,18,34)
SVM	Two-class problem based on SVM (44)
Evolution Pursuit	Enhanced GA learning (45)
Feature Lines	Point-to-line distance based (46)
ICA	ICA-based feature analysis (47)
Other Representations	
LDA/FLD	FLD/LDA on raw image (17)
PDBNN	Probabilistic decision-based NN (48)
Kernel faces	Kernel methods (39–41)
Tensorfaces	Multilinear analysis (42,49)
Feature-based methods	
Pure geometry methods	Earlier methods (9,10); recent methods (20,50)
Dynamic Link Architecture	Graph matching methods (19)
Hidden Markov Model	HMM methods (51,52)
Convolution Neural Network	SOM learning based CNN methods (53)
Hybrid methods	
Modular Eigenfaces	Eigenfaces and eigenmodules (54)
Hybrid LFA	Local feature method (55)
Shape-normalized	Flexible appearance models (28)
Component-based	Face region and components (56)

important services in the future. Prototypes of intelligent robots have been built, including Honda's ASIMO and Sony's QRIO.

Advanced Research Topics

To build a machine perception system someday that is close to or even better than the human perception system, researchers need to look at both aspects of this challenging problem: (*1*) the fundamental aspect of how human perception system works and (*2*) the systematic aspect of how to improve system performance based on best theories and technologies available. To illustrate the fascinating characteristics of the human perception system and how it is different from currently available machine perception systems, we plot the negative and upside-down photos of a person in Fig. 9. It is well known that negative or upside-down photos make human perception of faces more difficult (59)). Also we know that no difference exists in terms of information (bits used to encode images) between a digitized normal photo and a digitized negative or upside-down photo (except the sign and orientation information).

From the system perspective, many research challenges remain. For example, recent system evaluations (60) suggested at least two major challenges: the illumination variation problem and the pose variation problem. Although many existing systems build in some sort of performance invariance by applying pre-processes, such as histogram equalization or pose learning, significant illumination or pose change can cause serious performance degradation. In addition, face images could be partially occluded, or the system needs to recognize a person from an image in the database that was acquired some time ago. In an extreme scenario, for example, the search for missing children, the time interval could be up to 10 years. Such a scenario poses a significant challenge to build a robust system that can tolerate the variations in appearances across many years.

Real problems exist when face images are acquired under uncontrolled and uncooperative environments, for example, in surveillance applications. Although illumination and pose variations are well-defined and well-researched problems, other problems can be studied systematically, for example, through mathematical modeling. Mathematical modeling allows us to describe physical entities mathematically and hence to transfer the physical

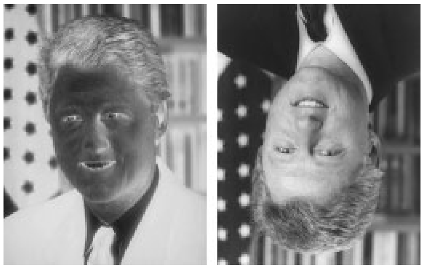

Figure 9. Typical limitation of human perception system with negative and upside-down photos: which makes it difficult or takes much longer for us to recognize people from the photos. Interestingly, we can manage eventually to overcome this limitation when recognizing famous people (President Bill Clinton in this case).

phenomena into a series of numbers (31). The decomposition of a face image into a linear combination of eigenfaces is a classic. example of mathematical modeling. In addition, mathematical modeling can be applied to handle the issues of occlusion, low resolution, and aging.

As an application of image analysis and understanding, machine recognition of faces benefits tremendously from advances in many relevant disciplines. To conclude our article, we list these disciplines for further reading and mention their direct impact on face recognition briefly

- **Pattern recognition.** The ultimate goal of face recognition is recognition of personal ID based on facial patterns, including 2-D images, 3-D structures, and any pre-processed features that are finally fed into a classifier.
- **Image processing.** Given a single or a sequence of raw face images, it is important to normalize the image size, enhance the image quality, and to localize local features before recognition.
- **Computer vision.** The first step in face recognition involves the detection of face regions based on appearance, color, and motion. Computer vision techniques also make it possible to build a 3-D face model from a sequence of images by aligning them together. Finally, 3-D face modeling holds great promises for robust face recognition.
- **Computer graphics.** Traditionally, computer graphics are used to render human faces with increasingly realistic appearances. Combined with computer vision, it has been applied to build 3-D models from images.
- **Learning.** Learning plays a significant role to building a mathematical model. For example, given a training set (or bootstrap set by many researchers) of 2-D or 3-D images, a generative model can be learned and applied to other novel objects in the same class of face images.
- **Neuroscience and Psychology.** Study of the amazing capability of human perception of faces can shed some light on how to improve existing systems for machine perception of faces.

FINGERPRINT IDENTIFICATION

HISTORY OF FINGERPRINTS

Biometrics such as fingerprint, palm, face, gait, ear, signature, and speech are used to ensure a high confidence in the recognition of an individual for high-security applications (1). Among these biometric traits, fingerprints have been used for a long period of time because of their distinctiveness and immutability. The study of fingerprint characteristics can be traced back to about 4500 years, the era of the pyramid-building in Egypt. However, the use of fingerprints for identification began in the mid-1800s.

Sir William Herschel discovered that fingerprints remain stable over time and distinct across individuals. In 1877, he commenced placing the inked palm and thumb impressions of some members of the local population on contracts. These prints were used as a form of signature on the documents. However, Herschel never claimed that he had developed a method to identify criminals.

In the late 1800s, the most advanced findings in fingerprint study was made by Dr. Henry Faulds. He found that fingerprints will not change even with superficial injury and that the latent prints left on objects can be used to identify criminals. In 1892, Sir Francis Galton published an accurate and in-depth study of fingerprint science in a book called *Finger Prints,* in which he described an attempt at a fingerprint classification system to facilitate the handling of large collections of fingerprints. Although the work of Galton proved to be sound and became the foundation of modern fingerprint science, his approach to classification was inadequate. Juan Vucetich, an Argentinian police officer who corresponded with Galton, devised his own fingerprint classification system, which was put into practice in September 1891. In 1897, Sir Edward Henry established the famous *Henry System*(2), which is a systematic and effective method of classifying fingerprints. He published the book *Classification and Uses of Fingerprints* in 1900. About 10 years later, his classification system was being used widely by police forces and prison authorities in the English-speaking world.

Since the early 1960s, researchers have begun to develop an *automatic* fingerprint identification system (AFIS) to improve the efficiency of fingerprint recognition. Today, almost all law enforcement agencies around the world use an AFIS. And fingerprint science is a well-researched field with research and development activities worldwide. Several publicly available databases (3,4) exist for evaluating the performance of various fingerprint recognition algorithms. New high-resolution electronic sensors, which are quite affordable (5,6), are available for use in portable laptop computers, mobile phones, and personal digital assistants (PDAs).

FINGERPRINT FEATURES

Fingerprints have two fundamentally important characteristics: permanence and distinctiveness. It has been found that fingerprints are formed in the fetal stage and do not change naturally. Also, no two fingerprints ever are found to be exactly the same. Because of these interesting characteristics, fingerprints are used widely for human recognition and identification.

Fingerprints are represented by features that are classified at three levels.

- Level 1 features describe the patterns of the fingerprints, which include ridge flow, core and delta, and pattern type. Ridge flow is the orientation image of the fingerprint. This feature is commonly used for classification. Figure 1 shows an example of the original image and the orientation image. Core and delta are singular points that are defined as the points where the orientation field of a fingerprint is discontinuous. Core is the topmost point on the innermost recurving ridge, and delta is the center of a triangular region where flows from three different directions meet. Figure 2 is an example of the core and delta in a fingerprint. Fingerprints are generally classified into five classes: right loop (R), left loop (L), whorl (W), arch (A), and tented arch (T). Figure 3 shows examples of the fingerprints from these five classes.
- Level 2 features are the points of the fingerprints. They include minutiae, scar, crease, and dot (7). A fingerprint consists of white and dark curves. The white curves are called the *valley* and the dark curves are called the *ridge*. Minutiae features are the ridge characteristics that correspond to the crossings and endings of ridges. They include endpoint, bifurcation, forks, island, and enclosures. The endpoint and bifurcation are used commonly in fingerprint recognition. Figure 4 is an example of the endpoint and bifurcation. Scar is the crossing of two or more adjacent ridges. Figure 5 (a) shows an example of a scar. A crease appears as a white line in a fingerprint. It is a linear depression (or grooves) in the skin. Figure 5 (b) shows an example of a crease. A dot is an isolated ridge unit with a pore on it. Figure 5 (c) shows an example of a dot.
- Level 3 features (5) describe the fingerprint shape that refers to pores and ridge contours. Pores are small openings on ridges. We need a high resolution sensor ($\geq$1000 pixels per inch (ppi)) to get this feature. Figure 6 is an example of sweat pores. Ridge contours are morphological features that include ridge width, shape, path deviation, and so forth.

Fingerprint sensors, the very front end of the fingerprint recognition systems, are used to capture the

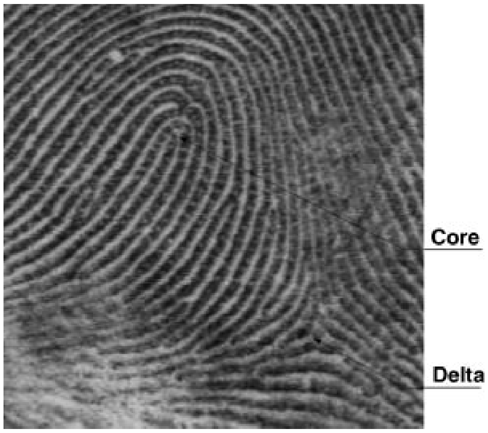

Figure 2. Level 1 features: core and delta.

fingerprint images. The kinds of fingerprint sensors are: optical sensors, semiconductor sensors, and ultrasound sensors. Among these sensors, optical sensors are considered to be stable and reliable, semiconductor sensors are considered to be low cost and portable, and ultrasound sensors are considered to be accurate but more expensive.

FINGERPRINT RECOGNITION

Depending on an application two kinds of fingerprint recognition systems exist: verification systems and identification systems (8). A verification system generally stores the fingerprint images or feature sets of users in a database. At a future time, it compares the fingerprint of a person with her/his own fingerprint image or feature set to verify that this person is, indeed, who she/he claims to be. This problem is a one-to-one matching problem. The system can accept or reject this person, according to the verification result. An identification system is more complex where, for a query fingerprint, the system searches the entire database to find out if any fingerprint images or feature sets saved in the database can match it. It conducts one-to-many matching (8). Two kinds of identification systems exists: the closed-set identification system and the open-set identification system (9). The closed-set identification system is the identification system for which all potential users are enrolled in the system. Usually, the closed-set identification is used for research purposes. The open-set identification system is the identification system for which some potential users are not enrolled in the system. The open-set identification is performed in real operational systems. The verification and the closed-set identification are special cases of the open-set identification.

Three kinds of approaches (see Fig. 7) exist to solve the fingerprint identification problem (10): (1) Repeat the verification procedure for each fingerprint in the database and select the best match; (2) use fingerprint classification followed by verification; and (3) use fingerprint indexing followed by verification (10,11). Fingerprint matching, classification, and indexing are three basic problems in fingerprint identification.

Fingerprint Matching

A fingerprint matching algorithm aligns the two given fingerprints, finds the correspondences between them,

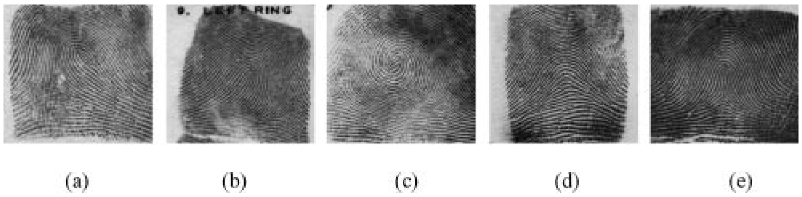

Figure 3. Examples of fingerprints for each class based on the *Henry System:* (a) right loop, (b) left loop, (c) whorl, (d) arch, and (e) tented.

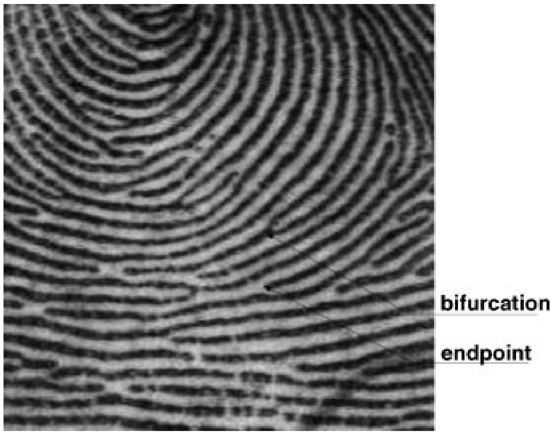

Figure 4. Minutiae: endpoint and bifurcation.

and returns a measure of the degree of similarity. Usually, the similarity score is used to represent the degree of similarity between the two given fingerprints. Fingerprint matching is a challenging problem because different impressions of the same finger could be very different because of distortion, displacement, rotation, noise, skin condition, pressure, noise, and so forth (8). Furthermore the impressions from different fingers could be quite similar. Figure 8 shows two impressions of one fingerprint from the NIST-4 database (10). The fingerprint matching algorithms can be classified into three different types: (1) the correlation-based approach, (2) the minutiae-based approach, and (3) the ridge feature-based approach.

1. *Correlation-based matching:* The correlation-based approach uses the gray-level information of fingerprints. For a template fingerprint (in the database) and a query fingerprint, it computes the sum of the squared differences in gray values of all the pixels to evaluate the diversity of the template fingerprint and the query fingerprint. To deal with the distortion problem, it computes the correlation in local regions instead of the global correlation on the entire image. In Bazen et al. (12), the correlation-based evaluation is used to find the distinctive regions of the template fingerprint. These local regions fit very well at the original locations and much worse at other locations. During the matching, they compute the gray-level distance between the distinctive regions of a template and the corresponding areas in the query fingerprints. Then, they sum up the squared gray-level difference for each local region. The position of a region of the template with the minimal distance is considered as the corresponding region in the query fingerprint.

   Compared with the other matching algorithms described below, correlation-based matching approaches use gray-level information of the fingerprint. When the quality of the fingerprint image is not good, especially when a large number of minutiae are missing, the correlation-based matching algorithm may be considered. However, it is expensive computationally.

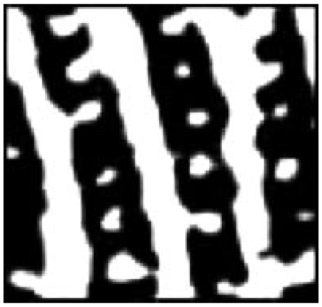

Figure 6. Example of sweat pores.

2. *Minutiae-based matching:* Minutiae-based matching is the most commonly used method for fingerprint recognition systems. In this approach, a fingerprint is represented by a set of minutiae features. Thus, the fingerprint recognition problem is reduced to a point-matching problem. Therefore, any point matching approach, such as the relaxation algorithms, can be used to recognize the fingerprints (13,14).

- Feature extraction: The first step of the minutiae-matching algorithm is the minutiae extraction. Figure 9 is the block diagram of the minutiae-based feature extraction procedure, which is used widely in most fingerprint recognition systems. As an example, Bhanu and Tan present a learned template-based algorithm for feature extraction (15). Templates are learned from examples by optimizing a criterion function using the Lagrange method. To detect the presence of minutiae in fingerprints, templates for endpoints and bifurcations are applied with appropriate orientation to the binary fingerprints at selected potential minutiae locations.

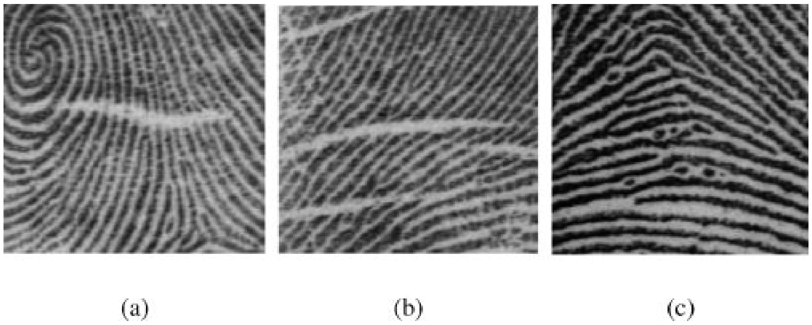

Figure 5. Level 2 features: (a) scar, (b) crease, and (c) dot.

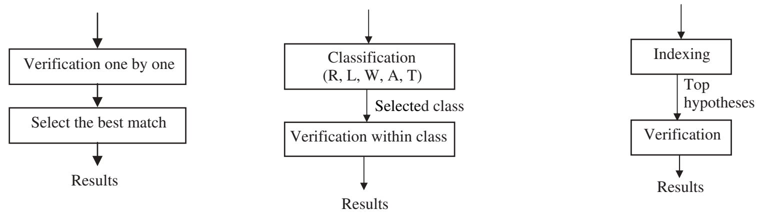

(1) Repeat verification (2) Classification followed by verification (3) Indexing followed by verification

Figure 7. Block diagram of three kinds of approaches to solve the identification problem.

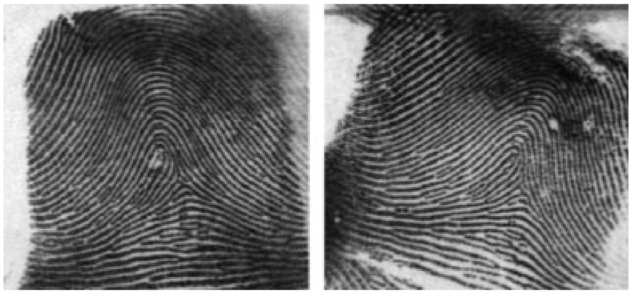

Figure 8. Two impressions of one fingerprint.

- Matching: Tan and Bhanu (13,14) present a fingerprint-matching approach, based on genetic algorithms (GA). This method can achieve a globally optimized solution for the transformation between two sets of minutiae extracted from two different fingerprints. In their approach, the fitness function is based on the local properties of triplets of minutiae, such as minimum angle, maximum angle, triangle handedness, triangle direction, maximum side, minutiae density, and ridge counts. These features are described in the "Fingerprint Indexing" section below.

  Jiang and Yau (16) use both the local and global structures of minutiae in their minutiae-matching approach. The local structure of a minutia describes the features independent of the rotation and translation in its l-nearest neighborhood. The global structure is variant with the rotation and translation. Using the local structure, the best matched minutiae pair is found and used to align the template and query fingerprint. Then, the elastic bounding box of the global features is used for the fingerprint matching.

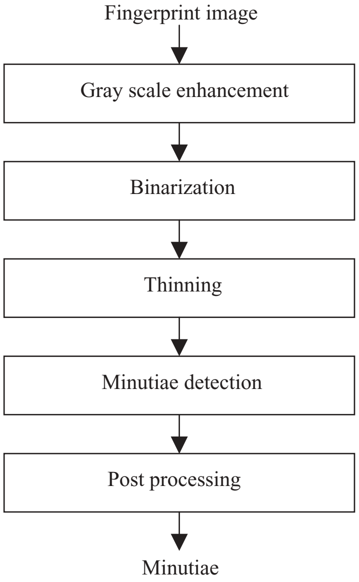

Figure 9. Block diagram for minutiae-based feature extraction.

  Kovacs-Vajna (17) used triangular matching to deal with deformations of fingerprints. In this approach, the minutiae regions of the template fingerprint are moved around the query fingerprint to find the possible correspondence. The triangular matching algorithm is used to obtain the matching minutiae set. Then, the dynamic time-warping algorithm is applied to validate the final matching results.

3. *Ridge feature-based matching:* For a good quality fingerprint with size 480 × 512 [500 pixels per inch (ppi)], about 80 minutiae features could exist. Thus, for the triangular minutiae matching, hundreds of thousands of triangles could exist. So, the minutiae matching approach needs high computational power. However, when the image quality is not good, the minutiae extraction would be difficult. Because fingerprints consist of natural valley and ridges, researchers have used them for fingerprint matching. Maltoni et al. (8) present a filter-based algorithm for fingerprint recognition. It is based on the grayscale image. First, they determine a reference point with the maximum curvature of the concave ridges and an interest region in the fingerprint. After tessellating the interest region around the reference point, they use a bank of Gabor filters to capture both local and global details in a fingerprint. Then, they compute the average absolute deviation from the mean to define the compact fixed-length FingerCode as the feature vector. Finally, they match the fingerprint by computing the Euclidean distance between the corresponding FingerCode between the template and query fingerprints.

With the improvement of the fingerprint sensor technology, now it is possible to extract features at a high resolution. In Jain et al. (5), authors use pores and ridge contours combined with minutiae features to improve fingerprint recognition performance. In their approach, they use Gabor filter and wavelet transform to extract pores and ridge contours. During the matching process, they extract orientation field and minutiae features and establish alignment between the template and query fingerprint. If the orientation fields match, then the system uses a minutiae-based matching algorithm to verify the query fingerprint or to reject the query fingerprint. If the number of the corresponding minutiae between the template fingerprint and query fingerprint is greater than a threshold, then these two fingerprints match; if not, then the system extracts pores and ridge contours and they use the Iterative Closest Point (ICP) algorithm to match these features. This hierarchical matching system requires 1000 ppi resolution for the sensor.

FINGERPRINT CLASSIFICATION

Most fingerprint classification systems use the Henry system for fingerprint classification, which has five classes as shown in Fig. 3. The most widely-used approaches for fingerprint classification are based on the number and relations of the singular points, including the core and the delta. Karu and Jain (24) present a classification approach based on the structural information around the singular points. Three steps are in this algorithm: (1) Compute the ridge direction in a fingerprint image; (2) find the singular points based on the changes in the directional angle around the curve; and (3) classify the fingerprints according to the number and locations of the core and delta. Other researchers use a similar method: first, find the singular point; then use a classification algorithm to find the difference in areas, which are around the singular points for different classes. Several representations based on principal component analysis (PCA) (3), a self-organizing map (18), and Gabor filters (8) are used. The problems with these approaches are:

- It is not easy to detect singular points, and some fingerprints do not have singular points.
- Uncertainty in the location of the singular points is large, which has a great effect on the classification performance because the features around the singular points are used.

Cappelli et al. (19) present a structural analysis of the orientation field of a fingerprint. In their approach, the directional image is calculated and enhanced. A set of dynamic masks is used in the segmentation step, and each dynamic mask is adapted independently to best fit the directional image according to a cost function. The resulting cost constitutes a basis for the final classification (3). Based on the orientation field, Cappelli et al. also present a fingerprint classification system based on the multispace KL transform (20). It uses a different number of principal components for different classes. Jain and Minut (31) propose a classification algorithm based on finding the kernel that best fits the flow field of a given fingerprint. For each class, a kernel is used to define the shape of the fingerprint in that class. In these approaches, it is not necessary to find the singular points.

Researchers also have tried different methods to combine different classifiers to improve the classification performance. Senior (21) combines the hidden Markov model (HMM), decision trees, and PCASYS (3). Yao et al. (22) present new fingerprint classification algorithms based on two machine learning approaches: support vector machines (SVMs) and recursive neural networks (RNNs). In their approach, the fingerprints are represented by the relational graphs. Then, RNNs are used to train these graphs and extract distributed features for the fingerprints. SVMs integrated with distributed features are used for classification. To solve the ambiguity problem in fingerprint classification, an error-correcting code scheme is combined with SVMs.

Tan et al. (23) present a fingerprint classification approach based on genetic programming (GP) to learn composite operators that help to find useful features. During the training, they use GP to generate composite operators. Then, the composite operators are used to generate the feature vectors for fingerprint classification. A Bayesian classifier is used for classification. Fitness values are computed for the composite operators based on the classification results. During the testing, the learned composite operator is applied directly to generate feature vectors. In their approach, they do not need to find the reference points. Table 1 summarizes representative fingerprint classification approaches.

FINGERPRINT INDEXING

The purpose of indexing algorithms is to generate, in an efficient manner, a set of hypotheses that is a potential match to a query fingerprint. Indexing techniques can be considered as front-end processing, which then would be followed by back-end verification processing in a complete fingerprint recognition system.

A prominent approach for fingerprint indexing is by Germain et al. (11). They use the triplets of minutiae in their indexing procedure. The features they use are: the length of each side, the ridge count between each pair of vertices, and the angles that the ridges make with respect to the x-axis of the reference frame. The number of corresponding triangles is defined as the similarity score between the query and the template fingerprints. In their approach, a hash table is built where all possible triplets are saved. For each triplet, a list of IDs, including the fingerprints that have this triplet, is saved. During the identification process, the triplets of the query fingerprint are extracted and—by a hashing process described below—the potential IDs of the query fingerprint are determined.

Because some features in Ref. (11) may not be reliable, Bhanu and Tan (33) use a novel set of features of a triplet for fingerprint indexing. These features are:

- Minimum angle α_{min} and median angle α_{med}. Assume α_i are three angles in a triplet, where i = 1, 2, 3. $\alpha_{min} = min\{\alpha_i\}$, $\alpha_{max} = max\{\alpha_i\}$, $\alpha_{med} = 180° - \alpha_{min} - \alpha_{max}$.
- Triangle handedness ϕ. Let $Z_i = x_i + jy_i$ be the complex number corresponding to the location (x_i, y_i) of point P_i, i = 1,2, 3. Define $Z_{21} = Z_2 - Z_1$, $Z_{32} = Z_3 - Z_2$, and $Z_{13} = Z_1 - Z_3$. Let triangle handedness $\phi = sign\ (Z_{21} \times Z_{32})$, where *sign* is the signum function and × is the cross product of two complex numbers. Points P_1, P_2, and P_3 are noncolinear points, so ϕ = 1 or -1.
- Triangle direction η. Search the minutiae in the image from top to bottom and left to right. If the minutiae is the start point, then $\upsilon = 1$; otherwise $\upsilon = 0$. Let $\eta = 4\upsilon_1 + 2\upsilon_2 + \upsilon_3$, where υ_i is the υ value of point P_i, i = 1,2,3, and $0 \leq \eta \leq 7$.
- Maximum side λ. Let $\lambda = max\{L_i\}$, where $L_1 = |Z_{21}|, L_2 = |Z_{32}|$, and $L_3 = |Z_{13}|$.
- Minutiae density χ. In a local area (32 × 32 pixels) centered at the minutiae P_i, if χ_i minutiae exists then the minutiae density for P_i is χ_i. Minutiae density χ is a vector consisting of all χ_i.
- Ridge counts ξ. Let ξ_1, ξ_2, and ξ_3 be the ridge counts of sides P_1P_2, P_2P_3, and P_3P_1, respectively. Then, ξ is a vector consisting of all ξ_i.

During the offline hashing process, the above features for each template fingerprint (33) are computed and a hash table $H(\alpha_{min}, \alpha_{med}, \phi, \eta, \lambda, \chi, \xi)$ is generated. During the online hashing process, the same features are computed for each query fingerprint and compared with the features represented by H. If the difference in features is small enough, then the query fingerprint is probably the same as the "stored" fingerprints that have similar features. Figure 10 is an example of two corresponding triangles in a pair of fingerprints that are two impressions of one fingerprint. In the first impression, three noncolinear minutiae A, B, and C are picked randomly to form a triangle ΔABC. The features in this triangle are $\{\alpha_{min} = 30°, \alpha_{med} = 65°, \phi = 1, \eta = 6, \lambda = |AC|, \chi = \{0,0,0\}, \Delta\xi = \{6,5,12\}\}$. Similarly, three noncolinear minutiae a, b, and c in the second impression form Δabc. Its features are $\{\alpha_{min} = 31°, \alpha_{med} = 63°, \phi = 1, \eta = 6, \lambda = |ac|, \chi = \{0,2,0\}, \xi = \{6,5,12\}\}$. If the error between these two triangles are within the error tolerance (34), then these two triangles are considered the corresponding triangles. The output of this process, carried out for all the triplets, is a list of hypotheses, which is sorted in the descending order of the number of potential corresponding triangles. Top T hypotheses are the input to the verification process.

PERFORMANCE EVALUATION

Two classes in the fingerprint recognition systems exist: match and nonmatch. Let s and n denote match and non-match. Assume that x is the similarity score. Then, $f(x\,|\,s)$ is the probability density function given s is true, and $f(x\,|\,n)$ is the probability density function given n is true. Figure 11 is an example of these two distributions. For a criterion k, one can define

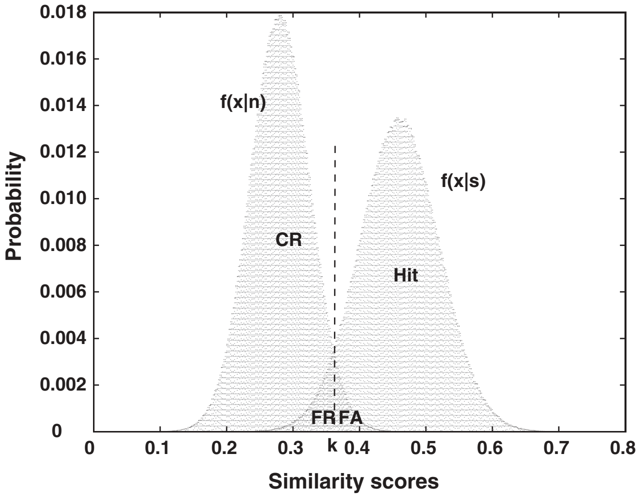

Figure 11. Densities of the match and nonmatch scores.

- Hit: the probability that x is above k given s, where $Hit = \int_k^\infty f(x|s)dx$
- False alarm: the probability that x is above k given n, where $FA = \int_k^\infty f(x|n)dx$
- False rejection: the probability that x is below k given s, where $FR = \int_{-\infty}^k f(x|s)dx$
- Correct rejection: the probability that x is below k given n, where $CR = \int_{-\infty}^k f(x|n)dx$

A *receiver operating characteristic (ROC)* curve is a graphical plot whose x-axis is the *false alarm (FA)* rate and y-axis is the *hit (Hit)* rate. A *ROC* curve is used to evaluate the performance of a recognition system because it represents the changes in *FA* rate and *Hit* rate with different discrimination criteria (thresholds). A *detection error tradoff (DET)* curve plots the *FA* rate and the *false rejection (FR)* rate with the change of discrimination criteria. A confidence interval is an interval within which the estimation is likely to be determined. The ISO standard performance testing report gives the detail of recommendations and requirements for the performance evaluations (9).

Public fingerprint databases are used to evaluate the performance of different fingerprint recognition algorithms and fingerprint acquisition sensors. The National Institute of Standards and Technology (NIST) provides several special fingerprint databases with different acquisition methods and scenarios. Most images in these databases are rolling fingerprints that are scanned from paper cards. The *NIST* special database 24 is a digital video of live-scan fingerprint data. The detail of the *NIST* special databases can be found in Ref. (35). Since 2000, fingerprint verification competition (FVC) has provided public databases for a competition that is held every 2 years. For each competition, four disjoint databases are created that are collected with different sensors and technologies. The performance of different recognition algorithms is addressed in the reports of each competition (36–39). The fingerprint vendor technology evaluation (F$_p$VTE) 2003 is conducted by *NIST* to evaluate the performance of the fingerprint recognition systems. A total of 18 companies competed in the *FpVTE*, and 34 systems from U.S government were examined. The performance of different recognition algorithms is discussed in Ref. (40).

PERFORMANCE PREDICTION

Several research efforts exist for analyzing the performance of fingerprint recognition. Galton (41) assumes that 24 independent square regions could cover a fingerprint and that he could reconstruct correctly any of the regions with a probability of 1/2 by looking at the surrounding ridges. Accordingly, the Galton formulation of the distinctiveness of a fingerprint is given by $(1/16) \times (1/256) \times (1/2)^{24}$, where 1/16 is the probability of the occurrence of a fingerprint type and 1/256 is the probability of the occurrence of the correct number of ridges entering and exiting each of the 24 regions. Pankanti et al. (8) present a fingerprint individuality model that is based on the analysis of feature space and derive an expression to estimate the probability of false match based on the minutiae between two fingerprints. It measures the amount of information needed to establish correspondence between two fingerprints. Tan and Bhanu (42) present a two-point model and a three-point model to estimate the error rate for the minutiae-based fingerprint recognition. Their approach not only measures the position and orientation of the minutiae but also the relations between different minutiae to find the probability of correspondence between fingerprints. They allow the overlap of uncertainty area of any two minutiae. Tabassi et al. (43) and Wein and Baveja (44) use the fingerprint image quality to predict the performance. They define the quality as an indication of the degree of separation between the match score and nonmatch score distributions. The farther these two distributions are from each other, the better the system performs.

Predicting large population recognition performance based on a small template database is another important topic for the fingerprint performance characterization. Wang and Bhanu (45) present an integrated model that considers data distortion to predict the fingerprint identification performance on large populations. Learning is incorporated in the prediction process to find the optimal small gallery size. The Chernoff and Chebychev inequalities are used as a guide to obtain the small gallery size given the margin of error and confidence interval. The confidence interval can describe the uncertainty associated with the estimation. This confidence interval gives an interval within which the true algorithm performance for a large population is expected to fall, along with the probability that it is expected to fall there.

FINGERPRINT SECURITY

Traditionally, cryptosystems use secret keys to protect information. Assume that we have two agents, called Alice and Bob. Alice wants to send a message to Bob over the public channel. Eve, the third party, eavesdrops over the public channel and tries to figure out what Alice and Bob are saying to each other. When Alice sends a message to Bob, she uses a secret encryption algorithm to encrypt the message. After Bob gets the encrypted message, he will use a secret decryption algorithm to decrypt the message. The secret keys are used in the encryption and decryption processes. Because the secret keys can be forgotten, lost, and broken, biometric cryptosystems are possible for security.

Uludag et al. (46) propose a cryptographic construct that combines the fuzzy vault with fingerprint minutiae data to protect information. The procedure for constructing the fuzzy vault is like what follows in the example of Alice and Bob. Alice places a secret value k in a vault and locks it using an unordered set A of the polynomial coefficients. She selects a polynomial p of variable x to encode k. Then, she computes the polynomial projections for the elements of A and adds some randomly generated chaff points that do not lie on p to arrive at the final point set R. Bob uses an unordered set B of the polynomial coefficients to unlock the vault only if B overlaps with A to a great extent. He tries to learn k, that is to find p. By using error-correction coding, he can reconstruct p. Uludag et al. (46) present a curve-based transformed minutia representation in securing the fuzzy fingerprint vault.

We know that the biometrics is permanently related with a user. So if the biometrics is lost, then the biometrics recognition system will be compromised forever. Also, a user can be tracked by cross-matching with all the potential uses of the fingerprint biometrics, such as access to the house, bank account, vehicle, and laptop computer. Ratha et al. (47) presents a solution to overcome these problems in the fingerprint recognition systems. Instead of storing the original biometrics image, authors apply a one-way transformation function to the biometrics. Then, they store the transformed biometrics and the transformation to preserve the privacy. If a biometrics is lost, then it can be restored by applyings a different transformation function. For different applications of the same biometrics, they use different transformation functions to avoid a user being tracked by performing a cross match.

Like other security systems, fingerprint sensors are prone to spoofing by fake fingerprints molded with artificial materials. Parthasaradhi et al. (48) developed an anti spoofing method that is based on the distinctive moisture pattern of live fingers contacting fingerprint sensors. This method uses the physiological process of perspiration to determine the liveness of a fingerprint. First, they extract the gray values along the ridges to form a signal. This process maps a 2 fingerprint image into a signal. Then, they calculate a set of features that are represented by a set of dynamic measurements. Finally, they use a neural network to perform classification (live vs. not live).

CONCLUSIONS

Because of their characteristics, such as distinctiveness, permanence, and collectability, fingerprints have been used widely for recognition for more than 100 years. Fingerprints have three levels of features: pattern, point, and shape. With the improvement of the sensor resolution, more and better fingerprint features can be extracted to improve the fingerprint recognition performance. Three kinds of approaches exist to solve the fingerprint identification problem: (1) Repeat the verification procedure for each fingerprint in the database and select the best match; (2) perform fingerprint classification followed by verification; and (3) create fingerprint indexing, followed by verification. Fingerprint verification is done by matching a query fingerprint with a template. The feature extraction, matching, classification, indexing and performance prediction are the basic problems for fingerprint recognition.

Fingerprint prediction, security, liveness detection, and cancelable biometrics are the important current research problems. The area of biometric cryptosystems, especially the fingerprint cryptosystem, is an upcoming area of interest because the traditional secret key can be forgotten, lost, and broken.

GEOMETRIC CAMERA CALIBRATION

INTRODUCTION

Geometric camera calibration is the process of determining geometric properties of a camera. Here, the camera is considered as a ray-based sensing device, and the camera geometry defines how the observed rays of light are mapped onto the image. The purpose of calibration is to discover the mapping between the rays and image points. Hence, a calibrated camera can be used as a direction sensor for which both the forward-projection and back-projection are known, that is, one may compute the image point corresponding to a given projection ray and vice versa.

The geometric calibration of a camera is usually performed by imaging a calibration object whose geometric properties are known. The calibration object often consists of one to three planes that contain visible control points in known positions. The calibration is achieved by fitting a camera model to the observations, which are the measured positions of the control points in the calibration images. The camera model contains two kinds of parameters: The *external* parameters relate the camera orientation and position to the object coordinate frame, and the *internal* parameters determine the projection from the camera coordinate frame onto image coordinates. Typically, both the external and the internal camera parameters are estimated in the calibration process, which usually involves nonlinear optimization and minimizes a suitable cost function over the camera parameters. The sum of squared distances between the measured and modeled control point projections is used frequently as the cost function because it gives the maximum-likelihood parameter estimates assuming isotropic and independent normally distributed measurement errors.

Calibration by nonlinear optimization requires a good initial guess for the camera parameters. Hence, various methods have been proposed for the direct estimation of the parameters. Most methods deal with conventional perspective cameras, but recently effort has been made in developing models and calibration methods for more general cameras. In fact, the choice of a suitable camera model is an important issue in camera calibration. For example, the pinhole camera model, which is based on the ideal perspective projection model and often used for conventional cameras, is not a suitable model for omnidirectional cameras that have a very large field of view. Hence, a recent trend has occurred towards generic calibration techniques that would allow the calibration of various types of cameras.

In this article, we will provide an overview into geometric camera calibration and its current state. However, because the literature for camera calibration is vast and ever-evolving, it is not possible to cover all aspects in detail. Nevertheless, we hope that this article serves as an introduction to the literature in which more details can be found. The article is structured as follows. First, in the Background section, we describe some historical background for camera calibration. Thereafter, we review different camera models with an emphasis on central cameras. After describing camera models we discuss methods for camera calibration. The focus is on our previous works (1, 2). Finally, in the calibration examples section, we present some calibration examples with real cameras.

BACKGROUND

Geometric camera calibration is a prerequisite for image-based metric three-dimensional measurements, and it has a long history in photogrammetry and computer vision. One of the first references is by Conrady (3), who derived an analytical expression for the geometric distortion in a decentered lens system. Conrady's model for decentering distortion was used by Brown (4), who proposed a plumb line method for calibrating radial and decentering distortion. Later the approach used by Brown was commonly adopted in photogrammetric camera calibration (5).

In photogrammetry, the emphasis has traditionally been in the rigorous geometric modeling of the camera and optics. On the other hand, in computer vision it is considered important that the calibration procedure is automatic and fast. For example, the well-known calibration method developed by Tsai (6) was designed to be an automatic and efficient calibration technique for machine vision metrology. This method uses a simpler camera model than Brown (4) and avoids the full-scale nonlinear search by using simplifying approximations. However, because of the increased processing power of personal computers, the nonlinear optimization is not as time-consuming now as it was before. Hence, when the calibration accuracy is important the camera parameters are usually refined by a full-scale nonlinear optimization.

Besides increasing the theoretical understanding, the advances in geometric computer vision have also affected the practice of image-based 3-D reconstruction during the last two decades (7,8). For example, although the traditional photogrammetric approach assumes a precalibrated camera, an alternative approach is to compute a projective reconstruction with an uncalibrated perspective camera. The projective reconstruction is defined up to a 3-D projective transformation, and it can be upgraded to a metric reconstruction by self-calibration (8). In self-calibration, the camera parameters are determined without a calibration object; feature correspondences over multiple images are used instead. However, the conventional calibration is typically more accurate and stable than self-calibration. In fact, self-calibration methods are beyond the scope of this article.

CAMERA MODELS

In this section, we describe several camera models that have appeared in the literature. We concentrate on central

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

cameras, that is, cameras with a single effective viewpoint. Single viewpoint means that all the rays of light that arrive onto the image travel through a single point in space.

Perspective Cameras

The pinhole camera model is the most common camera model, and it is a fair approximation for most conventional cameras that obey the perspective model. Typically these conventional cameras have a small field of view, up to 60°. The pinhole camera model is widely used and simple; essentially, it is just a perspective projection followed by an affine transformation in the image plane (8).

The pinhole camera geometry is illustrated in Fig. 1. In a pinhole camera, the projection rays meet at a single point that is the camera center **C** and its distance from the image plane is the focal length f. By similar triangles, it may be seen in Fig. 1 that the point $(X_c, Y_c, Z_c)^{\mathrm{T}}$ in the camera coordinate frame is projected to the point $(fX_c/Z_c,\ fY_c/Z_c)^{\mathrm{T}}$ in the image coordinate frame. In terms of homogeneous coordinates, this perspective projection can be represented by a 3×4 projection matrix,

$$\begin{pmatrix} x \\ y \\ 1 \end{pmatrix} \simeq \begin{bmatrix} f & 0 & 0 & 0 \\ 0 & f & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} \begin{pmatrix} X_c \\ Y_c \\ Z_c \\ 1 \end{pmatrix}$$

where $\simeq$ denotes equality up to scale.

However, instead of the image coordinates $(x, y)^{\mathrm{T}}$, the pixel coordinates $(u, v)^{\mathrm{T}}$ are usually used, and they are obtained by the affine transformation

$$\begin{pmatrix} u \\ v \end{pmatrix} = \begin{bmatrix} m_u & -m_u \cot\alpha \\ 0 & \dfrac{m_v}{\sin\alpha} \end{bmatrix} \begin{pmatrix} x \\ y \end{pmatrix} + \begin{pmatrix} u_0 \\ v_0 \end{pmatrix} \tag{1}$$

where $(u_0, v_0)^{\mathrm{T}}$ is the principal point, α is the angle between u and v axis, and m_u and m_v give the number of pixels per unit distance in u and v directions, respectively. The angle α is $\frac{\pi}{2}$ in the conventional case of orthogonal pixel coordinate axes.

In practice, the 3-D point is expressed in some world coordinate system that is different from the camera coordinate system. The motion between these coordinate systems is given by a rotation **R** and translation **t**. Hence, in homogeneous coordinates, the mapping of the 3-D point **X** to its image **m** is given by

$$\begin{aligned} \mathbf{m} &\simeq \begin{bmatrix} m_u & -m_u \cot\alpha & u_0 \\ 0 & \dfrac{m_v}{\sin\alpha} & v_0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} f & 0 & 0 & 0 \\ 0 & f & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} \mathbf{R} & \mathbf{t} \\ 0 & 1 \end{bmatrix} \mathbf{X} \\ &= \begin{bmatrix} m_u f & -m_u f \cot\alpha & u_0 \\ 0 & \dfrac{m_v}{\sin\alpha} & v_0 \\ 0 & 0 & 1 \end{bmatrix} [\mathbf{R} \quad \mathbf{t}] \mathbf{X} \\ &= \begin{bmatrix} m_u f & m_u s f & u_0 \\ 0 & m_u \gamma f & v_0 \\ 0 & 0 & 1 \end{bmatrix} [\mathbf{R} \quad \mathbf{t}] \mathbf{X} \end{aligned} \tag{2}$$

where we have introduced the parameters $\gamma = \frac{m_v}{m_u \sin\alpha}$ and

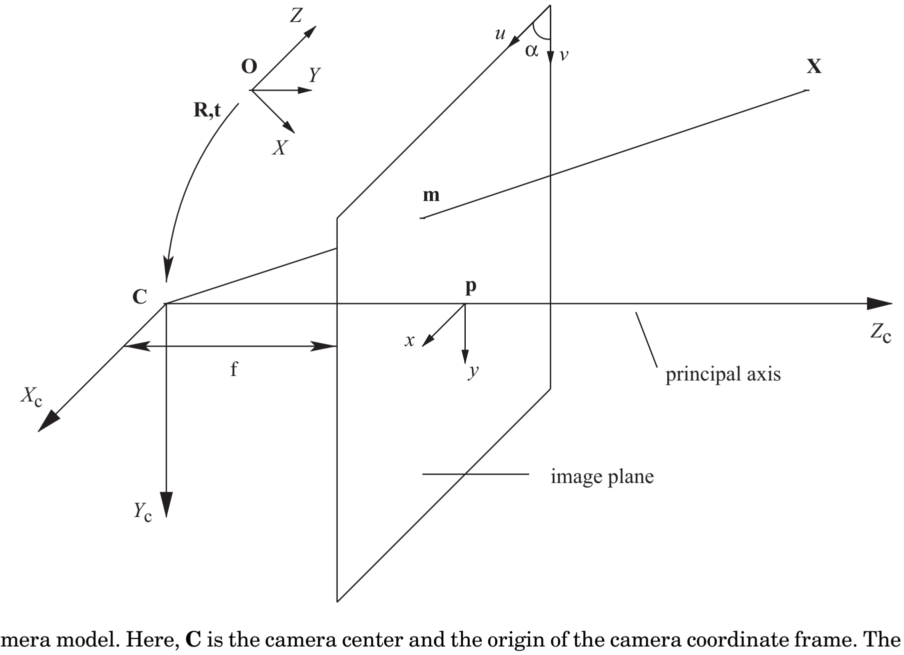

Figure 1. Pinhole camera model. Here, **C** is the camera center and the origin of the camera coordinate frame. The principal point **p** is the origin of the normalized image coordinate system (x, y). The pixel image coordinate system is (u, v).

$s = -\cot\alpha$ to simplify the notation. Because a change in the focal length and a change in the pixel units are indistinguishable above, we may set $m_u = 1$ and write the projection equation in the form

$$\mathbf{m} \simeq \mathbf{K}\begin{bmatrix}\mathbf{R} & \mathbf{t}\end{bmatrix}\mathbf{X} \tag{3}$$

where the upper triangular matrix

$$\mathbf{K} = \begin{bmatrix} f & sf & u_0 \\ 0 & \gamma f & v_0 \\ 0 & 0 & 1 \end{bmatrix} \tag{4}$$

is the *camera calibration matrix* and contains the five internal parameters of a pinhole camera.

It follows from Eq. (3) that a general pinhole camera may be represented by a homogeneous 3 × 4 matrix

$$\mathbf{P} = \mathbf{K}\begin{bmatrix}\mathbf{R} & \mathbf{t}\end{bmatrix} \tag{5}$$

which is called the *camera projection matrix*. If the left hand submatrix **KR** is nonsingular, as it is for perspective cameras, the camera **P** is called a *finite projective camera*.

A camera represented by an arbitrary homogeneous 3 × 4 matrix of rank 3 is called a *general projective camera*. This class covers the *affine cameras*, which have a projection matrix whose last row is (0, 0, 0, 1) up to scale. A common example of an affine camera is the orthographic camera in which the scene points are orthogonally projected onto the image plane (8).

Lens Distortion. The pinhole camera is an idealized mathematical model for real cameras that may often deviate from the ideal perspective imaging model. Hence, the basic pinhole model is often accompanied with lens distortion models for more accurate calibration of real lens systems. The most important type of geometric distortion is the radial distortion that causes an inward or outward displacement of a given image point from its ideal location. Decentering of lens elements causes additional distortion, which also has tangential components.

A commonly used model for lens distortion accounts for radial and decentering distortion (4, 5). According to this model, the corrected image coordinates x', y' are obtained by

$$\begin{aligned} x' &= x + \bar{x}(\kappa_1 r^2 + \kappa_2 r^4 + \kappa_3 r^6 + \cdots) \\ &\quad + (\rho_1(r^2 + 2\bar{x}^2) + 2\rho_2 \bar{x}\bar{y})(1 + \rho_3 r^2 + \cdots) \\ y' &= y + \bar{y}(\kappa_1 r^2 + \kappa_2 r^4 + \kappa_3 r^6 + \cdots) \\ &\quad + (2\rho_1 \bar{x}\bar{y} + \rho_2(r^2 + 2\bar{y}^2))(1 + \rho_3 r^2 + \cdots) \end{aligned} \tag{6}$$

where x and y are the measured coordinates, and

$$\begin{aligned} \bar{x} &= x - x_p \\ \bar{y} &= y - y_p \\ r &= \sqrt{(x - x_p)^2 + (y - y_p)^2} \end{aligned}$$

Here, the center of distortion (x_p, y_p) is a free parameter in addition to the radial distortion coefficients κ_i and decentering distortion coefficients ρ_i. In the traditional photogrammetric approach, the values for the distortion parameters are computed by least-squares adjustment by requiring that images of straight lines are straight after the correction (4). However, the problem with this approach is that not only the distortion coefficients but also the other camera parameters are initially unknown. For example, the formulation above requires that the scales in both coordinate directions are equal, which is not the case with pixel coordinates unless the pixels are square.

In Ref. 1, the distortion model of Eq. (6) was adapted and combined with the pinhole model to make a complete and accurate model for real cameras. This camera model has the form

$$\mathbf{m} = \mathcal{P}(\mathbf{X}) = \mathbf{P}\mathbf{X} + \mathcal{C}(\mathbf{P}\mathbf{X}) \tag{7}$$

where $\mathcal{P}$ denotes the non linear camera projection and **P** is the camera projection matrix of a pinhole camera. The nonlinear part $\mathcal{C}$ is the distortion model derived from Eq. (6). In Ref. 1, two parameters were used for both the radial and decentering distortion (i.e., the parameters κ_1, κ_2 and ρ_1, ρ_2), and it was assumed that the center of distortion coincides with the principal point of the pinhole camera.

Central Omnidirectional Cameras

Although the pinhole model accompanied with lens distortion models is a fair approximation for most conventional cameras, it is not a suitable model for omnidirectional cameras whose field of view is over 180°. The reason is that, when the angle between the incoming light ray and the optical axis of the camera approaches 90°, the perspective projection maps the ray infinitely far in the image, and it is not possible to remove this singularity with the distortion model described above. Hence, more flexible models are needed, and below we discuss different models for central omnidirectional cameras.

Catadioptric Cameras. In a catadioptric omnidirectional camera, the wide field of view is achieved by placing a mirror in front of the camera lens. In a central catadioptric camera, the shape and configuration of the mirror are such that the complete catadioptric system has a single effective viewpoint. It has been shown that the mirror surfaces that produce a single viewpoint are surfaces of revolution whose two-dimensional profile is a conic section (9). Practically useful mirror surfaces used in real central catadioptric cameras are planar, hyperbolic, elliptical, and parabolic. However, a planar mirror does not change the field of view of the camera (9).

The central catadioptric configurations with hyperbolic, elliptical, and parabolic mirrors are illustrated in Fig. 2. To satisfy the single viewpoint constraint, the parabolic mirror is combined with an orthographic camera, whereas the other mirrors are combined with a perspective camera. In each case, the effective viewpoint of the catadioptric system is the focal point of the mirror denoted by F in Fig. 2.

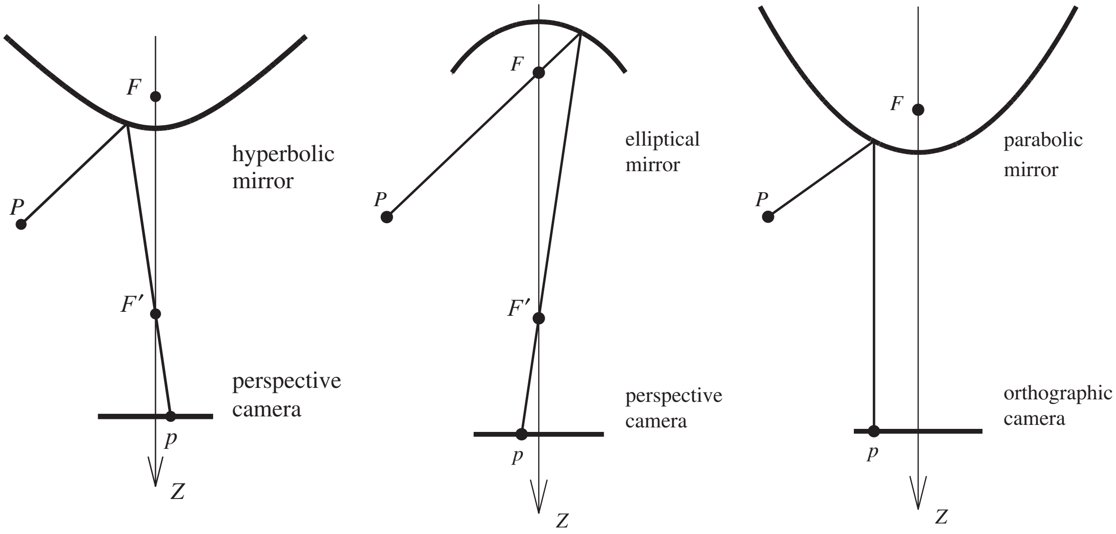

Figure 2. Central catadioptric camera with a hyperbolic, elliptical and parabolic mirror. The Z-axis is the optical axis of the camera and the axis of revolution for the mirror surface. The scene point P is imaged at p. In each case, the viewpoint of the catadioptric system is the focal point of the mirror denoted by F. In the case of hyperbolic and elliptical mirrors, the effective pinhole of the perspective camera must be placed at the other focal point, which is here denoted by F'.

Single-viewpoint catadioptric image formation is well studied (9, 10), and it has been shown that a central catadioptric projection, including the cases shown in Fig. 2, is equivalent to a two-step mapping via the unit sphere (10, 11). As described in Refs. 11 and 12, the unifying model for central catadioptric cameras may be represented by a composed function $\mathcal{H} \circ \mathcal{F}$ so that

$$\mathbf{m} = (\mathcal{H} \circ \mathcal{F})(\mathbf{\Phi}) \tag{8}$$

where $\mathbf{\Phi} = (\theta, \varphi)^{\mathrm{T}}$ defines the direction of the incoming light ray, which is mapped to the image point $\mathbf{m} = (u, v, 1)^{\mathrm{T}}$. Here $\mathcal{F}$ first projects the object point onto a virtual image plane, and then the planar projective transformation $\mathcal{H}$ maps the virtual image point to the observed image point $\mathbf{m}$. The two-step mapping $\mathcal{F}$ is illustrated in Fig. 3(a), in which the object point $\mathbf{X}$ is first projected to $\mathbf{q} = (\cos\varphi \sin\theta, \sin\varphi \sin\theta, \cos\theta)$ on the unit sphere, whose center O is the effective viewpoint of the camera. Thereafter, the point $\mathbf{q}$ is perspectively projected to $\mathbf{x}$ from another point Q so that the line determined by O and Q is perpendicular to the image plane. The distance $l = |OQ|$ is a parameter of the catadioptric camera.

Mathematically the function $\mathcal{F}$ has the form

$$\mathbf{x} = \mathcal{F}(\mathbf{\Phi}) = r(\theta)\begin{pmatrix} \cos\varphi \\ \sin\varphi \end{pmatrix} \tag{9}$$

where the function r is the radial projection that does not depend on φ because of radial symmetry. The precise form of r as a function of θ is determined by the parameter l, that is,

$$r = \frac{(l+1)\sin\theta}{l + \cos\theta} \tag{10}$$

This follows from the fact that the corresponding sides of similar triangles must have the same ratio, thus $\frac{r}{\sin\theta} = \frac{l+1}{l+\cos\theta}$, as Fig. 3(a) illustrates.

In a central catadioptric system with a hyperbolic or elliptical mirror, the camera axis does not have to be aligned with the mirror symmetry axis. The camera can be rotated with respect to the mirror as long as the camera center is at the focal point of the mirror. Hence, in the general case, the mapping $\mathcal{H}$ from the virtual image plane to the real image plane is a planar projective transformation (12). However, often the axes of the camera and mirror are close to collinear so that the mapping $\mathcal{H}$ can be approximated with an affine transformation $\mathcal{A}$ (11). That is,

$$\mathbf{m} = \mathcal{A}(\mathbf{x}) = \mathbf{K}\begin{pmatrix} \mathbf{x} \\ 1 \end{pmatrix} \tag{11}$$

where the upper triangular matrix $\mathbf{K}$ is defined in Eq. (4) and contains five parameters. (Here the affine transformation $\mathcal{A}$ has only five degrees of freedom because we may always fix the camera coordinate frame so that the x-axis is parallel to the u-axis.)

Fish-Eye Lenses. Fish-eye cameras achieve a large field of view by using only lenses, whereas the catadioptric cameras use both mirrors and lenses. Fish-eye lenses are designed to cover the whole hemispherical field in front of the camera, and the angle of view is very large, possibly over 180°. Because it is impossible to project the hemispherical field of view on a finite image plane by a perspective projection, the fish-eye lenses are designed to obey some other projection model (13).

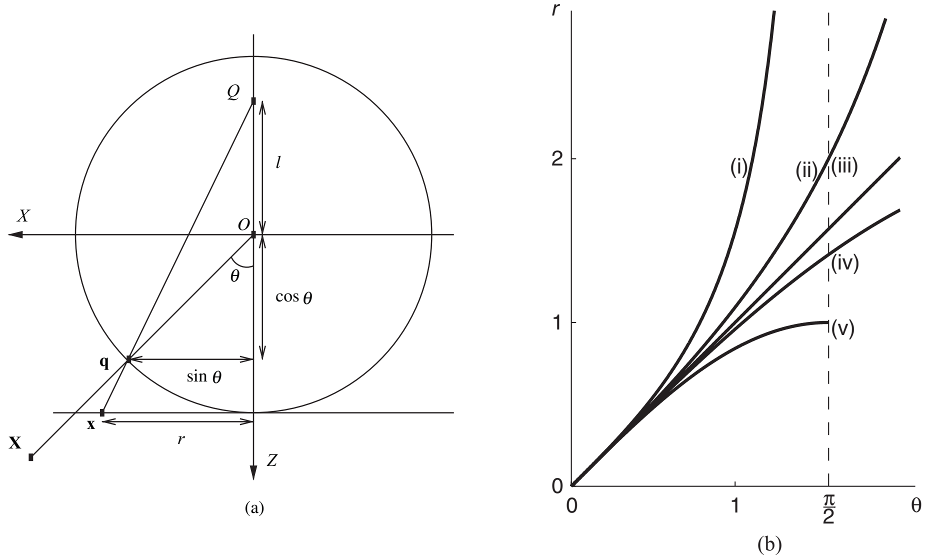

Figure 3. (a) A generic model for a central catadioptric camera (11). The Z-axis is the optical axis, and the plane $Z = 1$ is the virtual image plane. The object point $\mathbf{X}$ is first projected to $\mathbf{q}$ on the unit sphere, and thereafter $\mathbf{q}$ is perspectively projected to $\mathbf{x}$ from Q. (b) The projections of Eqs. (12)–(16).

The perspective projection of a pinhole camera can be represented by the formula

$$r = \tan\theta \qquad \text{(i. perspective projection)} \tag{12}$$

where θ is the angle between the principal axis and the incoming ray, and r is the distance between the image point and the principal point measured on a virtual image plane that is placed at a unit distance from the pinhole. Fish-eye lenses instead are usually designed to obey one of the following projections:

$$r = 2\tan(\theta/2) \qquad \text{(ii. stereographic projection)} \tag{13}$$

$$r = \theta \qquad \text{(iii. equidistance projection)} \tag{14}$$

$$r = 2\sin(\theta/2) \qquad \text{(iv. equisolid angle projection)} \tag{15}$$

$$r = \sin(\theta) \qquad \text{(v. orthogonal projection)} \tag{16}$$

where the equidistance projection is perhaps the most common model. The behavior of the different projection models is illustrated in Fig. 3(b).

Although the central catadioptric cameras and fish-eye cameras have a different physical construction, they are not too different from the viewpoint of mathematical modeling. In fact, the radial projection curves defined by Eq. (10) are similar to those shown in Fig. 3(b). In particular, when $l = 0$ Eq. (10) defines the perspective projection, $l = 1$ gives the stereographic projection (because $\tan\frac{\theta}{2} = \frac{\sin\theta}{1+\cos\theta}$), and on the limit $l \to \infty$ we obtain the orthogonal projection. Hence, the problem of modeling radially symmetric central cameras is essentially reduced to modeling radial projection functions such as those in Fig. 3(b).

Generic Model for Central Cameras. Here we describe a generic camera model, which was proposed in Ref. 2 and is suitable for central omnidirectional cameras as well as for conventional cameras. As discussed above, the radially symmetric central cameras may be represented by Eq. (10) where the function $\mathcal{F}$ is given by Eq. (9). The radial projection function r in $\mathcal{F}$ is an essential part of the model. If r is fixed to have the form of Eq. (12), then the model is reduced to the pinhole model. However, modeling of omnidirectional cameras requires a more flexible model and here we consider the model

$$r = k_1\theta + k_2\theta^3 + k_3\theta^5 + k_4\theta^7 + k_5\theta^9 + \cdots \tag{17}$$

which allows good approximation of all the projections in Fig. 3(b). In Ref. 2 it was shown that the first five terms, up to the ninth power of θ, give enough degrees of freedom for accurate approximation of different projection curves. Hence, the generic camera model used here contains five parameters in the radial projection function r.

However, real lenses may deviate from precise radial symmetry and, therefore, the radially symmetric model above was supplemented with an asymmetric part in Ref. 2. Hence, instead of Eq. (10) the camera model proposed in Ref. 2 has the form

$$\mathbf{m} = (\mathcal{A} \circ \mathcal{D} \circ \mathcal{F}) \times (\boldsymbol{\Phi}) \tag{18}$$

where $\mathcal{D}$ is the asymmetric distortion function so that $\mathcal{D} \circ \mathcal{F}$ gives the distorted image point x_d, which is then transformed to pixel coordinates by the affine transformation $\mathcal{A}$. In detail,

$$\begin{aligned}\mathbf{x}_\mathrm{d} &= (\mathcal{D} \circ \mathcal{F})(\boldsymbol{\Phi}) \\ &= r(\theta)\mathbf{u}_r(\varphi) + \Delta_\mathrm{r}(\theta, \varphi)\mathbf{u}_r(\varphi) + \Delta_\mathrm{t}(\theta, \varphi)\mathbf{u}_\varphi(\varphi)\end{aligned} \tag{19}$$

where $\mathbf{u}_r(\varphi)$ and $\mathbf{u}_\varphi(\varphi)$ are the unit vectors in the radial and tangential directions and

$$\begin{aligned}\Delta_\mathrm{r}(\theta, \varphi) = (g_1\theta + g_2\theta^3 + g_3\theta^5)(i_1\cos\varphi + i_2\sin\varphi + i_3\cos 2\varphi \\ + i_4\sin 2\varphi)\end{aligned} \tag{20}$$

$$\begin{aligned}\Delta_\mathrm{t}(\theta, \varphi) = (h_1\theta + h_2\theta^3 + h_3\theta^5)(j_1\cos\varphi + j_2\sin\varphi + j_3\cos 2\varphi \\ + j_4\sin 2\varphi)\end{aligned} \tag{21}$$

Here both the radial and tangential distortion terms contain seven parameters.

The asymmetric part in Eq. (19) models the imperfections in the optical system in a somewhat similar manner as the distortion model by Brown (4). However, instead of rigorous modeling of optical distortions, here the aim is to provide a flexible mathematical distortion model that is just fitted to agree with the observations. This approach is often practical because several possible sources of imperfections may exist in the optical system, and it is difficult to model all of them in detail.

The camera model defined above is denoted by $\mathcal{M}_{24}$ in the following because the number of parameters is 24: $\mathcal{F}$ and $\mathcal{A}$ have both 5 parameters and $\mathcal{D}$ has 14 parameters. However, often it is assumed that the pixel coordinate system is orthogonal [i.e., $s = 0$ in Eq. (4)], so that the number of parameters in $\mathcal{A}$ is only four. This model is denoted by $\mathcal{M}_{23}$. In addition, sometimes it may be useful to leave out the asymmetric part to avoid overfitting. The corresponding radially symmetric models are here denoted by $\mathcal{M}_9$ and $\mathcal{M}_6$. The model $\mathcal{M}_6$ contains only two terms in Eq. (17) whereas $\mathcal{M}_9$ contains five.

Other Distortion Models. In addition to the camera models described in the previous sections, also several other models have appeared in the literature. For example, the so-called division model for radial distortion is defined by

$$r = \frac{r_\mathrm{d}}{1 - cr_\mathrm{d}^2} \tag{22}$$

where r_d is the measured distance between the image point and the distortion center and r is the ideal undistorted distance (14, 15). A positive value of the distortion coefficient c corresponds to the typical case of barrel distortion (14). However, the division model is not suitable for cameras whose field of view exceeds 180°. Hence, other models must be used in this case and, for instance, the two-parametric projection model

$$r = \frac{a - \sqrt{a^2 - 4b\theta^2}}{2b\theta} \tag{23}$$

has been used for fish-eye lenses (16). Furthermore, a parameter-free method for determining the radial distortion was proposed in Ref. 17.

Noncentral Cameras

Most real cameras are strictly speaking noncentral. For example, in the case of parabolic mirror in Fig. 2, it is difficult to align the mirror axis and the axis of the camera precisely. Likewise, in the hyperbolic and elliptic configurations, the precise positioning of the optical center of the perspective camera in the focal point of the mirror is practically infeasible. In addition, if the shape of the mirror is not a conic section or the real cameras are not truly orthographic or perspective the configuration is noncentral. However, in practice the camera is usually negligibly small compared with the viewed region so that it is effectively point-like. Hence, the central camera models are widely used and tenable in most situations so that also here, in this article, we concentrate on central cameras.

Still, some works suggest the single viewpoint constraint is relaxed and a noncentral camera model is used. For example, a completely generic camera calibration approach was discussed in Refs. 18 and 19, in which a nonparametric camera model was used. In this model, each pixel of the camera is associated with a ray in 3-D and the task of calibration is to determine the coordinates of these rays in some local coordinate system. In addition, work has been published about designing mirrors for noncentral catadioptric systems that are compliant with predefined requirements (20).

Finally, as a generalization of central cameras, we would like to mention the axial cameras in which all the projection rays go through a single line in space (19). For example, a catadioptric camera that consists of a mirror and a central camera is an axial camera if the mirror is any surface of revolution and the camera center lies on the mirror axis of revolution. A central camera is a special case of an axial camera. The equiangular (21, 22) and equiareal (23) catadioptric cameras are other classes of axial cameras. In equiareal cameras, the projection is area preserving, whereas the equiangular mirrors are designed so that the radial distance measured from the center of symmetry in the image is linearly proportional to the angle between the incoming ray and the optical axis.

CALIBRATION METHODS

Camera calibration is the process of determining the parameters of the camera model. Here we consider conventional calibration techniques that use images of a calibration object that contains control points in known positions. The choice of a suitable calibration algorithm depends on the camera model, and below we describe methods for calibrating both perspective and omnidirectional central cameras.

Although the details of the calibration procedure may differ depending on the camera, the final step of the procedure is usually the refinement of camera parameters by nonlinear optimization regardless of the camera model. The cost function normally used in the minimization is the sum of squared distances between the measured and modeled control point projections, that is

$$\sum_{j=1}^{N}\sum_{i=1}^{N}\delta_j^i d(\mathbf{m}_j^i, \hat{\mathbf{m}}_j^i)^2 \tag{24}$$

where $\mathbf{m}_j^i$ contains the measured image coordinates of the control point i in the view j, the binary variable δ_j^i indicates whether the control point i is observed in the view j and

$$\hat{\mathbf{m}}_j^i = \mathcal{P}_j(\mathbf{X}^i) \tag{25}$$

is the projection of the control point $\mathbf{X}^i$ in the view j. Here, $\mathcal{P}_j$ denotes the camera projection in the view j and it is determined by the external and internal camera parameters. The justification for minimizing Eq. (24) is that it gives the maximum likelihood solution for the camera parameters when the image measurement errors obey a zero-mean isotropic Gaussian distribution. However, the successful minimization of Eq. (24) with standard local optimization methods requires a good initial guess for the parameters. Methods for computing such an initial guess are discussed below.

Perspective Cameras

In the case of a perspective camera, the camera projection $\mathcal{P}$ is represented by a 3×4 matrix $\mathbf{P}$ as described in the section on perspective cameras. In general, the projection matrix $\mathbf{P}$ can be determined from a single view of a noncoplanar calibration object using the Direct Linear Transform (DLT) method, which is described below. Then, given $\mathbf{P}$, the parameters $\mathbf{K}$ and $\mathbf{R}$ in Eq. (5) are obtained by decomposing the left 3×3 submatrix of $\mathbf{P}$ using the QR-decomposition whereafter also $\mathbf{t}$ can be computed (8).

On the other hand, if the calibration object is planar and the internal parameters in $\mathbf{K}$ are all unknown, several views are needed. In this case, the constant camera calibration matrix $\mathbf{K}$ can be determined first using the approach described below in the section on planar calibration object. Thereafter, the view dependent parameters $\mathbf{R}_j$ and $\mathbf{t}_j$ can be computed and used for initializing the nonlinear optimization. If the perspective camera model is accompanied with a lens distortion model, then the distortion parameters in Eq. (7) may be initialized by setting them to zero (24).

Noncoplanar Calibration Object. Assuming that the known space points $\mathbf{X}^i$ are projected at the image points $\mathbf{m}^i$, the unknown projection matrix $\mathbf{P}$ can be estimated using the DLT method (8, 25, 26). The projection equation gives

$$\mathbf{m}^i \simeq \mathbf{P}\mathbf{X}^i \tag{26}$$

which can be written in the equivalent form

$$\mathbf{m}^i \times \mathbf{P}\mathbf{X}^i = 0 \tag{27}$$

where the unknown scale in Eq. (26) is eliminated by the cross product. The equations above are linear in the elements of $\mathbf{P}$ so they can be written in the form

$$\mathbf{A}^i\mathbf{v} = 0 \tag{28}$$

where

$$\mathbf{v} = (P_{11}\,P_{12}\,P_{13}\,P_{14}\,P_{21}\,P_{22}\,P_{23}\,P_{24}\,P_{31}\,P_{32}\,P_{33}\,P_{34})^{\mathrm{T}} \tag{29}$$

and

$$\mathbf{A}^i = \begin{bmatrix} 0^{\mathrm{T}} & -m_3^i\mathbf{X}^{i^{\mathrm{T}}} & m_2^i\mathbf{X}^{i^{\mathrm{T}}} \\ m_3^i\mathbf{X}^{i^{\mathrm{T}}} & 0^{\mathrm{T}} & -m_1^i\mathbf{X}^{i^{\mathrm{T}}} \\ -m_2^i\mathbf{X}^{i^{\mathrm{T}}} & m_1^i\mathbf{X}^{i^{\mathrm{T}}} & 0^{\mathrm{T}} \end{bmatrix} \tag{30}$$

Thus, each point correspondence provides three equations, but only two of them are linearly independent. Hence, given $M \geq 6$ point correspondences, we get an overdetermined set of equations $\mathbf{A}\mathbf{v} = 0$, where the matrix $\mathbf{A}$ is obtained by stacking the matrices $\mathbf{A}^i, i = 1, \cdots, M$. In practice, because of the measurement errors no exact solution to these equations exist, but the solution $\mathbf{v}$ that minimizes $||\mathbf{A}\mathbf{v}||$ can be computed using the singular value decomposition of $\mathbf{A}$ (8). However, if the points $\mathbf{X}^i$ are coplanar, then ambiguous solutions exist for $\mathbf{v}$, and hence the DLT method is not applicable in such case.

The DLT method for solving $\mathbf{P}$ is a linear method that minimizes the algebraic error $||\mathbf{A}\mathbf{v}||$ instead of the geometric error in Eq. (24). This method implies that, in the presence of noise, the estimation result depends on the coordinate frames in which the points are expressed. In practice, it has been observed that a good idea is to normalize the coordinates in both $\mathbf{m}^i$ and $\mathbf{X}^i$ so that they have zero mean and unit variance. This kind of normalization may significantly improve the estimation result in the presence of noise (8).

Planar Calibration Object. In the case of a planar calibration object, the camera calibration matrix $\mathbf{K}$ can be solved by using several views. This approach was described in Refs. 24 and 27, and it is briefly summarized in the following.

The mapping between a scene plane and its perspective image is a planar homography. Because one may assume that the calibration plane is the plane $Z = 0$, the homography is defined by

$$\mathbf{m} \simeq \mathbf{K}\begin{bmatrix}\mathbf{R} & \mathbf{t}\end{bmatrix}\begin{pmatrix}X\\Y\\0\\1\end{pmatrix} = \mathbf{H}\begin{pmatrix}X\\Y\\1\end{pmatrix} \tag{31}$$

where the 3×3 homography matrix

$$\mathbf{H} = \mathbf{K}[\,\mathbf{r}^1 \quad \mathbf{r}^2 \quad \mathbf{t}\,] \tag{32}$$

where the columns of the rotation matrix $\mathbf{R}$ are denoted by $\mathbf{r}^i$. The outline of the calibration method is to first determine the homographies for each view and then use Eq. (32) to derive constraints for the determination of $\mathbf{K}$. The constraints for $\mathbf{K}$ are described in more detail below. Methods for determining a homography from point correspondences are described, for example, in Ref. 8.

Denoting the columns of $\mathbf{H}$ by $\mathbf{h}^i$ and using the fact that $\mathbf{r}^1$ and $\mathbf{r}^2$ are orthonormal one obtains from Eq. (32) that

$$\mathbf{h}^{1^{\mathrm{T}}}\mathbf{K}^{-\mathrm{T}}\mathbf{K}^{-1}\mathbf{h}^2 = 0 \tag{33}$$

$$\mathbf{h}^{1^{\mathrm{T}}}\mathbf{K}^{-\mathrm{T}}\mathbf{K}^{-1}\mathbf{h}^1 = \mathbf{h}^{2^{\mathrm{T}}}\mathbf{K}^{-\mathrm{T}}\mathbf{K}^{-1}\mathbf{h}^2 \tag{34}$$

Thus, each homography provides two constraints that may be written as linear equations on the elements of the homogeneous symmetric matrix $\boldsymbol{\omega} = \mathbf{K}^{-\mathrm{T}}\mathbf{K}^{-1}$. Hence, the system of equations, derived from Eqs. (33) and (34) above, is of the form $\mathbf{Av} = 0$, where the vector of unknowns $\mathbf{v} = (\omega_{11}, \omega_{12}, \omega_{13}, \omega_{22}, \omega_{23}, \omega_{33})^{\mathrm{T}}$ consists of the elements of $\boldsymbol{\omega}$. Matrix $\mathbf{A}$ has $2N$ rows, where N is the number of views. Given three or more views, the solution vector $\mathbf{v}$ is the right singular vector of $\mathbf{A}$ that corresponds to the smallest singular value. When $\boldsymbol{\omega}$ is solved (up to scale), one may compute the upper triangular matrix $\mathbf{K}$ by Cholesky-factorization. Thereafter, given $\mathbf{H}$ and $\mathbf{K}$, the external camera parameters can be retrieved from Eq. (32). Finally, the obtained estimates should be refined by minimizing the error of Eq. (24) in all views.

Omnidirectional Cameras

In this section, we describe a method that uses a planar calibration pattern to calibrate the parameters of the camera model introduced in the section entitled "Generic Model for Central Cameras" (2). Planar calibration patterns are very common because they are easy to create. In fact, often also the noncoplanar calibration objects contain planar patterns because they usually consist of two or three different planes.

The calibration procedure consists of four steps that are described below. We assume that M control points are observed in N views so that, for each view j, a rotation matrix $\mathbf{R}_j$ and a translation vector $\mathbf{t}_j$ exist, which describe the orientation and position of the camera with respect to the calibration object. In addition, we assume that the object coordinate frame is chosen so that the plane $Z = 0$ contains the calibration pattern and the coordinates of the control point i are denoted by $\mathbf{X}^i = (X^i, Y^i, 0)^{\mathrm{T}}$. The corresponding homogeneous coordinates in the calibration plane are denoted by $\mathbf{x}_{\mathrm{p}}^i = (X^i, Y^i, 1)^{\mathrm{T}}$ and the observed image coordinates in the view j are $\mathbf{m}_{\mathrm{j}}^{\mathrm{i}} = (u_j^i, v_j^i, 1)^{\mathrm{T}}$.

Step 1: Initialization of internal parameters.
In the first three steps of the calibration procedure, we use the camera model $\mathcal{M}_6$, which contains only six nonzero internal parameters [i.e., the parameters $(k_1, k_2, f, \gamma, u_0, v_0)$]. These parameters are initialized using a priori knowledge about the camera. For example, the principal point (u_0, v_0) is usually located close to the image center, γ has a value close to 1, and f is the focal length in pixels. The initial values for k_1 and k_2 can be obtained by fitting the model $r = k_1\theta + k_2\theta^3$ to the desired projection curve in Fig. 3(b).

Step 2: Back-projection and computation of homographies.
Given the internal parameters, we may back-project the observed points $\mathbf{m}_j^i$ onto the unit sphere centered at the camera origin. For each $\mathbf{m}_j^i$ the back-projection gives the direction $\boldsymbol{\Phi}_j^i = (\theta_j^i, \varphi_j^i)^{\mathrm{T}}$ and the points on the unit sphere are defined by $\mathbf{q}_j^i = (\sin\varphi_j^i \sin\theta_j^i,\ \cos\varphi_j^i \sin\theta_j^i,\ \cos\theta_j^i)^{\mathrm{T}}$. Because the mapping between the points on the calibration plane and on the unit sphere is a central projection, a planar homography $\mathbf{H}_j$ exists so that $\mathbf{q}_j^i \simeq \mathbf{H}_j\mathbf{x}_{\mathrm{p}}^{\mathrm{i}}$. For each view j, the homography $\mathbf{H}_j$ is estimated from the correspondences $(\mathbf{q}_j^i, \mathbf{x}_{\mathrm{p}}^{\mathrm{i}})$. In detail, the initial estimate for $\mathbf{H}_j$ is computed by the linear algorithm (8), and it is then refined by minimizing $\sum_i \sin^2\alpha_j^i$,, where α_j^i is the angle between the unit vectors $\mathbf{q}_j^i$ and $\mathbf{H}_j\mathbf{x}_{\mathrm{p}}^{\mathrm{i}}/||\mathbf{H}_j\mathbf{x}_{\mathrm{p}}^{\mathrm{i}}||$.

Step 3: Initialization of external parameters.
The initial values for the external camera parameters are extracted from the homographies $\mathbf{H}_j$. It holds that

$$\mathbf{q}_j^i \simeq \begin{bmatrix}\mathbf{R}_j & \mathbf{t}_j\end{bmatrix}\begin{pmatrix}X^i\\Y^i\\0\\1\end{pmatrix} = [\,\mathbf{r}_j^1 \quad \mathbf{r}_j^2 \quad \mathbf{t}_j\,]\begin{pmatrix}X^i\\Y^i\\1\end{pmatrix}$$

which implies $\mathbf{H}_j \simeq [\mathbf{r}_j^1\,\mathbf{r}_j^2\,\mathbf{t}_j]$. Hence,

$$\mathbf{r}_j^1 = \lambda_j\mathbf{h}_j^1, \quad \mathbf{r}_j^2 = \lambda_j\mathbf{h}_j^2, \quad \mathbf{r}_j^3 = \mathbf{r}_j^1 \times \mathbf{r}_j^2, \quad \mathbf{t}_j = \lambda_j\mathbf{h}_j^3$$

where $\lambda_j = \pm \,||\, \mathbf{h}_j^1 \,||^{-1}$. The sign of λ_j can be determined by requiring that the camera is always on the front side of the calibration plane. However, the obtained rotation matrices may not be orthogonal because of estimation errors. Hence, the singular value decomposition is used to compute the closest orthogonal matrices in the sense of Frobenius norm, which are then used for initializing each $\mathbf{R}_j$.

Step 4: Minimization of projection error.

If a camera model with more than six parameters is used, then the additional camera parameters are initialized to zero at this stage. As we have the estimates for the internal and external camera parameters, we may compute the imaging function $\mathcal{P}_j$ for each camera, in which a control point is projected to $\hat{\mathbf{m}}^i_j = \mathcal{P}_j(\mathbf{X}^i)$. Finally, all the camera parameters are refined by minimizing Eq. (24) using nonlinear optimization, such as the Levenberg-Marquardt algorithm.

Precise Calibration with Circular Control Points

To achieve an accurate calibration, we have used a calibration plane with circular control points because the centroids of the projected circles can be detected with a sub-pixel level of accuracy (28). However, in this case the problem is that the centroid of the *projected* circle is not the image of the center of the original circle. Therefore, because $\mathbf{m}^i_j$ in Eq. (24) is the measured centroid, we should not project the centers as points $\hat{\mathbf{m}}^i_j$ because it may introduce bias in the estimates. Of course, it is not an issue if the control points are really pointlike, such as the corners of a checkerboard pattern.

In the case of a perspective camera, the centroids of the projected circles can be solved analytically given the camera parameters and the circles on the calibration plane (1). However, in the case of more generic camera models, the projection is more complicated and the centroids of the projected circles must be solved numerically (2).

CALIBRATION EXAMPLES

In this section, we illustrate camera calibration with real examples involving different kinds of cameras.

Conventional Cameras with Moderate Lens Distortion

The first calibrated camera was a Canon S1 IS digital camera with a zoom lens whose focal length range is 5.8–58.0 mm, which corresponds to a range of 38–380 mm in the 35-mm film format. The calibration was performed with the zoom fixed to 11.2 mm. Hence, the diagonal field of view was about 30°, which is a relatively narrow angle. The other camera was a Sony DFW-X710 digital video camera equipped with a Cosmicar H416 wide-angle lens. The focal length of this wide-angle lens is 4.2 mm, and it produces a diagonal field of view of about 80°.

Both cameras were calibrated by using a planar calibration pattern that contains white circles on black background. The pattern was displayed on a digital plasma display (Samsung PPM50M6HS) whose size is 1204 × 724 mm^2. A digital flat-screen display provides a reasonably planar object and because of its self-illuminating property, it is easy to avoid specular reflections that might otherwise hamper the accurate localization of the control points. Some examples of the calibration images are shown in Fig. 4. The image in Fig. 4(a) was taken with the narrow-angle lens and the image in Fig. 4(b) with the wide-angle lens. The resolution of the images is 2048 × 1536 pixels and 1024 × 768 pixels, respectively. The lens distortion is clearly visible in the wide-angle image.

The number of calibration images was six for both cameras, and each image contained 220 control points. The images were chosen so that the whole image area was covered by the control points. In addition to the set of calibration images we took another set of images that likewise contained six images in which the control points were distributed onto the whole image area. These images were used as a test set to validate the results of calibration. In all cases, the control points were localized from the images by computing their grayscale centroids (28).

The cameras were calibrated using four different camera models. The first model, denoted by $\mathcal{M}_\mathrm{p}$, was the skew-zero pinhole model accompanied with four distortion parameters. This model was used in Ref. 1, and it is described in the section on lens distortion. The other three models were the models $\mathcal{M}_6$, $\mathcal{M}_9$, and $\mathcal{M}_{23}$ defined in the section entitled "Generic Model for Central Cameras." All calibrations were performed by minimizing the sum of squared projection errors as described in the section on calibration methods. The computations were carried out by using the publicly available implementations of the calibration procedures proposed in Refs. 1 and 2.[1]

The calibration results are shown in Table 1 in which the first four rows give the figures for the narrow-angle and wide-angle lenses introduced above. The first and third row in Table 1 contain the RMS calibration errors, that is, the root-mean-squared distances between the measured and modeled control point projections in the calibration images. The second and fourth row show the RMS projection errors in the test images. In the test case, the values of the internal camera parameters were those estimated from the calibration images, and only the external camera parameters were optimized by minimizing the sum of the squared projection errors.

The results illustrate that the most flexible model $\mathcal{M}_{23}$ generally performs the best. However, the difference between the models $\mathcal{M}_6$, $\mathcal{M}_9$, and $\mathcal{M}_{23}$ is not large for the narrow-angle and wide-angle lens. The model $\mathcal{M}_\mathrm{p}$ performs well with the narrow-angle lens, but it seems that the other models are better in modeling the severe radial distortion of the wide-angle lens. The relatively low values of the test set error indicate that the risk of overfitting is small. This risk could be decreased even more by using more calibration images. The RMS error is somewhat larger for the narrow-angle lens than for the wide-angle lens, but it may be caused by the fact that the image resolution is higher in the narrow-angle case. Hence, the pixel units are not directly comparable for the different cameras.

(c) (d)

Figure 4. Images of the calibration pattern taken with different types of cameras, a) narrow-angle lens, b) wide-angle lens, c) fish-eye lens, d) hyperbolic mirror combined with a narrow-angle lens.

Omnidirectional Cameras

We calibrated a fish-eye lens camera and two different catadioptric cameras. The fish-eye lens that was used in the experiments is the ORIFL190-3 lens manufactured by Omnitech Robotics (Englewood, CA). This lens has a 190° field of view, and it was attached to a PointGrey Dragonfly (PointGrey, Vancouver, BC, Canada) color video camera, which has a resolution of 1024 × 768 pixels. The catadioptric cameras were constructed by placing two different mirrors in front of the Canon S1 IS camera (Canon, Tokyo, Japan), which has a resolution of 2048 × 1536 pixels. The first mirror was a hyperbolic mirror from Eizoh (Tokyo, Japan) and the other mirror was an equiangular mirror from Kaidan (Feasterville, PA). The field of view provided by the hyperbolic mirror is such that when the mirror is placed above the camera so that the optical axis is vertical, the camera observes about 30° above and 50° below the horizon (the region directly below the mirror is obscured by the camera). The equiangular mirror by Kaidan provides a slightly larger view of field because it observes about 50° above and below the horizon. In the azimuthal direction the viewing angle is 360° for both mirrors.

Table 1. The RMS projection errors in pixels

	$\mathcal{M}_p$	$\mathcal{M}_6$	$\mathcal{M}_9$	$\mathcal{M}_{23}$
narrow-angle lens	0.293	0.339	0.325	0.280
test set error	0.249	0.309	0.259	0.236
wide-angle lens	0.908	0.078	0.077	0.067
test set error	0.823	0.089	0.088	0.088
fish-eye lens	-	0.359	0.233	0.206
test set error	-	0.437	0.168	0.187
hyperbolic mirror	-	4.178	1.225	0.432
test set error	-	3.708	1.094	0.392
equiangular mirror	-	2.716	0.992	0.788
test set error	-	3.129	1.065	0.984

Because the field of view of all three omnidirectional cameras exceeds a hemisphere, the calibration was not performed with the model $\mathcal{M}_p$, which is based on the perspective projection model. Hence, we only report the results obtained with the central camera models $\mathcal{M}_6$, $\mathcal{M}_9$, and $\mathcal{M}_{23}$. The calibration experiments were conducted in a similar way as for the conventional cameras above, and the same calibration object was used. However, here the number of images was 12 both in the calibration set and the test set. The number of images was increased to have a better coverage for the wider field of view.

The results are illustrated in Table 1, where it can be observed that the model $\mathcal{M}_{23}$ again shows best performance. The radially symmetric model $\mathcal{M}_9$ performs almost equally well with the fish-eye camera and the equiangular camera. However, for the hyperbolic camera, the additional degrees of freedom in $\mathcal{M}_{23}$ clearly improve the calibration accuracy. This improvement might be an indication that the optical axis of the camera is not aligned precisely with the mirror axis. Nevertheless, the asymmetric central camera model $\mathcal{M}_{23}$ provides a good approximation for this catadioptric camera. Likewise, here the central model seems to be tenable also for the equiangular catadioptric camera, which is strictly speaking noncentral. Note that the sensor resolution of the fish-eye camera was different than that of the catadioptric cameras.

CONCLUSION

Geometric camera calibration is a prerequisite for image-based, accurate 3-D measurements, and it is therefore a fundamental task in computer vision and photogrammetry. In this article, we presented a review of calibration techniques and camera models that commonly occur in applications. We concentrated on the traditional calibration approach in which the camera parameters are estimated by using a calibration object whose geometry is known. The emphasis was on central camera models, which are the most common in applications and provide a reasonable approximation for a wide range of cameras. The process of camera calibration was additionally demonstrated with practical examples in which several different kinds of real cameras were calibrated.

Camera calibration is a wide-ranging topic and much research exists that was not possible to be covered here. For example, recently research efforts have focused toward completely generic camera calibration techniques that could be used for all kinds of cameras, including the noncentral ones. In addition, camera self-calibration is an active research area that was not discussed in the scope of this article. However, camera calibration using a calibration object and a parametric camera model, as discussed here, is the most viable approach when a high level of accuracy is required.

LEVEL SET METHODS

The shape of a real-world object can be represented by a parametric or a nonparametric contour in the image plane. The parametric contour representation is referred to as an explicit representation and is defined in the Lagrangian coordinate system. In this coordinate system, two different objects have two different representations stemming from the different sets of control points that define the object contours. The control points constitute the finite elements, which is a common formalism used to represent shapes in the Lagrangian coordinates. In contrast to the parametric Lagrangian representation, the nonparametric representation defines the object contour implicitly in the Eulerian coordinates, which remains constant for two different objects. The level set method is a nonparametric representation defined in the Eulerian coordinate system and is used commonly in the computer vision community to represent the shape of an object in an image.

The level set method has been introduced in the field of fluid dynamics by the seminal work of Osher and Sethian in 1988 (1). After its introduction, it has been applied successfully in the fields of fluid mechanics, computational physics, computer graphics, and computer vision. In the level set representation, the value of each grid point (pixel) is set traditionally to the Euclidean distance between the grid point and the contour. Hence, moving the contour from one configuration to the other is achieved by changing the distance values in the grid points. During its motion, the contour can change implicitly its topology by splitting into two disjoint contours or by merging from two contours to one.

The implicit nature of the representation becomes essential to handle the topology changes for the case when an initial configuration is required to solve a time-dependent problem. Upon initialization, the level set converges to a solution by re-evaluating the values at the grid points iteratively. This iterative procedure is referred to as the "contour evolution."

CONTOUR EVOLUTION

Without loss of generality, I will discuss the level set formalism in the two-dimensional image coordinates (x, y), which can be extended to higher dimensions without complicating the formulation. Let there be a closed contour Γ defined in the image coordinates as shown in Fig. 1(a). The contour can be visualized as the boundary of an object in an image. To represent the evolution of the contour, the level set formalism introduces two additional dimensions that define the surface in z and the time t: $[0,T)$:

$$z = \Phi(x, y, t)$$

The surface dimension, $z \in R$, encodes the signed Euclidean distance from the contour. More specifically, the value of z inside the closed contour has a negative sign, and outside the contour has a positive sign [see Fig. 1(b)]. At any given time instant t, the cross section of the surface at $z = 0$ corresponds to the contour, which is also referred to as the zero-level set.

The time dimension t is introduced as an artificial dimension to account for the iterative approach to finding the steady state of an initial configuration. In computer vision, the initial configuration of the level set surface relates to an initial hypothesis of the object boundary, which is evolved iteratively to the correct object boundary. The iterations are governed by a velocity field, which specifies how the contour moves in time. In general, the velocity field is defined by the domain-related physics. For instance, in fluid mechanics, the velocity of the contour is defined by the physical characteristics of the fluid and the environment in which it will dissolve; whereas in computer vision, the velocity is defined by the appearance of the objects in the image.

At each iteration, the equations that govern the contour evolution are derived from the zero-level set at time t: $\Phi(\mathbf{x}(t), t) = 0$, where $\mathbf{x} = (x, y)$. Because the moving contour is always at the zero level, the rate of contour motion in time is given by:

$$\frac{\partial \Phi(x(t), t)}{\partial t} = 0 \tag{1}$$

By applying the chain rule, Equation (1) becomes $\Phi_t + \Delta\Phi(\mathbf{x}(t), t)\mathbf{x}'(t) = 0$. In Fig. 2, a contouris present that evolves using the curvature flow, which moves rapidly in the areas where the curvature is high.

An important aspect of the level set method is its ability to compute the geometric properties of the contour Γ from the level set grid by implicit differentiation. For instance, the contour normal is computed by $\vec{n} = -\frac{\Delta\Phi}{|\Delta\Phi|}$. Hence, dividing both sides by $|\Delta\Phi|$ and replacing $\mathbf{x}(t)\vec{n}$ by F results in the well-known level set evolution equation:

$$\Phi_t + |\Delta\Phi| F = 0 \tag{2}$$

which evolves the contour in the normal direction with speed F. The sign of F defines whether the contour will move inward or outward. Particularly, a negative F value shrinks the contour and a positive F value expands the contour. In computer vision, F is computed at each grid point based on its appearance and the priors defined from the inside and the outside of the contour. As Equation (2) includes only first-order derivatives, it can be written as a Hamilton–Jacobi equation $\Phi_t + H(\phi(x), \phi(y)) = 0$, where $H(\phi(x), \phi(y)) = |\Delta\Phi| F$. Based on this observation, the numerical approximations of the implicit derivatives can be computed by using the forward Euler time-discretization (see Ref. 2 for more details).

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

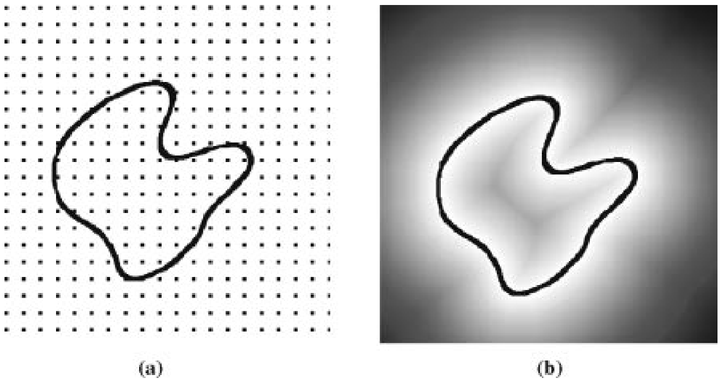

Figure 1. (a) The contour is denned in the spatial image coordinates, *(x,y)*. Each black dot represents a grid point on the plane, (b) The level set function denning the contour given in (a). The blue-colored grid points denote positive values, and the red-colored grid points denote negative values. The distance of a grid point from the contour is expressed by the variation in the color value from light to dark.

REINITIALIZATION OF THE LEVEL SET FUNCTION

To eliminate numeric instabilities during the contour evaluation, it is necessary to reinitialize the level set function at each evolution iteration. This requirement, however, is a major limitation of the level set framework when fast convergence is required, such as in video-based surveillance. An intuitive approach to reinitialize the level set grid is to follow a two-step approach. The first step is to recover the contour by detecting the zero crossings. The second step is to regenerate the level set surface to preserve the geometric properties of the new contour. In computer vision, the second step is to apply the Euclidean distance transform to find the distance of each grid point from the recovered contour.

Application of the distance transform to update the level set is a time-consuming operation, especially considering that it needs to be done at every iteration. One way to reduce the complexity of the level set update is to apply the "narrow band" approach (3). The narrow band approach performs reinitialization only in a neighborhood denned by a band. This band also defines the limits in which the distance transform is applied. The procedure involves recovering the contour, positioning the band-limits from the extracted contour, reinitializing the values residing in the band, and updating the level set bounded by the band. The narrow band approach still must recover the contour and reinitializate the level set function before a solution is reached; hence, the error during the evolution may accumulate from one iteration to the next.

An alternate approach to level set reinitialization is to use an additional partial differential equation (PDE) evaluated on the level set function. In this approach, after the PDE, which operates on the level set, moves the contour, a second PDE re-evaluates the grid values while preserving the zero crossings and geometric properties of the contour (4). The level set reinitialization PDE is given by:

$$\phi_t = \text{sign}(\phi_0)(1 - |\Delta\phi|)$$

where the sign function defines the update of all the levels except for the zero-level. An example sign function is

$$\text{sign}_{\varepsilon}(\phi_0) = \frac{\phi_0}{\sqrt{\phi_0^2 + \varepsilon^2}}$$

FAST MARCHING LEVEL SET

Constraining the contour to to either shrink or to expand eliminates the limitations posed by the level set reinitialization. In this case, the sign of *F* in Equation (2) is constant. Practically, the constant sign guarantees a single visit to each level set grid point. This property results in a very useful formulation referred to as the "fast marching level set."

Compared with the aforementioned approaches, the fast marching method moves the contour one pixel at a time. Hence the distance traveled by the contour becomes constant, $d = 1$. The traveled distance also is attributed to the speed of the contour, $F(x, y)$, as well as the time it takes to travel it, $T(x, y)$. Constrained by these observations, the

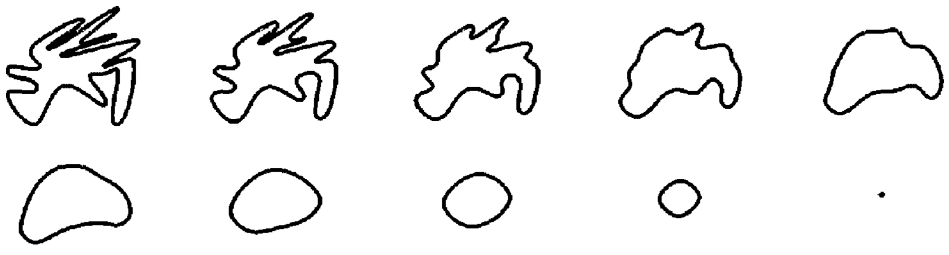

Figure 2. A contour moving with the curvature flow in the level set framework. Note the fast evolution in the regions where the contour bends more than the other regions.

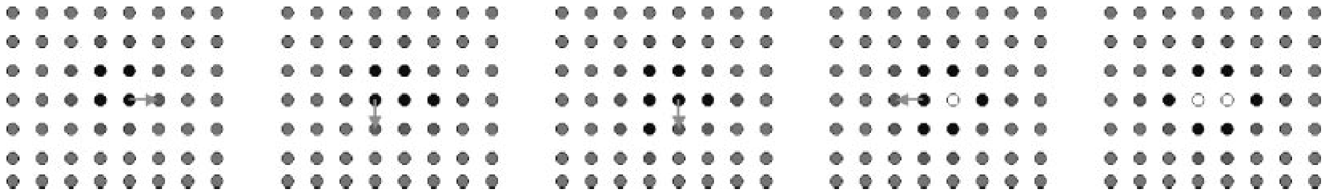

Figure 3. The fast marching level set iterations. The black nodes denote the active contour pixels, the red nodes denote the alive level set grid points, the blue nodes are the nodes that are not considered during the iteration (faraway), and the white nodes denote already visited nodes.

level set becomes a stationary formulation given by $1 = F|\Delta T|$, such that at time t the contour is denned by $\{\Gamma | T(x,y) = t\}$. Based on the stationary formation, the time required to move the contour is computed by $T(x,y) = \frac{1}{F(x,y)}$.

Comparatively, the implementation of the fast matching method is easier than its alternatives. Given an initial contour, the pixels on the contour are labeled as *active*, the pixels within the reach of the contour in the next iteration are labeled as *alive* (pixels with distance of ≤ 1), and the pixels that the contour cannot reach are labeled as *faraway*. The iterations start by computing the time required $T(x, y)$ to travel to each alive pixel. From among alive pixels, the pixel with the lowest arrival time changes its status to active (new contour position). This change introduces new set of alive points. This process is iteratively performed until $F = 0$ for all live pixels. See Fig. 3 for a visualization of this iterative process.

AN EXAMPLE: OBJECT SEGMENTATION

The level set method has become a very successful tool to solve problems ranging from noise removal, image segmentation, registration, object tracking, and stereo. A common property in all these domains is to formulate the problem by a partial differential equation that is solved using the level set formalism.

In the context of level sets, the cost or gain function is required to be in the form of a Hamilton–Jacobi equation, $\phi_t + H(\phi_x, \phi_y) = 0$ that allows only the first-order differentiation of (ϕ). Hence, given a task, the first goal is to come up with a cost function that can be converted to a Hamiltonian $H(\phi_x, \phi_y)$. Let us consider the object segmentation problem as an example. In the following discussion, a region-based object segmentation approach will be considered that is formulated in terms of the appearance similarity inside and outside of the contour (see Fig. 4). Practically, the appearance of the object inside and outside the contour should be different, hence, to minimize this similarity would result in the segmentation of the object. Let us assume the contour is initialized outside the object (inside initialization is also possible), such that the appearance of the region outside the contour serves as a prior. Using this prior, the likelihood of object boundary can be denned in terms of the probability of inside pixels given the outside prior: $p(I(R_{\text{inside}})|R_{\text{outside}})$. Maximizing the gain function formulated using this likelihood measure segments the object as follows:

$$E(\Gamma) = -\int_{x \in R_{\text{inside}}} \log p(I(\mathbf{x}))|R_{\text{outside}})d\mathbf{x} \qquad (3)$$

Equation (3), however, is not in the form of a Hamiltonian. Application of Green's theorem converts this gain function

to a Hamiltonian and results in the level set propagation speed given by $F(x,y) = -\log p(I(x,y)|R_{\text{outside}})$ (see Ref. (5), Chapter 5] for application of Green's theorem). In Fig. 5, several segmentation results are shown for different domains.

DISCUSSION

Because of its robustness, its efficiency, and its applicability to a wide range of problems, the level set method has become very popular among many researchers in different fields. The Hamilton–Jacobi formulation of the level set can be extended easily to higher dimensions. It can model any topology including sharp corners, and can handle the changes to that topology during its evolution. The level set method has overcome the contour initialization problems associated with the classic active contour approach to segment images, such that the initial contour can include part of the object and part of the background simultaneously (see Fig. 5 for possible contour initialization). These properties, however, come at the price of requiring careful thinking to formulate the problem to be solved using the level set framework. Especially, converting a computer vision problem to a PDE may require considerable attention.

On the down side, because of the reinitialization of the level set after each iteration, the level set method becomes a computationally expensive minimization technique. The narrow band approach is proposed to overcome this limitation by bounding the region for reinitialization to a band around the contour. Despite reduced complexity, the narrow band method remains unsuitable for tasks that require realtime processing, such as object tracking in a surveillance scenario. The other possible solution to the complexity problem is the fast marching approach, which works in real time when implemented carefully. However, the fast marching method evolves the contour only in one direction. Hence, the initial position of the contour becomes very important. For instance, the contour has to be either outside or inside the object of interest, and the initializations that involve both inside and outside of the object may not converge.

MEDICAL IMAGE PROCESSING

INTRODUCTION

The discovery of *x rays* in 1895 by Professor Wilhelm Conrad Röntgen led to a transformation of medicine and science. In medicine, x rays provided a noninvasive way to visualize the internal parts of the body. A beam of radiation passing through the body is absorbed and scattered by tissue and bone structures in the path of the beam to varying extents depending on their composition and the energy level of the beam. The resulting absorption and scatter patterns are captured by a film that is exposed during imaging to produce an image of the tissues and bone structures. By using varying amounts of energy levels of different sources of radiant energy, radiographic images can be produced for different tissues, organs and bone structures.

The simple planar x-ray imaging, the main radiologic imaging method used for most of the last century, produced high-quality analog two-dimensional (2-D) projected images of three-dimensional (3-D) organs. Over the last few decades, increasingly sophisticated methods of diagnosis have been made possible by using different types of radiant energy, including X rays, gamma rays, radio waves, and ultrasound waves. The introduction of the first *x-ray computed tomography* (x-ray CT) scanner in the early 1970s totally changed the medical imaging landscape. The CT scanner uses instrumentation and computer technology for image reconstruction to produce images of cross sections of the human body. With the clinical experience accumulated over the years and the establishment of its usefulness, the CT scanner became very popular.

The exceptional multidimensional digital images of internal anatomy produced by medical imaging technology can be processed and manipulated using a computer to visualize subtle or hidden features that are not easily visible. *Medical image analysis and processing* algorithms for enhancing the features of interest for easy analysis and quantification are rapidly expanding the role of medical imaging beyond noninvasive examination to a tool for aiding surgical planning and intraoperative navigation. Extracting information about the shape details of anatomical structures, for example, enables careful preoperative planning of surgical procedures.

In medical image analysis, the goal is to accurately and efficiently extract information from medical images to support a range of medical investigations and clinical activities from diagnosis to surgery. The extraction of information about anatomical structures from medical images is fairly complex. This information has led to many algorithms that have been specifically proposed for biomedical applications, such as the quantification of tissue volumes (1), diagnosis (2), localization of pathology (3), study of anatomical structures (4), treatment planning (5), partial volume correction of functional imaging data (6), and computer-integrated surgery (7,8).

Technological advances in medical imaging modalities have provided doctors with significant capabilities for accurate noninvasive examination. In modern medical imaging systems, the ability to effectively process and analyze medical images to accurately extract, quantify, and interpret information to achieve an understanding of the internal structures being imaged is critical in order to support a spectrum of medical activities from diagnosis, to radiotherapy, to surgery. Advances in computer technology and microelectronics have made available significant computational power in small desktop computers. This capability has spurred the development of software-based biomedical image analysis methods such as *image enhancement and restoration, segmentation of internal structures and features of interest, image classification,* and *quantification.*

In the next section, different medical imaging modalities are discussed before the most common methods for medical image processing and analysis are presented. An exhaustive survey of such methods can be found in Refs. 9 and 10.

ACQUISITION OF MEDICAL IMAGES

A biomedical image analysis system comprises three major elements: an image acquisition system, a computer for processing the acquired information, and a display system for visualizing the processed images. In medical image acquisition, the primary objective is to capture and record information about the physical and possibly functional properties of organs or tissues by using either external or internal energy sources or a combination of these energy sources.

Conventional Radiography

In *conventional radiography,* a beam of x rays from an external source passing through the body is differentially absorbed and scattered by structures. The amount of absorption depends on the composition of these structures and on the energy of the x ray beam. Conventional imaging methods, which are still the most commonly used diagnostic imaging procedure, form a projection image on standard radiographic film. With the advent of digital imaging technology, radiographs, which are x-ray projections, are increasingly being viewed, stored, transported, and manipulated digitally. Figure 1 shows a normal chest x-ray image.

Computed Tomography

The realization that x-ray images taken at different angles contain sufficient information for uniquely determining the internal structures, led to the development of x-ray CT scanners in the 1970s that essentially reconstruct accurate cross-sectional images from x-ray radiographs. The

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

(b) CT image of brain

Figure 2. CT images of normal liver and brain.

conventional x-ray CT consists of a rotating frame that has an x-ray source at one end and an array of detectors that accurately measure the total attenuation along the path of the x ray at the other end. A fan beam of x rays is created as the rotating frame spins the x-ray tube and detectors around the patient. During the 360° rotation, the detector captures numerous snapshots of the attenuated x-ray beam corresponding to a single slice of tissue whose thickness is determined by the collimation of the x-ray beam. This information is then processed by a computer to generate a 2-D image of the slice. Multiple slices are obtained by moving the patient in incremental steps. In the more recent spiral CT (also known as the helical CT), projection acquisition is carried out in a spiral trajectory as the patient continuously moves through the scanner. This process results in faster scans and higher definition of internal structures, which enables greater visualization of blood vessels and internal tissues. CT images of a normal liver and brain are shown in Fig. 2. In comparison with conventional x-ray imaging, CT imaging is a major breakthrough. It can image the structures with subtle differences in x-ray absorption capacity even when almost obscured by a structure with a strong ability on x-radiation absorption. For example, the CT can image the internal structures of the brain, which is enclosed by the skull [as shown in Fig. 2(b)], whereas the x ray fails to do so.

Magnetic Resonance Imaging

Medical imaging methods using magnetic resonance include MRI, PET, and SPECT. MRI is based on the principles of nuclear magnetic resonance (NMR), which is a spectroscopic technique used to obtain microscopic chemical and physical information about molecules. An MRI can produce high-quality multidimensional images of the inside of the human body, as shown in Fig. 3, providing both structural and physiologic information of internal organs and tissues. Unlike the CT, which depicts the x-ray opacity of the structure being imaged, MRIs depict the density as well as biochemical properties based on physiologic function, including blood flow and oxygenation. A major advantage of the MRI is the fast signal acquisition with a very high spatial resolution.

Radiographic imaging modalities such as those based on x rays provide anatomical information about the body but not the functional or metabolic information about an organ or tissue. In addition to anatomical information, MRI methods are capable of providing some functional and metabolic information. *Nuclear medicine*-based imaging systems image the distribution of radioisotopes distributed within specific organs of interest by injection or inhalation of radio-pharmaceuticals that metabolize the tissue, which makes them a source of radiation. The images acquired by these systems provide a direct representation of the metabolism or function of the tissue or organ being imaged as it becomes a source of radiation that is used in the imaging

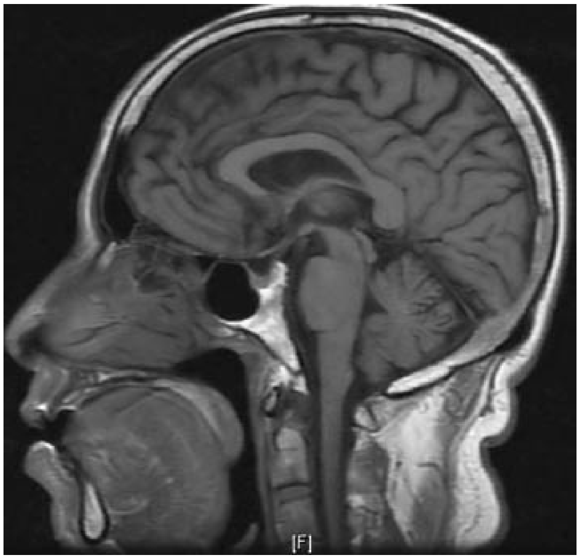

Figure 3. MRI of the brain.

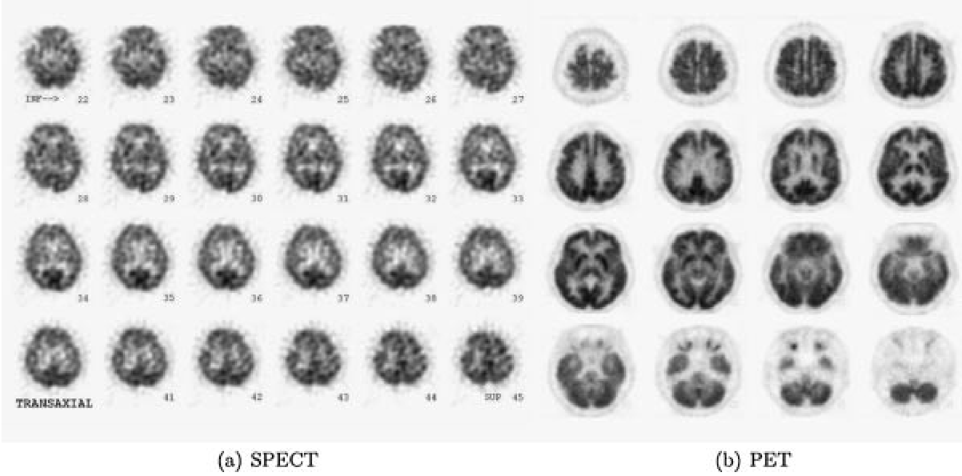

(a) SPECT

(b) PET

Figure 4. SPECT and PET sequences of a normal brain.

process. SPECT and PET are nuclear medicine-based imaging systems.

SPECT systems use gamma cameras to image photons that are emitted during decay. Like the x-ray CT, many SPECT systems rotate a gamma camera around the object being imaged and process the acquired projections using a tomographic reconstruction algorithm to yield a 3-D reconstruction. SPECT systems do not provide good resolution images of anatomical structures like CT or MR images, but they show distribution of radioactivity in the tissue, which represents a specific metabolism or blood flow as shown in Fig. 4(a). PET systems, like SPECT, also produce images of the body by detecting the emitted radiation, but the radioactive substances used in PET scans are increasingly used with CT or MRI scans so as to provide both anatomical and metabolic information. Some slices of a PET brain image are shown in Fig. 4(b).

Ultrasound Imaging

Ultrasound or *acoustic imaging* is an external source-based imaging method. Ultrasound imaging produces images of organs and tissues by using the absorption and reflection of ultrasound waves traveling through the body (Fig. 5). It has been successfully used for imaging of anatomical structures, blood flow measurements, and tissue characterization. A major advantage of this method, which does not involve electromagnetic radiation, is that it is almost nonintrusive, and hence, the examined structures can be subjected to uninterrupted and long-term observations while the subject does not suffer any ill effects.

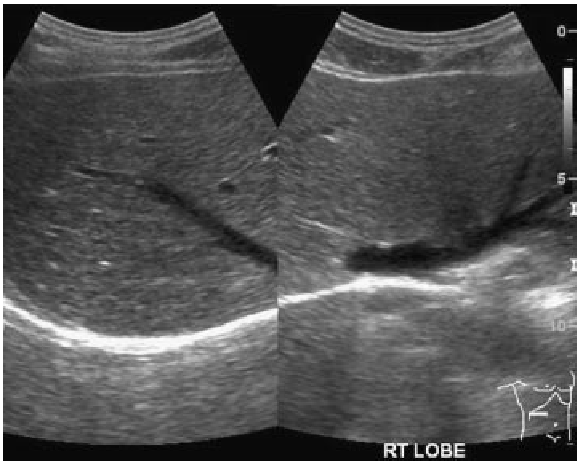

Figure 5. Ultrasound image of a normal liver.

IMAGE ENHANCEMENT AND RESTORATION

In image enhancement, the purpose is to process an acquired image to improve the contrast and visibility of the features of interest. The contrast and visibility of images actually depend on the imaging modality and on the nature of the anatomical regions. Therefore, the type of image enhancement to be applied has to be suitably chosen. *Image restoration* also leads to image enhancement, and generally, it involves mean-squared error operations and other methods that are based on an understanding of the type of degradation inherent in the image. However, procedures that reduce noise tend to reduce the details, whereas those that enhance details also increase the noise. Image enhancement methods can be broadly classified into two categories: *spatial-domain methods*(11) and *frequency-domain methods*(12).

Spatial-domain methods involve manipulation on a pixel-to-pixel basis and include histogram-based methods, spatial filtering, and so on. The *histogram* provides information about the distribution of pixel intensities in an image and is normally expressed as a 2-D graph that provides information of the occurrence of specific gray-level pixel values in the image. *Histogram equalization* is a commonly used technique that involves "spreading out" or "stretching" the gray levels to ensure that the gray levels are redistributed as evenly as possible (12,13). Minor variations in structures or features are better visualized within regions that originally looked uniform by this operation. Figure 6 shows the result of applying histogram equalization to a CT image.

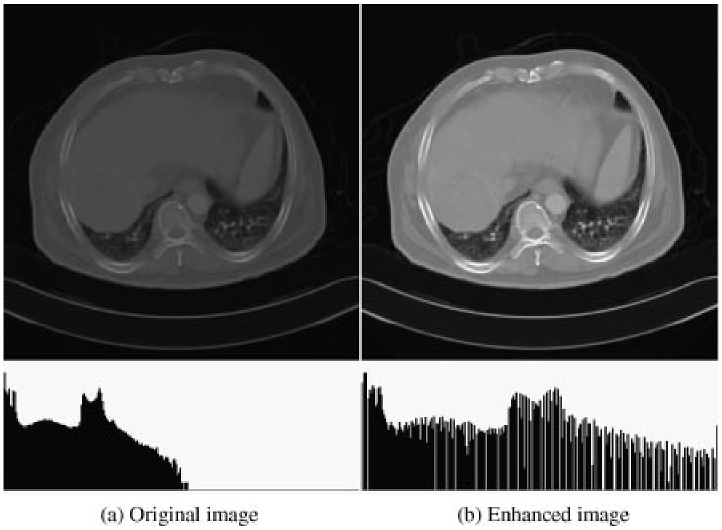

Figure 6. CT images of the liver and the associated histograms: (a) original image and (b) enhanced image.

In some instances, however, global equalization across all possible pixel values could result in loss of important details and/or high-frequency information. For such situations, local histogram modifications, including localized or regional histogram equalization, can be applied to obtain good results (14). In spatial-domain methods, pixel values in an image are replaced with some function of the pixel and its neighbors. *Image averaging* is a form of spatial filtering where each pixel value is replaced by the mean of its neighboring pixels and the pixel itself. Edges in an image can be enhanced easily by subtracting the pixel value with the mean of its neighborhood. However, this approach usually increases the noise in the image. Figure 7 shows the results of applying local spatial-domain methods.

Frequency-domain methods are usually faster and simpler to implement than spatial domain methods (12). The processing is carried out in the Fourier domain for removing or reducing image noise, enhancing edge details, and improving contrast. A *low-pass filter* can be used to suppress noise by removing high frequencies in the image, whereas a *high-pass filter* can be used to enhance the high frequencies resulting in an increase of detail and noise. Different filters can be designed to selectively enhance or suppress features or details of interest.

MEDICAL IMAGE SEGMENTATION

A fundamental operation in medical image analysis is the *segmentation* of anatomical structures. It is not surprising that segmentation of medical images has been an important research topic for a long time. It essentially involves partitioning an image into distinct regions by grouping together neighboring pixels that are related. The extraction or segmentation of structures from medical images and reconstructing a compact geometric representation of these structures is fairly complex because of the complexity and variability of the anatomical shapes of interest. Inherent shortcomings of the acquired medical images, such as sampling artifacts, spatial aliasing, partial volume effects, noise, and motion, may cause the boundaries of structures to be not clearly distinct. Furthermore, each imaging modality with its own characteristics could produce images that are quite different when imaging the same structures. Thus, it is challenging to accurately extract the boundaries of the same anatomical structures. Traditional image processing methods are not easily applied for analyzing medical images unless supplemented with considerable amounts of expert intervention (15).

There has been a significant body of work on algorithms for the segmentation of anatomical structures and other

Figure 8. Binary thresholding of MR image of the brain.

regions of interest that aims to assist and automate specific radiologic tasks (16). They vary depending on the specific application, imaging modality, and other factors. Currently, no segmentation method yields acceptable results for different types of medical images. Although general methods can be applied to a variety of data (10,15,17), they are specific for particular applications and can often achieve better performance by taking into account the specific nature of the image modalities. In the following subsections, the most commonly used segmentation methods are briefly introduced.

Thresholding

Thresholding is a very simple approach for segmentation that attempts to partition images by grouping pixels that have similar intensities or range of intensities into one class and the remaining pixels into another class. It is often effective for segmenting images with structures that have contrasting intensities (18,19). A simple approach for thresholding involves analyzing the histogram and setting the threshold value to a point between two major peaks in the distribution of the histogram. Although there are automated methods for segmentation, thresholding is usually performed interactively based on visual assessment of the resulting segmentation (20). Figure 8 shows the result of a thresholding operation on an MR image of brain where only pixels within a certain range of intensities are displayed.

The main limitations of thresholding are that only two classes are generated, and that it typically does not take into account the spatial characteristics of an image, which causes it to be sensitive to noise and intensity inhomogeneities which tend to occur in many medical imaging modalities. Nevertheless, thresholding is often used as an initial step in a sequence of image-processing operations.

Region-Based Segmentation

Region growing algorithms (21) have proven to be an effective approach for image segmentation. The basic approach in these algorithms is to start from a seed point or region that is considered to be inside the object to be segmented. Neighboring pixels with similar properties are evaluated to determine whether they should also be considered as being part of the object, and those pixels that should be are added to the region. The process continues as long as new pixels are added to the region. Region growing algorithms differ in that they use different criteria to decide whether a pixel should be included in the region, the strategy used to select neighboring pixels to evaluate, and the stopping criteria that stop the growing. Figure 9 illustrates several examples of region growing-based segmentation. Like thresholding-based segmentation, region growing is seldom used alone but usually as part of set of image-processing operations, particularly for segmenting small and simple structures such as tumors and lesions (23,24). Disadvantages of region growing methods include the need for manual intervention to specify the initial seed point and its sensitivity to noise, which causes extracted regions to have holes or to even become disconnected.

Region splitting and merging algorithms (25,26) evaluate the homogeneity of a region based on different criteria such as the mean, variance, and so on. If a region of interest is found to be inhomogeneous according to some similarity constraint, it is split into two or more regions. Since some neighboring regions may have identical or similar properties after splitting, a merging operation is incorporated that compares neighboring regions and merges them if necessary.

Segmentation Through Clustering

Segmentation of images can be achieved through clustering pixel data values or feature vectors whose elements consist of the parameters to be segmented. Examples of *multidimensional feature vectors* include the red, green, and blue (RGB) components of each image pixel and different attenuation values for the same pixel in dual-energy x-ray images. Such datasets are very useful as each dimension of data allows for different distinctions to be made about each pixel in the image.

In clustering, the objective is to group similar feature vectors that are close together in the *feature space* into a single cluster, whereas others are placed in different clusters. Clustering is thus a form of *classification*. Sonka and

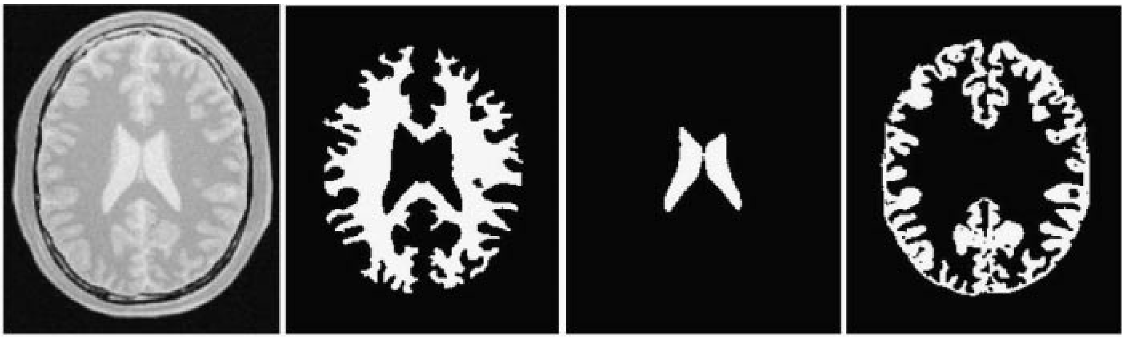

Figure 9. Segmentation results of region growing with various seed points obtained by using Insight Toolkit (22).

Fitzpatrick (27) provide a thorough review of classification methods, many of which have been applied in object recognition, registration, segmentation, and feature extraction. Classification algorithms are usually categorized as *unsupervised* and *supervised.* In supervised methods, sample feature vectors exist for each class (i.e., a priori knowledge) and the classifier merely decides on how to classify new data based on these samples. In unsupervised methods, there is no a priori knowledge and the algorithms, which are based on clustering analysis, examine the data to determine natural groupings or classes.

Unsupervised Clustering. Unlike supervised classification, very few inputs are needed for unsupervised classification as the data are clustered into groupings without any user-defined training. In most approaches, an initial set of grouping or classes is defined. However, the initial set could be inaccurate and possibly split along two or more actual classes. Thus, additional processing is required to correctly label these classes.

The *k-means clustering algorithm*(28,29) partitions the data into *k* clusters by optimizing an objective function of feature vectors of clusters in terms of similarity and distance measures. The objective function used is usually the sum of squared error based on the Euclidean distance measure. In general, an initial set of *k* clusters at arbitrary centroids is first created by the k-means algorithm. The centroids are then modified using the objective function resulting in new clusters. The k-means clustering algorithms have been applied in medical imaging for segmentation/classification problems (30,31). However, their performance is limited when compared with that achieved using more advanced methods.

While the k-means clustering algorithm uses fixed values that relate a data point to a cluster, the *fuzzy k-means* clustering algorithm (32) (also known as the *fuzzy c-means)* uses a membership value that can be updated based on distribution of the data. Essentially, the fuzzy k-means method enables any data sample to belong to any cluster with different degrees of membership. Fuzzy partitioning is carried out through an iterative optimization of the objective function, which is also a sum of squared error based on the Euclidean distance measure factored by the *degree of membership* with a cluster. Fuzzy k-means algorithms have been applied successfully in medical image analysis (33–36), most commonly for segmentation of MRI images of the brain. Pham and Prince (33) were the first to use adaptive fuzzy k-means in medical imaging. In Ref. 34, Boudraa et al. segment multiple sclerosis lesions, whereas the algorithm of Ahmed et al. (35) uses a modified objective function of the standard fuzzy k-means algorithm to compensate for inhomogeneities. Current fuzzy k-means methods use adaptive schemes that iteratively vary the number of clusters as the data are processed.

Supervised Clustering. Supervised methods use sample feature vectors (known as *training data*) whose classes are known. New feature vectors are classified into *one of the known classes* on the basis of how similar they are to the known sample vectors. Supervised methods assume that classes in multidimensional feature spaces can be described by *multivariate probability density functions*. The probability or *likelihood* of a data point belonging to a class is related to the distance from the class center in the feature space. *Bayesian classifiers* adopt such probabilistic approaches and have been applied to medical images usually as part of more elaborate approaches (37,38). The accuracy of such methods depends very much on having good estimates for the mean (center) and covariance matrix of each class, which in turn requires large training datasets.

When the training data are limited, it would be better to use *minimum distance* or *nearest neighbor classifiers* that merely assign unknown data to the class of the sample vector that is closest in the feature space, which is measured usually in terms of the Euclidean distance. In the *k-nearest neighbor* method, the class of the unknown data is the class of majority of the k-nearest neighbors of the unknown data. Another similar approach is called the *Parzen windows* classifier, which labels the class of the unknown data as that of the class of the majority of samples in a volume centered about the unknown data that have the same class. The nearest neighbor and Parzen windows methods may seem easier to implement because they do not require a priori knowledge, but their performance is strongly dependent on the number of data samples available. These supervised classification approaches have been used in various medical imaging applications (39,40).

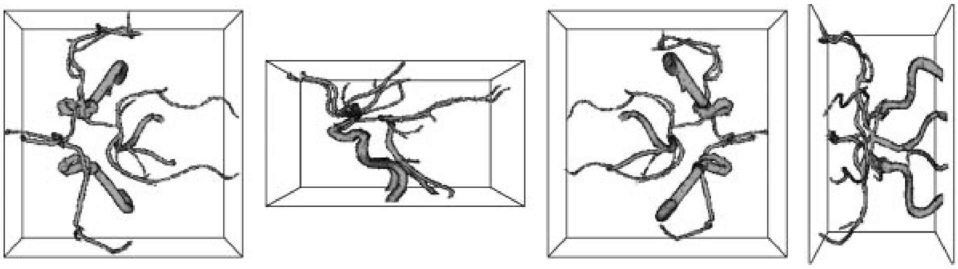

Figure 10. Different views of the MRA segmentation results using the capillary active contour.

Model Fitting Approaches

Model fitting is a segmentation method where attempts are made to fit simple geometric shapes to the locations of extracted features in an image (41). The techniques and models used are usually specific to the structures that need to be segmented to ensure good results. Prior knowledge about the anatomical structure to be segmented enables the construction of shape models. In Ref. 42, *active shape models* are constructed from a set of training images. These models can be fitted to an image by adjusting some parameters and can also be supplemented with textural information (43). Active shape models have been widely used for medical image segmentation (44–46).

Deformable Models

Segmentation techniques that combine *deformable models* with local edge extraction have achieved considerable success in medical image segmentation (10,15). Deformable models are capable of accommodating the often significant variability of biological structures. Furthermore, different regularizers can be easily incorporated into deformable models to get better segmentation results for specific types of images. In comparison with other segmentation methods, deformable models can be considered as “high-level segmentation” methods (15).

Deformable models (15) are referred by different names in the literature. In 2-D segmentation, deformable models are usually referred to as snakes (47,48), active contours (49,50), balloons (51), and deformable contours (52). They are usually referred to as active surfaces (53) and deformable surfaces (54,55) in 3-D segmentation.

Deformable models were first introduced into computer vision by Kass et al. (47) as “snakes” or active contours, and they are now well known as *parametric deformable models* because of their explicit representation as parameterized contours in a Lagrangian framework. By designing a global shape model, boundary gaps are easily bridged, and overall consistency is more likely to be achieved. Parametric deformable models are commonly used when some prior information of the geometrical shape is available, which can be encoded using, preferably, a small number of parameters. They have been used extensively, but their main drawback is the inability to adapt to topology (15,48). *Geometric deformable models* are represented implicitly as a level set of higher dimensional, scalar-level set functions, and they evolve in an Eulerian fashion (56,57). Geometric deformable models were introduced more recently by Caselles et al. (58) and by Malladi et al. (59). A major advantage of these models over parametric deformable models is topological flexibility because of their implicit representation. During the past decade, tremendous efforts have been made on various medical image segmentation applications based on level set methods (60). Many new algorithms have been reported to improve the precision and robustness of level set methods. For example, Chan and Vese (61) proposed an active contour model that can detect objects whose boundaries are not necessarily defined by gray-level gradients.

When applying for segmentation, an initialization of the deformable model is needed. It can be manually selected or generated by using other low-level methods such as thresholding or region growing. An energy functional is designed so that the model lies on the object boundary when it is minimized. Yan and Kassim (62,63) proposed the *capillary active contour* for *magnetic resonance angiography* (MRA) image segmentation. Inspired by capillary action, a novel energy functional is formulated, which is minimized when the active contour snaps to the boundary of blood vessels. Figure 10 shows the segmentation results of MRA using a special geometric deformable model, the capillary active contour.

MEDICAL IMAGE REGISTRATION

Multiple images of the same subject, acquired possibly using different medical imaging modalities, contain useful information usually of complementary nature. Proper integration of the data and tools for visualizing the combined information offers potential benefits to physicians. For this integration to be achieved, there is a need to *spatially align* the separately acquired images, and this process is called *image registration*. Registration involves determining a *transformation* that can relate the position of features in one image with the position of the corresponding features in another image. To determine the transformation, which is also known as *spatial mapping,* registration algorithms use geometrical features such as points, lines, and surfaces that correspond to the same physical entity visible in both images. After accurate registration, different images will have the same coordinate system so that each set of points in one image will occupy the same volume as the corresponding set of points in another image. In addition to combining images of the same subject from different modalities, the other applications of image registration include aligning temporal image sequences to compensate for motion of the subject between scans and image guidance during medical procedures.

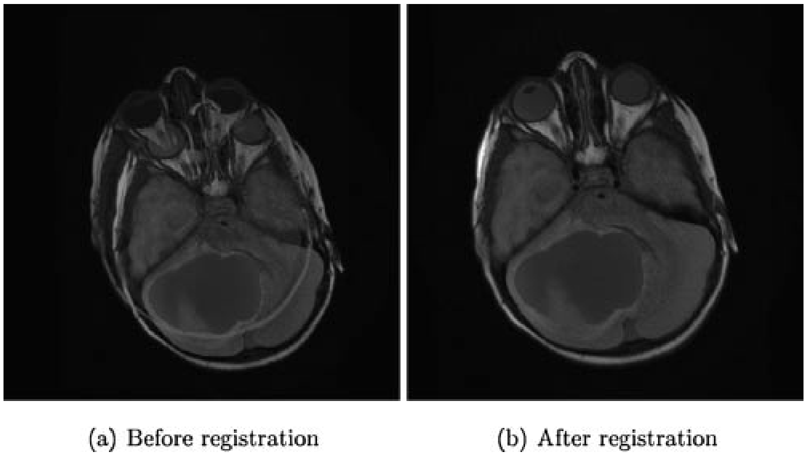

Figure 11. (a) Result of direct overlapping of brain MR images without registration. (b) Result of overlapping of images after rigid registration.

The evaluation of the transformation parameters can be computationally intensive but can be simplified by assuming that the structures of interest do not deform or distort between image acquisitions. However, many organs do deform during image acquisition, for example, during the cardiac and respiratory cycles. Many medical image registration algorithms calculate *rigid body* or *affine* transformations, and thus, their applicability is restricted to parts of the body where deformation is small. As bones are rigid, *rigid body registration* is widely used where the structures of interest are either bone or are enclosed in bone. The brain, which is enclosed by the skull, is reasonably nondeformable, and several registration approaches have been applied to the rigid body registration of brain images. Figure 11 shows an example of rigid registration of brain MR images. Image registration based on rigid body transformations is widely used for aligning multiple 3-D tomographic images of the same subject acquired using different modalities *(intermodality registration*) or using the same modality *(intramodality registration*) (64–66).

The problem of aligning images of structures with deformed shapes is an active area of research. Such *deformable (nonaffine)* registration algorithms usually involve the use of an initial rigid body or affine transformation to provide a starting estimate (65–68).

After registration, *fusion* is required for the integrated display. Some fusion methods involve direct combination of multiple registered images. One example is the superimposition of PET data on MRI data to provide a single image containing both structure and function (69). Another example involves the use of MR and CT combined to delineate tumor tissues (70).

Atlas-Based Approaches

In atlas-based registration and segmentation of medical images, prior anatomical and/or functional knowledge is exploited. The atlas is actually a reference image in which objects of interest have been carefully segmented. In this method (65,66,71), the objective is essentially to carry out a *nonrigid registration* between the image of the patient and the atlas. The first step, known as atlas warping, involves finding a transformation that maps the atlas image to the target image to be segmented. The warping usually consists of a combination of linear and nonlinear transformations to ensure good registration despite anatomical variability. Even with nonlinear registration methods, accurate atlas-based segmentation of complex structures is difficult because of anatomical variability, but these approaches are generally suited for segmentation of structures that are stable in large numbers of people. Probabilistic atlases 72–75 help to overcome anatomical variability.

CONCLUDING REMARKS

Significant advances made in medical imaging modalities have led to several new methodologies that provide significant capabilities for noninvasive and accurate examination of anatomical, physiological, metabolic, and functional structures and features. three- and four dimensional medical images contain a significant amount of information about the structures being imaged. Sophisticated software-based image processing and analysis methods enhance the information acquired by medical imaging equipment to improve the visibility of features of interest and thereby enable visual examination, diagnosis, and analysis. There are, however, several *challenges* in medical imaging ranging from accurate analysis of cardiac motion and tumors to nonaffine registration applications involving organs other than the brain and so on (76,77). Also, new imaging modalities, such as optical (78), microwave, and electrical impedance (79) imaging methods hold the promise of breakthroughs when new associated algorithms for processing and analyzing the resulting information acquired via these modalities are available.

ACKNOWLEDGMENTS

The authors would like to thank the Department of Nuclear Medicine at the Singapore General Hospital for providing the PET image and Prof. S. C. Wang of the Department of Diagnostic Imaging at the National University Hospital for providing the images used in this chapter. The authors are also grateful to Dr. P. K. Sadasivan for his valuable inputs.

RADIOMETRIC CAMERA CALIBRATION

Radiometric calibration is a method of capturing digital images and processing the digital image data so that the pixel values represent actual measurements of light. Even without radiometric calibration, it is usually the case that a higher-valued pixel in an image represents a greater light intensity, but one cannot say how much light is represented by each pixel value. If the purposes of digital images are merely to be viewed or analyzed for their structural content, then radiometric calibration is not usually necessary. However, when detailed information about brightness, color, or shading is important, radiometric calibration may be essential.

Radiometry is the measurement of electromagnetic radiation, including light (1). Devices called radiometers are designed specifically to measure radiation in units of energy or power. Digital cameras contain many small light-sensitive devices usually arranged in a rectangular grid. Each of these light-sensitive devices may potentially be used as a radiometer if the output (a pixel value) can be interpreted as a light measurement in units of energy or power. Radiometric camera calibration provides the link between raw pixel values obtained by a camera and calibrated pixel values that measure light energy. Radiometric camera calibration converts ordinary digital images into radiometric images.

TYPES OF CALIBRATION

Two types of radiometric calibration exist, absolute and relative (2). Absolute radiometric calibration means that the image pixels are calibrated with reference to physical units such as watts per steradian per square meter ($W.sr^{-1}.m^{-2}$) or photon counts. For absolute calibration, a known or measurable relationship exists between the pixel values and the corresponding measurements expressed in physical units. Relative radiometric calibration means that the image pixels are calibrated with reference to each other—the ratio of two image pixels is the same as the ratio of the corresponding physical measurements of light. Relative radiometric calibration implies that the image pixels have a fixed but unknown multiplicative relationship to the corresponding measurements expressed in physical units. A set of images has shared relative radiometric calibration if the pixels in different images are calibrated with reference to each other. Relative radiometric calibration can be converted to absolute radiometric calibration by including a target with known radiance in an image, then considering the relationship between the known radiance of the target and the corresponding relative radiometric pixel values.

A related calibration is reflective calibration in which image pixels are calibrated with reference to the reflective properties of objects in the scene such as albedo or color. Relative radiometric calibration can be converted to reflective calibration by including a target with known reflectance properties in an image, then using the pixel values corresponding to the target to calibrate the image.

Radiometric calibration has a wide range of applications in science and technology. Astronomy uses radiometric calibration to measure the brightness of stars, galaxies, and other astronomical objects. Remote sensing (2) uses radiometric imaging of the surface of the earth (such as aerial and satellite imaging) to map surface features (e.g., identification of ground cover, forest, specific crops, etc.). Remote sensing systems may use infrared and/or ultraviolet imaging in addition to visible-light imaging. Machine vision systems use radiometric imaging techniques to measure the reflective and transmissive properties of materials when illuminated with controlled light sources. Shape-from-shading and photometric stereo techniques estimate surface orientation from relative radiometric calibrated images. Image analysis techniques such as subpixel edge detection benefit from relative radiometric calibration. Techniques that combine multiple images, such as image stitching and high dynamic range (HDR) imaging, also benefit from radiometric calibration of the component images, although these particular applications do not strictly require radiometric calibration as will be explained below.

METHODS

Methods for radiometric calibration typically involve up to four steps. First, the camera response is corrected to be linear. Second, the camera's black response is subtracted. Third, corrections are applied for spatial variations in the effective aperture of the lens and the sensor sensitivity. This correction yields a relative radiometric calibration. A final step converts the relative calibration to absolute or reflective calibration by applying an appropriate scaling factor.

The first step is linear correction of the camera response function (CRF). Linear correction is required because electronic and digital cameras typically respond nonlinearly to light. A variety of techniques is available for estimating the nonlinear response curve. The inverted response curve is used to transform the pixel values, which yield linear corrected images.

The second step corrects the camera's black response—the pixel value produced by the camera when no light reaches the sensor. Once linear correction is applied, the black response can be estimated from sample images. Subtracting the black response yields an image in which pixel values of zero represent absolute black.

The third step corrects spatial variations in the camera's response to light. The response of individual sensor elements to light depends on their position in the sensor array. Optical effects in the camera's lens cause a radial variation in the intensity of light reaching the sensor elements—usually, elements further from the optical axis

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

receive less light. In addition, manufacturing tolerances mean that individual sensor elements may have different sensitivity to light. These effects can be corrected by applying an individual scaling factor to each pixel value, which yields a relative radiometric image. A set of such images will have shared relative radiometric calibration if the camera's exposure parameters and behavior are consistent for all the images.

The final step of converting the relative radiometric calibration to absolute or reflective calibration requires a scaling factor. If the camera's response is consistent (i.e., the same amount of light always produces the same pixel value), then the necessary scaling factor can be obtained by analyzing a sample image of a known radiometric standard (for absolute radiometric calibration) or of a known reflectance standard (for reflective calibration). However, if the camera's response changes from image to image (for example, because of an automatic iris in the lens), then a reference target should be included in each image to allow calibration between the images. For shared relative radiometric calibration of a set of images, an unknown constant reference target is sufficient, but for absolute radiometric calibration, a reference target with known radiance is required.

If reflective calibration is required for measurement of albedo or color, then a reference target with known reflectance properties is used instead of a known radiance target. The derived scaling factor automatically adjusts for temporal variations in source-illumination brightness.

The remainder of this article first considers the basis of radiometric calibration—the additive property of light and the formation of digital images. Techniques for radiometric calibration are then explained, focusing on the four steps of estimating the camera response function, measuring the black response, correcting for vignetting and sensitivity, and using calibration targets. Finally, applications of radiometric imaging are briefly discussed.

THE ADDITIVE PROPERTY OF LIGHT

Consider a scene illuminated by multiple light sources, each of which can be turned on or off. Assume that the light sources are independent so that the interaction of light from the different sources does not produce interference effects. Also assume that the scene disperses light by reflection and transmission, but it does not exhibit fluorescence. Under these assumptions, light behaves additively; that is, the scene radiance that results from the combined illumination of multiple light sources is the sum of the radiances that result from the individual light sources operating separately.

The additive property of light is useful for testing the linearity of a camera and for estimating the CRF. It was first used in 1893 by Elster and Giedel to demonstrate that the photoelectric current produced by a photocell is proportional to the irradiance (the quantity of light falling on the photocell), and is still used for testing and calibrating spectrophotometers (3,4) and photometers (5).

HOW DIGITAL IMAGES ARE FORMED

Radiometric calibration techniques are based on mathematical models of digital image formation. Digital image pixel values depend on the source illumination, the reflection of light by the scene, and the conversion of light to digital data by the camera. It is particularly important to mathematically model the camera so that image data can be related to the quantity of light arriving at the camera. However, it may also be necessary to model some aspects of the interplay of light with objects in the scene as part of the calibration process. Here, we will briefly describe that process and then present mathematical models that are suitable for understanding radiometric calibration techniques.

Images begin with light. One or more light sources illuminate objects in a scene that the camera is viewing. Reflection (both specular and diffuse), absorption, and transmission of light by the objects direct a portion of the light towards the camera. This light is measured with radiometric imaging.

The camera lens focuses the light onto an array of sensors. The lens usually includes an adjustable aperture that restricts the light reaching the sensors to prevent too much light falling on the sensors, because the sensors have a limited range of response. The aperture may be automatically adjusted under the control of a signal from the camera (auto iris), or it may be manually adjustable (manual iris).

The amount of light admitted by the lens depends on the angle between the light ray and the optical axis of the lens. As a result of optical geometry, less light is admitted for light rays that are farther from the optical axis, which modifies the effective aperture of the lens depending on the direction of the arriving light ray.

When the light strikes the sensors, photons of light are converted to electrical signals. In charge coupled device (CCD) and complementary metal oxide semiconductor (CMOS) sensors, photons dislodge individual electrons that are collected in a charge well. The exposure time of the sensors is controlled by the camera electronics. Before exposure commences, the charge wells are drained to remove all accumulated charge. During exposure, the charge well collects electrons dislodged by photons. The charge well also collects additional electrons dislodged by thermal motion, which produces a dark current—a base level of sensor response in the complete absence of light that is dependent on the sensor temperature and the exposure time. After the exposure time is complete, CCD arrays shift the collected charges to storage locations, one for each pixel. The charges are then read out by shifting them through the CCD array from one storage location to another until they reach an output amplifier. The amplifier produces an electrical signal in proportion to the charge it is reading at each point in time. Healey and Kondepudy present a more detailed model of CCD cameras for radiometric calibration, including consideration of noise characteristics (6). In contrast to CCD sensors, CMOS sensors amplify the collected charge at each pixel individually.

In digital cameras, the amplifier's signal is converted internally to digital pixel values that are transmitted to a computer for analysis. Some imaging systems use analog cameras that produce a video signal that is then converted to digital pixel values by a separate frame grabber card. The use of analog cameras is becoming less common as the availability, price, and quality of digital cameras has improved.

MATHEMATICAL MODEL OF IMAGE FORMATION

Mathematically, we can model the process of digital image formation for each individual pixel. First, we will model a typical digital camera including the lens.

Digital Camera Model

Let p designate a pixel. Let $L_p(\lambda)$ denote the radiance of light emanating toward the camera from the small portion of the scene that is imaged by pixel p. Here, the radiance is expressed as a function of wavelength λ, which represents the spectral characteristics (e.g., the color) of the light. Mathematically, $L_p(\lambda) = \mathrm{d}L_p/\mathrm{d}\lambda$ where L_p is the radiance as defined by the CIE (1).

Aperture. Let A_p denote the effective aperture for the pixel p. The effective aperture A_p has a multiplicative effect on the sensor response and is assumed to be wavelength independent. It includes the lens aperture and other effects such as vignetting and the $\cos^4$ effect. The effective aperture A_p is typically different for different pixel locations.

Sensor Sensitivity. Let $S_p(\lambda)$ denote the sensor sensitivity function of pixel p. $S_p(\lambda)$ is a function of the wave length λ of the incident light; for example, CCD sensors are typically more sensitive to red light than to blue light. Some cameras employ specific filters to modify the sensitivity function; an infrared blocking filter may be used to inhibit the response of a CCD sensor to infrared light. For the purposes of our equations, $S_p(\lambda)$ includes the effects of any such filters. The sensitivity function has a multiplicative effect on the light reaching the sensor for each wavelength λ. For a color or multispectral imaging system, a separate sensitivity function $S_{bp}(\lambda)$ exists for each spectral band b. Typically, we assume that $S_{bp}(\lambda) = s_{bp}S_b(\lambda)$ for all pixels p; that is, the spectral sensitivity curve is the same for all pixels for each spectral band b. Here, $S_b(\lambda)$ is the spectral sensitivity curve for spectral band b, and s_{bp} is the absolute sensitivity of the individual pixel p for spectral band b. Manufacturing tolerances can mean that individual pixel sensors have different dimensions and hence different sensitivity.

Exposure. Let t represent the exposure time. The exposure time has a multiplicative effect on the signal produced by light striking the sensor. The longer the exposure time, the greater the signal until the sensor reaches its operating limit and saturates.

Expressing the above concepts in mathematical notation, the following equation describes the sensor's exposure to light X_{bp}. X_{bp} is a linear equation of the scene radiance $L_p(\lambda)$.

$$X_{bp} = t\,A_p\,s_{bp} \int S_b(\lambda)\,L_p(\lambda)\,\mathrm{d}\lambda \tag{1}$$

Dark Current. In typical sensors, thermal motion dislodges some electrons even without light striking the sensor. These electrons are called dark current. Let D_{bp} denote the dark current of pixel p for spectral band b. The sensor's output signal is the sum of the dark current and the response to light striking the sensor. The dark current is part of the black response of the camera.

Camera Response Function. Let f_{bp} denote the CRF for pixel p and spectral band b. The CRF represents the nonlinearity of the camera. It combines the nonlinearity of the output amplifier and any subsequent electrical signal processing up to and including the conversion to a digital pixel value. Note that the electrical processing may also contribute to the black response of the camera; for example, the black response may be adjusted by modifying the video offset parameter that is often provided in video frame grabbers and digital cameras.

Camera Model. Let V_{bp} represent the digital value of pixel p for spectral band b. Then the following equation represents the formation of a multiband image as described above.

$$\begin{aligned} V_{bp} &= f_{bp}(X_{bp} + D_{bp}) \\ &= f_{bp}(t\,A_p\,s_{bp} \textstyle\int S_b(\lambda)\,L_p(\lambda)\,\mathrm{d}\lambda + D_{bp}) \end{aligned} \tag{2}$$

Ideally, we would like to estimate $L_p(\lambda)$ as a radiometric image with full spectral data for each pixel, but it is not possible with the limited spectral data from a camera. Instead, we estimate $C_{bp} = \int S_b(\lambda)\,L_p(\lambda)\,\mathrm{d}\lambda$ as a radiometric image for each spectral band b. If we know f_{bp}, A_p, s_{bp}, t and D_{bp}, then we can determine C_{bp} directly from V_{bp}. Under reasonable assumptions (such as monotonicity of f_{bp}), we obtain $C_{bp} = (\,f_p^{-1}(V_{bp}) - D_p)/(t\,A_p\,s_{bp})$, where f_p^{-1} is the inverse CRF. Unfortunately, it is unlikely that we have prior knowledge of all relevant parameters for a particular camera, so some method is required to estimate them. The estimation process produces radiometric calibration data for the camera.

Scene Illumination and Reflectance Model

Radiometric calibration techniques typically involve estimating f_{bp} and some or all other parameters. The estimation is based on images in which relevant parameters are known or controlled. These images may require some control over the scene radiance $L_p(\lambda)$. Because it is difficult to directly control the scene radiance, it is useful to model the formation of the scene radiance $L_p(\lambda)$ in terms of the illumination and reflection within the scene.

Let $E_{ip}(\lambda)$ denote the radiance of light from a particular light source i that falls on the small portion of the scene imaged by pixel p. Let $R_p(\lambda)$ denote the reflectance function of the small portion of the scene that is imaged by pixel p. $R_p(\lambda)$ denotes the proportion of incident illumination of wavelength λ that is reflected toward the camera, assuming no fluorescence.

Assuming that the conditions hold for the additive property of light, we can express the scene radiance in terms of the illumination and reflectance as $L_p(\lambda) = \sum_i E_{ip}(\lambda) R_p(\lambda)$. It follows that

$$X_{bp} = t A_p s_{bp} \sum_i \left(\int S_b(\lambda) E_{ip}(\lambda) R_p(\lambda) \, \mathrm{d}\lambda \right) \quad (3)$$

and thus

$$V_{bp} = f_{bp} \left(t A_p s_{bp} \left(\sum_i \int S_b(\lambda) E_{ip}(\lambda) R_p(\lambda) \, \mathrm{d}\lambda \right) + D_{bp} \right) \quad (4)$$

Some techniques for radiometric camera calibration can be understood primarily as methods for estimating f_{bp} by measuring or controlling some or all of the parameters and functions V_{bp}, t, A_p, s_{bp}, S_b, E_{ip}, R_p and D_p. If all these parameters are measured or controlled accurately in a sufficiently large and diverse set of sample images, then the camera response function f_{bp} can be accurately determined, and the inverse of this function can then be used to perform radiometric calibration. A later section considers techniques for radiometric calibration, including specific methods for estimating the CRF.

Modeling Effective Aperture

The lens aperture controls the light admitted by the lens. The aperture is an iris that may be controlled manually or automatically, depending on the lens design. Each aperture step (f-stop) typically represents a factor of approximately two in aperture area and hence a factor of two in light admitted by the lens. Larger f-stop numbers represent smaller aperture areas.

As a result of optical geometry, the amount of light admitted by the lens varies depending on the angle between the arriving light ray and the optical axis of the lens. This variation is captured in the effective aperture, which varies from one pixel to another. Two significant factors that affect the effective aperture are vignetting and the $\cos^4$ effect. The effective aperture is also affected by lens distortions such as pin-cushion and barrel distortions that change the density of the projected image.

Vignetting. Vignetting occurs for pixels that are far from the center of the image. It occurs because the light admitted to the lens does not fill the exit pupil of the lens—a portion of the exit pupil is in shadow (Fig. 1), so the effective aperture is reduced. Vignetting is most noticeable in the corners of an image and is strongest when the aperture area is large (i.e., for small f-stops). Vignetting results from the combination of lens design and use. A good lens design can reduce or eliminate vignetting entirely provided that the lens is used as intended. In particular, the sensor array physical dimensions should not exceed the dimensions assumed in the lens design. Asada et al. (8) mathematically model and correct vignetting in zoom lenses.

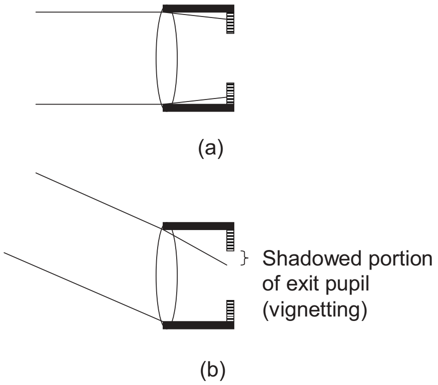

Figure 1. Vignetting in a lens. (a) Ray aligned with optical axis has no vignetting. (b) Ray produces vignetting due to angle from optical axis.

Cos^4 Effect

The $\cos^4$ effect applies to light arriving at the lens opening from directions that are not parallel to the optical axis. For most lenses, the effective illumination of the image sensor falls off as the fourth power of the cosine of the angle between the incident light ray and the optical axis (7). The $\cos^4$ effect is unavoidable, but some lens designs modify the $\cos^4$ effect through other factors (9). Graded neutral density filters can be used to optically correct the $\cos^4$ effect.

The combination of vignetting, the $\cos^4$ effect and lens distortion reduces the light that reaches an optical sensor by a factor that depends primarily on the angle between the incident light ray and the optical axis. For a fixed lens, the angle can be computed from the position of the pixel relative to the optical centre of the image. Note that the optical center of an image may not be the center of the image coordinates, because the sensor array may be off-center relative to the optics.

TECHNIQUES FOR RADIOMETRIC CALIBRATION

The first step in radiometric calibration is to estimate the CRF. The inverse of this function is used to correct the pixel data to be linear. The second step is to subtract the black response so that zero pixels represent absolute black. After this, the effective aperture and sensitivity corrections are applied, dividing each pixel by an individual scaling factor. These steps yield a relative radiometric image. For absolute radiometric calibration, a final step converts relative calibration to absolute based on a standard radiance.

Modeling the Camera Response Function

Direct modeling of the CRF assumes that the physical processes are sufficiently well understood, and a mathematical model of f_{bp} can be used. The simplest model is linear—the response is assumed to be a linear function of the incident light. For example, CCD sensors are known to be linear over a reasonable operating range. If the camera electronics are of sufficient quality, the sensor linearity may be adequately maintained during the conversion to digital pixels, which simplifies radiometric calibration. It is recommended, however, to check the linearity of the camera using one of the techniques described below.

Gamma Encoding. Many cameras deliberately introduce nonlinearity into the video signal, which is called gamma encoding. The original video signal V_0 is transformed by a power-law equation parameterized by gamma (γ), which yields a nonlinear video signal V_e.

$$V_e = V_0^{1/\gamma} \tag{5}$$

When this video signal is displayed on a cathode ray tube (CRT) monitor, the inverse gamma transformation is applied so that the light output from the monitor is a linear function of the light originally captured by the camera. Gamma encoding compresses the dynamic range of bright pixels relative to dark pixels in the transmitted video signal V_e, which provides improved transmission of detail in dark portions of the image. A gamma value of 2.2 is typical in television (10); the reciprocal (0.45) is used for simple gamma correction (11). Figure 2 shows ideal gamma response curves with $\gamma = 2.2$ and $\gamma = 1.4$, with a linear response curve for comparison.

Camera Response Function Models. Gamma encoding is often implemented in electronics and may not exactly follow the power-law curve. Errors in the model of the CRF limit the accuracy of the radiometric calibration, so more sophisticated functions are often used to model the CRF.

Grossberg and Nayar (12) model the CRF as the weighted sum of a set of basis functions. Principal components analysis is used to derive the basis functions from a database of 175 real-world response functions, including film brands, digital and video cameras, and a small selection of gamma curves. Three basis functions are sufficient to fit most CRFs with a RMSE of 0.7%.

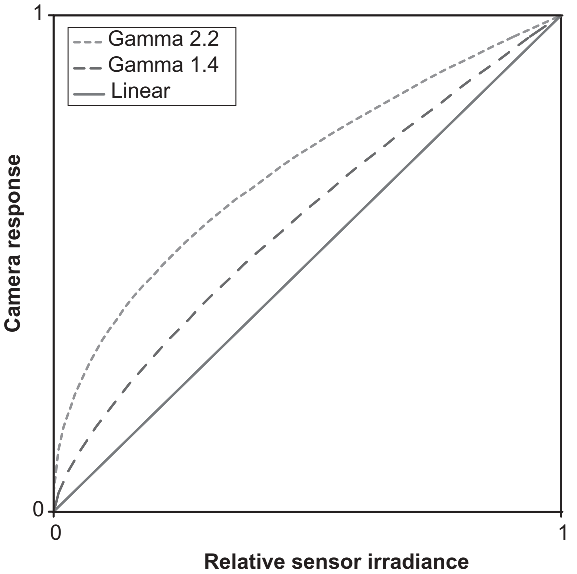

Figure 2. Examples of gamma response curves.

General-purpose modeling functions may also be used. Klinker, et al. (10) model the CRF using cubic splines. Hamey (13) uses a feed-forward artificial neural network. Mitsunaga and Nayar (14) use a polynomial model. Robertson et al. (15) represent the CRF as a mapping from 256 discrete camera response values to corresponding linear pixel values. They use Gauss-Seidel relaxation to solve this highly parameterized model.

Estimating the CRF

The CRF may be estimated from image data captured with the camera itself. To reduce the image data requirements, we may assume that the CRF is the same for all pixels (i.e., $f_{bp} = f_b$). With this assumption, we estimate a single CRF for each spectral (color) band of the camera, combining the data from multiple pixel locations. The validity of this assumption depends on the design and manufacture of the imaging system. For example, if all the pixels of a CCD array are read out by the same amplifier and analog-to-digital circuitry, we may reasonably assume that the CRF is the same for all pixels, provided that no pixel-specific nonlinearity exists in the camera design. Recent CCD cameras use two or more amplifiers (taps) to read the pixels out of the CCD array. The assumption of a common CRF may only be applicable to the regions of the images that share a single tap because manufacturing tolerances may produce different nonlinearity for each tap. CMOS sensors individually amplify each pixel, so manufacturing tolerances may produce different nonlinearity for each image pixel in CMOS cameras.

Typically, the CRF is estimated independently for each camera. Multiple cameras of the same make and model may have different CRFs because of manufacturing tolerances. Hamey (13) observed a difference of 1% between the CRFs for two cameras of the same make and model.

Estimating Gamma. If a gamma model is assumed, but the gamma parameter is unknown, then gamma may be estimated from image data. Farid (16) estimates gamma to an accuracy of 7.5% by analyzing the spatial frequency effects of the non-linear transformation introduced by gamma encoding. The nonlinear CRF introduces high spatial-frequency harmonics into the image. Using bispectral analysis, he recovers the gamma value that minimizes these harmonics in the corrected image.

Shafique and Shah (17) estimate gamma to an accuracy of 3% based on image invariants. In their technique, the same scene is imaged with different illumination conditions such as four separate light sources, one at a time. The technique uses cross-ratios of exposure terms that involve three color bands. These cross-ratios are invariant to changing illumination conditions under suitable models of scene reflection. The technique requires at least three spectral bands. Each spectral band may have a different gamma parameter.

Exposure Time-Based Methods. Controlling the exposure time t in Equation (2) gives direct control over the major part of the parameter of the function f_{bp}. A set of images is captured with different exposure times but with all other parameters remaining constant. For each pixel, the different images provide known relative exposures and corresponding camera response values that can be used to reconstruct the CRF.

Under the assumption of a shared CRF f_b, naturally occurring brightness variations in the scene increase the available information. For example, suppose n images are captured using exposure times t_1 through t_n. For each pixel location, these images yield a vector of camera response values (V_{1p}, V_{2p}, $\ldots$ V_{np}) corresponding to the exposures ($k_p t_1$, $k_p t_2$, $\ldots$, $k_p t_n$) for some unknown constant k_p that depends upon the scene radiance, effective aperture and other variables. The CRF is reconstructed by analyzing these data vectors.

The simplest method of recovering the CRF from such data is to collect many images with exposures densely covering the entire range of camera response for a single pixel. Plotting the pixel values against the corresponding exposure times for a single pixel reveals the CRF. More sophisticated analysis combines incomplete curves from different pixels to derive an overall curve from fewer images.

Techniques based on exposure time are limited by the accuracy of the camera's exposure time control. In addition, theoretical limitations exist. Grossberg and Nayar (18) show that a self-similar ambiguity exists when only two images are used or when the exposure ratios of multiple images are similar, such as doubling the exposure of each image compared with the previous image. The ambiguity can be resolved by using at least three images with exposure ratios $a = t_2/t_1$ and $b = t_3/t_2$ such that $\log_a b$ is irrational. Alternatively, the ambiguity may be resolved by imposing smoothness constraints on the CRF (15), or by assuming a model with a limited number of parameters such as basis functions (12) or a polynomial model (14). Radiometric calibration based on known exposure times is included in HALCON, a commercial machine vision library (19).

Chart-Based Methods. In this approach, the CRF is estimated from images that contain calibration targets with known reflective properties. For example, a Kodak grayscale contains 21 reflectance targets with different gray levels. In one method, each reflectance target is imaged in turn at the same physical location under time-constant illumination. In a slightly different approach, the entire grayscale is imaged under uniform illumination. Using either source of image data, the mean pixel value of each target is calculated and related to the known reflectance level of the corresponding target. The CRF is estimated by interpolating the data points. The accuracy of this technique is limited by the accuracy of the reflectance data provided with the reflectance targets and also by interpolation errors. When the entire gray scale is imaged at once, the accuracy of the technique is limited further by spatial variations in the effective aperture and sensitivity.

Klinker et al. (10) use the GretagMacbeth Color Checker (X-Rite Incorporated, Grand Rapids, MI) to estimate the CRF by fitting cubic splines to the camera response data from a single image. Grossberg and Nayar (12) also use the GretagMacbeth Color Checker to estimate the CRF by fitting a set of basis functions derived from a database of known CRFs.

Additive Illumination. Using the additive property of light, it is possible to solve for unknown illumination levels, scene reflectance values, and camera response function simultaneously. The techniques use multiple light sources. Images are taken with each light source individually and with combinations of the light sources. Because of the additive property of light, the exposure of images with multiple light sources is the sum of the exposures with the individual light sources.

Manders et al. (20) use a static real-world scene with two different illumination sources. Taking an image with each source independently and a third image with both sources, they use singular value decomposition (SVD) to solve for the inverse CRF using the equation

$$f^{-1}(V_{1p}) + f^{-1}(V_{2p}) = f^{-1}(V_{3p}). \qquad (6)$$

Here, V_{1p} and V_{2p} represent corresponding pixels from the images taken with individual light sources, whereas V_{3p} is the corresponding pixel with both light sources active. The technique assumes no ambient illumination. The inverse CRF is represented as a discrete function.

Hamey (13) uses four illumination sources and a collection of reflectance targets. Each reflectance target is imaged under all combinations of the four lights being gated on and off. The experiments are conducted in a dark room so that the only ambient illumination is scatter from the lights. At least 40 targets are used, which vary from black through white, yielding 640 images. A neural network model is fitted to estimate the CRF, the unknown illumination level of each light, and the unknown relative reflectance value of each target for each pixel location simultaneously.

The model simplifies Equation (4) above. Assuming that the spectral distribution of all light sources is the same, let $E_{ip}(\lambda) = e_{ip} E(\lambda)$ where e_{ip} is the relative brightness of lamp i illuminating the region of the target imaged by pixel p, and $E(\lambda)$ is the common spectral curve. Let T represent a reflectance target, and let $R_{pT}(\lambda)$ denote the reflectance curve of target T. Let $R_{bpT} = t A_p s_{bp} \int S_b(\lambda) E(\lambda) R_{pT}(\lambda)\, d\lambda$, which combines the spectral curves and the exposure parameters into a single relative reflectance value. Allowing the CRF to be an arbitrary monotonic function g_{bp}, subsume the dark current D_{bp} into the CRF. With some manipulation, we derive

$$V_{bp}(j) = g_{bp}\left(\left(\sum_T P_T(j)\, R_{bpT}\right)\left(\sum_i (L_i(j)\, e_{ip}\right)\right). \qquad (7)$$

Here, j denotes an image, $P_T(j) = 1$ when target T is present in image j and $L_i(j) = 1$ when lamp i is on in image j. Ambient illumination is assumed to be constant and is represented by $i = 0$ with $L_0(j) = 1$ for all j.

Fitting the above model as a neural network, Hamey (13) recovered CRFs with a root mean squared error (RMSE) of 0.15%, applying the results to the color inspection of baked goods.

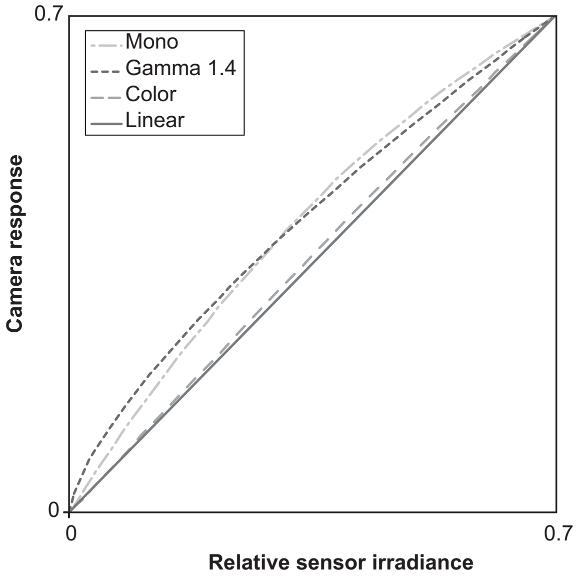

Figure 3. Examples of camera response functions for a monochome CCD camera and a color CCD camera, with a gamma curve and linear response for comparison.

Figure 3 shows measured camera response functions for a monochrome CCD camera and for one band of a color CCD camera. The camera response functions are shown over the range from absolute black to approximately 70% of the camera response range (pixel value 183) to avoid sensor saturation effects. For comparison, the figure includes a linear response curve and a gamma response curve with $\gamma = 1.4$. The monochrome camera's response curve was nominally a gamma curve, but it deviates significantly from the ideal gamma response curve. The color camera was operated with gamma encoding disabled, but it deviates from linear by up to 1.7%. In contrast, the monochrome camera deviates from a linear response by up to 12%.

Figure 4 shows the linear correction function for the monochrome camera. It is implemented as a lookup table that converts camera pixel values to the corresponding linear response values. Note that, for this camera, pixel value 26 corresponds to absolute black.

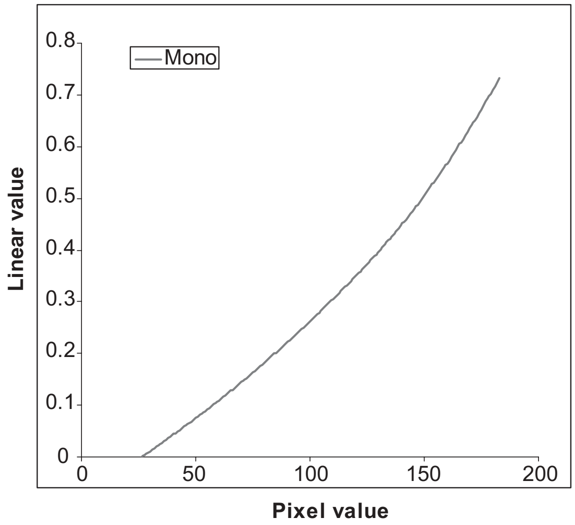

Figure 4. Linear correction function for a monochrome camera.

Comparametric Analysis. The comparametric approach involves solving equations of the form $h(f(X_1)) = f(kX_2)$ where f is the unknown CRF, k is the unknown exposure ratio between a pair of images, X_1 and X_2 are unknown exposure levels for corresponding pixels in the pair of images, and h is the comparametric function (also known as a mapping function or registration function) that maps pixel values in one image to the corresponding pixel values in another image (i.e., $h(V_1) = V_2$). Mann (21) shows that f is related to h. For example, if f is gamma encoding, then h is a straight line. Fitting h yields a corresponding solution for f, but this solution is exponentially ambiguous (18), because it yields an unknown gamma encoding unless the exposure ratio is known. An unknown gamma encoding is not suitable for radiometric calibration but remains useful for image stitching and HDR imaging applications as discussed below.

Measuring the Black Response

Radiometric calibration requires that the calibrated response value is zero when the camera views absolute black. However, a linear CRF may have a nonzero response value for black. A relative radiometric calibration can be achieved by measuring the black response and subtracting it from the linear pixels. The following are some techniques that may be used to measure the black response.

Lens Cap Technique. A simple technique for measuring the camera's black response is to cover the camera lens so that no light is admitted and then capture a black image. The black image is subtracted from other images to remove the black response.

This technique is widely used but may yield incorrect results depending on the camera and frame grabber. In particular, if the frame grabber dynamically adjusts the digitization range to the range of the video signal, then an all-black image may yield different pixel values than an equally dark object in an ordinary image. When using the lens cap technique, the all-black image should be compared with a black reference in a normal image to ensure that the imaging system has not adjusted inappropriately to the all-black image conditions.

Masked Pixels. Some machine vision cameras can measure the sensor dark current and automatically subtract it from the image data. The design uses masked pixels (not exposed to light) to measure the dark current.

Shadowed Black Reference. It is difficult to create a truly black object. Black materials still reflect some light, typically 2% or more. To achieve blackness that is close to 0% reflectance, the black material must be overshadowed to protect it from all sources of illumination.

A simple technique previously used by the author involves creating a black box (Fig. 5). The box is painted matte black on the inside and has a small hole in one face.

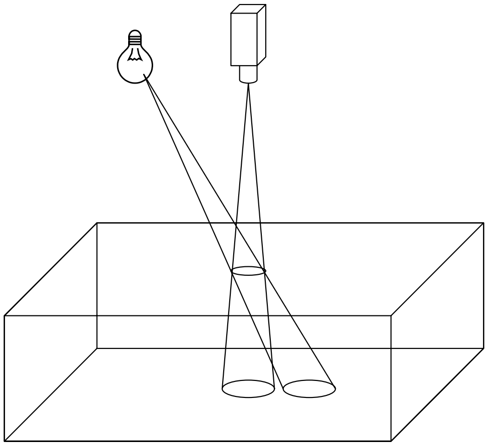

Figure 5. Black box black reference.

The camera views a portion of the far side of the box through the hole. The depth of the box is such that lamp light that passes through the hole does not directly illuminate the area viewed by the camera. Lamp light entering the hole is scattered inside the box and is absorbed by the black paint so that very little of it ever reaches the camera. A large box with a small hole produces a black reference region that is very close to 0% reflectance.

Calibrated Reflectance Targets. Using two targets with known reflectance values, the linear camera response can be extrapolated to estimate the absolute black response. For example, one may use targets with known reflectance values of $R_1 = 2\%$ and $R_2 = 99\%$. If the corresponding (average) linear pixel values over the targets are T_1 and T_2, then the estimated black response is $T_1 - R_1(T_2 - T_1)/(R_2 - R_1)$.

To eliminate effective aperture effects, the two reflectance targets should be placed in the same position in separate images (assuming constant illumination). If a single image is used, then the targets should be placed in comparable positions relative to the optical axis of the camera and the illumination should be uniform for both targets.

It is also important to ensure that the illumination and viewing conditions in which the calibrated target is used are consistent with the original calibration method. The reflectance of a surface depends on the angles of illumination and viewing, so if the original calibration used a different configuration, then the calibration data may be inaccurate for the particular application.

Measuring the Effective Aperture and Sensitivity

As discussed above, the effective aperture depends on the radial position of the sensor element relative to the optical axis. The effective aperture can be modeled as a combination of vignetting (8) and the $\cos^4$ effect (7). However, the model parameters depend on the lens design, and it is difficult to ensure their accuracy. An alternative approach is to measure the effective aperture and sensitivity as a combined per-pixel response field.

For measurement, a flat radiance field is required. A flat Lambertian surface under uniform illumination is suitable. After linear correction and black response subtraction, an image of the flat radiance field records the combined sensitivity and effective aperture for each pixel. To avoid the effects of small imperfections in the Lambertian surface, the surface or the camera may be moved between taking multiple images. Linear correct these images, subtract the black response, and combine them on a per-pixel basis using a robust technique such as a trimmed mean. The result is a response field image that may be normalized to have a maximum value of one. To calibrate subsequent data images, first apply linear correction and subtract the dark response, then divide corresponding pixels by the response field. This process yields relative radiometric calibrated images.

It may be difficult to obtain uniform illumination. If it is not possible to obtain a large, truly flat radiance field, then a small time-invariant flat radiance field can be used to measure the response field of small areas of the sensor array, one area at a time, by changing the camera view angle between sets of images.

Absolute and Reflective Radiometric Calibration

The final step for absolute or reflective radiometric calibration involves multiplying the relative radiometric image by a scale factor. To obtain the scale factor, capture and calibrate a reference image that contains an appropriate reference target. For absolute calibration, a radiance standard is appropriate, such as a calibrated lamp or the sun (22), whereas reflective calibration requires a reflectance standard such as a calibrated target. The required scale factor is the reciprocal of the average pixel value that corresponds to the standard in the reference image. The camera and lens settings must be the same for all images, including the reference image.

APPLICATIONS OF RADIOMETRIC IMAGING

Object Shape Estimation

Shape from shading estimates the local surface orientation of Lambertian objects. For such surfaces, the reflected light is proportional to the cosine of the angle between the local surface normal and the incident light ray. Assuming smoothness of the object surface, an under-constrained set of equations can be solved to estimate the local surface orientation over the object. Shape from shading requires relative radiometric calibration to relate the reflected light values to each other and to estimate the surface orientation.

Photometric stereo is similar to shape from shading but uses more than one image. Each image is taken with a different light source, which provides multiple light measurements at each point. With at least three light measurements, the local surface orientation can be calculated directly from the light measurements. Photometric stereo also requires relative radiometric calibration.

Remote Sensing

Remote sensing uses multispectral data to measure properties of the earth's surface such as identifying minerals, crops, or other land use. Each material to be identified has a characteristic spectral reflectance signature. To recognize particular spectral signatures, the image data must be radiometric. Both relative and absolute radiometric calibrations are used (2) with the ultimate goal of reflective calibration. Slater et al. (22) discuss absolute calibration using the sun as a reference light source.

Color Measurement

Color measurement uses reflected light to measure the color of objects. Color may be expressed in RGB color space or converted to another color space such as CIE $L^*a^*b^*$. The color space conversion assumes a linear (relative radiometric) RGB color measurement. The image is calibrated to produce color measurements using color standards for reflective calibration. Uneven illumination may also be corrected (23).

Subpixel Edge Detection

Subpixel edge detection locates edges in images to a fraction of a pixel position. The technique is based on the profile of the pixel values across the edge. Because of lens limitations and the dimensions of the sensor elements, pixel values close to an edge are illuminated by light from both sides of the edge. For a straight edge, the subpixel edge location is the position where the pixel receives equal portions of light from each side of the edge. If the camera response function is linear, then the corresponding pixel value is halfway between the pixel values that represent the regions on either side of the edge. However, if the camera response function is nonlinear, then the edge response curve is distorted, and the subpixel edge location may be incorrect. Relative radiometric calibration produces linear pixel values, which are suitable for accurately estimating the subpixel edge location.

Image Stitching and HDR Imaging

Image stitching (24) combines multiple overlapping images of a scene to produce a single, large image. It has applications that range from consumer digital photography, in which panoramas are created by stitching images together to scientific applications in space exploration. Images to be stitched together must be transformed to have the same exposure and CRF to eliminate brightness steps at the stitch lines.

HDR imaging (14, 15, 21) combines multiple images of the same scene to provide an increased dynamic range. For example, one image may be taken with a short exposure time to expose a sunlit scene of a hillside correctly while underexposing the interior of a tunnel in the hillside. A second image may be taken with a long exposure time to expose the interior of the tunnel correctly while overexposing the brightly lit hillside. Combining the two images would provide a HDR image that shows both the hillside and the interior of the tunnel.

Radiometric calibration is sufficient but not required for these applications. It is sufficient that all the images have the same arbitrary monotonic relationship between scene radiance and pixel values. In practice, images are transformed to a common brightness scale that may include an unknown gamma encoding. Comparametric analysis may be used to derive the transformation from a collection of spatially-registered images with different unknown exposures. These images may be the source images themselves (21, 25).

RAY TRACING ACCELERATION TECHNIQUES

INTRODUCTION

Today, ray-tracing techniques (RTT) are being used successfully in many computer applications (1–4). The most common applications are static and dynamic scene visualizations, movies, commercials, and video games, wherein near perfect realism can be achieved. Virtual reality is also an important field for the application of RTT, not only for recreational purposes, but also for scientific and engineering research. Another field in which RTT play a crucial role is in the study of acoustic and electromagnetic wave propagation in complex scenarios (5). The deployment of modern radio communication networks, particularly for communication or surveillance wireless systems, requires high-quality RTT that are well fitted to the particular needs of this field.

The aforementioned RTT applications (including many others that are not cited or that will be developed in the future) have a common need for computational efficiency in the vein of central processing unit time and memory usage. Often, very complex scenarios are visualized or analyzed in “real time” for many observation points or illumination sources.

This article is devoted to presenting a tutorial view of modern RTT. Although all the aforementioned techniques share the common need for computational efficiency, the geometry and morphology of scenarios, the nature of the lightsources, and the phenomenology of wave transmission and scattering can differ drastically. Each application requires a partially or completely specialized RTT.

In the next section, we consider the different kinds of geometries, morphologies, and qualities of illumination found in ray-tracing problems. Then, we introduce ray-tracing mechanisms to elucidate the different tasks involved in successfully applying RTT. The problems and corresponding complexity of these tasks in typical scenarios are covered in the section on problems and complexity of RTT, wherein the two main subproblems associated with RTT are discussed: flash-points searching, that is, searching for reflection, diffraction, and transmission points, and ray shooting query, which consists of determining whether a given segment is cut by any entity of the scene. The two main strategies for addressing the first subproblem are discussed in the sections on RTT strategies for the *flash-point searching* (FPS): the shooting and bouncing of rays and the solution of the inverse problem. Several efficient techniques for solving a ray shooting query are outlined in the section on Algorithms to reduce the computationalcost. The section on the angular Z-Buffer algorithm introduces the angular zeta buffer algorithm as a solution to the inverse problem strategy and also as a tool for flash-point searching. Finally, the last section compares the techniques presented in the previous two sections.

RTT SCENARIOS. DESCRIPTION OF THE GEOMETRY

The data that describe a scenario can be defined in a raster or a vector format (6). For the raster format, a scenario is divided into cells (i.e., pixels). For the vector format, the scene is defined by a set of geometrical entities (i.e., surfaces or volumes). Scenarios will be defined using the vector format for RTT applications. Several algorithms are available to transform raster formatted scenes into vector scenes (7).

Flat-facet models define the geometry of many visualization applications. Flat-facet models are also employed in many electromagnetic tools for analyzing radio propagation or for studying the scattering from complex structures. This method can approximate an object’s curved surface using interconnected sets of plane facets and straight edges. This approach has been used ubiquitously because of its simplicity. The high number of flat facets, which can range from the thousands to the millions, required to approximate a complex curved object can generate artificial edges (edges between two approximating facets) that are not present in the real curved object. Figure 1 depicts an example of a DC 10 aircraft modeled by plane facets. A total of 2317 facets are required to model the object accurately.

As a result of flat facet-induced error, some computer graphics applications, especially in the automobile and aerospace industries, and industries using computer-aided design software, require the usage of curved surfaces, which are often in the format of nonuniform rational b-spline surfaces (NURBS) (7,8). Using NURBS as an approximating surface set provides an accurate representation of a real object that employs significantly less information (on the order of a thousand curved surfaces), and mitigates the inherent problem of flat-facet approximation-induced artificial edges. Figure 2 shows the same aircraft from Fig. 1, but it is modeled by NURBS surfaces. Only 168 surfaces are necessary to represent the object accurately, and no artificial edges are generated. The primary disadvantage of the NURBS representation is that the computational cost of the ray-tracing is much greater than that of the flat facets model (5,9,10). The details of this will be discussed later.

RAY-TRACING MECHANISMS

A ray-tracing mechanism is defined as a set of coupling rays that link a source with an observation point (see Fig. 3). As illustrated in Fig. 3, these rays can be a direct ray from the source to the observation point, simple effect rays, double effect rays, and higher-order effect rays. Simple effect ray-tracing mechanisms are the reflected rays, the transmitted rays, and the diffracted rays. Reflected rays are defined as rays that leave a source, are reflected in a facet, and then arrive at the observation point. Rays that link the source and observation point by transmission through a facet are transmitted rays. Rays that link the source and observation point by scene edge diffraction are diffracted rays. Double or higher-order effects are combinations of simple effects.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

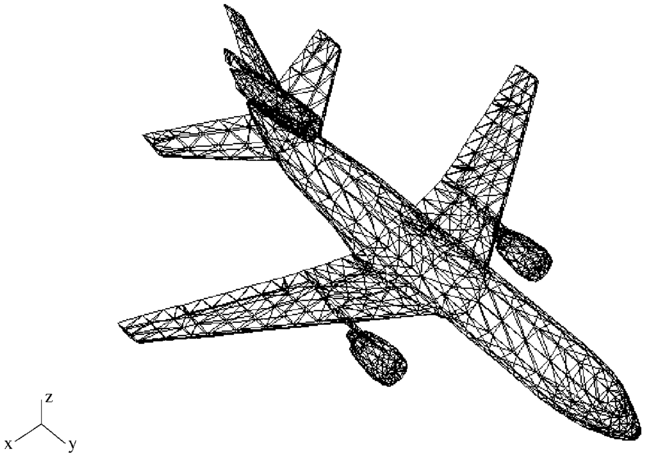

Figure 1. Geometrical model of a DC10 plane using 2317 flat facets.

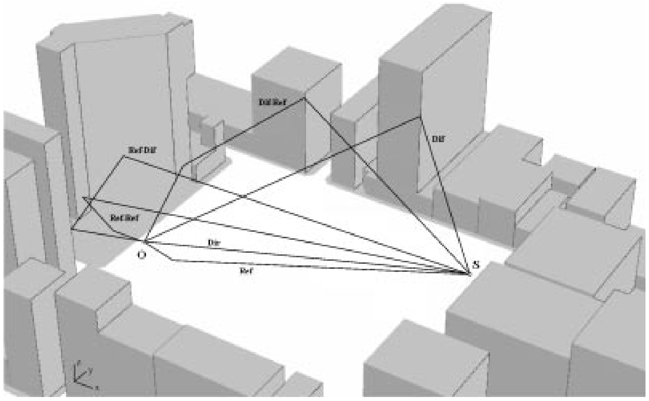

Figure 3. Example of ray-tracing mechanisms on an urban scene given the position of the source and the observation point. Only simple (direct, reflected, and diffracted rays) and double (double reflected, reflected-diffracted, and diffracted-reflected rays) effects are depicted in the figure for the sake of simplicity.

For example, a third-order ray can be a reflected-transmitted-reflected ray. The points involved in each ray are known as flash points. Shadowing is another relevant RTT mechanism; a ray is shadowed if any segments forming that ray are occluded by any of the scene facets. When occlusion occurs, the ray must then be discarded because it does not contribute to the illumination of the observation point. If the ray mechanism under analysis includes transmission, then the transmission facet should not be considered in the shadowing test, and the contribution of that ray should be considered for the illumination of the observation point.

Among the aforementioned mechanisms, the most common are the shadowing and diffuse reflection of rays that leave illuminating sources. The shadowing discard, as not visible from an observation point, includes many facets of a scene. The diffuse reflection permits a visualization of all points on every surface visible from the observation point. Transmission through surfaces (transparency), refractions in volumes, double, triple, and higher-order reflections on surfaces, may also be required for visualization. For RTT electromagnetic applications, the number of reflections, transmissions, and combinations of both is usually high, which require a different treatment. Reflections are treated as specular; however, if the surface is not smooth with respect to the wavelength, part of the energy is reflected in nonspecular directions. Models can be used to compute the energy fraction reflected along the specular direction for ray tracing, but energy reflected along nonspecular directions is not used in RTT, which is a significant limitation of this technique in electromagnetic applications. Furthermore, these applications require an accurate evaluation of the path length for phase computation, because illumination is achieved using coherent waves. Coherent waves can interfere destructively depending on their relative phase, whereas incoherent waves interfere constructively. Additionally, wedge-edge diffractions (11) play an important role in these applications because of the broad angular expansion of the waves after diffraction. This phenomenon has been demonstrated to supply the illumination in many areas of a scene.

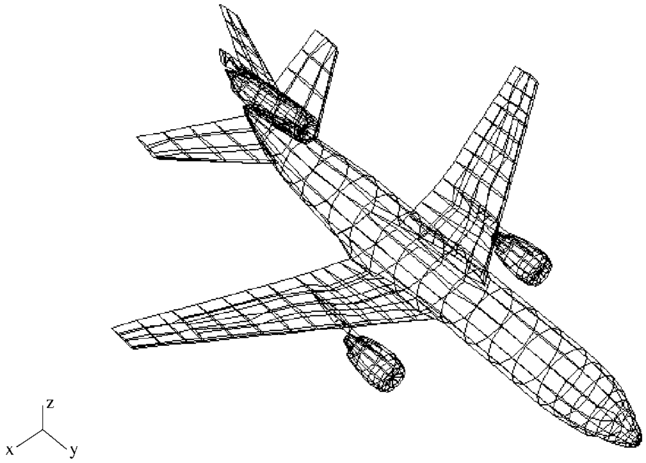

Figure 2. Geometrical model of a DC10 plane using 168 NURBS surfaces.

PROBLEMS AND COMPLEXITY OF RTT

The main problem inherent to RTT involves the fact that a complex scene is composed of many flat and/or curved facets illuminated by a source (see Fig. 4). We need to know all the coupling ray mechanisms that link the source with the observation point. These rays, as stated in the previous section, can be the direct ray from the source to the observation point, simple effect rays, double effect rays, and higher-order effect rays. Thus for a given problem, two subproblems must be solved:

1. We must establish the set of all facets that are involved in each ray mechanism (e.g., in a double reflection this set is formed by two facets). Furthermore, some additional information of the intersection point of the ray with its associated facets set must be obtained (e.g., intersection point coordinates, radii of

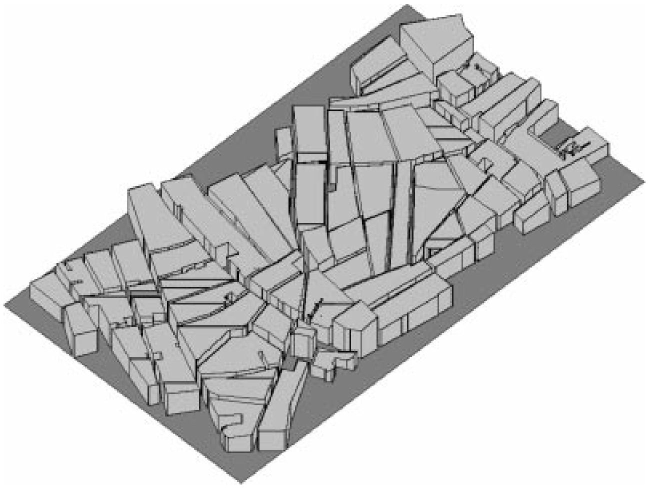

Figure 4. Example of an urban scene defined by several thousand facets. The fields radiated by a Base Station located at the top of a high building requires the evaluation of tens of thousands of observation points along the streets of the urban scene.

curvature, and surface roughness at those points). This part is known as *flash-point searching* (FPS) and is accomplished by using the strategies described in the next section.

2. We must conduct the shadowing analysis, as described in the previous section, to determine whether the rays contribute to the illumination of the observation point; if so, they must be discarded. To solve this problem, we must apply intersection tests to determine the facets that potentially can occlude a ray. This problem is known as the *ray-shooting query* (RSQ)

The RTT problem is usually solved for many observation points and for many source positions. Therefore, the level of complexity is very high.

In the vein of the first subproblem (the FPS), if we have a scene with N_f facets and N_e edges (see Fig. 4) for a given source and intersection point, then every facet can be involved with a reflected or transmitted ray, and every edge can be involved with diffracted rays. Therefore, they all must be investigated to determine whether these effects are present. The computational cost for reflection, transmission, and diffraction is on the order of $2N_f + N_e$. Once a simple effect is produced, a double effect can appear with any element in the scene except the one from which the simple effect originally took place. The computational cost to determine simple effects is on the order of $(2N_f+N_e)\cdot(2N_f+N_e-1)$. Following this thought process, the computational cost to solve the subproblem for an n-order effect is proportional to $(2N_f+N_e)\cdot(2N_f+N_e-1)\ldots.\ (2N_f+N_e-r+1)$, which can be greater than the computational capacity of a powerful computer running for several days (a typical value for N_f is 100,000, whereas 3 or 4 are common values for n in some electromagnetic applications).

With respect to the RSQ, the number of intersection tests that a naïve algorithm (an algorithm that exhaustively checks all facets) requires for determining whether a direct or simple effect ray is occluded by any facet of the scene is of the order of N_f. For a n-order effect ray, the number of intersection tests may become as high as $n \times N_f$. On the other hand, the number of facet sets that can produce an n-order effect is $N_f(N-1)\ldots.(N_f+1-n)\approx(N_f)^n$. Considering the previous typical value for N_f, a naïve procedure that exhaustively checks all the potential facets sets for a given ray will require unaffordable computer resources.

Therefore, for both subproblems, efficient algorithms should be used to reduce the computational cost of ray tracing. The following sections provide a description of the most efficient procedures developed therein.

RTT STRATEGIES FOR THE FPS

The complexity of the first subproblem can be reduced drastically by using modern RTT algorithms. Two main strategies are implemented in these algorithms:

(a) the shooting and bouncing of rays (SBR) strategy (11,12)

(b) the solution of the inverse problem (SIP) strategy (13)

The SBR strategy is illustrated in Fig. 5. This technique is based on shooting many rays in radial directions from the source. The path followed by each individual ray is obtained. This technique only considers the contribution from the reflections in the specular direction. Therefore, applying this technique, when a ray hits a surface, its path is redirected following Snell's law of reflection (14), and if the surface is penetrable, the law for transmission. The ray path is followed until it leaves the volume of the scene or when it has suffered a predetermined number of reflections. A ray is considered to contribute to the total illumination

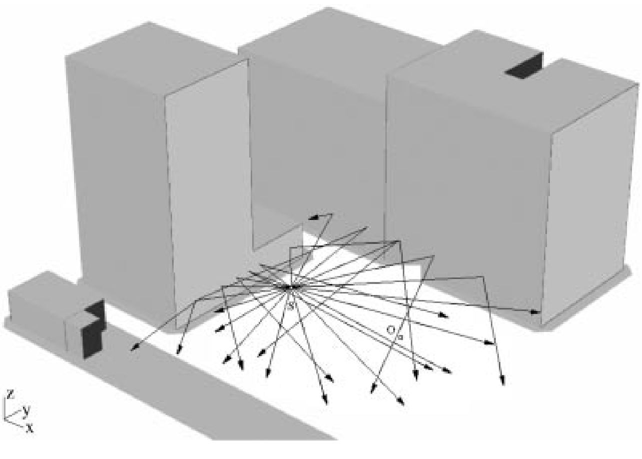

Figure 5. Example of SBR on a simple urban scene. Many rays are launched from the position of the source (S), and only the rays that pass close to the position of the observation point (O) are considered to illuminate that point.

strength at a given observation point when it passes near that point (5,15). The contribution of the ray is added to the total strength of the illumination at the observation point. This contribution is computed by considering the distance from the observation point to the ray and other ray parameters, such as the spread factor (which determines the variation of the amplitude of the ray because of the ray propagation and depends on the length of the ray path) and the number and nature of the reflections that the ray has suffered before approaching the observation point. This procedure estimates (or extrapolates) the parameters of the ray that has the same ray path history (e.g., reflected/transmitted on the same surfaces) and impacts the observation point. The estimation of the ray parameter is usually enough to obtain a good approximation of the contribution intensity of the ray to the total illumination at the observation point when the illumination is composed of incoherent waves. The SBR strategy works well for many applications of visualization of scenes, wherein the ray effect order is not greater than two or three (and often the simple reflection is enough to describe the problem). Also, in these applications, the illumination is incoherent light, which simplifies the evaluation of the ray contribution because no phase computation of the field is needed. The phase evaluation requires a very precise computation of the path length, which is difficult to obtain using the SBR strategy. In any case, the SBR needs to shoot an extremely dense beam of rays from the source point covering the entire spatial angle that illuminates the scene; typically more than 50,000 rays are shot.

The philosophy of the SIP strategy is different. Instead of shooting many rays from the source to find those that reach the observation point, the SIP attempts to solve the following inverse problems:

- Determine whether the direct ray connecting the source and observation points is occluded.
- Find all facets of the scene where reflected (or transmitted) rays can link the source and the observation points. After identifying these surfaces, the ray paths of the reflected (or transmitted) rays are obtained.
- Find all edges of the scene that can link the source and the observation point by diffraction. Determine the corresponding ray paths.
- Find all sets of facets that can join the source and the observation points by a second or higher order coupling mechanism and the corresponding ray paths.

The total strength of illumination is computed by adding the contribution of all ray paths found that link the source and the observation points. A rays path that connects the source and the observation points through reflections (or transmissions) can be computed in two different ways: using the image method for the case of a flat facets (5) or by minimizing the total length of the path (16) for curved facets.

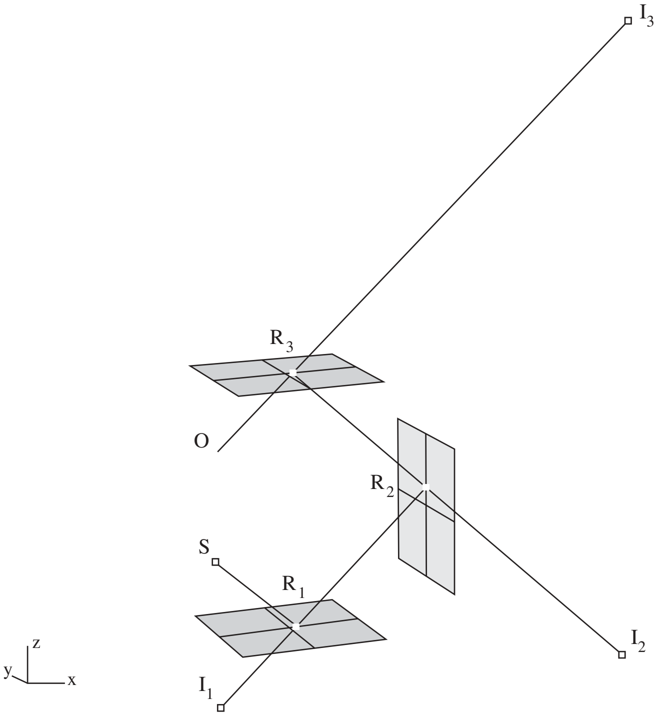

Figure 6. Example of the ray-tracing of a triple reflection using image method. Q1

The image method is based on image theory, which states that, given a source point and a flat facet, the reflected rays in the facet can be considered as rays radiated by the image source. The image source is a virtual source whose location is the specular image of the original source with respect to the plane that contains the flat facet. Once obtained, and given the observation point and image position, the position of the reflection point for that observer can be obtained easily as the intersection of the segment that links the image with the observation point and the facet. These procedures can be generalized to obtain multiple reflections, simply by obtaining the nth-order image of the source, and from that, obtaining the complete trajectory of the multiple-reflected ray. Figure 6 illustrates this procedure.

If curved facets are used to model the scenario, then the image method cannot be applied. The trajectory of the ray is obtained using the generalized Fermat's principle (14). This principle states that the length of the ray path that links two points is a minimum. A distance function can be defined whose value is the length of the ray as a function of the position of the points over the curved facet. The idea is to find the point whose distance function is a minimum, which determines this point as a reflection point. This procedure has two disadvantages: First, the computational cost associated to the minimization process is high, and second, the possibility of local minima in the distance function can provide an erroneous solution for the position of the reflection point. Therefore, this procedure should be implemented with these points in mind, because no alternative can be used if curved facets are present in the scenario.

The SIP strategy is more complex and difficult to implement than the SBR because it solves inverse problems. However, the SIP is superior to the SBR for problems that require the illumination phase, diffractions, and high-order coupling. These requirements occur in many applications of

RTT for radio-wave propagation and other electromagnetic analyses, wherein the illumination has a coherent nature and therefore the phase plays a fundamental role. The SIP strategy permits a precise computation of all ray parameters for rays that arrive at the observation point. The application of the SBR strategy is easy but less accurate than the SIP strategy.

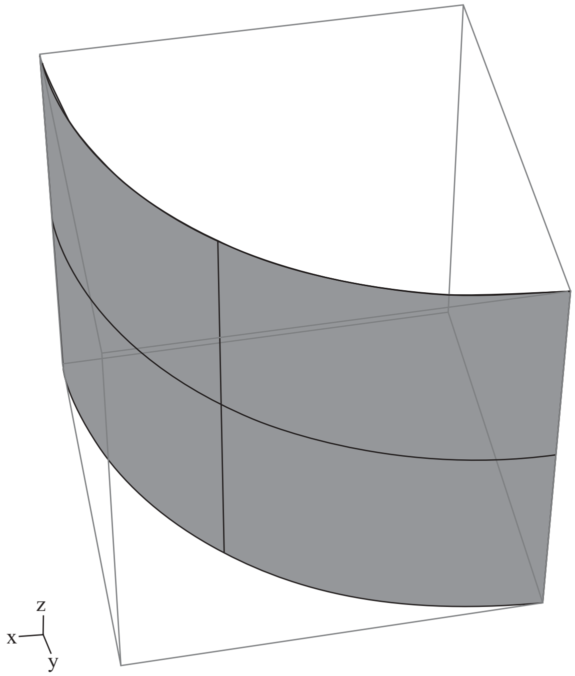

Figure 7. Example of the bounding box that encloses a curved surface.

ALGORITHMS TO REDUCE THE COMPUTATIONAL COST ASSOCIATED TO THE RSQ

The computational costs of RSQ have directed research to develop many powerful algorithms, some of which will be summarized here. It is important to note that the aim of these algorithms is to only reduce the cost associated to the second sub-problem described in the section on the Problems and complexity of RTT. These algorithms only address the shadowing problem (which appears in both SBR and SIP) and their application is the same, independent of the ray mechanism. The searching of the ray path associated to these mechanisms is not improved by these algorithmic techniques.

RSQ algorithms are usually applied in a preprocessing phase and in an execution phase (4). In the preprocessing phase, the input data structure that contains the information of the entities (usually facets) that define the geometry is reorganized. This reorganization groups close and/or visible geometrical entities together in the data structure, and/or relations of proximity or visibility are associated to the appropriate entities.

The simplest RSQ algorithm encloses completely each entity of the scene in a bounding box, preferably in a parallelepiped of minimum volume, with sides perpendicular to the Cartesian absolute system chosen to represent the geometry (see Fig. 7). The bounding box RSQ is compatible with other RSQ algorithms. It is performed as follows: Before checking the intersection of the ray with the curved facet, by means of a rigorous checking procedure, it is determined if a ray impacts the box. Obviously, the ray cannot be occluded by the surface if the check is negative. This surface is not considered in the shadowing test, which avoids more time-consuming procedures for checking the possible intersection of the ray with the facet.

Most RSQ algorithms are based on a volumetric spatial partition (VSP) of the scene (17). After this division, the scene is split into small subvolumes that contain groups of scene entities, with some subvolumes potentially empty. To determine whether a segment is occluded by one or more scene entities, we only need to check the entities contained in the subvolumes that the segment crosses. Figure 8 shows an example of the division of a simple two-dimensional (2-D) scene in voxels. An example of the ray tracing between a source (S) and an observation point (O) is depicted in the figure. It can be noted that only the entities contained in the voxels that the ray crosses (facets 3, 4, 9, 10, 11) are involved in the RSQ, which reduces the complexity of this task.

Many efficient RSQ algorithms are based on VSP. The major difference between these algorithms is the strategy used for space division, which can significantly impact final algorithm efficiency. One of those algorithms is binary space partitioning (BSP). BSP requires the space to be divided into subvolumes in successive steps such that each subvolume is split in two halves (binary partitioning). The BSP has two versions. In the polygon-aligned version, the space subdivision in two halves is made considering the regions above and below each flat facet of the scene (17). This version is not applicable when the scene has curved surfaces. In the axis-aligned version, a division into two halves of a subvolume is made by a plane perpendicular to

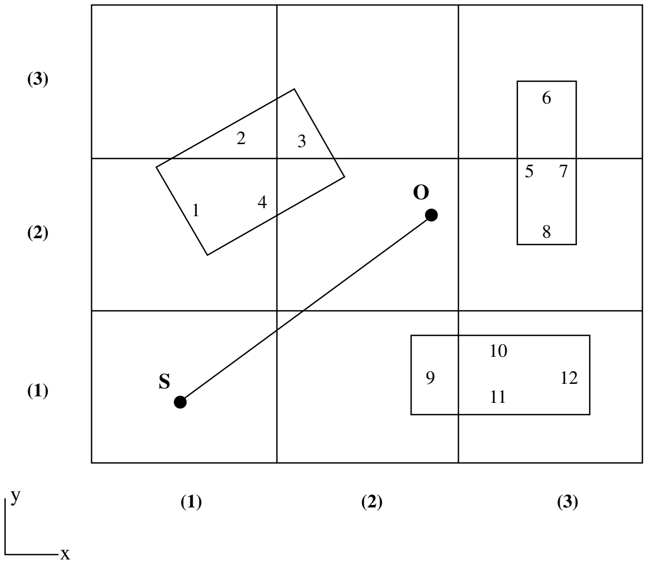

Figure 8. Example of the application of the SVP for a simple 2-D scene. The scene is divided in voxels.

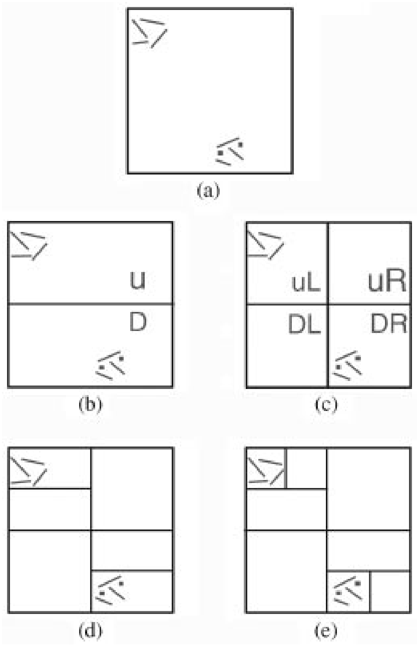

Figure 9. Example of spatial partition of and scene using the BSP axis-aligned technique. The scene has only two groups of entities, which are indicated by the small straight lines in the top and in the bottom of the scene rectangle.

the Cartesian coordinate system that defines the scene (18). Figure 9 shows the application of the axis-aligned version of BSP to a simple 2-D scene, and Fig. 10 presents the associated BSP tree. The subdivision in a level tree is perpendicular to a coordinate axis; the axes alternate in consecutive tree levels. Each node of the BSP tree corresponds to a division of a subvolume. When a subvolume is empty, it is not subdivided, and its tree node becomes a tree leaf. This tree is very helpful in the RSQ because, to determine the intersection of a ray segment with one of the entities of the scene, only the entities that belong to the low-level subvolumes of the BSP tree that the segment crosses. For example, in Fig. 10, if a segment joins two solid points in the subvolume of node DRDL when applying the BSP, only the entities in the subvolume DRLD must be checked, obviously reducing considerably the number of intersection tests to be performed.

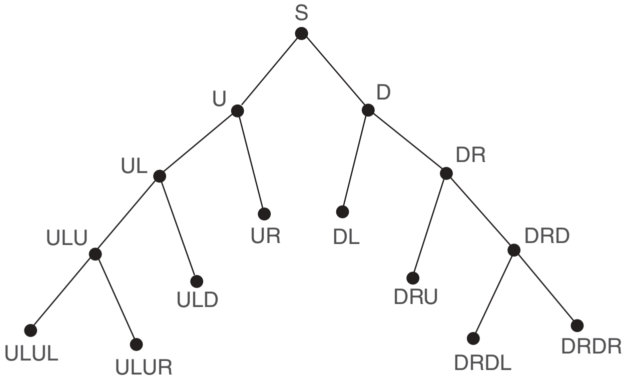

Figure 10. BSP tree for the case of Fig. 6.

Today, one of the most efficient algorithms for solving the RSQ is the *kd*-tree algorithm (19), which is similar to the axis-aligned version of the BSP. The difference between these algorithms is that, during the preprocessing phase of the *kd*-tree, the subvolumes in each binary division do not necessarily have the same size. The size of the subvolumes is fitted to give the bigger size to the empty or less populated subvolume.

Octree Space subdivision is another technique for solving the RSQ that is similar to the BSP, except that now each subvolume is split into eight small subvolumes (called octrees) by the three coordinate planes (20). Other variants of the VSP are the division of the scene volume into a uniform grid of equal-sized sub-volumes (21). Simultaneously, each subvolume can be split into a new grid of uniform sub-volumes. This process can be repeated several times to form hierarchical grids (22).

THE ANGULAR ZBUFFER ALGORITHM (AZB)

The AZB algorithm deserves special attention because it possesses features markedly different compared with the techniques presented in the previous section. The main advantage of this algorithm is that, not only can it be used to solve the RSQ problem (second subproblem of the RTT), but also it is especially applicable to the SIP strategy to solve the FPS (first subproblem) of the RTT. The AZB algorithm is based on the light buffer technique (23) used in computer graphic design for solving problems of hidden lines or surfaces to determine which areas of a given environment are visible from a point in space (the source).

The algorithm is based on the division of the space observed from the source point or from the facets in spherical sectors. These spherical sectors are called anxels, and they are defined by the spherical coordinates θ and ϕ with respect to the coordinate system defined by the source or by the facets (see Fig. 11) (17). The number of anxels depends of the angular increments Δθ and Δϕ) that define the size of the anxel:

$$\begin{aligned} N_\theta &= 180/\Delta\theta; N_\phi = 360/\Delta\phi \\ & N_{\text{anxels}} = N_\theta * N_\phi \end{aligned}$$

The coordinates θ and ϕ define a plane called the AZB plane that contains the objects located in each anxel, and it identifies the directions where the object is located, taking the source point or each facet as reference. The AZB plane of a point (like the source) is easier to obtain than the AZB plane of a facet.

The 2-D scene with planar facets depicted in Fig. 12 illustrates AZB of the source point. S marks the position of the source. If the space is divided into eight angular regions, each region will contain the facets given in Table 1 that contain the information of the so-called AZB matrix associated with the source point. For example, in anxel 2 (angular margin from 0° to 45°), there are only two facets. Then, to determine whether a direct ray reaches an observation

point placed in anxel 1, the RSQ must only be performed for the two facets contained in that anxel, instead of for the 16 facets that appear in the scene. The facets that do not satisfy the criterion of the back face culling (5) cannot hide a ray traced from the source to a given observer, and they are not stored in the AZB matrix. For this reason, facets 11 and 12 have not been considered in the table for anxel 1.

This idea can be generalized easily to a three-dimensional (3-D) case. If a model composed of planar facets is considered, the spherical coordinates of the facet vertices are calculated, which define a window based on the minimum and maximum θ and ϕ coordinates ($\theta_{\min}$, $\theta_{\max}$, $\phi_{\min}$, $\phi_{\max}$) used to determine the anxel where the facet must be stored. If the scene contains curved surfaces, then the computation of this window becomes more complex. A good solution to this problem consists of enclosing the surface within a bounding box. Once the surface is enclosed, the eight vertices of the box can be considered for the creation of the AZB matrix by considering the spherical coordinates of the eight vertices as a whole, in a similar way to the vertices of a facet for the case of planar surfaces (see Fig. 13). All information that corresponds to the planar and the curved surfaces is stored in the AZB matrix, which can be considered as a grid in the coordinates θ and ϕ, as depicted in Fig. 14. Each vertex of an entity is placed in an element of the grid, and the entity will be contained in the set of elements of the grid defined by its vertices.

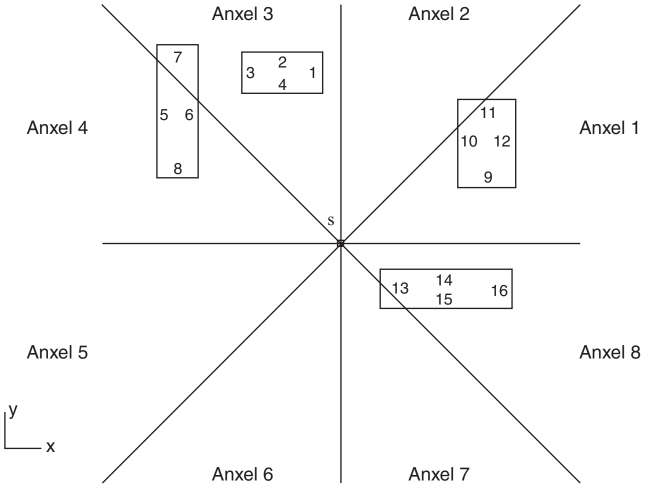

Figure 12. Example of 2-D scenario and additional division in angular sectors.

The application of the aforementioned algorithm is only valid for the analysis of direct ray shadowing because the source has been taken as a reference. Some modifications must be performed to apply this algorithm to reflected and diffracted rays. In reflection, the application of the algorithm is very easy for the planar entities of the scenario, and subsequently image method for reflection can be applied. Therefore, an AZB matrix can be built for every image in a given scenario. The only difference is that the space to be divided in this case, is only the region where the reflected ray can appear. The so-called reflection window defines this region (see Fig. 15).

The definition of the reflection window is more complicated for a curved surface. In this case, all possible directions of reflection have to be considered with respect to all points on the surface. To avoid this, an AZB matrix is

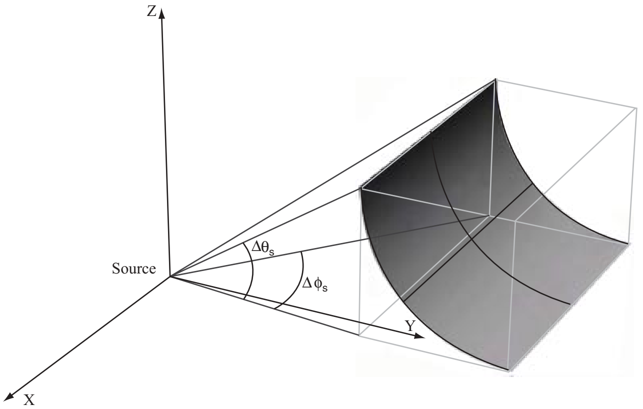

Figure 13. Angular margins of a surface considering the enclosing box.

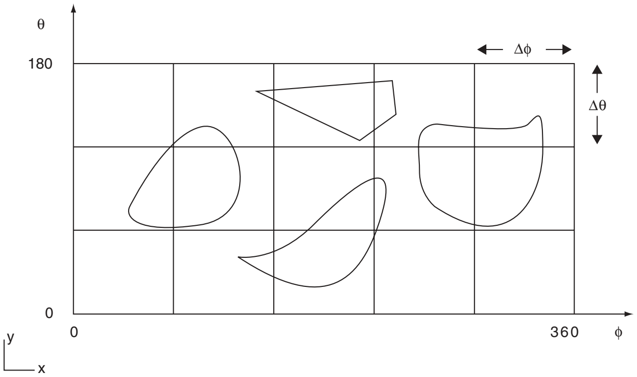

Figure 14. Example of the storage of different surfaces in a grid defined by the AZB matrix.

created for each of the eight vertices that define the box that encloses the surface. The angular margin for the total reflection window is obtained as the union of the regions defined by each of the vertices of the box (see Fig. 16). More details about the complete procedure to create this window can be found in Reference 24.

In the case of a diffracted ray, a diffraction window must be created from the properties of this effect. When a ray arrives at an edge, infinite rays are diffracted, forming a cone whose vertex is the diffraction point, the axis is the edge itself, and the angle is the same as that formed between the edge and the incident ray. This cone is called "Keller's cone" (14). The region contained within this cone defines the diffraction window. New angular coordinates must be considered to limit this diffraction window according to these properties. This coordinates are α and β, defined in Fig. 17. Therefore, analogous to the reflection case, there is a diffracted window for every illuminated edge that corresponds to an AZB diffraction matrix.

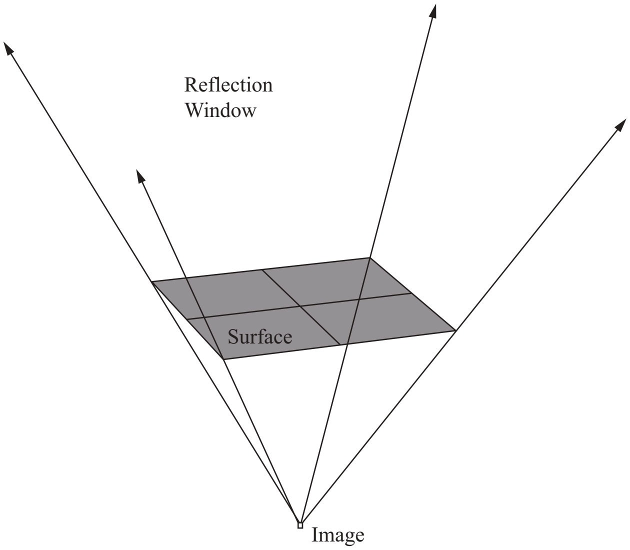

Figure 15. Reflection window for a planar surface.

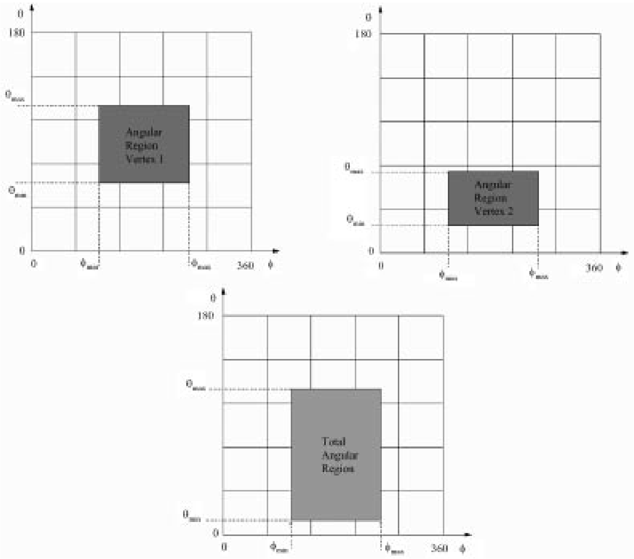

Figure 16. Generation of the total angular margin of a surface from the angular margin of two points. The procedure can be generalized to the eight vertices of the enclosing parallelepiped.

COMPARISON BETWEEN THE DIFFERENT ACCELERATION RTT

In this section, a comparison between the features of different RTT is outlined. The idea is to help the reader select the most suitable technique for their application. This comparison is performed considering only the features related to the RSQ, because only the AZB technique has been presented to accelerate the FPS.

First of all, it can be stated that the BSP technique is efficient for 2-D scenes and making the BSP tree is relatively easy. Unfortunately, for 3-D scenarios, this task is more complex because finding an optimum tree is difficult. Often, these trees are long and with many broken facets, and they are not useful for efficient analysis.

The VSP, when applied to large scenes, requires many voxels to load a low amount of facets per voxel. Furthermore, when the source is far away from the observation point, the number of voxels that cross the ray is high and,

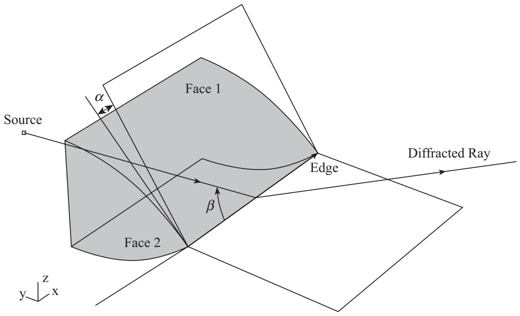

Figure 17. Coordinates α and β that define the AZB window for diffraction.

therefore, the amount of facets that are considered in the intersection test is enormous. Fortunately, VSP has the advantage of a low memory requirement, since it only needs a matrix that depends only on the scene. In contrast, the AZB technique generates a matrix depending on the source (antenna, image, edge, etc.). For higher-order effects, and when the number of sources is large and the number of observation points involved in the effect is low, it is not efficient to create the AZB matrices. In these cases, the SVP method can be combined with the AZB.

Finally, the AZB technique has the advantage, with respect to the other methods, of only loading the facets not shadowed by illumination or eclipse (those that satisfy the back-face culling criterion as explained in the previous section), because the space is divided taking the source as a reference. This method allows a reduction in the number of facets stored in each matrix.

CONCLUSIONS

A short summary of RTT has been presented. The complexity of the ray tracing has been discussed in the context of its varied applications to different kinds of scenarios. Because of this complexity, efficient techniques are necessary for implementing RTT, and most of this article has been dedicated to describing the most commonly used among these techniques. Finally, ray-tracing acceleration techniques have been presented, with special attention dedicated to AZB because of its features that permit the reduction of the computational cost associated with the two subproblems related to the RTT. Readers interested in additional investigation of this subject are encouraged to read the cited works as well as References 25–27.

SCALE-SPACE

THE NEED FOR MULTI-SCALE REPRESENTATION OF IMAGE DATA

An inherent property of real-world objects is that only they exist as meaningful entities over certain ranges of scale. A simple example is the concept of a branch of a tree, which makes sense only at a scale from, say, a few centimeters to at most a few meters; it is meaningless to discuss the tree concept at the nanometer or kilometer level. At those scales, it is more relevant to talk about the molecules that form the leaves of the tree or the forest in which the tree grows. When observing such real-world objects with a camera or an eye, an addition scale problem exists because of perspective effects. A nearby object will seem larger in the image space than a distant object, although the two objects may have the same size in the world. These facts, that objects in the world appear in different ways depending on the scale of observation and in addition may undergo scale changes during an imaging process, have important implications if one aims to describe them. It shows that the notion of *scale* is fundamental to understand both natural and artificial perception.

In computer vision and image analysis, the notion of scale is essential to design methods for deriving information from images and multidimensional signals. To extract any information from image data, obviously one must interact with the data in some way, using some operator or measurement probe. The type of information that can be obtained is largely determined by the relationship between the size of the actual structures in the data and the size (resolution) of the operators (probes). Some very fundamental problems in computer vision and image processing concern *what* operators to use, *where* to apply them, and *how large* they should be. If these problems are not addressed appropriately, then the task of interpreting the operator response can be very hard. Notably, the scale information required to view the image data at an appropriate scale may in many cases be a priori unknown.

The idea behind a scale-space representation of image data is that in the absence of any prior information about what scales are appropriate for a given visual task, the only reasonable approach is to represent the data at multiple scales. Taken to the limit, a scale-space representation furthermore considers representations at *all* scales simultaneously. Thus, given any input image, this image is embedded into a one-parameter family of derived signals, in which fine-scale structures are progressively suppressed. When constructing such a multiscale representation, a crucial requirement is that the coarse-scale representations should constitute simplifications of corresponding structures at finer scales—they should not be accidental phenomena created by the smoothing method intended to suppress fine scale structures. This idea has been formalized in a variety of ways by different authors, and a noteworthy coincidence is that similar conclusions can be obtained from several different starting points. A fundamental result of scale-space theory is that if general conditions are imposed on the types of computations that are to be performed in the earliest stages of visual processing, then convolution by the Gaussian kernel and its derivatives provide a canonical class of image operators with unique properties. The requirements (scale-space axioms; see below) that specify the uniqueness essentially are linearity and spatial shift invariance, combined with different ways of formalizing the notion that "new structures should not be created" in the transformation from fine to coarse scales.

In summary, for any two-dimensional (2-D) signal $f : \mathbb{R}^2 \to \mathbb{R}$, its *scale-space representation* $L : \mathbb{R}^2 \times \mathbb{R}_+ \to \mathbb{R}$ is defined by (1–6)

$$L(x,y;\, t) = \int_{(\xi,\eta)\in \mathbb{R}^2} f(x-\xi, y-\eta)\, g(\xi,\eta;\, t)\, d\xi\, d\eta \qquad (1)$$

where $g : \mathbb{R}^2 \times \mathbb{R}_+ \to \mathbb{R}$ denotes the Gaussian kernel

$$g(x,y;\, t) = \frac{1}{2\pi t} e^{-(x^2+y^2)/2t} \qquad (2)$$

and the variance $t = \sigma^2$ of this kernel is referred to as the *scale parameter*. Equivalently, the scale-space family can be obtained as the solution of the (linear) diffusion equation

$$\partial_t L = \frac{1}{2}\nabla^2 L \qquad (3)$$

with initial condition $L(\cdot,\cdot;\, t) = f$. Then, based on this representation, *scale-space derivatives* at any scale t can be computed either by differentiating the scale-space directly or by convolving the original image with Gaussian derivative kernels:

$$L_{x^\alpha y^\beta}(\cdot,\cdot;\, t) = \partial_{x^\alpha y^\beta} L(\cdot,\cdot;\, t) = (\partial_{x^\alpha y^\beta} g(\cdot,\cdot;\, t)) * f(\cdot,\cdot) \qquad (4)$$

Because scale-space derivatives can also be computed by convolving the original image with Gaussian derivative operators $g_{x^\alpha y^\beta}(\cdot,\cdot;\, t)$ they are also referred to as *Gaussian derivatives*. This way of defining derivatives in scale-space makes the inherently ill-posed problem of computing image derivatives well-posed, with a close connection to generalized functions.

For simplicity, we shall here restrict ourselves to 2-D images. With appropriate generalizations or restrictions, however, most of these concepts apply in arbitrary dimensions.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

FEATURE DETECTION AT A GIVEN SCALE IN SCALE-SPACE

The set of scale-space derivatives up to order N at a given image point and a given scale is referred to as the *N-jet* (7,8) and corresponds to a truncated Taylor expansion of a locally smoothed image patch. Together, these derivatives constitute a basic type of feature within the scale-space framework and provide a compact characterization of the local image structure around the image point at that scale. For $N = 2$, the 2-jet at a single scale contains the partial derivatives

$$(L_x, L_y, L_{xx}, L_{xy}, L_{yy}) \tag{5}$$

and directional filters in any direction $(\cos\varphi, \sin\varphi)$ can be obtained from

$$\begin{aligned} \partial_\varphi L &= \cos\varphi\, L_x + \sin\varphi\, L_y \quad \text{and} \\ \partial_{\varphi\varphi} L &= \cos^2\varphi L_{xx} + 2\cos\varphi\sin\varphi\, L_{xy} + \sin^2\varphi\, L_{yy} \end{aligned} \tag{6}$$

From the five components in the 2-jet, four differential invariants can be constructed, which are invariant to local rotations: the gradient magnitude $|\nabla L|$, the Laplacian $\nabla^2 L$, the determinant of the Hessian det $\mathcal{H}L$, and the rescaled level curve curvature $\tilde{\kappa}(L)$:

$$\begin{cases} |\nabla L|^2 = L_x^2 + L_{yx}^2 \\ \nabla^2 L - L_{xx} + L_{yyl} \\ det\,\mathcal{H}L = L_{xx}L_{yy} - L_{xy}^2 \\ \tilde{\kappa}(L) = L_x^2 L_{yy} + L_y^2 L_{xx} - 2L_x L_y L_{xy} \end{cases} \tag{7}$$

A theoretically well-founded approach to feature detection is to use rotationally variant descriptors such as the N-jet, directional filter banks, or rotationally invariant differential invariants as primitives for expressing visual modules. For example, with v denoting the gradient direction $(L_x, L_y)^T$ a differential geometric formulation of *edge detection* at a given scale can be expressed from the image points for which the second-order directional derivative in the gradient direction L_{vv} is zero and the third-order directional derivative L_{vvv} is negative:

$$\begin{cases} \tilde{L}_{vv} = L_x^2\, L_{xx} + 2\, L_x\, L_y\, L_{xy} + L_y^2\, L_{yy} = 0, \\ \tilde{L}_{vvv} = L_x^3\, L_{xxx} + 3\, L_x^2\, L_y\, L_{xxy} + 3\, L_x\, L_y^2\, L_{xyy} + L_y^3\, L_{yyy} < 0 \end{cases} \tag{8}$$

A single-scale *blob detector* that responds to bright and dark blobs can be expressed from the minima and the maxima of the Laplacian response $\nabla^2 L$. An affine covariant blob detector that also responds to saddles can be expressed from the maxima and the minima of the determinant of the Hessian det $\mathcal{H}L$. A straight forward and affine covariant *corner detector* can be expressed from the maxima and minima of the rescaled level curve curvature $\tilde{\kappa}(L)$. With p denoting the main eigendirection of the Hessian matrix, which is parallel to the vector

$$(\cos\varphi, \sin\varphi)^{\sim} \left(\sqrt{1 + \frac{L_{xx} - L_{yy}}{\sqrt{(L_{xx} - L_{yy})^2 + 4L_{xy}^2}}}, \right. \\ \left. \operatorname{sign}(L_{xy}) \sqrt{1 - \frac{L_{xx} - L_{yy}}{\sqrt{(L_{xx} - L_{yy})^2 + 4L_{xy}^2}}} \right) \tag{9}$$

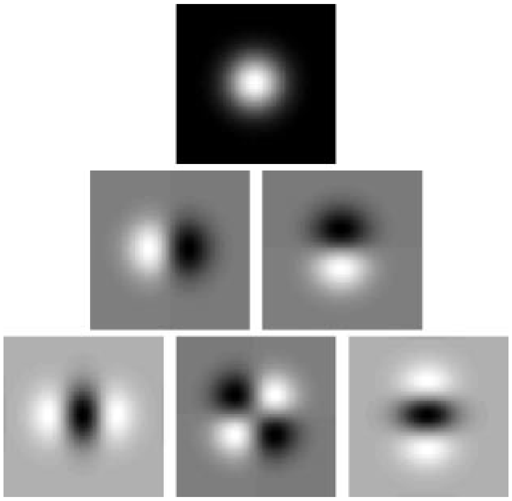

Figure 2. The Gaussian kernel and its derivatives up to order two in the 2-D case.

a differential geometric *ridge detector*at a fixed scale can be expressed from the zero-crossings of the first derivative L_p in this direction for which the second-order directional derivative L_{pp} is negative and in addition $|L_{pp}| \geq |L_{qq}|$. Similarly, valleys can be extracted from the zero-crossings of L_q that satisfy $L_{qq} \geq 0$ and $|L_{qq}| \geq |L_{pp}|$.

FEATURE-CLASSIFICATION AND IMAGE MATCHING FROM THE MULTISCALE N-IET

By combining N-jet representations at multiple scales, usually with the scale levels distributed by ratios of two when the scale parameter is measured in units of the standard deviation $\sigma = \sqrt{t}$ of the Gaussian, we obtain a *multiscale N-jet vector*. This descriptor is useful for a variety of different tasks. For example, the task of *texture classification* can be expressed as a classification and/or clustering problem on the multi-scale N-jet over regions in the image (9). Methods for *stereo matching* can be formulated in terms of comparisons of local N-jets (10), either in terms of explicit search or coarse-to-fine schemes based on differential corrections within the support region of the multi-scale N-jet. Moreover, straightforward (rotationally dependent) methods for *image-based object recognition* can expressed in terms of vectors or (global or regional) histograms of multi-scale N-jets (11–14). Methods for rotationally invariant image-based recognition can formulated in terms of histograms of multiscale vectors of differential invariants.

WINDOWED IMAGE DESCRIPTORS WITH TWO SCALE PARAMETERS

The image descriptors considered so far are all dependent on a single scale parameter t. For certain problems, it is useful to introduce image descriptors that depend on two scale parameters. One such descriptor is the *second-moment matrix* (structure tensor) defined as

$$\begin{aligned}\mu(x,y;\,t,s) &= \int_{(\xi,\eta)\in \boldsymbol{R}^2} \begin{pmatrix} L_x^2(\xi,\eta;\,t) & L_x(\xi,\eta;\,t)L_y(\xi,\eta;\,t) \\ L_x(\xi,\eta;\,t)L_y(\xi,\eta;\,t) & L_y^2(\xi,\eta;\,t)\end{pmatrix} \\ &\quad \times g(x-\xi,y-\eta;\,s)\,d\xi\,d\eta \end{aligned} \tag{10}$$

where t is a local scale parameter that describes the scale of differentiation, and s is an integration scale parameter that describes the extent over which local statistics of derivatives is accumulated. In principle, the formulation of this descriptor implies a two-parameter variation. In many practical applications, however, it is common practice to couple the two scale parameters by a constant factor C such that $s = Ct$ where $C > 1$.

One common application of this descriptor is for a multiscale version of the *Harris corner detector*(15), by detecting positive spatial maxima of the entity

$$H = det(\mu) - k\,\mathrm{trace}^2(\mu) \tag{11}$$

where $k \approx 0.04$ is a constant. Another common application is for affine normalization/shape adaptation and will be developed below. The eigenvalues $\lambda_{1,2} = \mu_{11} + \mu_{22} \pm \sqrt{(\mu_{11} - \mu_{22})^2 + 4\mu_{12}^2}$ and the orientation $\arg(\mu_{11} -$

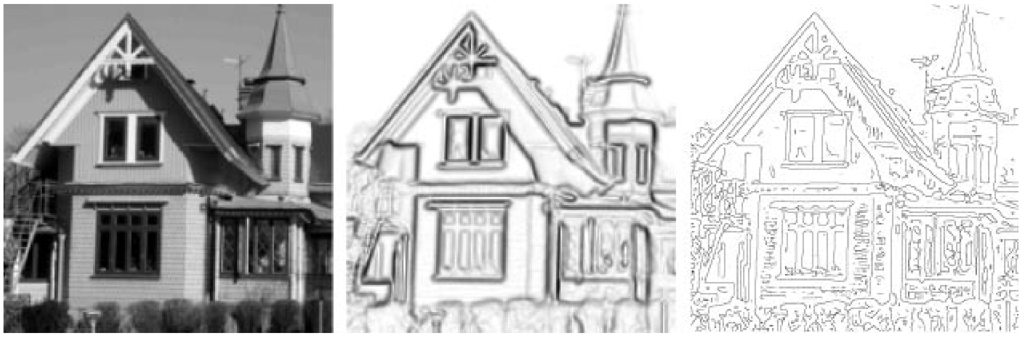

Figure 3. *Edge detection*: (left) A gray-level image of size 180 × 180 pixels, (middle) The negative value of the gradient magnitude $|\nabla L|$ computed at $t = 1$. (right) Differential geometric edges at $t = 1$ with a complementary low threshold $\sqrt{t}|\nabla L| \geq 1$ on the gradient magnitude.

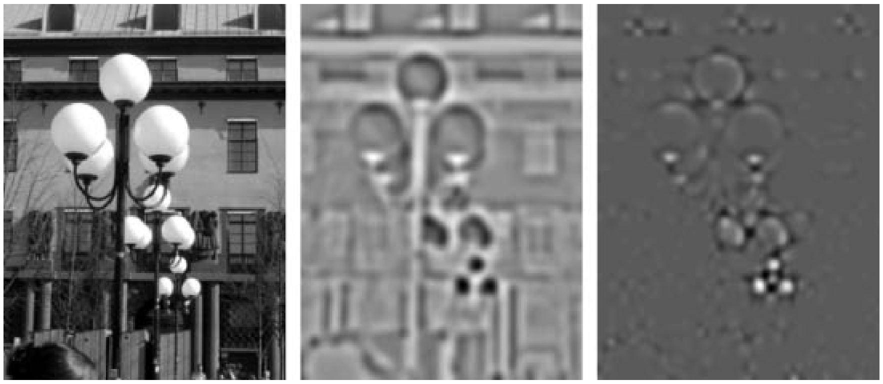

Figure 4. *Differential descriptors for blob detection / interest point detection*: (left) A gray level image of size 210 × 280 pixels, (middle) The Laplacian $\nabla^2 L$ computed at $t = 16$. (right) The determinant of the Hessian det $\mathcal{H}L$ computed at $t = 16$.

$\mu_{22}, 2\mu_{12}$) of μ are also useful for texture segmentation and for *texture classification*.

Other commonly used image descriptors that depend an additional integration scale parameter include regional histograms obtained using Gaussian window functions as weights (16).

SCALE-SPACE REPRESENTATION OF COLOR IMAGES

The input images *f* considered so far have all been assumed to be scalar gray-level images. For a vision system, however, color images are often available, and the use of color cues can increase the robustness and discriminatory power of image operators. For the purpose of scale-space representation of color images, an initial red green blue-yellow color opponent transformation is often advantageous (17). Although the combination of a scale-space representation of the RGB channels independently does not necessarily constitute the best way to define a color scale-space, by performing the following pretransformation prior to scale-space smoothing

$$\begin{cases} I = (R+G+B)/3 \\ U = R - G \\ V = B - (R+G)/2 \end{cases} \tag{12}$$

Gaussian scale-space smoothing, Gaussian derivatives, and differential invariants can then be defined from the IUV color channels separately. The luminance channel I will then reflect mainly, the interaction between reflectance, illuminance direction, and intensity, whereas the chromatic channels, $U$and V, will largely make the interaction between illumination color and surface pigmentation more explicit. This approach has been applied successfully to the tasks of image feature detection and image-based recognition based on the N-jet. For example, red-green and blue-yellow color opponent receptive fields of center-surround type can be obtained by applying the Laplacian $\nabla^2 L$ to the chromatic U and V channels.

An alternative approach to handling colors in scale-space is provided by the *Gaussian color model*, in which the spectral energy distribution $E(\lambda)$ over all wavelengths λ is approximated by the sum of a Gaussian function and first- and second-order derivatives of Gaussians (18). In this way a 3-D color space is obtained, where the channels $\hat{E}, \hat{E}_{\lambda}$ and $\hat{E}_{\lambda\lambda}$ correspond to a second-order Taylor expansion of a Gaussian-weighted spectral energy distribution around a specific wavelength λ_0 and smoothed to a fixed spectral scale t_{λ_0}. In practice, this model can be implemented in different ways. For example, with $\lambda_0 = 520$ nm and $t_{\lambda_0} = 55$ nm,

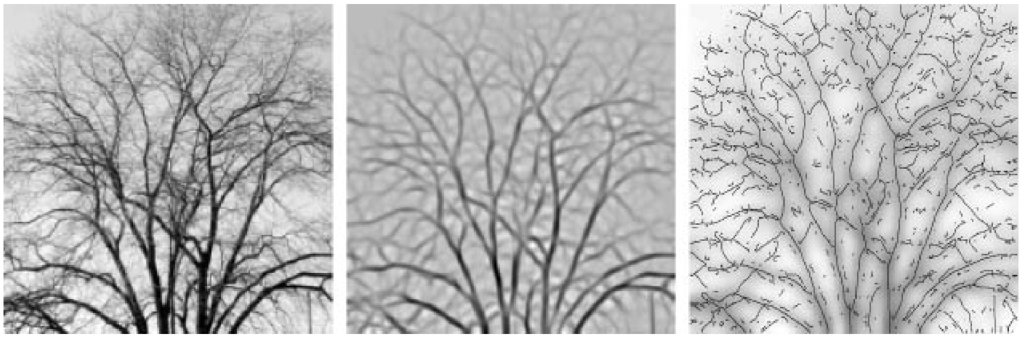

Figure 5. *Fixed scale valley detection*: (left) A gray-level image of size 180 × 180 pixels, (middle) The negative value of the valley strength measure L_{qq} computed at $t = 4$. (right) Differential geometric valleys detected at $t = 4$ using a complementary low threshold on $t|L_{qq}| \geq 1$ and then overlayed on a bright copy of the original gray-level image.

the Gaussian color model has been approximated by the following color space transformation (19):

$$\begin{pmatrix} \hat{E} \\ \hat{E}_\lambda \\ \hat{E}_{\lambda\lambda} \end{pmatrix} = \begin{pmatrix} -0.019 & 0.048 & 0.011 \\ 0.019 & 0 & -0.016 \\ 0.047 & -0.052 & 0 \end{pmatrix} \begin{pmatrix} 0.621 & 0.113 & 0.194 \\ 0.297 & 0.563 & 0.049 \\ -0.009 & 0.027 & 1.105 \end{pmatrix} \begin{pmatrix} R \\ G \\ B \end{pmatrix} \qquad (13)$$

using the CIE 1931 XYZ color basis as an intermediate representation. In analogy with the IUV color space, spatio-spectral Gaussian derivatives and differential invariants can then be defined by applying Gaussian smoothing and Gaussian derivatives to the channels in this representation. This approach has been applied for constructing approximations of color invariants assuming specific models for illumination and/or surface properties (20).

AFFINE SCALE-SPACE, AFFINE IMAGE DEFORMATIONS, AND AFFINE COVARIANCE

The regular linear scale-space representation obtained by smoothing with the rotationally symmetric Gaussian kernel is closed under translations, rotations, and rescalings. This property means that image transformations within this group can be captured perfectly by regular scale-space operators. To obtain a scale-space representation that is closed under affine transformations, a natural generalization is to consider an *affine scale-space*(3) obtained by the convolution with Gaussian kernels with their shapes determined by positive definite covariance matrices Σ:

$$g(\bar{x};\, \Sigma_t) = \frac{1}{2\pi\sqrt{det\,\Sigma_t}} e^{-\bar{x}^T \Sigma_t^{-1} \bar{x}/2} \qquad (14)$$

where $\bar{x} = (x,y)^T$. This affine scale-space combined with directional derivatives can serve as a model for *oriented elongated filter banks*. Consider two input images f and f' that are related by an affine transformation $\bar{x}' = A\bar{x}$ such that $f'(A\bar{x}) = f(\bar{x})$. Then, the affine scale-space representations L and L' of f and f' are related according to $L'(x';\, \Sigma') = L(x;\, \Sigma)$ where $\Sigma' = A\Sigma A^T$. A second-moment matrix [Equation 10] defined from an affine scale-space with covariance matrices Σ_t and Σ_s transforms according to

$$\mu'(A\bar{x};\, A\Sigma_t A^T, A\Sigma_s A^T) = A^{-T}\mu(x;\, \Sigma_t, \Sigma_s)A^{-1} \qquad (15)$$

If we can determine covariance matrices Σ_t and Σ_s such that $\mu(x;\, \Sigma_t, \Sigma_s) = c_1\Sigma_t^{-1} = c_2\Sigma_s^{-1}$ for some constants c_1 and c_2, we obtain a fixed-point that is preserved under affine transformations. This property has been used to express *affine invariant interest point operators, affine invariant stereo matching*, as well as *affine invariant texture segmentation and texture recognition methods*. (21–25). In practice, affine invariants at a given image point can (up to an unknown scale factor and a free rotation angle) be accomplished by *shape adaptation*, that is by estimating the second-moment matrix μ using a rotationally symmetric scale-space and then iteratively by choosing the covariance matrices $\sum_t$ and $\sum_s$ proportional to μ^{-1} until the fixed-point has been reached or equivalently by warping the input image by linear transformations proportional to $A = \mu^{1/2}$ until the second-moment matrix is sufficiently close to a constant times the unit matrix.

AUTOMATIC SCALE SELECTION AND SCALE INVARIANT IMAGE DESCRIPTORS

Although the scale-space theory presented so far provides a well-founded framework for expressing visual operations at multiple scales, it does not address the problem of how to *select* locally appropriate scales for additional analysis. Whereas the problem of finding "the best scales" for handling a given data set may be regarded as intractable unless more information is available, in many situations a mechanism is required to generate hypotheses about interesting scales for additional analysis. Specifically, because the size of and the distance to objects may vary in real-life applications, a need exists to define scale invariant image descriptors. A general methodology (28) for generating hypotheses about interesting scale levels is by studying the evolution properties over scales of (possibly non-linear) combinations of γ-*normalized derivatives* defined by

$$\partial_\xi = t^{\gamma/2}\partial_x \quad \text{and} \quad \partial_\eta = t^{\gamma/2}\partial_y \qquad (16)$$

where γ is a free parameter to be determined for the task at hand. Specifically, *scale levels can be selected from the scales at which* γ-*normalized derivative expressions assume local extrema with respect to scale*. A general rationale for this statement is that under a scaling transformation $(x',y') = (sx, sy)$ for some scaling factor s with $f'(sx,sy) = f(x,y)$, if follows that for matching scale levels $t' = s^2t$ the m:th order normalized derivatives at corresponding scales $t' = s^2t$ in scale-space transform according to

$$L'_{\xi'^m}(x',y';\, t') = s^{m(\gamma-1)}L_{\xi^m}(x,y;\, t) \qquad (17)$$

Hence, for any differential expression that can be expressed as a homogeneous polynomial in terms of γ-normalized derivatives, it follows that local extrema over scales will be preserved under scaling transformations. In other words, if a γ-normalized differential entity $D_{norm}L$ assumes an extremum over scales at the point $(x_0, y_0;\, t_0)$ in scale-space, then under a rescaling transformation an extremum in the transformed differential invariant is assumed at $(sx_0, sy_0;\, s^2t_0)$, in the scale-space L' of the transformed image. This general property means that if we can find an expression based on γ-normalized Gaussian

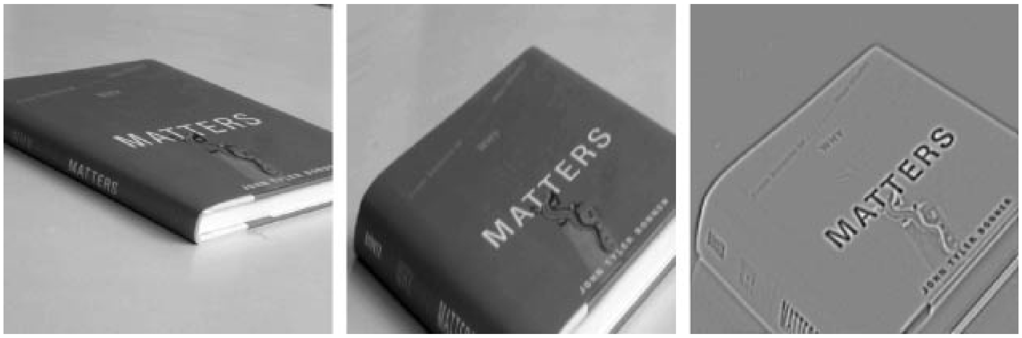

Figure 6. *Affine normalization by shape adaptation in affine scale-space*: (left) A gray-level image with an oblique view of a book cover. (middle) The result of effine normalization of a central image patch using iterative shape adaptation with affine transformations proportional to $A = \mu^{1/2}$ (right) An example of computing differential geometric descriptors, here the Laplacian $\nabla^2 L$ at scale $t = 2$, in the affinely normalized frame.

derivatives that assumes a local extremum over scales for a suitable set of image structures, then we can define a *scale invariant feature detector and / or image descriptor* by computing it at the scale at which the local extremum over scales is assumed.

The scale estimate $\hat{t}$ obtained from the scale selection step and can therefore be used for tuning or for guiding other early visual processes to be truly scale invariant (3,26) . With the incorporation of a mechanism for automatic scale selection, *scale-tuned visual modules* in a vision system can handle objects of different sizes as well as objects with different distances to the camera in the same manner. These requirements are essential for any vision system intended to function robustly in a complex dynamic world.

By studying the γ-normalized derivative response to a one-dimensional sine wave $f(x) = \sin(\omega x)$, for which the maximum over scales in the m:th order derivative is assumed at scale

$$\sigma_{max} = \sqrt{\frac{\gamma m \lambda}{2\pi}}$$

(measured in units of the standard deviation of the Gaussian) proportional to the wavelength $\lambda = 2\pi/\omega$ of the signal, one can see that a qualitative similarity exists between this construction and a peak in a local Fourier transform. However, also two major difference exist: *(1)* no window size is needed compute the Fourier transform and *(2)* this approach applies also to nonlinear differential expressions.

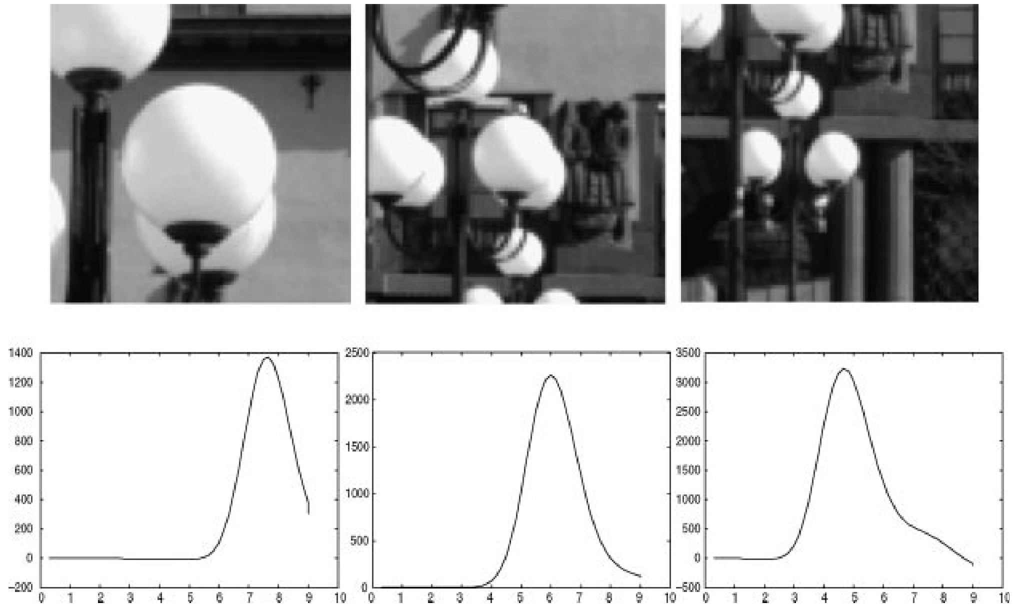

Figure 7. *Automatic scale selection from local extrema over scales of normalized derivatives*: (top row) Subwindows showing different details from Fig. 4 with image structures of different size, (bottom row) *Scale-space signatures* of the scale normalized determinant of the Hessian det $\mathcal{H}_{norm}L$ accumulated at the centre of each window. The essential property of the scale dependency of these scale normalized differential entities is that *the scale at which a local extremum over scales is assumed is proportional to the size of the corresponding image structure in the image domain*. The horizontal axis on these graphs represent effective scale, which corresponds roughly to the logarithm of the scale parameter: $\tau \approx \log_2 t$.

Specifically, if we choose γ=1, then under scaling transformations the magnitudes of normalized scale-space derivatives in Equation (17) are *equal* at corresponding points in scale-space. For $\gamma \neq 1$ they are related according to a (known) power of the scaling factor (see also Ref. 27 for earlier work on receptive field responses under similarity transformations).

SCALE INVARIANT FEATURE DETECTORS WITH INTERGRATED SCALE SELECTION MECHANISM

The most commonly used entity for automatic scale selection is the *scale normalized Laplacian* (3,26)

$$\nabla^2_{\text{norm}} L = t(L_{xx} + L_{yy}) \tag{18}$$

with $\gamma = 1$. A general motivation for the usefulness of this descriptor for general purpose scale selection can be obtained from the fact that the scale-space representation at any point can be decomposed into an integral of Laplacian responses over scales:

$$\begin{aligned} L(x,y;\, t_0) &= -(L(x,y;\, \infty) - L(x,y;\, t_0)) \\ &= -\int_{t=t_0}^{\infty} \partial_t L(x,y;\, t)\, dt \\ &= -\tfrac{1}{2}\textstyle\int_{t=t_0}^{\infty} \nabla^2 L(x,y;\, t)\, dt \end{aligned} \tag{19}$$

After a reparameterization of the scale parameter into *effective scale* $\tau = \log t$, we obtain:

$$\begin{aligned} L(x,y;\, t_0) &= -\tfrac{1}{2}\textstyle\int_{t=t_0}^{\infty} t\nabla^2 L(x,y;\, t)\, \frac{dt}{t} \\ &= -\textstyle\int_{\tau=\tau_0}^{\infty} \nabla^2_{norm} L(x,y;\, \tau)\, d\tau \end{aligned} \tag{20}$$

By detecting the scale at which the normalized Laplacian assumes its positive maximum or negative minimum over scales, we determine the scale for which the image in a scale-normalized bandpass sense contains the maximum amount of information.

Another motivation for using the scale-normalized Laplacian operator for early scale selection is that it serves as an excellent blob detector. For any (possibly nonlinear) γ-normalized differential expression $D_{norm}L$, let us first define a *scale-space maximum* (minimum) as a point for which the γ-normalized differential expression assumes a maximum (minimum) over *both* space and scale. Then, we obtain a straightforward *blob detector with automatic scale selection that responds to dark and bright blobs*, from the scale-space maxima and the scale-space minima of $\nabla^2_{norm}L$ Another *blob detector with automatic scale selection that also responds to saddles* can be defined from the scale-space maxima and minima of the scale-normalized determinant of the Hessian (26):

$$det\, \mathcal{H}_{\text{norm}} L = t^2 (L_{xx} L_{yy} - L_{xy}^2) \tag{21}$$

For both scale invariant blob detectors, *the selected scale reflects the size of the blob*. For the purpose of scale invariance, it is, however, not necessary to use the same entity to determine spatial interest points as to determine interesting scales for those points. An alternative approach to *scale interest point detection* is to use the Harris operator in Equation (11) to determine spatial interest points and the scale normalized Laplacian for determining the scales at these points (23). *Affine covariant interest points* can in turn be obtained by combining any of these three interest point operators with subsequent affine shape adaptation following Equation (15) combined with a determination of the remaining free rotation angle using, for example, the orientation of the image gradient.

The free parameter γ in the γ-normalized derivative concept can be related to the dimensionality of the type of image features to be detected or to a normalization of the Gaussian derivative kernels to constant L_{p^-}norm over scales. For blob-like image descriptors, such as the interest points described above, $\gamma = 1$ is a good choice and corresponds to L_1-normalization. For other types of image structures, such as thin edges, elongated ridges, or rounded corners, other values will be preferred. For example, for the problem of edge detection, $\gamma = 1/2$ is a useful choice to capture the width of diffuse edges, whereas for the purpose of ridge detection, $\gamma = 3/4$ is preferable for tuning the scale levels to the width of an elongated ridge (28–30).

SCALE-SPACE AXIOMS

Besides its practical use for computer vision problems, the scale-space representation satisfies several theoretic properties that define it as a unique form of multiscale image representation: The linear scale-space representation is obtained from *linear* and *shift-invariant* transformations. Moreover, the Gaussian kernels are *positive* and satisfy the *semi-group property*

$$g(\cdot,\cdot;\, t_1) * g(\cdot,\cdot;\, t_2) = g(\cdot,\cdot;\, t_1 + t_2) \tag{22}$$

which implies that any coarse-scale representation can be computed from any fine-scale representation using a similar transformation as in the transformation from the original image

$$L(\cdot,\cdot;\, t_2) = g(\cdot;\, t_2 - t_1) * L(\cdot,\cdot;\, t_1) \tag{23}$$

In one dimension, Gaussian smoothing implies that *new local extrema or new zero-crossings cannot be created with increasing scales* (1,3). In 2-D and higher dimensions scale-space representation obeys *nonenhancement of local extrema* (causality), which implies that the value at a local maximum is guaranteed not to increase while the vaiue at a local minimum is guaranteed to not decrease (2,3,31). The regular linear scale-space is *closed* under translations, rotations and scaling transformations. In fact, it can be shown that Gaussian smoothing arises *uniquely* for different

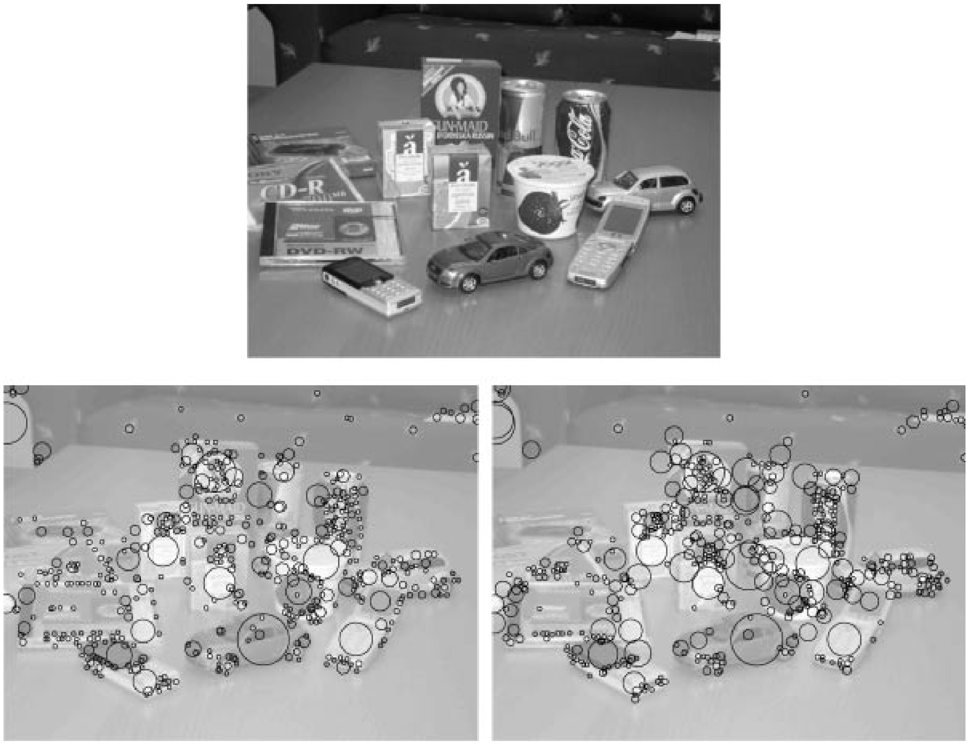

Figure 8. *Scale-invariant feature detection*: (top) Original gray-level image, (bottom left) The 1000 strongest scale-space extrema of the scale normalized Laplacian ∇^2_{norm}. (bottom right) The 1000 strongest scale-space extrema of the scale normalized determinant of the Hessian det $\mathcal{H}_{norm}L$. Each feature is displayed by a circle with its size proportional to the detection scale. In addition, the color of the circle indicates the type of image feature: red for dark features, blue for bright features, and green for saddle-like features.

subsets of combinations of these special and highly useful properties. For partial views of the history of scale-space axiomatics, please refer to Refs. 31 and 32 and the references therein.

Concerning the topic of automatic scale selection, it can be shown that, the notion of γ-normalized derivatives in Equation (16) devlops necessity from the requirement that local extrema over scales should be preserved under scaling transformations (26).

RELATIONS TO BIOLOGIC, VISION

Interestingly, the results of this computationally motivated analysis of early visual operations are in qualitative agreement with current knowledge about biologic vision. Neurophysiologic studies have shown that receptive field profiles exists in the mammalian retina and the visual cortex that can be well modeled by Gaussian derivative operators (33,34).

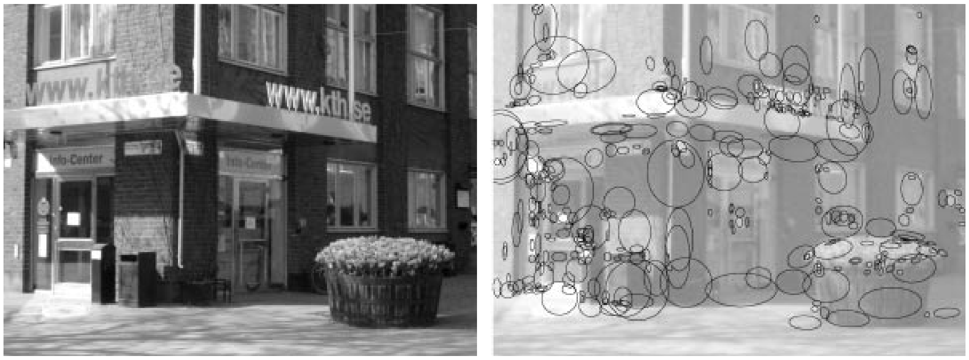

Figure 9. *Affine covariant image features*: (left) Original gray-level image. (right) The result of applying affine shape adaptation to the 500 strongest scale-space extrema of the scale normalized determinant of the Hessian det $\mathcal{H}_{norm}L$ (resulting in 384 features for which the iterative scheme converged). Each feature is displayed by an ellipse with its size proportional to the detection scale and the shape determined from a linear transformation A determined from a second-moment matrix μ. In addition, the color of the ellipse indicates the type of image feature: red for dark features, blue for bright features, and green for saddle-like features.

SUMMARY AND OUTLOOK

Scale-space theory provides a well-founded framework for modeling image structures at multiple scales, and the output from the scale-space representation can be used as input to a large variety of visual modules. Visual operations such as feature detection, feature classification, stereo matching, motion estimation, shape cues, and image-based recognition can be expressed directly in terms of (possibly nonlinear) combinations of Gaussian derivatives at multiple scales. In this sense, scale-space representation can serve as a basis for early vision.

The set of early uncommitted operations in a vision system, which perform scale-space smoothing, compute Gaussian derivatives at multiple scales, and combine these into differential invariants or other types of general purpose features to be used as input to later stage visual processes, is often referred to as a *visual front-end*.

Pyramid representation is a predecessor to scale-space representation, constructed by simultaneously smoothing and subsampling a given signal (35,36) In this way, computationally highly efficient algorithms can be obtained. A problem with pyramid representations, how-ever, is that it is algorithmically harder to relate structures at different scales, due to the discrete nature of the scale levels. In a scale-space representation, the existence of a continuous scale parameter makes it conceptually much easier to express this *deep structure*. For features defined as zero-crossings of differential invariants, the implicit function theorem defines trajectories directly across scales, and at those scales where bifurcations occur, the local behavior can be modeled by singularity theory. Nevertheless, pyramids are frequently used to express computationally more efficient approximations to different scale-space algorithms.

Extensions of linear scale-space theory concern the formulation of nonlinear scale-space concepts more committed to specific purposes (37,38). Strong relations exist between scale-space theory and *wavelets*, although these two notions of multiscale representations have been developed from somewhat different premises.

BEHAVIORAL SCIENCES AND COMPUTING

This article presents an overview of behavioral science research on human–computer interactions. The use of high-speed digital computers in homes, schools, and the workplace has been the impetus for thousands of research studies in the behavioral sciences since the 1950s. As computers have become an increasingly important part of daily life, more studies in the behavioral sciences have been directed at human–computer use. Research continues to proliferate, in part, because rapid technological advances continue to lead to the development of new products and applications from which emerge new forms of human–computer interactions. Examples include engaging in social interactions through electronic mail, chat, and discussion groups; using commercial websites for shopping and banking; using Internet resources and multimedia curriculum packages to learn in schools and at home; using handheld computers for work and personal life; collaborating in computer-supported shared workspaces; telecommuting via the Internet; engaging in one–many or many–many synchronous and asynchronous communications; and performing in "virtual" environments. Given the sheer quantity of empirical investigations in behavioral sciences computing research, the reader should appreciate the highly selective nature of this article. Even the reading list of current journals and books included at the end of this article is highly selective.

We present behavioral science computing research according to the following three categories: (1) antecedent-consequence effects, (2) model building, and (3) individual-social perspectives. The first category, antecedent-consequent effects, asks questions such as follows: How does variability in human abilities, traits, and prior performance affect computer use? How does use of computers affect variability in human abilities, traits, and subsequent performance? The second category, model building, consists of research on the nature of human abilities and performance using metaphors from computer science and related fields. Here, the behavioral scientist is primarily interested in understanding the nature of human beings but uses computer metaphors as a basis for describing and explaining human behavior. Model building can also start with assumptions about the nature of human beings, for example, limitations on human attention or types of motivation that serve as the basis for the development of new products and applications for human use. In this case, the behavioral scientist is mainly interested in product development but may investigate actual use. Such data may serve to modify the original assumptions about human performance, which in turn lead to refinements in the product. The third category, individual-social perspective, investigates the effects of increased access to and acceptance of computers in everyday life on human social relations. Questions addressed here are those such as follows: Do computers serve to isolate or connect persons to one another? What are the implications of lack of either access or acceptance of computers in modern cultures? These three categories of work in behavioral science computing are not mutually exclusive as the boundaries between any two of them are not fixed and firm.

ANTECEDENT-CONSEQUENCE RESEARCH

Personality

Research conducted since the 1970s has sought to identify what type of person is likely to use computers and related information technologies, succeed in learning about these technologies and pursue careers that deal with the development and testing of computer products. Most recently a great deal of attention has been given to human behavior on the Internet. Personality factors have been shown to be relevant in defining Internet behavior. Studies indicate that extroversion-introversion, shyness, anxiety, and neuroticism are related to computer use. Extroverts are outer directed, sociable, enjoy stimulation, and are generally regarded to be "people oriented" in contrast to introverts who are inner directed, reflective, quiet, and socially reserved. The degree of extroversion-introversion is related to many aspects of everyday life, including vocational choice, performance in work groups, and interpersonal functioning. Early studies suggested that heavy computer users tended to be introverts, and programming ability, in particular, was found to be associated with introversion. Recent studies reveal less relationship between introversion-extroversion and degree of computer use or related factors such as computer anxiety, positive attitudes toward computers, and programming aptitude or achievement. However, the decision to pursue a career in computer-related fields still shows some association with introversion.

Neuroticism is a tendency to worry, to be anxious and moody, and to evidence negative emotions and outlooks. Studies of undergraduate students and of individuals using computers in work settings have found that neuroticism is associated with anxiety about computers and negative attitudes toward computers. Neurotic individuals tend to be low users of computers, with the exception of the Internet, where there is a positive correlation between neuroticism and some online behavior. Neurotic people are more likely than others to engage in chat and discussion groups and to seek addresses of other people online. It is possible that this use of the Internet is mediated by loneliness, so that as neurotic people alienate others through their negative behaviors, they begin to feel lonely and then seek relationships online (1). Anxious people are less likely, however, to use the Internet for information searches and may find the many hyperlinks and obscure organization disturbing. Shyness, a specific type of anxiety related to social situations, makes it difficult for individuals to interact with others and to create social ties. Shy people

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

are more likely to engage in social discourse online than they are offline and can form online relationships more easily. There is a danger that as they engage in social discourse online, shy people may become even less likely to interact with people offline. There has been some indication, however, that shy people who engage in online relationships may become less shy in their offline relationships (2).

As people spend time on the Internet instead of in the real world, behavioral scientists are concerned that they will become more isolated and will lose crucial social support. Several studies support this view, finding that Internet use is associated with reduced social networks, loneliness, and difficulties in the family and at work. Caplan and others suggest that these consequences may result from existing psychosocial conditions such as depression, low self-efficacy, and negative self-appraisals, which make some people susceptible to feelings of loneliness, guilt, and other negative outcomes, so that significant time spent online becomes problematic for them but not for others (3). There is some evidence of positive effects of Internet use: Involvement in chat sessions can decrease loneliness and depression in individuals while increasing their self-esteem, sense of belonging, and perceived availability of people whom they could confide in or could provide material aid (4). However, Caplan cautions that the unnatural quality of online communication, with its increased anonymity and poor social cues, makes it a poor substitute for face-to-face relationships, and that this new context for communication is one that behavioral scientists are just beginning to understand.

As computer technologies become more integral to many aspects of life, it is increasingly important to be able to use them effectively. This is difficult for individuals who have anxiety about technology that makes them excessively cautious near computers. Exposure to computers and training in computer use can decrease this anxiety, particularly if the training takes place in a relaxed setting in small groups with a user-friendly interface, provides both demonstrations and written instructions, and includes important learning strategies that help to integrate new understanding with what is already known (5). However, some individuals evidence such a high degree of anxiety about computer use that they have been termed "computerphobics." Here the fear of computers is intense and irrational, and exposure to computers may cause distinct signs of agitation including trembling, facial expressions of distress, and physical or communicative withdrawal. In extreme cases, a generalized anxiety reaction to all forms of technology termed "technophobia" has been observed. Personality styles differ when individuals with such phobias are compared with those who are simply uncomfortable with computer use. Individuals with great anxiety about computers have personality characteristics of low problem-solving persistence and unwillingness to seek help from others (6). The training methods mentioned above are less likely to benefit individuals who evidence severe computerphobia or very high levels of neuroticism. Intensive intervention efforts are probably necessary because the anxiety about computers is related to a personality pattern marked by anxiety in general rather than an isolated fear of computers exacerbated by lack of experience with technology.

Gender

Studies over many years have found that gender is an important factor in human–computer interaction. Gender differences occur in virtually every area of computing including occupational tasks, games, online interaction, and programming, with computer use and expertise generally higher in males than in females, although recent studies indicate that the gender gap in use has closed and in expertise is narrowing. This change is especially noticeable in the schools and should become more apparent in the workforce over time. In the case of the Internet, males and females have a similar overall level of use, but they differ in their patterns of use. Males are found to more often engage in information gathering and entertainment tasks, and women spend more time in communication functions, seeking social interaction online (7). Females use e-mail more than males and enjoy it more, and they find the Internet more useful overall for social interaction. These differences emerge early. Girls and boys conceptualize computers differently, with boys more likely to view computers as toys, meant for recreation and fun, and to be interested in them as machines, whereas girls view computers as tools to accomplish something they want to do, especially in regard to social interaction (8). This may be due, in part, to differences in gender role identity, an aspect of personality that is related to, but not completely determined by, biological sex. Gender role identity is one's sense of self as masculine and/or feminine. Both men and women have traits that are stereotypically viewed as masculine (assertiveness, for example) and traits that are stereotypically viewed as feminine (nurturance, for example) and often see themselves as possessing both masculine and feminine traits. Computer use differs between people with a high masculine gender role identity and those with a high feminine gender role identity (9). Some narrowing of the gender gap in computer use may be due to changing views of gender roles.

Age

Mead et al. (10) reviewed several consequences of computer use for older adults, including increased social interaction and mental stimulation, increased self-esteem, and improvements in life satisfaction. They noted, however, that older adults are less likely to use computers than younger adults and are less likely to own computers; have greater difficulty learning how to use technology; and face particular challenges adapting to the computer-based technologies they encounter in situations that at one time involved personal interactions, such as automated check-out lines and ATM machines. They also make more mistakes and take more time to complete computer-based tasks. In view of these factors, Mead et al. suggested psychologists apply insights gained from studying the effects of age on cognition toward the development of appropriate training and computer interfaces for older adults. Such interfaces could provide more clear indications to the user of previously followed hyperlinks, for example, to compensate for failures in episodic memory, and employ cursors with larger activation areas to compensate for reduced motor control.

Aptitudes

Intelligence or aptitude factors are also predictors of computer use. In fact, spatial ability, mathematical problem-solving skills, and understanding of logic may be better than personality factors as predictors. A study of learning styles, visualization ability, and user preferences found that high visualizers performed better than low visualizers and thought computer systems were easier to use than did low visualizers (11). High visualization ability is often related to spatial and mathematical ability, which in turn has been related to computer use, positive attitudes about computers, and educational achievement in computer courses. Others have found that, like cognitive abilities, the amount of prior experience using computers for activities such as game playing or writing is a better predictor of attitudes about computers than personality characteristics. This may be because people who have more positive attitudes toward computers are therefore more likely to use them. However, training studies with people who have negative views of computers reveal that certain types of exposure to computers improve attitudes and lead to increased computer use. Several researchers have suggested that attitudes may play an intermediary role in computer use, facilitating experiences with computers, which in turn enhance knowledge and skills and the likelihood of increased use. Some have suggested that attitudes are especially important in relation to user applications that require little or no special computing skills, whereas cognitive abilities and practical skills may play a more important role in determining computer activities such as programming and design.

Attitudes

Attitudes about self-use of computers and attitudes about the impact of computers on society have been investigated. Research on attitudes about self-use and comfort level with computers presumes that cognitive, affective, and behavioral components of an attitude are each implicated in a person's reaction to computers. That is, the person may believe that computers will hinder or enhance performance on some task or job (a cognitive component), the person may enjoy computer use or may experience anxiety (affective components), and the individual may approach or avoid computer experiences (behavioral component). In each case, a person's attitude about him- or herself in interaction with computers is the focus of the analysis. Attitudes are an important mediator between personality factors and cognitive ability factors and actual computer use.

Individuals' attitudes with respect to the impact of computers on society vary. Some people believe that computers are dehumanizing, reduce human–human interaction, and pose a threat to society. Others view computers as liberating and enhancing the development of humans within society. These attitudes about computers and society can influence the individual's own behavior with computers, but they also have potential influence on individuals' views of computer use by others and their attitudes toward technological change in a range of settings.

Numerous studies have shown that anxiety about using computers is negatively related to amount of experience with computers and level of confidence in human–computer interaction. As discussed, people who show anxiety as a general personality trait evidence more computer use anxiety. In addition, anxiety about mathematics and a belief that computers have a negative influence on society are related to computer anxiety. Thus, both types of attitudes—attitudes about one's own computer use and attitudes about the impact of computers on society—contribute to computer anxieties (12).

With training, adult students' attitudes about computers become more positive. That is, attitudes about one's own interaction with computers and attitudes about the influence of computers on society at large generally become more positive as a result of instruction through computer courses in educational settings and of specific training in a variety of work settings. Figure 1 presents a general model of individual differences in computer use. The model indicates that attitudes are affected by personality and cognitive factors, and that they in turn can affect computer use either directly or by influencing values and expectations. The model also indicates that computer use can influence attitudes toward computers and personality factors such as loneliness.

Influence of Gender on Attitudes. Gender differences in attitudes toward computer use, although becoming less pronounced, appear relatively early, during the elementary school years, and persist into adulthood. Male students have more positive attitudes than female students, express greater interest in computers and greater confidence in their own abilities, and view computers as having greater utility in society than females at nearly every age level. One study revealed a moderate difference between males and females in their personal anxiety about using computers, with women displaying greater levels than men, and holding more negative views than men about the influence of computers on society. The findings of this study suggest that gender differences in computer-related behavior are due in part to differences in anxiety. When anxiety about computers was controlled, there were few differences between males and female's in computer behavior: It seems that anxiety mediates some gender differences in computer-related behavior (13). Other studies confirm that gender differences in computer behavior seem to be due to attitudinal and experiential factors. Compared with men, women report greater anxiety about computer use, lower confidence about their ability to use the computer, and lower levels of liking computer work. However, when investigators control the degree to which tasks are viewed as masculine or feminine and/or control differences in prior experiences with computers, gender differences in attitudes are no longer significant (14).

Middle-school students differ by gender in their reactions to multimedia learning interfaces and may have different sources for intrinsic satisfaction when using computers. Boys particularly enjoy control over computers and

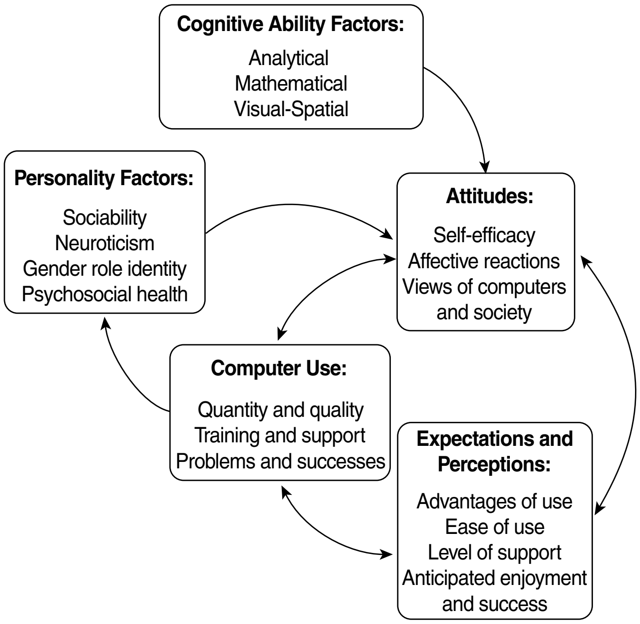

Figure 1. General model of individual differences in computer use.

look for navigational assistance within computer games, whereas girls prefer calmer games that include writing and ask for assistance rather than try to find navigational controls (15). This indicates that gender differences in attitudes about computers may be influenced in part through experience with gender-preferred computer interfaces, and that attitudes of girls toward computer use improve when gender-specific attention is paid to the design of the interface and the type of tasks presented. The differences by gender in patterns of Internet use by adults support this conclusion. When individuals are free to determine what type of tasks they do online, gender differences in overall use disappear, although males are more likely to gather information and seek entertainment and women are more likely to interact socially.

Other studies suggest that gender differences in attitudes toward computers may vary with the nature of the task. In one study, college students performed simple or more complex computer tasks. Men and women did not differ in attitudes following the simple tasks. However, the men reported a greater sense of self-efficacy (such as feelings of effective problem-solving and control) than the women after completing the complex tasks (16). Such findings suggest that, in addition to anxiety, a lack of confidence affects women more than men in the area of computer use. Training does not always reduce these differences: Although people generally become less anxious about computer use over the course of training, in some cases women become more anxious (17). This increase in anxiety may occur even though women report a concomitant increase in a sense of enjoyment with computers as training progressed. With training, both men and women have more positive social attitudes toward computers and perceive computers to be more like humans and less like machines.

To summarize the state of information on attitudes about computer use thus far, results suggest that attitudes about one's own computer use are related to personal anxiety about computer use as well as to math anxiety. These relationships are more likely to occur in women than in men. However, when women have more computer experiences, the relationship between anxiety and computer use is diminished and the gender difference is often not observed. Several attitudinal factors seem to be involved in computer use, including math anxiety, feelings of self-efficacy and confidence, personal enjoyment, and positive views of the usefulness of computers for society.

Workplace

Computers are used in a variety of ways in organizations, and computing attitudes and skills can affect both the daily tasks that must be performed in a routine manner and the ability of companies to remain efficient and competitive. The degree of success of computer systems in the workplace is often attributed to the attitudes of the employees who are end users of Inter- and intranet-based applications for communications and workflow, shared workspaces, financial applications, database management systems, data analysis software, and applications for producing Web resources and graphics. A study of factors influencing attitudes about computing technologies and acceptance of particular technologies showed that three factors were most important in determining user acceptance behaviors: perceived advantages to using the technology for improving job performance, perceived ease of use, and degree of enjoyment in using the technology. Anticipated organizational support, including technical support as well as higher management encouragement and resource allocation, had a significant effect on perceived advantage toward improving job performance, so is an additional factor in determining whether users make use of particular systems (18). The study also showed that the perceived potential for improving job performance was influenced by the extent to which the system was observed as consistent with existing needs, values, and past experiences of potential adopters. Overall, however, this and other research shows that the perception that systems will improve job performance is by far the strongest predictor of anticipated use.

Research on the attitudes of employees toward computers in the workplace reveals that, for the most part, computers are observed as having a positive effect on jobs, making jobs more interesting, and/or increasing employee effectiveness. Employees who report negative attitudes cite increased job complexity with the use of computers instead of increased effectiveness. They also report negative attitudes about the necessity for additional training and refer to a reduction in their feelings of competence. These mixed feelings may be related to their job satisfaction attitudes. When confusion and frustration about computer systems increase, job satisfaction decreases. The negative feelings about their own ability to use computers effectively lead employees to express greater dissatisfaction with the job as a whole (19).

Work-related computer problems can increase stress. Problems with computer systems (e.g., downtime, difficulties with access, lack of familiarity with software, etc.) often result in an increase of overall work time, a perception of increased workload and pressure, and less feeling of control over the job. In these situations, computers can be viewed as a detrimental force in the workplace even when users have a generally positive attitude toward them. There is some indication that individuals differ in their reactions to problems with computers, and that these differences play a role in views of the utility of computers on the job. Older staff who feel threatened by computers tend to complain more about time pressures and health-related issues related to computer use, whereas same-age peers who view computers more neutrally or positively report few problems (20).

Computer-supported collaborative work systems can facilitate group projects by allowing people to work together from different places and different times. Kunzer et al. (21) discuss guidelines for their effective design and use. For a system to be effective, it is important that its functions are transparent so that it is highly usable, and that it provides an information space structured for specific tasks for a particular group. Web-based portals that include these workspaces can greatly enhance collaborative activities. However, systems that are not highly usable and do not consider the unique requirements of the user are not well accepted and therefore not used. For example, inadequate consideration of user preferences regarding software applications can make it impossible for users to work with familiar sets of tools. Users then are likely to find other ways to collaborate either offline or in separate, more poorly coordinated applications. Successful shared workspace systems provide basic features such as a document component that allows various file formats with revision control and audit trails; calendars with search capabilities, schedule-conflict notification, and priority settings; threaded discussions with attachments, e-mail notification, and specification of read rights; and contact, project, and workflow management components. Finally, the most usable shared workspaces can be customized to different cooperation scenarios.

Differences in computer anxiety and negative attitudes about the social impact of computers are more likely to occur in some occupations than in others. Individuals in professional and managerial positions generally evidence more positive attitudes toward computers. Particular aspects of some jobs may influence individuals' attitudes and account for some of these differences. Medcof (22) found that the relative amounts of computing and noncomputing tasks, the job characteristics (such as skill variety, level of significance of assigned tasks, and autonomy), and the cognitive demand (e.g., task complexity) of the computing tasks interact with one another to influence attitudes toward computer use. When job characteristics are low and the computing components of the job also have low cognitive demand on the user (as in the case of data entry in a clerical job), attitudes toward computer use are negative, and the job is viewed as increasingly negative as the proportion of time spent on the low cognitive demand task increases. If a larger proportion of the work time is spent on a high cognitive demand task involving computer use, attitudes toward computer use and toward the job will be more positive.

Medcof's findings suggest that under some conditions job quality is reduced when computers are used to fulfill assigned tasks, although such job degradation can be minimized or avoided. Specifically, when jobs involve the use of computers for tasks that have low levels of cognitive challenge and require a narrow range of skills, little autonomy, and little opportunity for interaction with others, attitudes toward computer use, and toward the job, are negative. But varying types of noncomputing tasks within the job (increased autonomy or social interaction in noncomputing tasks, for example) reduces the negative impact; inclusion of more challenging cognitive tasks as part of the computing assignment of the job is especially effective in reducing negative views of computer use. The attitudes about computers in the workplace therefore depend on the relative degree of computer use in the entire job, the cognitive challenge involved in that use, and the type of noncomputing activities.

Older workers tend to use computers in the workplace less often than younger workers, and researchers have found that attitudes may be implicated in this difference. As older workers tend to have more negative attitudes toward computers than younger workers or those with less seniority, they use them less. Negative attitudes toward computer use and computer anxiety are better predictors of computer use than age alone (23).

MODEL BUILDING

Cognitive Processes

Modifications in theories of human behavior have been both the cause and the effect of research in behavioral science computing. A "cognitive" revolution in psychology occurred during the 1950s and 1960s, in which the human mind became the focus of study. A general approach called information processing, inspired by computer science, became dominant in the behavioral sciences during this time period. Attempts to model the flow of information from input-stimulation through output-behavior have included considerations of human attention, perception, cognition, memory, and, more recently, human emotional reactions and motivation. This general approach has become a standard model that is still in wide use.

Cognitive science's interest in computer technologies stems also from the potential to implement models and theories of human cognition as computer systems, such as Newell and Simon's General Problem Solver, Chomsky's transformational grammar, and Anderson's Atomic Components of Thought (ACT). ACT represents many components and activities of human cognition, including procedural knowledge, declarative knowledge, propositions, spreading activation, problem solving, and learning. One benefit to implementing models of human thought on computers is that the process of developing a computer model constrains theorists to be precise about their theories, making it easier to test and then refine them. As more has been learned about the human brain's ability to process many inputs and operations simultaneously, cognitive theorists have developed connectionist computer models made up of large networks of interconnected computer processors, each network comprising many interconnected nodes. The overall arrangement of interconnected nodes allows the system to organize concepts and relationships among them, simulating the human mental structure of knowledge in which single nodes may contain little meaning but meaning emerges in the pattern of connections. These and other implementations of psychological theories show how the interactions between computer scientists and behavioral scientists have informed understandings of human cognition.

Other recent theoretical developments include a focus on the social, contextual, and constructive aspects of human cognition and behavior. From this perspective, human cognition is viewed as socially situated, collaborative, and jointly constructed. Although these developments have coincided with shifts from stand-alone computers to networks and Internet-based systems that feature shared workspaces, it would be erroneous to attribute these changes in theoretical models and explanation solely to changes in available technology. Instead, many of today's behavioral scientists base their theories on approaches developed by early twentieth-century scholars such as Piaget and Vygotsky. Here the focus shifts from examining individual cognitive processing to evaluating how people work within a dynamic interplay of social factors, technological factors, and individual attitudes and experiences to solve problems and learn (24). This perspective encourages the development of systems that provide mechanisms for people to scaffold other learners with supports that can be strengthened or faded based on the learner's understanding. The shift in views of human learning from knowledge transfer to knowledge co-construction is evident in the evolution of products to support learning, from early computer-assisted instruction (CAI) systems, to intelligent tutoring systems (ITS), to learning from hypertext, to computer-supported collaborative learning (CSCL). An important principle in this evolution is that individuals need the motivation and capacity to be more actively in charge of their own learning.

Human Factors

Human factors is a branch of the behavioral sciences that attempts to optimize human performance in the context of a system that has been designed to achieve an objective or purpose. A general model of human performance includes the human, the activity being performed, and the context (25). In the area of human–computer interactions, human factors researchers investigate such matters as optimal workstation design (e.g., to minimize soft tissue and joint disorders); the perceptual and cognitive processes involved in using software interfaces; computer access for persons with disabilities such as visual impairments; and characteristics of textual displays that influence reading comprehension. An important principle in human factors research is that improvements to the system are limited if considered apart from interaction with actual users. This emphasis on contextual design is compatible with the ethnographic movement in psychology that focuses on very detailed observation of behavior in real situations (24). A human-factors analysis of human learning from hypermedia is presented next to illustrate this general approach.

Hypermedia is a method of creating and accessing nonlinear text, images, video, and audio resources. Information in hypermedia is organized as a network of electronic documents, each a self-contained segment of text or other interlinked media. Content is elaborated by providing bridges to various source collections and libraries. Links among resources can be based on a variety of relations, such as background information, examples, graphical representations, further explanations, and related topics. Hypermedia is intended to allow users to actively explore knowledge, selecting which portions of an electronic knowledge base to examine. However, following links through multiple resources can pose problems when users become disoriented and anxious, not knowing where they are and where they are going (26). Human factors research has been applied to the hypermedia environments of digital libraries, where users search and examine large-scale databases with hypermedia tools.

Rapp et al. (27) suggest that cognitive psychology's understanding of human cognition should be considered during the design of digital libraries. Hypermedia structures can be fashioned with an awareness of processes and limitations in human text comprehension, mental representations, spatial cognition, learning, memory, and other aspects of cognitive functioning. Digital libraries can in turn provide real-world environments to test and evaluate theories of human information processing. Understandings of both hypermedia and cognition can be informed through an iterative process of research and evaluation, where hypotheses about cognitive processes are developed and experiments within the hypermedia are conducted. Results are then evaluated, prompting revisions to hypermedia sources and interfaces, and generating implications for cognitive theory. Questions that arise during the process can be used to evaluate and improve the organization and interfaces in digital library collections. For example, how might the multiple sources of audio, video, and textual information in digital libraries be organized to promote more elaborated, integrated, and better encoded mental representations? Can the goal-directed, active exploration and search behaviors implicit in hypermedia generate the multiple cues and conceptual links that cognitive science has found best enhance memory formation and later retrieval?

The Superbook hypertext project at Bellcore was an early example of how the iterative process of human-factor analysis and system revision prompted modifications in original and subsequent designs before improvements over traditional text presentations were observed. Dillon (28) developed a framework of reader–document interaction that hypertext designers used to ensure usability from the learner's perspective. The framework, intended to be an approximate representation of cognition and behavior central to reading and information processing, consists of four interactive elements: (1) a task model that deals with the user's needs and uses for the material; (2) an information model that provides a model of the information space; (3) a set of manipulation skills and facilities that support physical use of the materials; and (4) a processor that represents the cognitive and perceptual processing involved in reading words and sentences. This model predicts that the users' acts of reading will vary with their needs and knowledge of the structure of the environment that contains textual information, in addition to their general ability to "read" (i.e., acquire a representation that approximates the author's intention via perceptual and cognitive processes). Research comparing learning from hypertext versus traditional linear text has not yielded a consistent pattern of results (29). User-oriented models such as Dillon's enable designers to increase the yield from hypertext versus traditional text environments.

Virtual environments provide a rich setting for human–computer interaction where input and output devices are adapted to the human senses. Individuals using virtual reality systems are immersed into a virtual world that provides authentic visual, acoustic, and tactile information. The systems employ interface devices such as data gloves that track movement and recognize gestures, stereoscopic visualizers that render scenes for each eye in real time, headphones that provide all characteristics of realistic sound, and head and eye tracking technologies. Users navigate the world by walking or even flying through it, and they can change scale so they effectively shrink to look at smaller structures in more detail. Krapichler et al. (30) present a virtual medical imaging system that allows physicians to interactively inspect all relevant internal and external areas of a structure such as a tumor from any angle. In these and similar applications, care is taken to ensure that both movement through the virtual environment and feedback from it are natural and intuitive.

The emerging field of affective computing applies human factors research to the emotional interaction between users and their computers. As people seek meaning and patterns in their interactions, they have a tendency to respond to computers as though they were people, perceiving that that they have human attributes and personalities, and experiencing appropriate emotions when flattered or ignored. For example, when a computer's voice is gendered, people respond according to gender-stereotypic roles, rating the female-voiced computer as more knowledgeable about love and the male voice as more knowledgeable about technical subjects, and conforming to the computer's suggestions if they fall within its gender-specific area of expertise (31). Picard and Klein lead a team of behavioral scientists who explore this willingness to ascribe personality to computers and to interact emotionally with them. They devise systems that can detect human emotions, better understand human intentions, and respond to signs of frustration and other negative emotions with expressions of comfort and support, so that users are better able to meet their needs and achieve their objectives (32). The development and implementation of products that make use of affective computing systems provide behavioral theorists a rich area for ongoing study.

INDIVIDUAL-SOCIAL PERSPECTIVE

In a previous section we presented an overview of research on gender differences, attitudes toward the impact of computers on society, and the use of computers in the workplace. Each of these issues relates to the effects of computers on human social relations. One prevalent perception is that as people spend time on the Internet instead of engaging with people face-to-face they will become more isolated, lonely, and depressed, and that as the kinds of social discourse available online to them may be less meaningful and fulfilling, they could lose social support. As we discussed, increased Internet use may at times be a result of loneliness, not a cause of it. The emerging research about this concern is inconclusive, making this an important area for further research. Kling (33) lists additional social controversies about the computerization of society: class divisions in society; human safety and critical computer systems; democratization; the structure of labor markets; health; education; military security; computer literacy; and privacy and encryption. These controversies have yet to be resolved and are still being studied by behavioral scientists.

Psychologists explore the influence of computers on relationships among people, not only in terms of their online behaviors and interactions, but also their perceptions of themselves and one another. Power among relationships is sometimes renegotiated because of differing attitudes and competencies with technology. One researcher proposed that relatively lower computer expertise among fathers in contrast to their sons, and a sense of dependence on their sons for technical support, can change the family dynamic and emasculate fathers, reducing perceptions of their strength and of their own sense of competence (34).

Computer-Mediated Communication

Much research on computer–human interactions is developed in the context of using computers to communicate with other people. Computer-mediated communication

(CMC) is a broad term that covers forms of communication including e-mail, listservs, discussion groups, chat, instant messaging, and videoconferencing. In comparison with face-to-face communication, CMC has fewer social and nonverbal cues but allows people to communicate easily from different places and different times. Computer-supported collaborative work systems we discussed in regard to computers in the workplace are examples of specialized CMC systems that facilitate collaborative group work. They include many forms of communication, allowing both synchronous and asynchronous interactions among multiple participants. In the cases of chat, instant messaging, and videoconferencing, people communicate at the same time but may be in different locations. E-mail, listservs, and discussion groups have the added benefits and difficulties of asynchronous communication. The reduction in social and nonverbal cues in these forms of communication can be problematic, as people misinterpret messages that are not carefully constructed and may respond negatively. It has been found that these problems diminish with experience. As users adapt to the medium and create means of improving communication, and become more adept using linguistic cues, differences between CMC and face-to-face communication may be lessened. Social norms and conventions within groups serve to reduce individual variability across formats rendering CMC similar to face-to-face communication, especially in established organizations. For example, messages from superiors receive more attention than messages from coworkers or from subordinates.

Research on learning in the workplace and in educational institutions has examined CMC's ability to support the transfer of knowledge (an "instructional" perspective) and the social, co-construction of knowledge (a "conversational" perspective) (35). Grabe and Grabe (36) discuss how CMC can change the role of the teacher, effectively decentering interactions so that students feel freer to communicate and to become more involved in their own learning. CMC results in more diverse participation and a greater number of interactions among students when compared with traditional classroom discussion characterized by longer periods of talking by the teacher and shorter, less complex individual responses from students. With CMC, instructors can focus on observing and facilitating student learning and can intervene to help with scaffolding or direct instruction as needed. Structure provided by the teacher during CMC learning is important to help create a social presence and to encourage participation. Grabe and Grabe suggest that teachers assume responsibility for managing the discussion by defining the overall purpose of the discussion, specifying roles of participants, establishing expectations, and responding to negative or passive behaviors. In a study of interaction in an online graduate course, increased structure led to more interaction and increased dialogue (37).

Another potential area for discussion, computer-supported collaborative learning, is somewhat beyond the scope of this article but is included in our reading list.

Access

Behavioral scientists are interested in what inequities exist in access to technology, how the inequities developed, and what can be done to reduce them. Until recently, the number of computers in schools was significantly lower for poorer communities. These data are changing, and the differences are diminishing. However, socioeconomic factors continue to be powerful predictors for whether people have computers or Internet access in their homes. The National Telecommunications and Information Administration (NTIA) (38) reported that, although Internet use is increasing dramatically for Americans of all incomes, education levels, ages, and races, many inequities remain. Individuals in high-income households are much more likely to be computer and Internet users than those in low-income households (over 80% for the highest income households; 25% for the lowest income households). Age and level of education are also powerful predictors: Computer and Internet use is higher among those who are younger and those who are more highly educated. In addition, people with mental or physical disabilities are less likely than others to use computers or the Internet.

Many inequities in access to computers are declining. According to the NTIA's report, rates of use are rising much more rapidly among poorer, less educated, and elderly people, the very groups who have been most disadvantaged. The report attributes this development to the lowering cost of computer technology, and to the expanding use of the Internet at schools, work, and libraries, which makes these resources available to people who do not own computers.

BIOLOGY COMPUTING

INTRODUCTION

The modern era of molecular biology began with the discovery of the double helical structure of DNA. Today, sequencing nucleic acids, the determination of genetic information at the most fundamental level, is a major tool of biological research (1). This revolution in biology has created a huge amount of data at great speed by directly reading DNA sequences. The growth rate of data volume is exponential. For instance, the volume of DNA and protein sequence data is currently doubling every 22 months (2). One important reason for this exceptional growth rate of biological data is the medical use of such information in the design of diagnostics and therapeutics (3,4). For example, identification of genetic markers in DNA sequences would provide important information regarding which portions of the DNA are significant and would allow the researchers to find many disease genes of interest (by recognizing them from the pattern of inheritance). Naturally, the large amount of available data poses a serious challenge in storing, retrieving, and analyzing biological information.

A rapidly developing area, *computational biology*, is emerging to meet the rapidly increasing computational need. It consists of many important areas such as information storage, sequence analysis, evolutionary tree construction, protein structure prediction, and so on (3,4). It is playing an important role in some biological research. For example, sequence comparison is one of the most important methodological issues and most active research areas in current *biological sequence analysis*. Without the help of computers, it is almost impossible to compare two or more biological sequences (typically, at least a few hundred characters long).

In this chapter, we survey recent results on evolutionary tree construction and comparison, computing syntenic distances between multi-chromosome genomes, and multiple sequence alignment problems.

Evolutionary trees model the evolutionary histories of input data such as a set of species or molecular sequences. Evolutionary trees are useful for a variety of reasons, for example, in homology modeling of (DNA and protein) sequences for diagnostic or therapeutic design, as an aid for devising classifications of organisms, and in evaluating alternative hypotheses of adaption and ancient geographical relationships (for example, see Refs. 5 and 6 for discussions on the last two applications). Quite a few methods are known to construct evolutionary trees from the large volume of input data. We will discuss some of these methods in this chapter. We will also discuss methods for comparing and contrasting evolutionary trees constructed by various methods to find their similarities or dissimilarities, which is of vital importance in computational biology.

Syntenic distance is a measure of distance between multi-chromosome genomes (where each chromosome is viewed as a set of genes). Applications of computing distances between genomes can be traced back to the well-known **Human Genome Project**, whose objective is to decode this entire DNA sequence and to find the location and ordering of genetic markers along the length of the chromosome. These genetic markers can be used, for example, to trace the inheritance of chromosomes in families and thereby to find the location of disease genes. Genetic markers can be found by finding DNA polymorphisms (i.e., locations where two DNA sequences "spell" differently). A key step in finding DNA polymorphisms is the calculation of the *genetic distance*, which is a measure of the correlation (or similarity) between two genomes.

Multiple sequence alignment is an important tool for sequence analysis. It can help extracting and finding biologically important commonalities from a set of sequences. Many versions have been proposed and a huge number of papers have been written on effective and efficient methods for constructing multiple sequence alignment. We will discuss some of the important versions such as *SP-alignment, star alignment, tree alignment, generalized tree alignment*, and *fixed topology alignment with recombination*. Recent results on those versions are given.

We assume that the reader has the basic knowledge of algorithms and computational complexity (such as NP, P, and MAX-SNP). Otherwise, please consult, for example, Refs. 7–9.

The rest of this chapter is organized as follows. In the next section, we discuss construction and comparison methods for evolutionary trees. Then we discuss briefly various distances for comparing sequences and explain in details the syntenic distance measure. We then discuss multiple sequence alignment problems. We conclude with a few open problems.

CONSTRUCTION AND COMPARISON OF EVOLUTIONARY TREES

The evolutionary history of organisms is often conveniently represented as trees, called *phylogenetic trees* or simply *phylogenies*. Such a tree has uniquely labeled leaves and unlabeled interior nodes, can be *unrooted* or *rooted* if the evolutionary origin is known, and usually has internal nodes of degree 3. Figure 1 shows an example of a phylogeny. A phylogeny may also have *weights* on its edges, where an edge weight (more popularly known as *branch length* in genetics) could represent the evolutionary distance along the edge. Many phylogeny reconstruction methods, including the distance and maximum likelihood methods, actually produce weighted phylogenies. Figure 1 also shows a weighted phylogeny (the weights are for illustrative purposes only).

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

Phylogenetic Construction Methods

Phylogenetic construction methods use the knowledge of evolution of molecules to infer the evolutionary history of the species. The knowledge of evolution is usually in the form of two kinds of data commonly used in phylogeny inference, namely, character matrices (where each position (i, j) is base j in sequence i) and distance matrices (where each position (i,j) contains the computed distance between sequence i and sequence j). Three major types of phylogenetic construction methods are the *parsimony and compatibility method*, the *distance method*, and the *maximum-likelihood method*, Below, we discuss each of these methods briefly. See the excellent survey in Refs. 10 and 11 for more details.

Parsimony methods construct phylogenetic trees for the given sequences such that, in some sense, the total number of changes (i.e., base substitutions) or some weighted sum of the changes is minimized. See Refs. 12–14 for some of the papers in this direction.

Distance methods (15)–(17) try to fit a tree to a matrix of pairwise distances between a set of n species. Entries in the distance matrices are assumed to represent evolutionary distance between species represented by the sequences in the tree (i.e., the total number of mutations in both lineages since divergence from the common ancestor). If no tree fits the distance matrix perfectly, then a measure of the discrepancy of the distances in the distance matrix and those in the tree is taken, and the tree with the minimum discrepancy is selected as the best tree. An example of the measure of the discrepancy, which has been used in the literature (15,16), is a weighted least-square measure, for example, of the form

$$\sum_{1\leq i,j\leq n} w_{ij}(D_{ij} - d_{ij})^2$$

where D_{ij} are the given distances and d_{ij} are the distances computed from the tree.

Maximum-likelihood methods (12,18,19) relies on the statistical method of choosing a tree that maximizes the likelihood (i.e., maximizes the probability) that the observed data would have occurred. Although this method is quite general and powerful, it is computationally intensive because of the complexity of the likelihood function.

All the above methods have been investigated by simulation and theoretical analysis. None of the methods work well under all evolutionary conditions, but each works well under particular situations. Hence, one must choose the appropriate phylogeny construction method carefully for the best results (6).

Comparing Evolutionary Trees

As discussed in the previous section, over the past few decades, many approaches for reconstructing evolutionary trees have been developed, including (not exhaustively) parsimony, compatibility, distance, and maximum-likelihood methods. As a result, in practice, they often lead to different trees on the same set of species (20). It is thus of interest to compare evolutionary trees produced by different methods, or by the same method on different data. Several distance models for evolutionary trees have been proposed in the literature. Among them, the best known is perhaps the *nearest-neighbor interchange* (nni) distance introduced independently in Refs. 21 and 22. Other distances include the *subtree-transfer* distance introduced in Refs. 23 and 24 and the the *linear-cost subtree-transfer distance*(25,26). Below, we discuss very briefly a few of these distances.

Nearest-Neighbor Interchange Distance

An *nni* operation swaps two subtrees that are separated by an internal edge (u, v), as shown in Fig. 2. The nni operation is said to *operate* on this internal edge. The nni distance, $D_{nni}(T_1, T_2)$, between two trees T_1 and T_2 is denned as the minimum number of nni operations required to transform one tree into the other. Culik II and Wood (27) [improved later by Tramp and Zhang (28)] proved that $n\log n + O(n)$ nni moves are sufficient to transform a tree of n leaves to any other tree with the same set of leaves. Sleator et al. (29) proved an $\Omega(n\log n)$ lower bound for most pairs of trees. Although the distance has been studied extensively in the literature (21,22,27–34), the computational complexity of computing it has puzzled the research community for nearly 25 years until recently, when the authors in Ref. 25 showed this problem to be NP-hard an erroneous proof of the NP-hardness of the nni distance between unlabeled trees was published in Ref. 34. As computing the nni distance is shown to be NP-hard, the next obvious question is: *Can we get a good approximation of the distance?* The authors in Ref. 28 show that the nni distance can be approximated in polynomial time within a factor of $\log n + O(1)$.

Subtree-transfer Distances

An nni operation can also be viewed as moving a subtree past a neighboring internal node. A more general operation is to transfer a subtree from one place to another arbitrary place. Figure 3 shows such a *subtree-transfer* operation. The subtree-transfer distance, $D_{st}(T_1, T_2)$, between two trees T_1 and T_2 is the minimum number of subtrees we need to move to transform T_1 into T_2(23–26,35).

It is sometimes appropriate in practice to discriminate among subtree-transfer operations as they occur with different frequencies. In this case, we can charge each subtree-transfer operation a cost equal to the distance (the number of nodes passed) that the subtree has moved in the current tree. The *linear-cost* subtree-transfer distance, $D_{lcst}(T_1, T_2)$, between two trees T_1 and T_2 is then the minimum total cost required to transform T_1 into T_2 by subtree-transfer operations (25,26). Clearly, both subtree-transfer and linear-cost subtree-transfer models can also be used as alternative measures for comparing evolutionary trees generated by different tree reconstruction methods. In fact, on unweighted phylogenies, the linear-cost subtree-transfer distance is identical to the nni distance (26).

The authors in Ref. (35) show that computing the subtree-transfer distance between two evolutionary trees is NP-hard and give an approximation algorithm for this distance with performance ratio 3.

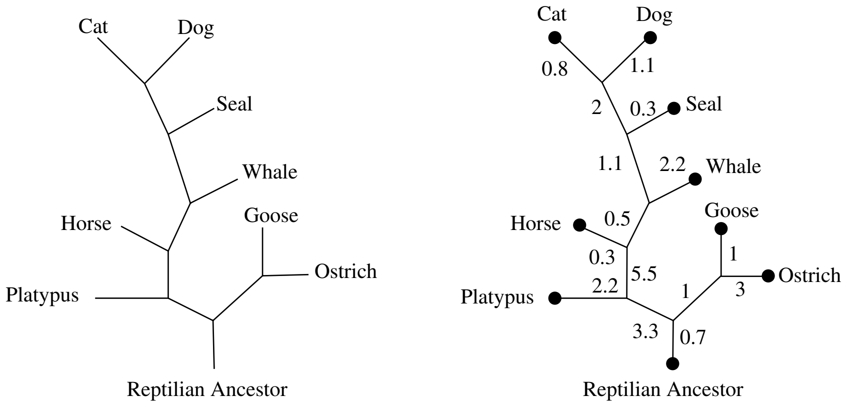

Figure 1. Examples of unweighted and weighted phylogenies.

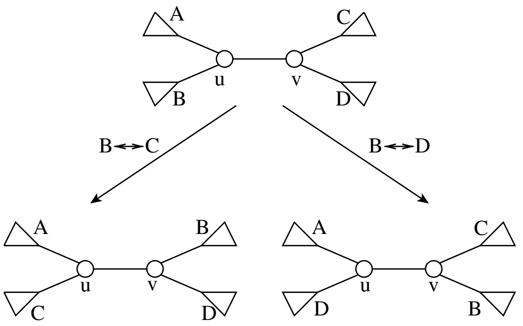

Figure 2. The two possible nni operations on an internal edge (u, v): exchange $B \leftrightarrow C$ or $B \leftrightarrow D$.

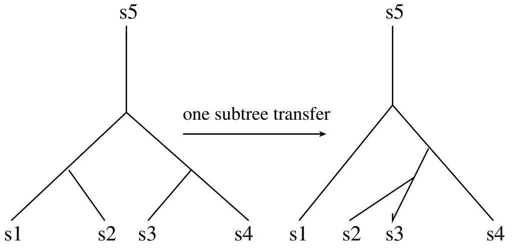

Figure 3. An example of a subtree-transfer operation on a tree.

Rotation Distance

Rotation distance is a variant of the nni distance for rooted, ordered trees. A *rotation* is an operation that changes one rooted binary tree into another with the same size. Figure 4 shows the general rotation rule. An easy approximation algorithm for computing distance with a performance ratio of 2 is given in Ref. 36. However, it is not known if computing this distance is NP-hard or not.

Distances on Weighted Phylogenies

Comparison of weighted evolutionary trees has recently been studied in Ref. 20. The distance measure adopted is based on the difference in the partitions of the leaves induced by the edges in both trees, and it has the drawback of being somewhat insensitive to the tree topologies. Both the linear-cost subtree-transfer and nni models can be naturally extended to weighted trees. The extension for nni is straightforward: An nni is simply charged a cost equal to the weight of the edge it operates on. In the case of linear-cost subtree-transfer, although the idea is immediate (i.e., a moving subtree should be charged for the weighted distance it travels), the formal definition needs some care and can be found in Ref. 26.

As computing the nni distance on unweighted phylogenies is NP-hard, it is obvious that computing this distance is NP-hard for weighted phylogenies also. The authors in Ref. 26 give an approximation algorithm for the linear-cost subtree-transfer distance on weighted phylogenies with performance ratio 2. In Ref. 25, the authors give an approximation algorithm for the nni distance on weighted phylogenies with performance ratio of $O(\log n)$. It is open whether the linear-cost subtree-transfer problem is NP-hard for weighted phylogenies. However, it has been shown that the problem is NP-hard for weighted trees with non-uniquely labeled leaves (26).

COMPUTING DISTANCES BETWEEN GENOMES

The definition and study of appropriate measures of distance between pairs of species is of great importance in

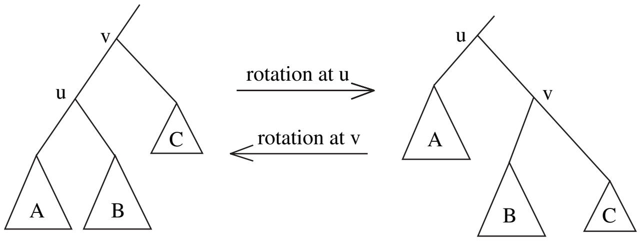

Figure 4. Left and right rotation operations on a rooted binary tree.

computational biology. Such measures of distance can be used, for example, in phylogeny construction and in taxonomic analysis.

As more and more molecular data become available, methods for denning distances between species have focused on such data. One of the most popular distance measures is the edit distance between homologous DNA or amino acid sequences obtained from different species. Such measures focus on point mutations and define the distance between two sequences as the minimum number of these moves required to transform one sequence into another. It has been recognized that the edit-distance may underestimate the distance between two sequences because of the possibility that multiple point mutations occurring at the same locus will be accounted for simply as one mutation. The problem is that the probability of a point mutation is not low enough to rule out this possibility.

Recently, there has been a spate of new definitions of distance that try to treat rarer, macro-level mutations as the basic moves. For example, if we know the order of genes on a chromosome for two different species, we can define the *reversal* distance between the two species to be the number of reversals of portions of the chromosome to transform the gene order in one species to the gene order in the other species. The question of finding the reversal distance was first explored in the computer science context by Kececioglu and Sankoff and by Bafna and Pevzner, and there has been significant progress made on this question by Bafna, Hannenhalli, Kececioglu, Pevzner, Ravi, Sankoff, and others (37–41). Other moves besides reversals have been considered as well. Breaking off a portion of the chromosome and inserting it elsewhere in the chromosome is referred to as a *transposition*, and one can similarly define the transposition distance (42). Similarly, allowing two chromosomes (viewed as strings of genes) to exchange suffixes (or sometimes a suffix with a prefix) is known as a *translocation*, and this move can also be used to define an appropriate measure of distance between two species for which much of the genome has been mapped (43).

Ferretti et al. (44) proposed a distance measure that is at an even higher level of abstraction. Here, even the order of genes on a particular chromosome of a species is ignored or presumed to be unknown. It is assumed that the genome of a species is given as a collection of sets. Each set in the collection corresponds to a set of genes that are on one chromosome and different sets in the collection correspond to different chromosomes (see Fig. 5). In this scenario, one can define a move to be an exchange of genes between two chromosomes, the fission of one chromosome into two, or the fusion of two chromosomes into one (see Fig. 6). The *syntenic distance* between two species has been defined by Ferretti et al. (44) to be the number of such moves required to transform the genome of one species to the genome of the other.

Figure 6. Different mutation operations.

Notice that any recombination of two chromosomes is permissible in this model. By contrast, the set of legal translocations (in the translocation distance model) is severely limited by the order of genes on the chromosomes being translocated. Furthermore, the transformation of the first genome into the second genome does not have to produce a specified order of genes in the second genome. The underlying justification of this model is that the exchange of genes between chromosomes is a much rarer event than the movement of genes within a chromosome and, hence, a distance function should measure the minimum number of such exchanges needed.

In Ref. 45, the authors prove various results on the syntenic distance. For example, they show that computing the syntenic distance exactly is NP-hard, there is a simple polynomial time approximation algorithm for the synteny problem with performance ratio 2, and computing the syntenic distance is fixed parameter tractable.

The median problem develops in connection with the phylogenetic inference problem (44) and denned as follows: Given three genomes $\mathcal{G}_1$, $\mathcal{G}_2$, and $\mathcal{G}_3$, we are required to construct a genome $\mathcal{G}$ such that the *median distance* $\alpha_{\mathcal{G}} = \sum_{i=1}^{3} D(\mathcal{G}, \mathcal{G}_i)$ is minimized (where D is the syntenic distance). Without any additional constraints, this problem is trivial, as we can take $\mathcal{G}$ to be empty (and then $\alpha_{\mathcal{G}} = 0$). In the context of syntenic distance, any one of the following three constraints seem relevant: (cl) $\mathcal{G}$ must contain all genes present in *all the three* given genomes, (c2) $\mathcal{G}$ must contain all genes present in *at least two* of the three given genomes, and (c3) $\mathcal{G}$ must contain all genes present in *at least one* of the three given genomes. Then, computing the median genome is NP-hard with any one of the three constraints (cl), (c2), or (c3). Moreover, one can approximate the median problem in polynomial time [under any one of the constraints (cl), (c2), or (c3)] with a constant performance ratio. See Ref. 45 for details.

MULTIPLE SEQUENCE ALIGNMENT PROBLEMS

Multiple sequence alignment is the most critical cutting-edge tool for sequence analysis. It can help extracting, finding, and representing biologically important commonalities from a set of sequences. These commonalities could represent some highly conserved subregions, common functions, or common structures. Multiple sequence alignment is also very useful in inferring the evolutionary history of a family of sequences (46–49).

A *multiple alignment*$\mathcal{A}$ of $k \geq 2$ sequences is obtained as follows: Spaces are inserted into each sequence so that the resulting sequences $s'_i (i = 1, 2, \ldots k)$ have the same length l, and the sequences are arranged in k rows of l columns each.

The value of the multiple alignment $\mathcal{A}$ is denned as

$$\sum_{i=1}^{l} \mu(s'_1(i), s'_2(i), \ldots s'_k(i))$$

where $s'_l(i)$ denotes the ith letter in the resulting sequence s'_l, and $\mu(s'_1(i), s'_2(i), \ldots s'_k(i))$ denotes the score of the ith column. The multiple sequence alignment problem is to construct a multiple alignment minimizing its value.

Many versions have been proposed based on different objective functions. We will discuss some of the important ones.

SP-Alignment and Steiner Consensus String

For *SP-score* (Sum-of-the-Pairs), the score of each column is denned as:

$$\mu(s'_1(i), s'_2(i), \ldots s'_k(i)) = \sum_{1 \leq j < l \leq k} \mu(s'_j(i), s'_l(i))$$

where $\mu(s'_j(i), s'_l(i))$ is the score of the two opposing letters $s'_j(i)$ and $s'_l(i)$. The SP-score is sensible and has previously been studied extensively.

SP-alignment problem is to find an alignment with the smallest SP-score. It is first studied in Ref. 50 and subsequently used in Refs. 51–54. SP-alignment problem can be solved exactly by using dynamic programming. However, if there are k sequences and the length of sequences is n, it takes $O(n^k)$ time. Thus, it works for only small numbers of sequences. Some techniques to reduce the time and space have been developed in Refs. 51 and 55–57. With these techniques, it is possible to optimally align up to six sequences of 200 characters in practice.

In fact, SP-alignment problem is NP-hard (58). Thus, it is impossible to have a polynomial time algorithm for this problem. In the proof of NP-hardness, it is assumed that some pairs of identical characters have a non-zero score. An interesting open problem is if each pair of two identical characters is scored 0.

The first approximation algorithm was given by Gusfield (53). He introduced the *center star* algorithm. The center star algorithm is very simple and efficient. It selects a sequence (called *center string*) s_c in the set of k given sequences S such that $\sum_{i=1}^{k} dist(s_c, s_i)$ is minimized. It then optimally aligns the sequences in $S - \{s_c\}$ to s_c and gets $k - 1$ pairwise alignments. These $k - 1$ pairwise alignments lead to a multiple alignment for the k sequences in S. If the score scheme for pairs of characters satisfies the triangle inequality, the cost of the multiple alignment produced by the center star algorithm is at most twice the optimum (47,53). Some improved results were reported in Refs. 54 and 59.

Another score called *consensus* score is denned as follows:

$$\mu(s'_1(i), s'_2(i), \ldots s'_k(i)) = \min_{s \in \Sigma} \sum_{j=1}^{k} \mu(s'_j(i), s)$$

where $\sum$ is the set of characters that form the sequences. Here, we reconstruct a character for each column and thus obtain a string. This string is called a *Steiner consensus string* and can be used as a representative for the set of given sequences. The problem is called the *Steiner consensus string* problem.

The Steiner consensus string problem was proved to be NP-complete (60) and MAX SNP-hard (58). In the proof of MAX SNP-hardness, it is assumed that there is a "wild card," and thus the triangle inequality does not hold. Combining with the results in Ref. 61, it shows that there is no polynomial time approximation scheme for this problem. Interestingly, the same center star algorithm also has performance ratio 2 for this problem (47).

Diagonal Band Alignment. The restriction of aligning sequences within a constant diagonal band is often used in practical situations. Methods under this assumption have been extensively studied too. Sankoff and Kruskal discussed the problem under the rubric of "cutting corners" in Ref. 62. Alignment within a band is used in the final stage of the well-known FASTA program for rapid searching of protein and DNA sequence databases (63,64). Pearson showed that alignment within a band gives very good results for many protein superfamilies (65).

Other references on the subject can be found in Refs. 51 and 66–69. Spouge gives a survey on this topic in Ref. 70.

Let $\mathcal{S} = \{s_1, s_2, \ldots, s_k\}$ be a set of k sequences, each of length m (for simplicity), and $\mathcal{M}$ an alignment of the k sequences. Let the length of the alignment $\mathcal{M}$ be M. $\mathcal{M}$ is called a *c-diagonal alignment* if for any $p \leq m$ and $1 < i < j < k$, if the pth letter of s_i is in column q of $\mathcal{M}$ and the pth letter of s_j is in column r of $\mathcal{M}$, then $|q - r| \leq c$. In other words, the inserted spaces are "evenly" distributed among all sequences and the ith position of a sequence is about at most c positions away from the ith. position of any other sequence.

In Ref. 71 Li, et al. presented polynomial time approximation schemes of c-diagonal alignment for both SP-score and consensus score.

Tree Alignment

Tree score: To define the score $\mu(s'_1(i), s'_2(i), \ldots s'_k(i))$ of the ith. column, an *evolutionary* (or *phylogenetic*) tree $T = (V, E)$ with k leaves is assumed, each leaf j corresponding to a sequence S_j. (Here, V and E denote the sets of nodes and edges in T, respectively.) Let $k + 1, K + 2, \ldots, k + m$ be the internal nodes of T. For each internal node j, reconstruct a letter (possibly a space) $s'_j(i)$ such that $\sum_{(p,q) \in E} \mu(s'_p(i), s'_q(i))$ is minimized. The score

$\mu(s'_1(i), s'_2(i), \ldots s'_k(i))$ of the ith column is thus denned as

$$\mu(s'_1(i), s'_2(i), \ldots s'_k(i)) = \sum_{(p,q)\in E} \mu\left(s'_p(i), s'_q(i)\right)$$

This measure has been discussed in Refs. 14,48,51,59 and 72. Multiple sequence alignment with tree score is often referred to as *tree alignment* in the literature.

Note that a tree alignment induces a set of *reconstructed* sequences, each corresponding to an internal node. Thus, it is convenient to reformulate a tree alignment as follows: Given a set X of k sequences and an evolutionary tree T with k leaves, where each leaf is associated with a given sequence, reconstruct a sequence for each internal node to minimize the *cost* of T. Here, the cost of T is the sum of the edit distance of each pair of (given or reconstructed) sequences associated with an edge. Observe that once a sequence for each internal node has been reconstructed, a multiple alignment can be obtained by optimally aligning the pair of sequences associated with each edge of the tree. Moreover, the tree score of this induced multiple alignment equals the cost of T. In this sense, the two formulations of tree alignment are equivalent.

Sankoff gave an exact algorithm for tree alignment that runs in $O(n^k)$, where n is the length of the sequences and k is the number of given sequences. Tree alignment was proved to be NP-hard (58).

Therefore, it is unlikely to have a polynomial time algorithm for tree alignment. Some heuristic algorithms have also been considered in the past. Altschul and Lipman tried to cut down the computation volume required by dynamic programming (51). Sankoff, et al. gave an iterative improvement method to speed up the computation (48,72). Waterman and Perlwitz devised a heuristic method when the sequences are related by a binary tree (73). Hein proposed a heuristic method based on the concept of a *sequence graph* (74,75). Ravi and Kececioglu designed an approximation algorithm with performance ratio $\frac{deg+1}{deg-1}$ when the given tree is a *regular deg-ary* tree (i.e., each internal node has exactly *deg* children) (76).

The first approximation algorithm with a guaranteed performance ratio was devised by Wang, et al. (77). A ratio-2 algorithm was given. The algorithm was then extended to a polynomial time approximation scheme (PTAS) (i.e., the performance ratio could arbitrarily approach 1). The PTAS requires computing exact solutions for depth-t subtrees. For a fixed t, the performance ratio was proved to be $1+\frac{3}{t}$, and the running time was proved to be $O((k/deg^t)^{deg^{t-1}+2}M(2, t-1, n))$, where *deg* is the degree of the given tree, n is the length of the sequences, and $M(deg, t-1, n)$ is the time needed to optimally align a tree with $deg^{t-1}+1$ leaves, which is upper-bounded by $O(n^{deg^{t-1}+1})$. Based on the analysis, to obtain a performance ratio less than 2, exact solutions for depth-4 subtrees must be computed, and thus optimally aligning nine sequences at a time is required, which is impractical even for sequences of length 100.

An improved version was given in Ref. 78. They proposed a new PTAS for the case where the given tree is a regular deg-ary tree. The algorithm is much faster than the one in Ref. 77. The algorithm also must do local optimizations for depth-t subtrees. For a fixed t, the performance ratio of the new PTAS is $1+\frac{2}{t}-\frac{2}{t2^t}$ and the running time is $O(\min\{2^t, k\}kdM(deg, t-1, n))$, where d is the depth of the tree. Presently, there are efficient programs (72) to do local optimizations for three sequences ($t = 2$). In fact, we can expect to obtain optimal solutions for five sequences ($t = 3$) of length 200 in practice as there is such a program (55,56) for SP-score and similar techniques can be used to attack the tree alignment problem. Therefore, solutions with costs at most 1.583 times the optimum can be obtained in practice for strings of length 200.

For tree alignment, the given tree is typically a binary tree. Recently, Wang et al. (79) designed a PTAS for binary trees. The new approximation scheme adopts a more clever partitioning strategy and has a better time efficiency for the same performance ratio. For any fixed r, where $r = 2^{t-1}+1-q$ and $0 \le q \le 2^{t-2}-1$, the new PTAS runs in time $O(kdn^r)$ and achieves an approximation ratio of $1+\frac{2^{t-1}}{2^{t-2}(t+1)-q}$. Here, the parameter r represents the "size" of local optimization. In particular, when $r = 2^{t-1}+1$, its approximation ratio is simply $1+\frac{2}{t+1}$.

Generalized Tree Alignment

In practice, we often face a more difficult problem called *generalized tree alignment*. Suppose we are given a set of sequences. The problem is to construct an evolutionary tree as well as a set of sequences (called reconstructed sequences) such that each leaf of the evolutionary tree is assigned a given sequence, each internal node of the tree is assigned a reconstructed sequence, and the cost of the tree is minimized over all possible evolutionary trees and reconstructed sequences.

Intuitively, the problem is harder than tree alignment because the tree is not given and we have to compute the tree structure as well as the sequences assigned to internal nodes. In fact, the problem was proved to be MAX SNP-hard (58) and a simplified proof was given in Ref. 80. It implies that it is impossible to have a PTAS for generalized tree alignment unless P=NP (61), which confirms the observation from an approximation point of view.

Generalized tree alignment problem is, in fact, the Steiner tree problem in sequence spaces. One might use the approximation algorithms with guaranteed performance ratios (81) to graph Steiner trees, which, however, may lead to a tree structure where a given sequence is an internal node. Sometimes, it is unacceptable. Schwikowski and Vingron give a method that combines clustering algorithms and Hein's sequence graph method (82). The produced solutions contain biologically reasonable trees and keep the guaranteed performance ratio.

Fixed Topology History/Alignment with Recombination

Multigene families, viruses, and alleles from within populations experience recombinations (23,24,83,84). When recombination happens, the ancestral material on the present sequence s_1 is located on two sequences s_2 and s_3. s_2 and s_3 can be cut at k locations (break points) into $k+1$ pieces, where $s_2 = s_{2,1}s_2 \ldots s_{2,l+1}$ and $s_3 = s_{3,1}s_{3,2} \ldots s_{3,l+1}$. s_1 can be represented as $s_{\hat{2},1} = s_{\hat{3},2}s_{\hat{2},3} \ldots s_{\hat{2},i}s_{3,\hat{i}+1} \ldots$, where subsequences $s_{\hat{2},i}$ and $s_{3,\hat{i}+1}$ differ from the corresponding $s_{2,i}$ and $s_{3,i+1}$ by insertion, deletion, and substitution of letters. k, the number of times s_1 switches between s_2 and s_3, is called the number of *crossovers*. The cost of the recombination is

$$dist(s_{1,1}, s_{\hat{1},1}) + dist(s_{2,2}, s_{\hat{2},2}), \ldots dist(s_{1,i}, s_{\hat{1},i}) + dist \times (s_{2,i+1}, s_{2,\hat{i}+1}) + \cdots + k\chi$$

where $dist(s_{2,i+1}, s_{2,\hat{i}+1})$ is the edit distance between the two sequences $s_{2,i+1}$ and $s_{2,\hat{i}+1}$, k is the number of crossovers, and χ the crossover penalty. The *recombination* distance to produce s_1 from s_2 and s_3 is the cost of a recombination that has the smallest cost among all possible recombinations. We use $r\_dist(s_1, s_2, s_3)$ to denote the recombination distance. For more details, see Refs. 83 and 85.

When recombination occurs, the given topology is no longer a binary tree. Instead, some nodes, called *recombination nodes*, in the given topology may have two parents (23,24). In a more general case, as described in Ref. 83, the topology may have more than one root. The set of roots is called a *pro-toset*. The edges incident to recombination nodes are called *recombination* edges [see Fig. 7 (b)]. A node/edge is *normal* if it is not a recombination node/edge.

The cost of a pair of recombination edges is the recombination distance to produce the sequence on the recombination node from the two sequences on its parents. The cost of other normal edges is the edit distance between two sequences. A topology is *fully labeled* if every node in the topology is labeled. For a fully labeled topology, the cost of the topology is the total cost of edges in the topology. Each node in the topology with degree greater than 1 is an internal node. Each leaf/terminal (degree 1 node) in the topology is labeled with a given sequence. The goal here is to construct a sequence for each internal node such that the cost of the topology is minimized. We call this problem *fixed topology history with recombination* (FTHB).

Obviously, this problem is a generalization of tree alignment. The difference is that the given topology is no longer a binary tree. Instead, there are some recombination nodes that have two parents instead of one. Moreover, there may be more than one root in the topology.

A different version called *fixed topology alignment with recombination* (FTAR) is also dicsussed (86). From an approximation point of view, FTHR and FTAR are much harder than tree alignment. It is shown that FTHR and FTAR cannot be approximated within any constant performance ratio unless $P = NP$ (86).

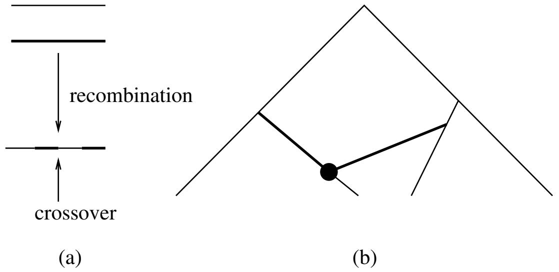

Figure 7. (a) Recombination operation, (b) The topology. The dark edges are recombination edges. The circled node is a recombination node.

A more restricted case, where each internal node has at most one recombination child and there are at most six parents of recombination nodes in any path from the root to a leaf in the given topology, is also considered. It is shown that the restricted version for both FTHR and FTAR is MAX-SNP-hard. That is, there is no polynomial time approximation scheme unless $P = NP$ (86).

The above hardness results are disappointing. However, recombination occurs infrequently. So, it is interesting to study some restricted cases. A *merge node* of recombination node v is the lowest common ancestor of v's two parents. The two different paths from a recombination node to its merge node are called *merge paths*. We then study the case, where

- (**C1**) each internal node has at most one recombination child and
- (**C2**) any two merge paths for different recombination nodes do not share any common node.

Using a method similar to the lifting method for tree alignment, one can get a ratio-3 approximation algorithm for both FTHR and HTAR when the given topology satisfies (**C1**) and (**C2**). The ratio-3 algorithm can be extended to a PTAS for FTAR with bounded number of crossovers (see Ref. 86).

Remarks: Hein might be the first to study the method to reconstruct the history of sequences subject to recombination (23,24). Hein observed that the evolution of a sequence with k recombinations could be described by k recombination points and $k + 1$ trees describing the evolution of the $k + 1$ intervals, where two neighboring trees were either identical or differed by one subtree transfer operation (23–26,35). A heuristic method was proposed to find the most parsimonious history of the sequences in terms of mutation and recombination operations.

Another strike was given by Kececioglu and Gusfield (83). They introduced two new problems, *recombination distance* and *bottleneck recombination history*. They tried to include higher-order evolutionary events such as block insertions and deletions (68) as well as tandem repeats (87,88).

CONCLUSION

In this article, we have discussed some important topics in the field of computational biology such as the phylogenetic construction and comparison methods, syntenic distance between genomes, and the multiple sequence alignment problems. Given the vast majority of topics in computational biology, these discussed topics constitute only a part of them. Some of the important topics that were *not* covered in this articls are as follows:

- protein structure prediction,
- DNA physical mapping problems,

- metabolic modeling, and
- string/database search problems.

We hope that this survey article will inspire the readers for further study and research of these and other related topics.

Papers on compuational molecular biology have started to appear in many different books, journals, and conferences. Below, we list some sources that could serve as excellent starting points for various problems that occur in computational biology:

Books: See Refs. 49,53,62 and 89–92.

Journals: Computer Applications in the Biosciences (recently renamed as Bioinformatics), Journal of Computational Biology, Bulletin of Mathematical Biology, Journal of Theoretical Biology, and so on.

Conferences: Annual Symposium on Combinatorial Pattern Matching (CPM), Pacific Symposium on Biocomputing (PSB), Annual International Conference on Computational Molecular Biology (RECOMB), Annual Conference on Intelligent Systems in Molecular Biology (ISMB), and so on.

Web pages: `http://www.cs.Washington.edu/education/courses/590bi`, `http://www.cse.ucsc.edu/research/compbio`, `http://www.cs.jhu.edu/salzberg/cs439. html`, and so on.

ACKNOWLEDGMENTS

We thank Prof. Tao Jiang for bringing the authors together. We also thank Dr. Todd Wareham for carefully reading the draft and giving valuable suggestions. Bhaskar DasGupta's work was partly supported by NSF grants CCR-0296041, CCR-0206795, and CCR-0208749. Lusheng Wang's work was fully supported by the Research Grants Council of the Hong Kong Special Administrative Region, China (Project No. CityU 1070/02E).

COMPUTATIONAL INTELLIGENCE

INTRODUCTION

Several interpretations of the notion of computational intelligence (CI) exist (1–9). Computationally intelligent systems have been characterized by Bezdek (1,2) relative to adaptivity, fault-tolerance, speed, and error rates. In its original conception, many technologies were identified to constitute the backbone of computational intelligence, namely, neural networks (10,11), genetic algorithms (10,11), fuzzy sets and fuzzy systems (10,11), evolutionary programming (10,11), and artificial life (12). More recently, rough set theory (13–33) has been considered in the context of computationally intelligent systems (3, 6–11, 13–16, 29–31, 34, 35) that naturally led to a generalization in the context of granular computing (32). Overall, CI can be regarded as a field of intelligent system design and analysis that dwells on a well-defined and clearly manifested synergy of genetic, granular, and neural computing. A detailed introduction to the different facets of such a synergy along with a discussion of various realizations of such synergistic links between CI technologies is given in Refs. 3, 4, 10, 11, 19, 36, and 37.

GENETIC ALGORITHMS

Genetic algorithms were proposed by Holland as a search mechanism in artificially adaptive populations (38). A *genetic algorithm* (GA) is a problem-solving method that simulates Darwinian evolutionary processes and naturally occurring genetic operations on chromosomes (39). In nature, a *chromosome* is a thread-like linear strand of DNA and associated proteins in the nucleus of animal and plant cells. A chromosome carries genes and serves as a vehicle in transmitting hereditary information. A *gene* is a hereditary unit that occupies a specific location on a chromosome and that determines a particular trait in an organism. Genes can undergo mutation (alteration or structural change). A consequence of the mutation of genes is the creation of a new trait in an organism. In genetic algorithms, the traits of artificial life forms are stored in bit strings that mimic chromosome strings found in nature. The traits of individuals in a population are represented by a set of evolving chromosomes. A GA transforms a set of chromosomes to obtain the next generation of an evolving population. Such transformations are the result of applying operations, such as reproduction based on survival of the fittest, and genetic operations, such as sexual recombination (also called crossover) and mutation.

Each artificial chromosome has an associated fitness, which is measured with a fitness function. The simplest form of fitness function is known as raw fitness, which is some form of performance score (e.g., number of pieces of food found, amount of energy consumed, or number of other life forms found). Each chromosome is assigned a probability of reproduction that is proportional to its fitness. In a Darwinian system, natural selection controls evolution (10). Consider, for example, a collection of artificial life forms with behaviors resembling ants. Fitness will be quantified relative to the total number of pieces of food found and eaten (partially eaten food is counted). Reproduction consists in selecting the fittest individual x and the weakest individual y in a population and replacing y with a copy of x. After reproduction, a population will then have two copies of the fittest individual. A crossover operation consists in exchanging genetic coding (bit values of one or more genes) in two different chromosomes. The steps in a crossover operation are as follows: (*1*) Randomly select a location (also called the interstitial location) between two bits in a chromosome string to form two fragments, (*2*) select two parents (chromosomes to be crossed), and (*3*) interchange the chromosome fragments. Because of the complexity of traits represented by a gene, substrings of bits in a chromosome are used to represent a trait (41). The evolution of a population resulting from the application of genetic operations results in changing the fitness of individual population members. A principal goal of GAs is to derive a population with optimal fitness.

The pioneering works of Holland (38) and Fogel et al. (42) gave birth to the new paradigm of population-driven computing (evolutionary computation) resulting in structural and parametric optimization. Evolutionary programming was introduced by Fogel in the 1960s (43). The evolution of competing algorithms defines *evolutionary programming*. Each algorithm operates on a sequence of symbols to produce an output symbol that is likely to maximize an algorithm's performance relative to a well-defined payoff function. Evolutionary programming is the precursor of genetic programming (39). In *genetic programming*, large populations of computer programs are bred genetically. One may also refer to biologically inspired optimization, such as particle swarm optimization (PSO), ant colonies, and others.

FUZZY SETS AND SYSTEMS

Fuzzy systems (models) are immediate constructs that result from a description of real-world systems (say, social, economic, ecological, engineering, or biological) in terms of information granules, fuzzy sets, and the relationships between them (44). The concept of a fuzzy set introduced by Zadeh in 1965 (45,46) becomes of paramount relevance when formalizing a notion of partial membership of an element. Fuzzy sets are distinguished from the fundamental notion of a set (also called a crisp set) by the fact that their boundaries are formed by elements whose degree of belonging is allowed to assume numeric values in the interval [0, 1]. Let us recall that the characteristic function for a set X returns a Boolean value {0, 1} indicating whether an element x is in X or is excluded from it. A fuzzy set is noncrisp inasmuch as the characteristic function for a fuzzy

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

set returns a value in [0, 1]. Let $U, X, \tilde{A}$, and x be a universe of objects, subset of U, fuzzy set in U, and an individual object x in X, respectively. For a set X, $\mu\tilde{A} : X \rightarrow [0,\ 1]$ is a function that determines the degree of membership of an object x in X. A fuzzy set $\tilde{A}$ is then defined to be a set of ordered pairs, where $\tilde{A} = \{(\mathrm{x}, \mu\tilde{A}\,(\mathrm{x}))|\mathrm{x} \in \mathrm{X}\}$. The counterparts of intersection and union (crisp sets) are the t-norm and s-norm operators in fuzzy set theory. For the intersection of fuzzy sets, the min operator was suggested by Zadeh (29), and it belongs to a class of intersection operators (min, product, and bold intersection) known as triangular or t-norms. A t-norm is a mapping $t : [0, 1]^2 \rightarrow [0,\ 1]$. The s-norm (t-conorm) is a mapping $s : [0, 1]^2 \rightarrow [0,\ 1]$ (also a triangular conorm) that is commonly used for the union of fuzzy sets. The properties of triangular norms are presented in Ref. 84.

Fuzzy sets exploit imprecision in conventional systems in an attempt to make system complexity manageable. It has been observed that fuzzy set theory offers a new model of vagueness (13–16). Many examples of fuzzy systems are given in Pedrycz (47) and in Kruse et al. (48)

NEURAL COMPUTING

Neural networks offer a powerful and distributed computing architecture equipped with significant learning abilities (predominantly as far as parametric learning is concerned). They help represent highly nonlinear and multivariable relationships between system variables. Starting from the pioneering research of McCulloch and Pitts (49), Rosenblatt (50) as well as Minsky and Pappert (51) neural networks have undergone a significant metamorphosis and have become an important reservoir of various learning methods (52) as well as an extension of conventional techniques in statistical pattern recognition (53). Artificial neural networks (ANNs) were introduced to model features of the human nervous system (49). An *artificial neural network* is a collection of highly interconnected processing elements called neurons. In ANNs, a neuron is a threshold device, which aggregates ("sums") its weighted inputs and applies an activation function to each aggregation to produce a response. The summing part of a neuron in an ANN is called an adaptive linear combiner (ALC) in Refs. 54 and 55. For instance, a McCulloch–Pitts neuron n_i is a binary threshold unit with an ALC that computes a weighted sum net, where $\mathrm{net} = \sum_{j=0}^{n} w_j x_j$. A weight w_i associated with x_i represents the strength of connection of the input to a neuron. Input x_0 represents a bias, which can be thought of as an input with weight 1. The response of a neuron can be computed in several ways. For example, the response of neuron n_i can be computed using sgn(net), where sgn(net) = 1 for $net > 0$, sgn(net) = 0 for net = 0, and sgn(net) = −1, if $net < 0$. A neuron comes with adaptive capabilities that could be exploited fully assuming that an effective procedure is introduced to modify the strengths of connections so that a correct response is obtained for a given input. A good discussion of learning algorithms for various forms of neural networks can be found in Freeman and Skapura (56) and in Bishop (53). Various forms of neural networks have been used successfully in system modeling, pattern recognition, robotics, and process control applications (10,11,35,57,58).

ROUGH SETS

Zdzislaw Pawlak (13–16,59,60) introduced rough sets in 1981 (24,25). The rough set approach to approximation and classification was then elaborated and refined in Refs. 13–21, 24–31, 33, 61, and 62. Rough set theory offers an approach to CI by drawing attention to the importance of set approximation in knowledge discovery and information granulation (32).

In particular, rough set methods provide a means of approximating a set by other sets (17,18). For computational reasons, a syntactic representation of knowledge is provided by rough sets in the form of data tables. In general, an information system (IS) is represented by a pair (U, F), where U is a nonempty set of objects and F is a nonempty, countable set of probe functions that are a source of measurements associated with object features (63). For example, a feature of an image may be color with probe functions that measure tristimulus values received from three primary color sensors, brightness (luminous flux), hue (dominant wavelength in a mixture of light waves), and saturation (amount of white light mixed with a hue). Each $f \in F$ maps an object to some value in a set V_f. In effect, we have $f : U \rightarrow V_f$ for every $f \in F$.

The notions of equivalence and equivalence class are fundamental in rough sets theory. A binary relation $R \subseteq X \times X$ is an equivalence relation if it is reflexive, symmetric, and transitive. A relation R is reflexive if every object $x \in X$ has relation R to itself. That is, we can assert $x R x$. The symmetric property holds for relation R if xRy implies yRx for every $x, y \in X$. The relation R is transitive for every $x, y, z \in X$; then xRy and yRz imply xRz. The equivalence class of an object $x \in X$ consists of all objects $y \in X$ so that xRy. For each set of functions $B \subseteq F$, an equivalence relation $\sim B = \{(x, x')|\,\forall a \in B.\, a(x) = a(x')\}$ (indiscernibility relation)is associat with it. If $(x, x') \in {}^{\sim}\mathrm{B}$, we say that objects x and x' are indiscernible from each other relative to attributes from B. This concept is fundamental to rough sets. The notation $[x]_B$ is a commonly used shorthand that denotes the equivalence class defined by x relative to a feature set B. In effect, $[x]_B = \{y \in U | x \sim B\, y\}$. Furthermore, $Ul \sim B$ denotes the partition of U defined by relation $\sim B$. Equivalence classes $[x]_B$ represent B-granules of an elementary portion of knowledge that we can perceive as relative to available data. Such a view of knowledge has led to the study of concept approximation (64) and pattern extraction (65). For $X \subseteq U$, the set X can be approximated only from information contained in B by constructing a B-lower approximation $B \times X = \cup\{[x]_B | [x]_B \in Ul \sim B \text{ and } [x]_B \subseteq X\}$ and a B-upper approximation $B * X = \cup\{[x]_B | [x]_B \in Ul \sim B \text{ and } [x]_B \cap X \neq \varnothing\}$, respectively. In other words, a lower approximation $B \times X$ of a set X is a collection of objects that can be classified with full certainty as members of X using the knowledge represented by B. By contrast, an upper approximation $B * X$ of a set X is a collection of objects representing both certain knowledge (i.e., classes entirely contained in X) and possible uncertain knowledge (i.e., possible classes partially contained in X). In the case in which $B * X$ is a proper subset of $B \times X$, then the objects in X cannot be classified with certainty and the set X is rough. It has recently been observed by Pawlak (13–16) that this is exactly the idea of vagueness proposed by Frege (65). That is, the vagueness of an approximation of a set stems from its borderline region.

The size of the difference between lower and upper approximations of a set (i.e., boundary region) provides a basis for the "roughness" of an approximation, which is important because vagueness is allocated to some regions of what is known as the universe of discourse (space) rather than to the whole space as encountered in fuzzy sets. The study of what it means *to be a part of* provides a basis for what is known as mereology, which was introduced by Lesniewski in 1927 (66). More recently, the study of what it means to be a part of *to a degree* has led to a calculus of granules (23, 67–70). In effect, granular computing allows us to quantify uncertainty and to take advantage of uncertainty rather than to discard it blindly.

Approximation spaces introduced by Pawlak (24) which were elaborated by Refs. 17–19, 22, 23, 29, 30, 61, 62, 70, 71, and applied in Refs. 6–8, 35, 64, 72, and 73 serve as a formal counterpart of our perception ability or observation (61,62), and they provide a framework for perceptual reasoning at the level of classes (63). In its simplest form, an approximation space is denoted by $(U, F, \sim B)$, where U is a nonempty set of objects (called a universe of discourse), F is a set of functions representing object features, $B \subseteq F$, and $\sim B$ is an equivalence relation that defines a partition of U. Equivalence classes belonging to a partition $Ul \sim B$ are called elementary sets (information granules). Given an approximation space $S = (U, F, \sim B)$, a subset X of U is definable if it can be represented as the union of some elementary sets. Not all subsets of U are definable in space S(61,62). Given a nondefinable subset X in U, our observation restricted by $\sim B$ causes X to be perceived relative to classes in the partition $Ul \sim B$. An upper approximation $B^{*}X$ is the set of all classes in $Ul \sim B$ that have elements in common with X, and the lower approximation $B \times X$ is the set of all classes in $Ul \sim B$ that are proper subsets of X.

Fuzzy set theory and rough set theory taken singly and in combination pave the way for a variety of approximate reasoning systems and applications representing a synergy of technologies from computational intelligence. This synergy can be found, for example, in recent work on the relation among fuzzy sets and rough sets (13–16,35,37, 74,75), rough mereology (19,37,67–69), rough control (76,77), fuzzy–rough–evolutionary control (36), machine learning (18,57,72,78), fuzzy neurocomputing (3), rough neurocomputing (35), data mining (6,7,13–16,31), diagnostic systems (18,79), multiagent systems (8,9,80), real-time decision making (34,81), robotics and unmanned vehicles (57,82,83), intelligent systems (8,13,29,57), signal analysis (84), perception and classification of perceptual objects (29, 30,61–63), software engineering (4,84–87), a dominance-based rough set approach to multicriteria decision making and data mining (31), VPRS (33), and shadowed sets (75).

COMPUTER ENGINEERING EDUCATION

Computer engineering education (CEE) is concerned with preparing qualified computer engineers who can take the lead and innovation in the rapid growth of technology and computer engineering fields that dominate all aspects in our life. The issues of computer engineering education rely on a broad mathematical and scientific knowledge base. Before discussing issues related to CEE, a short description of computer engineering is helpful.

Developments in technologies such as telecommunications, remote sensing and detection, electronic components and robotics, as well as computers have fundamentally altered human life. The field of computer engineering is at the epicenter of this development. Computer engineering is the design, construction, implementation, and maintenance of computers and computer-controlled equipment for the benefit of humankind. A computer engineer encompasses a blend of both electrical engineering and computer science. Computer engineers are involved in many aspects of computing, from the design of individual microprocessors, personal computers, and supercomputers, to circuit design. Those in computer engineering careers engage in activities that advance technology and provide new concepts. They then put those new concepts into physical form.

Usual tasks involving computer engineers include writing software and firmware for embedded microcontrollers, designing Very Large-Scale Integration (VLSI) chips, designing analog sensors, designing mixed signal circuit boards, and designing operating systems. Computer engineers are also suited for robotics research, which relies heavily on using digital systems to control and monitor electrical systems like motors, communications, and sensors. They also solve technical problems, develop new products from initial idea conception through completion, and install computer systems.

The computer engineering field provides an opportunity to work in the continually changing information technology sector. With the development of faster hardware components, new communication systems and software, there is a need for computer engineers. The computer engineer will work as part of a team helping to solve technical problems and pass that information on to software engineers who would do the programming or network engineers who can install and operate network and communication infrastructure.

All computer engineers may do any or all of the following tasks (1):

- Analyze information to determine client needs
- Conduct training and presentations
- Collaborate with clients, project managers, and team members to organize and plan projects
- Determine whether the project will meet the desired budget
- Research, develop, integrate, and distribute security tools and associated documentation
- Design systems
- Develop and direct testing procedures
- Provide technical support
- Coordinate installation of computer hardware or software
- Document and evaluate project progress
- Manage assigned accounts
- Specify project requirements
- Provide analysis and recommendations for overall system architecture
- Maintain equipment

To be able to achieve these tasks, computer engineers rely on a broad mathematical and scientific knowledge base, as well as on a modern (up-to-date) computer engineering education.

In the sequel of this work, we first will briefly introduce the history of computer engineering curriculum evolution. Then we will explore the computer engineering field as an academic discipline. A brief summary of the IEEE-CS/ACM joint task force report on computer engineering curriculum guidelines (CE2004) will be given. Next, we will discuss modern computer engineering education practices. By "modern" we mean applying advanced technology in the computer engineering learning process (such as multimedia, Web technologies, e-learning, simulations, etc.) to produce teaching/learning materials that meet the computer engineering students' learning preferences. Learning technologies such as learning design and learning management systems will then be discussed. Finally, a vision on the future of computer engineering education will be introduced followed by concluding remarks.

HISTORY AND EVOLUTION OF COMPUTER ENGINEERING EDUCATION

In the 1940s and 1950s, several traditional subjects and courses in engineering and science started to shift toward the then new born computer engineering courses. In the 1970s, most colleges and universities worldwide began offering majors in computer science and some in computer engineering.

The Association for Computing Machinery (ACM) began publishing curriculum recommendations for computer science in 1968 (a preliminary version appeared in 1965) and for information systems in 1972. In a parallel effort, The Computer Society of the Institute for Electrical and Electronic Engineers (IEEE-CS) began providing curriculum recommendations in 1977. The IEEE Computer Society published its first computer engineering curriculum around 1983 (2). Prior to the 1990s, each society produced its own curriculum recommendations. Over time, the advantages of cooperative work among them

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

became obvious. Today, the societies cooperate in creating curriculum standards and, in this way, unify the efforts and send a single message to the computing and engineering communities.

IEEE-CS and ACM joined forces in the late 1980s to create a joint curriculum report for computing. Published in 1991 and known as *Computing Curricula 1991*, or CC'91, it provided guidelines for curricula for four-year bachelor's degree programs in computer science. CC'91 defined computer science in terms of 3 processes, 9 fundamental subject areas, 12 recurring concepts, and a social and professional context.

According to CC'91, the three processes of computer science are defined as follows:

- Theory (mathematical roots)
- Abstraction (scientific roots)
- Design (engineering roots)

The curriculum also included nine fundamental subject areas:

1. Algorithms and data structures
2. Architecture
3. Artificial intelligence and robotics
4. Database and information retrieval
5. Human–computer communication
6. Numerical and symbolic computations
7. Operating systems
8. Programming languages
9. Software methodology and engineering

The 12 recurring concepts are listed as follows:

1. Binding
2. Complexity of large problems
3. Conceptual and formal models
4. Consistency and completeness
5. Efficiency
6. Evolution
7. Levels of abstraction
8. Ordering in space
9. Ordering in time
10. Reuse
11. Security
12. Trade-offs and consequences

Throughout the 1990s, various efforts were made to produce curricula guidelines for other programs in computing education. By 1993, ACM had produced five reports for two-year associate-degree programs, one report each for *computer science*, *computer engineering technology*, *information systems*, *computer support services*, and *computing for other disciplines*. By the end of the 1990s, it was becoming clear that the field of computing had not only grown rapidly but had also grown in many dimensions. This rapid growth in computing results in a growing number of kinds of computing degree programs. IEEE–CS and ACM again joined forces in the late 1990s to produce an up-to-date curriculum report to replace CC'91, and to tackle the problem of the growing number of kinds of computing degree programs. IEEE–CS and ACM created a joint task force with the goal of producing Computing Curricula 2001 (CC2001), a single report that would provide curriculum guidelines for degree programs for the various computing disciplines. However, the members of the task force soon recognized the new reality: Computing had grown in so many dimensions that no single view of the field seemed adequate. The days when the field of computing consisted of only *computer science, computer engineering*, and *information systems* were over, and the richness and breadth provided by the various computing disciplines called for a new way of defining what computing curricula should be. The work of this task force, known as *Computing Curricula 2001* (CC2001), was published in December 2001. The CC2001 Report contains detailed curricula guidelines for undergraduate degree programs in computer science (3).

In response to the CC2001 model, work soon began on other discipline-specific volumes:

- The *information systems* community published its updated *IS2002* report in 2002.
- The *software engineering* community published its first report, *SE2004*, in 2004.
- The *computer engineering* community published its *CE 2004* report in 2004.
- The *information technology* community published its (draft) *IT2005* report in 2005.

The post-1990s world presents meaningful choices: Computer science, software engineering, and computer engineering each include their own perspective on software development. These three choices imply real differences: For computer engineering, software attention is focused on hardware devices; for software engineering, the emphasis is on creating software that satisfies robust real-world requirements; and for computer science, software is the currency in which ideas are expressed and a wide range of computing problems and applications are explored (see Fig. 1) (3).

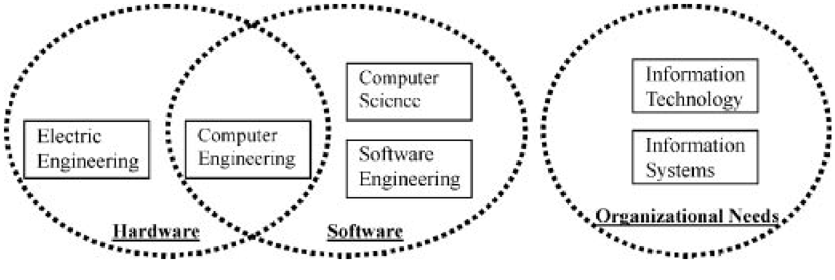

Figure 1. IEEE-CS/ACM joint task force classification for computing disciplines post-1990s (3).

COMPUTER ENGINEERING AS AN ACADEMIC DISCIPLINE AND A BRIEF OVERVIEW OF THE IEEE–CS/ACM CE 2004 REPORT

Computer engineering as an academic field encompasses the broad areas of computer science and electrical engineering.

According to the IEEE-CS/ACM joint task force classification for computing related subjects, there are three areas: hardware, software, and organizational needs. Hardware includes electric engineering and computer engineering. Software includes computer engineering, computer science, and software engineering. Organizational needs include information technology and information systems. According to this classification, computer engineering comes in the intersection between hardware and software areas. Figure 1 shows this classification.

Most universities offer computer engineering as either a degree program of its own or as a subdiscipline of electrical engineering. With the widespread use and integration of computers into our everyday lives, it is hard to separate what an electrical engineer needs to know and what a computer engineer needs to know. Because of this, several universities offer a dual degree in both electrical and computer engineering.

The field of computer science and engineering has been in a rapid growth phase for the last 50 years. This state of rapid growth and change has placed challenges on universities and colleges to define and administrate modern academic programs to prepare students adequately to enter this profession.

Due to increasing job requirements for engineers, who can design and manage all forms of computer systems used in industry, some tertiary institutions around the world offer a bachelor's degree generally called "computer engineering." Both computer engineering and electronic engineering programs include analog and digital circuit design in their curricula. As with most engineering disciplines, having a sound knowledge of mathematics and sciences is necessary for computer engineers.

A computer engineering program should contain sufficient coursework at the introductory, intermediate, and advanced levels based on a sound body of knowledge of computer engineering. Programs should be augmented by a judicious selection of elective courses that build on that foundation. Breadth and depth in science and mathematics are important to this discipline. The curriculum should also emphasize professional practice, legal and ethical issues, and the social context in which graduates implement engineering designs. A sound graduation project is also necessary. Problem-solving and critical thinking skills, oral and written communication skills, teamwork, and a variety of laboratory experiences are essential to the study of computer engineering.

The joint IEEE-CS/ACM *Curriculum Guidelines for Undergraduate Degree Programs in Computer Engineering* CE'2004 defines the core knowledge areas (that is, the topics the field should cover) of computer engineering as follows (4, pp. 12):

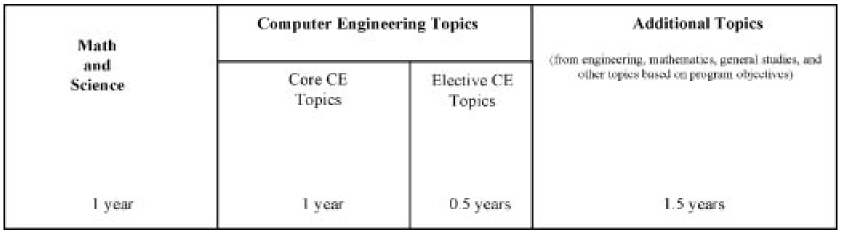
- Algorithms
- Computer architecture and organization
- Computer systems engineering
- Circuits and signals
- Database systems
- Digital logic
- Digital signal processing
- Electronics
- Embedded systems
- Human–computer interaction
- Computer networks
- Operating systems
- Programming fundamentals
- Social and professional issues
- Software engineering
- VLSI design and fabrication
- Descrite structures
- Probability and statistics

The last two areas cover related mathematical topics. The breadth of disciplines studied in computer engineering is not limited to the above subjects but can include any subject found in engineering. For example, the concepts of automata theory, which can model several hardware and software applications, are in the core of many computer science and computer engineering curriculum.

In addition to the core knowledge areas, the CE'2004 report introduced a set of possible elective courses that involves both hardware and software topics at an advanced level. Table 1 shows some examples of the proposed elective courses (4, pp. 35).

Table 1. Examples of Elective Courses

Fault-tolerant computer systems	Performance evaluation	Advanced computer architecture
Digital video processing	System-level integration	Audio signal processing
Parallel processing	High-performance computer systems	Mobile computer systems
Reconfigurable computing	Hardware software codesign	Multimedia signal processing
Intelligent systems	Computer security	Security in wireless systems
Safety critical systems	Tool development	Computer-based devices
Pervasive computing	Multimedia systems and algorithms	Novel computer architectures
Advanced graphical systems	Genetic algorithms	Distributed information systems
Computer-based medical systems	Entertainment systems	Virtual devices
Virtual environment	Robotics	Multivalued logic systems
Quantum computing	DNA computing	Nanocomputing



Math and Science	Computer Engineering Topics		Additional Topics (from engineering, mathematics, general studies, and other topics based on program objectives)
	Core CE Topics	Elective CE Topics	
1 year	1 year	0.5 years	1.5 years

Figure 2. Organization of a four-year computer engineering curriculum.

The CE'2004 report introduced a four-year model computer engineering program. The model includes one year of mathematics and science courses, one year of computer engineering core courses, one-half year of computer engineering electives, one-half year of additional engineering studies, and one year of general studies. Figure 2 illustrates this model program (4, pp. 19).

Program Evaluation and Accreditation

Professional evaluation and accreditation systems for engineering programs are critical to ensure that graduates have the proper preparation expected by society. Such accreditation is done by widely accepted professional institutions such as ABET in the United States, the *British Computer Society* (BCS) in the United Kingdom, and the *Japan Accreditation Board for Engineering Education* (JABEE) in Japan. The first accredited computer engineering degree program in the United States was established at Case Western Reserve University in 1971; as of October 1, 2007, there were 196 ABET-accredited computer engineering programs in the United States.

The evaluation criteria for accreditation of engineering programs could be summarized in the following general points:

1. Learning and educational objectives: The program must have a set of clear learning and educational objectives that reflect that the students will gain proper knowledge to have a positive impact on the society both from scientific and ethical points of view.
2. Students evaluation: The program must have a measure for evaluating the students' performances and achievements against the learning and educational objectives.
3. Curriculum requirements: The program must specify minimum curriculum requirements. For example, minimum hours for each core knowledge subject, contact office hours, and number of credit units required for graduation.
4. Educational environment: The program must ensure a proper educational environment such as facilities and equipments for labs and classes, and financial resources for operation and maintenance of the equipments, etc.
5. Learning and educational improvement: The program must have a system for continuing improvement in the learning process, such as student support system, proper use of students' feedback, and faculty development system, and so on.

These are some of the general criteria for the accreditation of engineering programs. More specific details vary from country to country. Many countries have established their own processes for evaluation and/or accreditation through governmental or professional societies.

TECHNOLOGY APPLICATIONS IN COMPUTER ENGINEERING EDUCATION

Applications of technology can provide course content with multimedia systems, active learning opportunities, and instructional technology to facilitate education in the area of computer engineering to a broad range of learners.

Multimedia in Computer Engineering Education

Multimedia is an exciting area that spans many disciplines within computer engineering—it is a computer-based communications system that integrates and delivers a complete package of audio, video, animations, graphics, and text to end users.

Throughout the 1980s and 1990s, the concept of multimedia took on a new meaning, as the capabilities of satellites, computers, audio, and video converged to create new media with enormous potential. Combined with the advances in hardware and software, these technologies were able to provide an enhanced learning facility with attention to the specific needs of individual users.

Besides being a powerful tool for making presentations, multimedia offers unique advantages in the field of education. For instance, text alone simply does not allow students to get a feel of how operating systems work. In teaching computer architecture, an instructor cannot make a simulation of a processor in a classroom. Multimedia enables us to provide a way by which learners can experience their subject in a vicarious manner. The key to providing this experience is having simultaneous graphics, video and audio, and computer simulation rather than in a text manner. The appeal of multimedia learning is best illustrated by the popularity of the video games currently available in the market. These are multimedia programs combining text, audio, video, and animated graphics in an easy-to-use fashion (5).

The benefits of using multimedia in education in general and in computer engineering in particular include, but are not limited to:

- Allowing students to act as designers by using simulation tools for analyzing the world.

- Encouraging deep reflective thinking by using more brain sensors.
- Creating personally meaningful learning opportunities.

Multimedia use has become a common practice in many computer engineering courses. For example, in Ref. 6, a simulation of electrooptic and acoustooptic theory and devices for computer engineering students was introduced. In this multimedia simulation, graphical outputs, hypertexts, and animations are widely used. There are hundreds of examples of using multimedia in computer engineering education. A few recent examples can be found in Refs. 7–13.

Web-based Technology in Computer Engineering Education

The Internet is a powerful new means of communication. It is global, it is fast, it is cheap, and it is growing rapidly. It has transformed information at nearly real-time speed. The World Wide Web is bringing rapid and radical change into all aspects of our lives. For education, the Internet is making it possible for more individuals than ever to access knowledge and to learn in new and different ways. The Internet enables bringing learning to students instead of bringing students to learning. It is allowing for the creation of learning communities that overcome the constraints of time, distance, and boundaries.

Web-based education is currently a hot research and development area. The benefits of Web-based education are clear: Learners from all over the world can enroll in learning activities, communicate with other students or teachers, as well as discuss and control their learning progress.

The Internet has provided the option of pursuing courses in computer engineering online as a part of the e-learning systems. The Web was first used as a telecontrol medium in 1994. Since then it has been applied more and more in the educational context.

The modern university needs to extend lifelong learning opportunities to its students at anytime and at anyplace to be successful in the global educational marketplace. Online Web-based learning is made possible by advancements in network infrastructure and the development of video/voice/multimedia protocols for seamless transport of information. However, the developer of a Web-based e-learning system, in addition to considering knowledge-domain requirements, must ensure good pedagogy and learning practices given the technical constraints with regard to bandwidth, quality of service, real-time interactions, multiple users, and security (14). Despite these challenges, Web-based education has been offered by universities in undergraduate computer engineering courses since 1996, with the number and sophistication of these efforts growing each year (15).

Web-based education is just beginning, with something of far greater promise emerging in the middle distance. For example, Web-based intelligent tutoring systems will soon be able to recognize a remote user's affective state and respond with an appropriate intervention. Web-based grading systems are being developed by which students can be automatically graded. All these environments seen to supplement greatly the active learning classroom/laboratory (16).

There are thousands of examples of using Web-based technology in computer engineering education. Here we refer to a few recent ones (11,12,17–19).

Active and Collaborative Learning in Computer Engineering Education

Active and collaborative learning provides a powerful mechanism to enhance depth of learning, increase material retention, and get students involved with the material instead of passively listening to a lecture. Active learning is a learning with students involved in the learning process as active partners: meaning they are "doing," "observing," and "communicating" instead of just "listening" as in the traditional (lecture-driven) learning style.

In traditional lecture-driven education, material to be learned is often transmitted to students by teachers. That is, learning is passive. In active learning, students are much more actively engaged in their own learning while educators take a more guiding role. This approach is thought to promote processing of skills/knowledge to a much deeper level than passive learning (20).

Rossati (21) and Hamada (11) showed that engineering students have strong active learning preferences. Such results suggest that active teaching materials are recommended for computer engineering students. In designing learning tools, computer engineering educators need to consider the active construction learning model (22,23), which has several basic design principles, including the following:

1. Teachers act as facilitators, not as knowledge transmitters. This means knowledge must be actively constructed by learners, not passively transmitted by teachers.
2. To motivate learners and get them actively involved in knowledge construction, learning activities should focus around a set of motivating problems and examples that have applications in the real world.
3. Learning should take place in a collaborative environment.
4. Assessment procedures should be embedded in the learning process and should consider learners' individual orientations.

As an example of recent application of active and collaborative teaching materials in computer engineering, we refer to Hamada (11).

LEARNING THEORIES IN COMPUTER ENGINEERING EDUCATION

Learning science research indicates that engineering students tend to have active and sensing learning preferences, and engineering-related educators are recognizing the need for more active and collaborative learning pedagogy (24). So far, several learning models have been developed (e.g., Refs. 25–28) for the realization of the learning preferences of learners. Among these models, Felder-Silverman (25) is simpler and easier to implement through a Web-based quiz system, as in Felder-Soloman (29). The model classifies engineering learners into four axes: active versus reflective, sensing versus intuitive, visual versus verbal, and sequential versus global. Active learners gain information through a learning-by-doing style, whereas reflective learners gain information by thinking about it. Sensing learners tend to learn facts through their senses, whereas intuitive learners prefer discovering possibilities and relationships. Visual learners prefer images, diagrams, tables, movies, and demos, whereas verbal learners prefer written and spoken words. Sequential learners gain understanding from details and logical sequential steps, whereas global learners tend to learn a whole concept in large jumps.

In Rosati (21), a study of this model was carried out to classify the learning style axes of engineering learners. The study showed that engineering learners tend to have strong active, sensing, visual, and sequential learning preferences. A similar result was obtained by Hamada (11) for computer engineering learners.

Learning Design

The central ideas behind learning design represent new possibilities for increasing the quality and variety of teaching and learning within an (e)-learning context (30, 31):

- The first general idea behind learning design is that people learn better when actively involved in doing something (i.e., are engaged in a *learning activity*).
- The second idea is that learning activities may be sequenced or otherwise structured carefully and deliberately in a *learning workflow* to promote more effective learning.
- The third idea is that it would be useful to be able to record "learning designs" for sharing and reuse in the future.

It is a recommended practice to follow the guidelines of learning design, such as the IMS-LD learning design specifications (31), when preparing teaching materials for computer engineering courses. For a recent example of using IMS-LD specifications in computer engineering, we refer to Ref. 32.

Learning Management Systems

A learning management system (LMS) is a software application or Web-based technology used to plan, implement, and assess a specific learning process. Typically, a learning management system provides an instructor with a way to create and deliver content, monitor student participation, and assess student performance. A learning management system may also provide students with the ability to use interactive features such as threaded discussions, video conferencing, and discussion forums. The Advanced Distance Learning group (33), sponsored by the United States Department of Defense, has created a set of specifications called Shareable Content Object Reference Model (SCORM) to encourage the standardization of learning management systems. Another well-known model of learning management systems is the Modular Object Oriented Dynamic Learning Environment (MOODLE) (34). MOODLE supports a range of different resource types that allow almost any kind of digital content into courses. The resource may already exist in electronic form so it can be linked to an uploaded file or external website, or simply display the complete contents of a directory in the course files and then users can pick the file themselves.

Several computer engineering courses are now integrated with such learning management systems to get benefits from its features in enhancing the learning process. See, for example, Refs. 29 and 35.

A VISION FOR THE FUTURE

Technology is growing rapidly. The following three laws are generally accepted as governing the spread of technology:

- *Moore's Law for computer performance.* The computing power is growing rapidly. According to Moore's law, which is widely believed will remain valid until at least 2020, the processing power of a chip doubles every 18 months. Moore's law suggests that performances are expected to rise to 10^{15} instructions/second (i.e., 1 petaflops/second) by 2010 and 10^{16} instructions/second by 2013.
- *Gilder's Law for communications systems.* Networks that operate at the rate of 100 GB/second exist (GB = Giga Byte, 1 GB = 1024 Megabyte). According to Gilder's law, the total bandwidth of communication systems triples every 12 months. Thus, by 2013, the capacity of communications systems will have moved to about 100 TB/second (TB = Tera Byte, 1 TB = 1024 GB).
- *Metcalfe's Law for value of a network.* Robert Metcalfe, originator of Ethernet and founder of 3COM, stated that: "the value of a network is proportional to the square of the number of nodes; so, as a network grows, the value of being connected to it grows at a polynomial rate, while the cost per user remains the same or even reduces."

In addition to this rapid growth in technology, several technical areas seem to be emerging and point to future developments in computing and computer engineering in particular. A few examples are as follows.

- *Quantum computing*: Quantum computing relies on quantum physics by taking advantage of certain quantum physics properties of atoms or nuclei that allow them to work together as quantum bits, or qubits, to be the computer's processor and memory. By interacting with each other while being isolated from the external environment, qubits can perform certain calculations exponentially faster than conventional computers. Currently, quantum computers and quantum information technology remain in the pioneering stage.

- *Nanotechnology*: Nanotechnology is the engineering of functional systems at the molecular scale. It refers to the projected ability to construct items from the bottom up to complete high-performance products. This process needs development of new techniques and tools.
- *Semantic web*: Associated with information is its semantics or meaning. If computer systems can address questions of semantics, the route becomes open for systems to engage in interesting exchanges and to carry out deduction. Currently, these developments are some way off.
- *Ubiquitous computing*: This is a paradigm shift where technology becomes virtually invisible in our lives. Instead of having a desktop or laptop machine, the technology we use will be embedded in our environment.

These technology developments suggest a new focus and possible new titles for new degrees in the future. There is no doubt that the undergraduate curriculum and the quality of its delivery are at the heart of shaping the professional life of an engineer and the degree to which he or she will be successful. The content must be relevant to the engineering community, and the pedagogy must ensure that students have a solid understanding of engineering principles and the ability to think. Furthermore, the curriculum must stimulate the motivation and development of both students and faculty.

When transforming the traditional lecture-driven educational paradigm in computer engineering into a new model that will promote learning activities that are independent of time and place, it is necessary to consider the infrastructure that allows such a model to function. The future of interactive media in a new computer engineering educational model is that of ubiquitous communication tools. This may be enabled by new technologies such as WebTVs, NetPCs, or others.

The potential for computer engineering students to author, as part of a creative educational program that is based on achievement of goals and competencies rather than on time served, will assist educators to shift from teacher to facilitator and mentor. Interactive communication tools will transform our capability to embrace an educational paradigm that deals with computer engineering learning as a vital, fulfilling, and continuing part of life at home and in the workplace as well as within educational institutions.

Because of the rapid pace of change in the computing field, computer engineers must be life-long learners to maintain their knowledge and skills within their chosen discipline.

CONCLUSION

At many universities, computer engineering emerged from electrical engineering during the late 1970s and the 1980s, but it was not until the 1990s that computer chips became basic components of most kinds of electrical devices and many kinds of mechanical devices. (For example, modern automobiles contain numerous computers that perform tasks that are transparent to the driver.) Computer engineers design and program the chips that permit digital control of many kinds of devices. The dramatic expansion in the kinds of devices that rely on chip-based digital logic helped computer engineering solidify its status as a strong field, and during the 1990s, unprecedented numbers of students applied to computer engineering programs. Computer engineering is a difficult major but it is a major that is in demand. Software engineering companies, telecommunications firms, designers of digital hardware, health-care industry, transportation, academics, financial institutions, and service-oriented businesses, as well as many other business enterprises, hire computer engineering majors right out of college (36).

The rapid advances in technology and the increasing demand for qualified computer engineers add new challenges for computer engineering educators. These challenges have caused the traditional lecture-driven classroom to give way to a new and more active environment, where students have access to a variety of multimedia and interactive course materials. Such interactive course materials have already been introduced for several topics in computer engineering courses; see, for example, Refs. 10, 13, 19, 37, and 38.

COMPUTER-SUPPORTED ASYNCHRONOUS LEARNING: THE RELEVANCE OF COMMUNICATION AND FACILITATION

INTRODUCTION

An increasing number of developments in the field of electronic support for asynchronous learning can be assigned to computer-supported collaborative learning (CSCL) (1). During collaborative learning, participants learn from each other by actively co-constructing knowledge (2). This active co-construction of knowledge bases on the theory of constructivism is described as the "motivating theory in CSCL literature" (3). The active involvement is the most important advantage of collaborative learning since participants get a deeper understanding of the learning object.

Computer-supported collaborative learning, which is often distributed locally and temporally, mainly focuses on communication since direct experience of a situation and learning by observation are mostly inapplicable. The more communication occurs, the better the situation is ranked by tutors, as well as by researchers (4). With respect to learning it was found that the communication has a crucial relevance for learning and the development of thinking (5). Thus, the support of communication is viewed as a precondition for computer-supported collaborative learning (6). These findings result in a high relevance of an appropriate communication support in CSCL systems.

This article deals on the one hand with the design of communication support for asynchronous communication and collaborative learning (see the next section). As an underlying approach for the design of communication support in CSCL systems, a communication theory is presented. In a second step, the typical characteristics of systems that follow the requirements based on this communication theory are described. This view of the theory gives the reader a chance to understand and rate the support for asynchronous learning, and this view of the characteristics of the system informs readers about actual developments in this field.

If the construction of knowledge is a joint process of several students, it is the main role of the teacher to support and facilitate the communication processes for constructing knowledge. Therefore, this article deals on the other hand with the facilitation of asynchronous discussions in CSCL processes. Based on related work, the main activities of facilitation and computer support are presented. From the presentation of communication and facilitation support, general guidelines for the design of communication and facilitation support for asynchronous collaborative learning are derived.

THE DESIGN OF ASYNCHRONOUS COMMUNICATION SUPPORT

Context-Oriented Communication Theory

In computer science, models of communication are generally characterized by the sender–recipient model by Shannon and Weaver (7). In this model, the transmission of a sender's message to a recipient by a channel is assumed, where the message is encoded before and decoded after the transmission. However, even if human communication acts are transmitted by a CSCL system, they are more than only the technical transport of a coded message from A to B and a following decoding. Psychologically oriented research shows that both communication partners have to contribute if the mutual understanding and construction of ideas is to succeed in dialogues (8). Communication is a process that is influenced by several selections. A communicator selects from the universe of his/her beliefs what he/she wants to say, and the recipient selects, with respect to his/her universe of beliefs, what he/she wants to understand. In the course of social interaction, these selection processes cannot be determined in advance but can only be influenced by the communication.

Another basic characteristic of communication is the relevance of context. Communication can only succeed, if the communicator's expressions are completed by the context that can be perceived by the communicator and the recipients (9). Context is understood as the physical and social setting in which the communication takes place (10). The context of the communicators is represented by what they perceive during communication and by what they have perceived before the moment of the communication act. Since context can refer to the past, an expression of the moment can become part of another expression's context in the future. The starting point or the boundaries of the context of a communication act cannot be defined deterministically. It belongs to the task of the communicators to encircle the scope of context that can support their communication.

By referring to the available context, two essential advantages are achieved. On the one hand, the explicitness of the conveyed content does not need to be maximal, because only these pieces of information have to be given that are required to complete the context in such a way that the message can be reconstructed and understood by the recipient. For example "Where is the car?" can be answered with "behind the red house" if there is only one red house that is part of the perceptible context. The communicator has to anticipate the scope of context that is available for the addressee. This anticipation can be supported by knowledge about the communication partner. Eventually, the need for explicit communication can be reduced ("where is the car?"—"same place as yesterday"). On the other hand,

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

the available context assists in finding out whether the communication partners understand each other. Depending on how a situation evolves, there are either indicators for the success of a communication task or an identifiable necessity to recheck the comprehension of the message or simply to improve the communication ("let's get up immediately" — "why are you not getting up right now" — don't you understand me?").

To emphasize the role of the context, this theory is called context-oriented communication support (11). It can and should be used for the design of CSCL systems, especially its communication support.

Computer Support for Context-Oriented Communication

In CSCL systems, the provided material can and has to be used to serve as context. For the design of CSCL systems, a design rationale for computer-supported communication is suggested that emphasizes the difference between communicative contributions and context as well as the tight interweavement of both. Hmelo-Silver, for example, mentions this requirement with respect to computer-supported, problem-based learning: "There needs to be a mechanism for the facilitator and other students to negotiate and discuss the contents of the whiteboards in an integrated fashion" (12).

These requirements are fulfilled in systems that use annotations for the support of communication. The annotations (= communicative contributions) are related to learning material (= context). Discussions occur by annotating annotations. The design of communicative contributions in the form of annotations in CSCL systems is inspired by systems for joint creating and editing of text like CoNote (13), CaMILE (14) or WebAnn (15). All these systems focus on functionalities enabling annotations but do not support the linkage of fine-grained material (CoNote and CaMILE) or material that is added by the learners (WebAnn). Therefore, the material cannot be used flexibly as context. Two CSCL systems that follow the context-oriented communication theory are anchored discussions (16) and KOLUMBUS (17).

In the following discussion, the main concepts for the support of context-oriented communication and facilitation are explained by the example KOLUMBUS. KOLUMBUS[1] is a Web-based CSCL system and should be viewed as one example for the class of CSCL systems that support asynchronous learning. The name is an acronym for a German term that stands for "Collaborative Learning Environment for Universities and Schools." The concentration on only one system in this article offers the possibility to show interrelations between different functionalities and to add experiences with the described functionalities.

The crucial feature of KOLUMBUS is to support the segmentation of content into small units. This segmentation allow the learners a highly flexible intertwining of content as context with communicative contributions in the form of annotations. KOLUMBUS provides two different views of content. In the tree view, each item is represented as a node in a hierarchical tree-structure. To focus on relevant content, parts of the tree or the whole tree can be expanded or minimized. Furthermore, newly inserted items are indicated as new. Although the structure of a set of interrelated annotations represents a dialogue-oriented discussion thread, the hierarchical structure of the material depends of the logical relationships between its content.

By contrast to the tree view, the article view shows content in a visually more attractive and readable way. Here, different types of presentations are combined to form a single document. Within the paper view, KOLUMBUS supports the perception of meaningful structures built up on a didactical basis. The teacher is responsible for preparing material, arranging how the (initial) material is displayed in the paper view. Didactically prepared material of the teacher can be used by the students as a starting point for their own research. In the paper view, it is also possible to expand or reduce the scope of displayed items and, therefore, to achieve an adaptable extent of context as being necessary to facilitate communicative understanding. Figure 1 shows the menu that can be activated at every single item. It allows users, for example, to add communicative contributions (in the form of annotations) or material. All these functions of KOLUMBUS are available in both types of representation (paper or tree view).

Both the tree view and the paper view can be used to work with an individual's own material as well as with that of others. To differentiate between annotations and material, the tree view uses different icons, whereas the paper view employs different colors. In the paper view, the communicative character of annotations is increased by prefixing the annotation with the author's name, which is similar to the convention with newsgroups. After switching from tree to paper view, annotations are hidden behind a nonintrusive symbol to offer the chance to assimilate the material first.

An advantage of the concept of the fine-grained item-structure is that communicative contributions can be directly linked to that part of the content to which they refer, and which therefore provides the relevant context. From this point of view, it becomes obvious that the definition of context depends on the communication act itself. Context is everything to which an annotation refers.

Figure 1 shows the paper view from a seminar in computer science: a title and some sections of material and two annotations (communicative contributions). Annotations are signed with an "A" and the name of the author in front. Because the communicative contributions are placed in the direct context, the author does not need to include hints for additional context. This leads to relatively short contributions and to the usage of direct references (in both annotations in Fig. 1, the word "hier" (German for "here") is used to reference the context).

Asynchronous learning by communication is supported by the possibility of discussion threads that can be developed by annotating other participants' annotations. These threads can be handled in the same manner as, for example, in newsgroups. Threads can occur in parallel; they can be expanded or minimized (as all items in KOLUMBUS). Figure 2 shows an example in the tree view. Items are signed with the pencil and post-it icon. Since the tree view

1.3.2 Gruppen-Lernsysteme

(FIT_Ernst) Hier stellt sich mir sofort die Frage, wie ein Gruppenlernsystem aufgebaut ist und welche Rollen man unterscheiden kann. Daher wäre es meiner Meinung nach sinnvoller, die Architektur aus Kapitel 2.3 an dieser Stelle nach vorne zu ziehen. Vielleicht kannst Du die Architektur auch graphisch darstellen.

Auf dem Gebiet der Grupp … orted Collaborative/Cooperative Learning (CSCL) etabliert.

(FIT_Helge) Was genau ist denn nun CSCL? Das sollte hier nochmal genauer 'definiert' verden.

Man unterscheidet zwischen zentralisierten CSCL-Systemen und verteilten CSCL-Systemen.

Zentraler Begriff bei den hier betrachteten Lernsystemen ist der der Gruppe.

Um zu erklären, wann aus isolierten Individuen eine Gruppe wird, bietet die Sozialpsychologie ein 4-Phasenschema zur Erklärung des Zustandekommens einer Gruppe (For87): Forming, Storming, Norming und Performing.

Figure 1. Communicative contributions in context.

should only give an overview, just the beginning of the annotations (as well as text-based material) is presented in one row. The whole content can be read in a tool tip that appears with the mouse-over.

Experiences with KOLUMBUS (see Ref. 17 for details) revealed on the one hand that the integration of communication and work on material is an appropriate concept to support context-oriented communication and collaborative learning. The studies support the requirements derived from the context-oriented model of communication. Learning material serves as context and supports the communication. The tight integration of communicative contributions in the form of annotations and segmented learning material helps in general the communicator to select the appropriate pieces of context information and the recipient to understand better the utterance of the communicator. However, problems with the detection of new communicative contributions occur when the content structure is growing very fast — this lead to the necessity for concepts like the annotation window. This problem is also related to the question of an appropriate granularity. A fine granularity helps a communicator to relate his expression exactly to the context but results in a fast-growing content tree. A coarse granularity, on the other hand, leads to a manageable content structure but does not offer the possibility to relate the annotation to exact context information. The granularity of paragraphs seems to be appropriate for the joint development of texts.

On the other hand, they emphasize improvements concerning the handling of communicative contributions in the form of annotations and their interweavement with material as context. These improvements deal with the following topics:

Differentiation between Organizational and Content-Related Annotations. Two requested types of annotations are available. A new annotation has the property "content-related" by default, but it can be labeled as "organizational" by the author. The different labels correspond to different colors in all views that help the reader to differentiate the annotations at a first glance. These categories are context information that helps the recipient to estimate the aim of the communicative contribution.

The second round of studies revealed many incorrect typed contributions with the default entry "content-related" although they include only organizational issues. This finding shows that the participants often did not reflect the type of their contributions and the recipients had the major burden to reconstruct the real aim of the annotation. The existence of a default entry is misleading because the entry suggests information that is not given by the communicator.

On the other hand, the recategorization showed that both types are relevant for collaborative learning. This is especially true in long period scenarios that do not include weekly face-to-face meetings because all organizational

Figure 2. Discussions by using annotations.

issues are discussed with the help of the CSCL system, and this requires organizational contributions. The studies showed that in short period scenarios the organizational effort is not that high, and in a setting with weekly face-to-face meetings, a lot of organizational issues were discussed in the meeting. To keep all these arguments in mind, the usage of the two categories content-related and organizational without a default entry are proposed. Thus, a context is not suggested that is not also given.

Usage of Keywords as Context Information. Keywords are a summary of the communicative contribution. The communicator labels the contribution with words that are important for him and that help the recipient to estimate the content. A keyword for the annotation can be added similarly to the subject field of an e-mail. This keyword summarizes the annotation and helps the reader to recognize the content of the annotation at a glance. The keyword as well as the author and the date are prefixed to the annotation itself.

The results of the studies revealed that keywords are more often used when the previous annotation was written a long time before. In timely nearby contributions, the communicator seems to suppose that the recipient can conclude the context in the form of the appropriate discussion thread. We conclude that keywords are a helpful kind of context information that has to be included in a CSCL system—especially in long period asynchronous discussions. A reply-entry (like in e-mail applications) could support a communicator in automatic filling the keyword when contributing to an already existing discussion thread.

Chronological View of Communicative Contributions. Another technical improvement contains an annotation window as an additional view (see Fig. 3). This window is comparable to an e-mail inbox that gives an overview of all annotations in the chosen content area. The entries in the list are links that guide the user to the annotation's position in the integrated view. The list can be sorted by different metadata (e.g., author, date, and subject) and filtered (e.g., only content-related annotations). This window helps to perceive the annotations in chronological order and to be aware of new annotations.

Figure 3. Annotation window as an overview of new contributions (names are hidden due to provacy reasons).

Studies revealed that the usefulness of the annotation window depends on the underlying learning scenario. In scenarios with the joint creation of material by the group of learners, the content structure is growing very fast and the detection of new annotations "somewhere" in this structure becomes difficult. For these scenarios, an annotation window comparable to an e-mail in- and outbox gives an overview of communicative contributions and serves as a helpful awareness feature.

FACILITATING ASYNCHRONOUS DISCUSSIONS

Activities of a Facilitator

Most of the present literature on facilitation in computer-supported settings addresses the practitioners in the field (18–20). These publications deal with the tasks and responsibilities of a facilitator in computer-supported situations that are on the one hand similar to activities well known from face-to-face situations (19). Generally speaking, these tasks are the initiation of discussions, the guidance of the discussion process (includes asking appropriate questions to push students to think deeply on the learning content), and the stimulation of summary generation by the learners (12).

On the other hand, it is stated that it is necessary to develop new strategies when facilitating computer-supported communication processes (18). One of the lesser known studies concerning these strategies was done by Friedrich et al. (21). They compared two different methods to initiate an asynchronous discussion. One method relied on a neutral opening statement, whereas the other made use of problem-centric, curiosity-arousing wording when initially characterizing the discussions' objective. They confirmed the assumption that the latter type of discussion initiation results in an increased number of contributions from discussion participants. Furthermore it was found that the fewer statements facilitators contribute to the discussion, the greater the number of participant statements.

This background leads to the necessity for research on two levels. (1) What are the main facilitation activities and (2) how are they supporter with technical functionalities. The following results from a study are presented that address both levels. Details of the study can be found in Ref. 22. In this study, a group of students had the task to discuss and write their final project documentation. To gain experience with the task of a facilitator, a professionally trained facilitator planned interventions in cooperation with the researcher. These interventions, resp. facilitation strategies, vary in the degree of content-related responsibility of the facilitator.

Open Questions without any Instructions. At the beginning of the study, the facilitator asked open questions as it is similarly the case with traditional facilitation in face-to-face groups. This implies in particular that the students had to decide by themselves which functionalities they used and when they answered the question. It leads to low participation. In the first group interview, the students were asked to explain their low participation, and they reported their uncertainty about when and in which form the answers were required. Furthermore, they described obscurities concerning the (subjective) cognition of the progress in a discussion thread, especially whether a discussion was finished. Following these answers, explicit deadlines were demanded. Furthermore, it was unclear for the students how the future development of a discussion thread will look like, especially how and when it will come to an end. With respect to this open-endedness, the students' preference for explicit deadlines became apparent in their answers.

Instruction, Deadline, and Finalizing Conclusion (One Step More Responsibility for the Facilitator). In a second step, the facilitator used more instructional contributions that included deadlines. This strategy led to higher participation levels in the discussion. The analysis reveals for the first time that students worked in a rhythm similar to that given by the facilitator. On deadline days, more contributions were added.

As known from traditional facilitation methods, the facilitator gave a summary after the deadline and asked for additional comments. Reaction to this query was reduced. In the following group, interview students complained that with such questions the discussion was not terminated. This is the first difference compared with face-to-face settings, in which closing queries are a widely accepted technique. Students believed that every discussion participant in computer-supported asynchronous settings has the opportunity to contribute because of the longer period of time. Therefore, no additional comments should be requested in the asynchronous settings compared with the face-to-face situations.

Reviewing the content and results of the discussion, it must be stated that the initial aim of generating a collaboratively developed table of contents accepted for the joint documentation of group work by all group members was not achieved in the computer-supported discussion. Students reported different problems in the group interview. The first issue was the starting point of students' participation in the discussion; the temptation to wait to see what others were going to add was great. A second problem concerned concurrency and easy negotiation of opinions, which proved to be unmanageable in the system; a simple agreement like head nodding in face-to-face situations seemed to be impossible in the computer-supported asynchronous setting.

To conclude, it was clear that although participation was high discussions were not terminated in the computer-supported discussion. Students felt termination or finalizing should be done by the facilitator.

Conclusions with Decisions by the Facilitator (Full Responsibility of the Facilitator). In a third step, the facilitator intervened more than during previous steps. She did not only formulate more instructions that included deadlines but terminated discussions. If some topics did not come to an end by the deadline, the facilitator decided to stop and proposed a solution. This is a second aspect in computer-supported asynchronous facilitation that differs from that in a face-to-face situation where the facilitator is mostly not responsible for the content of the discussion or of the group result.

A high level of participation was recorded in this step; once again the participation was highest on deadline days and more detailed some minutes before the deadline. Apparently, the students followed the rhythm set by the facilitator. The discussion in this step led to the aim of coordinating tasks for writing the group's documentation. In the group interview, the students confirmed that the progress of the process was achieved by the facilitators' intervention.

In the summarizing subsection of this chapter, these findings regarding the activities of a facilitator are related to the findings regarding the computer support of a facilitator.

Computer Support of a Facilitator

With respect to the computer support for the tasks of a facilitator, so far only a few approaches exist. Prominent examples concerning asynchronous settings are the facilitation of online forums (23) or electronic mailing lists (24). In these approaches, all communicative contributions are sent to the facilitator, which filters them and distributes them to others. For collaborative learning scenarios, these approaches seem to be too restrictive to support an open discussion of the learners because the facilitator is more seen as an editor than as a guide; discussions where the learners are the decision makers and lead their own discussion are repressed (25). Concerning the domain of asynchronous learning only, requirements for the support of a facilitator are published (12).

Figure 4 gives an overview of the proposed technical functionalities for asynchronous facilitation support realized in KOLUMBUS 2 (22). In contrast to the above-described approaches, the users can contribute unfiltered to the different discussions. In the discussion threads, **moderator contributions are highlighted** with bold type, directing attention of the discussion's participants to the facilitator's inputs. This bold type of the facilitator's statements does also visually structure the discussion and reduce the necessity to reconstruct the course of a debate when working asynchronously. By this structuring, the initiation, resp. leading over to the next phase, as well as the summarization are supported.

Students confirmed that emphasizing a facilitator's statements by using bold fonts proved to be helpful in following the course of a discussion. Since the contributions of a facilitator often brought up a new topic and thus resulted in a new discussion thread, emphasizing them pointed out the structure of an extensive discussion more clearly. For instance, if two facilitator statements were displayed one below the other, topics thus far not discussed became rapidly apparent.

To promote contributions to an ongoing discussion, two functionalities are offered. Emphasis can be placed on single contributions to a discussion by using **a highlighting functionality**. To label an element of a discussion thread, the facilitator can choose from a variety of background colors. Marking contributions in this way can be

Figure 4. The support of a facilitator.

used, for example, to group similar contributions or to accentuate important arguments or to stress (intermediary) the results of a discussion. There is no predefined meaning to the usage of different colors. It was intended that a user group develops the corresponding conventions without a predefined meaning. The discussion of the meaning assigned to the applied colors fosters the development of shared understanding of the applied functionalities.

Although it would have been useful to label similar or agreeing proposals when students were collecting ideas on outline and content of the documentation they had to compose, in the case study, the facilitator did not apply the highlighter functionality to draw attention to single contributions. Investigating possible reasons for this behavior, it turned out that she considered the design of the highlighting mechanism as too coarse-grained as only the entire contribution could be highlighted. In this context, the facilitator referred to a technique known from the facilitation of face-to-face meetings whereby crucial points are committed in writing to cards that can be arranged on a pin board. In these situations, one does not put down complete statements but confines oneself to recording only the most important keywords. According to this, calling attention to a whole contribution in a discussion thread by highlighting it proves to be an inappropriate means if one only intends to underscore essential propositions. An initial suggestion for improvement can be derived from these findings. Instead of being restricted to the level of items, subsequent versions of the highlighter mechanism described here should be applicable in a more fine-grained manner (i.e., facilitating the selection of single words) in order to allow for a precise accentuation.

Furthermore, **system-internal links** can be established if contributions that are semantically related to each other have to be interconnected. Establishing a relation between elements in such a way is especially reasonable if they deal with similar aspects of a topic but are distributed over several discussion threads and not directly connected to each other.

Since there was no situation where similar aspects of a topic were addressed in various discussion threads, there was no necessity to connect semantically related contributions using links between different discussion threads. Thus, the corresponding functionality remained unused. I assume that this is a consequence of the carefully planned interventions of the facilitator. The discussion was well guided—the participants added their contributions to the appropriate contribution of the facilitator. Because these well-prepared interventions from the facilitator cannot be expected in every case, I still propose that system-internal links may be a benefit when facilitating asynchronous discussions of group of learners.

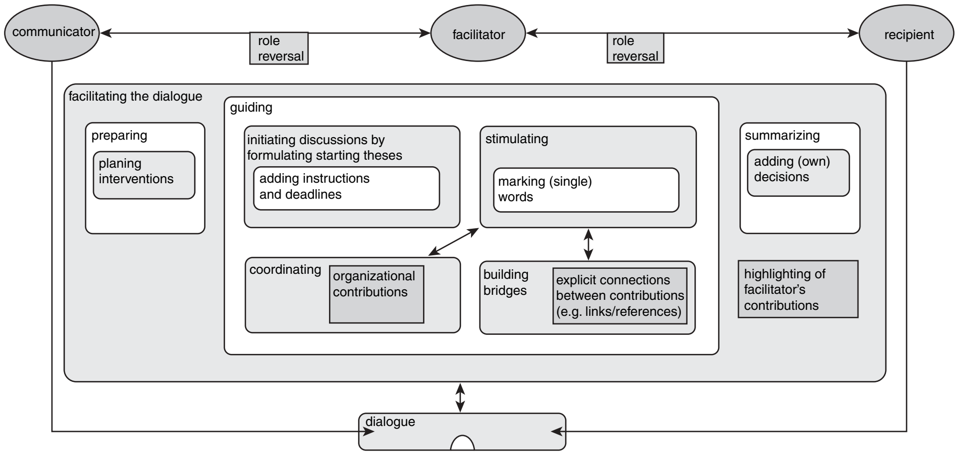
During the study, the facilitator made proposals for additional functionalities aimed at improved support for activities typical to the facilitation of both face-to-face and computer-supported discussions. First, a facilitator should be able to "assign questions and work orders individually" by means of a collaboratively shared task list. Supporting the assignment and handling of tasks is closely related to functionalities fostering the participant's awareness of the current state of the collaborative process in which they are involved. Furthermore, the facilitator asked for a means to support synchronous voting in order to speed up the process by which participants reach a group decision. To achieve results for asynchronous facilitation, synchronous communication was not offered. However, it confirms the need for synchronous facilitation as described in the following section as well as a fluent integration of both synchronous and asynchronous modes (for integration, see Ref. 17).

GENERAL GUIDELINES

Based on these findings, the general design guidelines for the technical support of communication as well as for the activities of a facilitator and their support can be derived.

For the design of the support of communication in asynchronous learning scenarios, be aware of the following guidelines:

1. Support context-orientation by integrating of communication as annotations into segmented learning material as context. The granularity of paragraphs is appropriate for the scenario of the joint development of material.



communicator
role reversal
facilitator
role reversal
recipient
facilitating the dialogue
preparing
planing interventions
guiding
initiating discussions by formulating starting theses
adding instructions and deadlines
stimulating
marking (single) words
summarizing
adding (own) decisions
coordinating
organizational contributions
building bridges
explicit connections between contributions (e.g. links/references)
highlighting of facilitator's contributions
dialogue

Figure 5. The facilitation of asynchronous learning: activities and supporting functionalities.

2. Support detailed information about the requested context information like categories and keywords. They are especially helpful in long-period settings and overlapping discourses because these situations request more explicit context information. Keep in mind that users have to be aware that they participate in communication acts and explain the benefit of using this context information.
3. Provide a special view that helps to overview the course of annotations. This is especially useful in scenarios of discourses that start with a divergent phase where annotations are connected to different items of material that are widely spread over the content.

For the support of a facilitator in asynchronous learning scenarios, a framework is derived that includes the activities of a facilitator of asynchronous learning scenarios and their support. Figure 5 combines in the middle the tasks of the facilitator that build the facilitation strategy (elements with rounded corners) and functionalities of the technical system (rectangles). When taking the role of the facilitator, the participant should be aware of the activities. For the design of technical systems that support asynchronous learning, it is recommended to add tips for fulfilling activities, for example, as help/tool tip for facilitators.

In general facilitation in the framework is divided into the activities of preparing, guiding, and summarizing that is inspired by related work as well as by the findings of the study. For asynchronous learning, a facilitator should prepare the discussions by carefully planning her/his interventions. This reduced, for example, parallel discussions with similar content that might result in misunderstandings.

During the discussion, a facilitator initiates it. In the asynchronous mode, a facilitator's contributions, especially starting a thesis, should contain instructions for the expected reactions on the starting thesis and deadlines.

For ongoing discussions, the facilitator has the task of stimulating the discussion. Here content should be emphasized (e.g., marking words). It is often accompanied by activities of building bridges and coordination acts. For these activities, technical functionalities are recommended based on the findings from the study. For the coordination, organizational contributions should be offered, for building bridges explicit connections by links.

At the end, discussions should be summarized in both modes. To increase the perception of these summaries, facilitators should ensure that participants be aware of these summaries. From a technical point of view, summaries should be placed in a prominent manner to emphasize their relevance. For asynchronous settings, it is important that the facilitator should include decisions made during the discussion. If necessary the facilitator makes decisions on his own—in contrast to face-to-face settings where the facilitator is not responsible for the content of decisions.

COMPUTING ACCREDITATION: EVOLUTION AND TRENDS ASSOCIATED WITH U.S. ACCREDITING AGENCIES

INTRODUCTION

Accreditation is the primary quality assurance mechanism for institutions and programs of higher education, which helps a program prove that it is of a quality acceptable to constituents (1). Its original emergence in the United States was to ensure that federal student loans were awarded in support of quality programs. Since then, the need for accreditation has strengthened considerably, as the need for quality assurance continues to be in the forefront of educational concerns. For example, a recent report from the Commission on Higher Education (2) identified several problems with the education system in the United States, a central one being the overall quality of higher education.

The continuing interest in accreditation emerges of three factors. First, recognition exists that the public is not always in a position to judge quality, certainly not for programs or institutions for higher education. Therefore, a need exists for an independently issued stamp of approval for programs and institutions of higher education.

Second, a lack of oversight exists in higher education. Unlike the public school system, colleges and universities have considerable freedom when it comes to curriculum design, hiring practices, and student expectations (1). This lack of oversight requires a different mechanism to ensure quality, and higher education has opted to use accreditation for this purpose. Finally, many organizations have recognized the importance of continuous quality improvement, and higher education is no exception. As explained in this article, recent developments in accreditation reflect this trend. The objective of accreditation is not only to ensure that educational institutions strive for excellence but also to make certain that the process for ensuring high quality is apposite.

Two major types of accreditation are available in the United States: (*1*) institutional accreditation (also called regional accreditation in the United States) and (*2*) specialized accreditation. Specialized accreditation includes both program and school-specific accreditation, with the former applied to a unique program and the latter applied to an administrative unit within an institution. In the United States, institutional accreditation is generally the responsibility of a regional accreditation body such as the Southern Association of Colleges and Schools (SACS) (www.sacs.org) or the Middle States Commission on Higher Education (www.msche.org).

This article concentrates on accreditation in the computing discipline, focusing on the primary accreditation bodies accrediting U.S. programs, namely ABET, Inc. (www.abet.org) and the Association to Advance Collegiate Schools of Business (AACSB) (www.aacsb.edu). ABET, Inc. is the primary body responsible for specialized program-level accreditation in computing. AACSB, on the other hand, provides specialized accreditation at the unit level and accredits business schools only. The latter implies that all the programs offered within the unit are accredited, including any computing programs that it may offer.

Both accrediting bodies have concentrated primarily on the accreditation of programs housed within U.S. institutions. ABET has evaluated programs outside the United States for "substantial equivalency," which means the program is comparable in educational outcomes with a U.S.-accredited program. "Substantial equivalency" has been phased out, and international accreditation pilot visits are now being employed for visits within the United States. In 2003, AACSB members approved the international visits as relevant and applicable to all business programs and have accredited several programs outside of the United States.

The purpose of this article is to (*1*) review key concepts associated with accreditation, (*2*) discuss the state of computing accreditation by U.S. accrediting organizations and how accreditation has evolved through recent years, (*3*) describe the criteria for accreditation put forth by the primary agencies that review computing programs, and (*4*) review the typical process of accreditation. Although many concepts are applicable to any accreditation process, we refer to AACSB and ABET, Inc., which well are recognized agencies that ensure quality in educational units that include technology or specialized computing programs. ABET's Computer Accreditation Commission (CAC), as the primary agency targeting computing programs, is emphasized.

KEY CONCEPTS OF ACCREDITATION

For many years, accrediting organizations established focused and specific guidelines to which a program had to adhere to receive its stamp of approval. For instance, a fixed number of credits, required in a specific area, had been the norm, and any program that wished to be granted accreditation had to offer the required number of credits in relevant areas. Quality was measured through a checklist of attributes that were expected to be met by the various inputs into learning processes, such as curriculum, teaching faculty, laboratory, and other facilities and resources. The definition of quality, implicit in this approach to accreditation, was that of meeting specific standards, to be followed by every institution.

Some proof exists that in computer science education, this approach is successful. In a study of accredited and nonaccredited programs, Rozanski (3) reports that although similarities and differences exist between these programs, accredited programs have more potential to increase specific quality indicators.

In the past it was straightforward to determine whether a program or institution met the accreditation criteria. A

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

major drawback of this approach was that it forced uniformity among institutions, preventing innovation and the consideration of specialized needs of a program's or school's constituencies. Other controversies centered on the expense and time necessary to navigate successfully the process. Smaller schools especially felt the guidelines were targeted toward the larger institution (3).

Partly in response to concerns and to the danger of a lack of innovation and, at least in the United States, partly under pressure from the federal government, accreditation agencies have moved to an outcomes-based approach, and accreditation criteria now embody a definition of quality more in line with that adopted by many quality improvement approaches, namely "fitness for purpose" (4). The basis for this approach is the premise that quality is multifaceted.

From the overall mission of an institution, units or programs are expected to establish long-term educational objectives or goals, which describe achievements of graduates a few years after graduation, and to derive a set of learning outcomes, which are statements defined as the aforementioned skills, knowledge, and behaviors that students are expected to acquire in their matriculation through the program (5). Additionally, an institution or program is expected to establish an assessment process to determine how well its graduates are achieving its objectives and outcomes and to establish a quality enhancement program that uses the data collected through this assessment process to improve the program. Assessment processes foster program improvement by enabling visit teams to make judgments about program effectiveness in preparing graduates for entry into a field.

Some differences exist between the various accreditation agencies concerning the range of decisions that they can make. Clearly, each will have the option of whether to accredit or not. However, different options are available should it be determined that a program or institution does not meet all criteria. For example, some accreditation agencies may reduce the period for which the program or institution is accredited. Alternatively, they may provisionally accredit but make a final decision contingent on an interim report by the program or institution in which it makes clear how it has addressed any weaknesses or concerns identified during the team visit.

Programs continue to be reviewed cyclically. Again, differences exist between the various agencies relative to the maximum length for which a program or institution can be accredited. The ABET CAC maximally accredits a program for 6 years, whereas the AACSB has operated on a 5- or 10-year cycle and is moving more toward the use of maintenance reports.

Clearly, given the importance of the agency in the accreditation process, the question develops concerning the basis used to determine whether an organization can become an accreditation agency. The answer differs from country to country. In many countries, accreditation agencies are governmental or quasi-governmental organizations established through an act or parliament. In the United States, most accreditation agencies are essentially private organizations. However, under the Higher Education Act, the U.S. Secretary of Education is required to recognize an accreditation agency before students enrolled in programs or institutions accredited by it can receive federal funding.

Also, several professional organizations recognize accreditation agencies, chief among then are the International Network for Quality Assurance Agencies in Higher Education (INQAAHE) and the Council of Higher Education Accreditation (CHEA) in the United States.

ACCREDITATION AGENCIES RELEVANT TO COMPUTING

The AACSB

The AACSB International accredits both undergraduate and graduate education for business and accounting. Founded in 1916, the first standards were adopted in 1919 (6). The AACSB accredits computing programs, typically in Management Information Systems (MIS) or Information Systems (IS), only as part of an evaluation of a business program, and it does not review any one specific program. By accrediting the unit that offers the various business-related programs, it accredits indirectly any specific program offered within the unit. The one exception is accounting, which can receive a program-specific evaluation.

Both undergraduate and graduate programs must be evaluated in making an accreditation decision. The AACSB puts forth standards for continuous quality improvement. Important in the process is the publication of a mission statement, academic and financial considerations, and student support.

AACSB International members approved mission-linked accreditation standards and the peer review process in 1991, and in 2003, members approved a revised set of worldwide standards. The application of the AACSB's accreditation standards is based on the stated mission of each institution, and the standards thus provide enough flexibility so that they can be applied to a wide variety of business schools with different missions. This flexibility offers the opportunity for many institutions that offer online and other distance learning programs, as well as the more conventional on-campus programs, to be accredited.

ABET Inc.

In the early 1980s, computer science accreditation was initiated by groups from the Association for Computing Machinery, Inc. (ACM) and the Institute of Electrical and Electronics Engineers, Inc. Computer Society (IEEE-CS). Criteria for accreditation of computer science were established, and visits started in 1984. The initial visits were made by the Computer Science Accreditation Commission (CSAC), which in 1985 established the Computer Science Accreditation Board (CSAB) with the explicit purpose "to advance the development and practices of computing disciplines in the public interest through the enhancement of quality educational degree programs in computing" (http://www.csab.org).

Eventually CSAC was incorporated into ABET with CSAB remaining as the lead society within ABET for accreditation of programs in computer science, information systems, information technology, and software engineering. It should be noted that the ABET Engineering Accreditation Commission (EAC) is responsible for software engineering accreditation visits. In this capacity, the CSAB is responsible for recommending changes to the accreditation criteria and for the recruitment, selection, and training of program evaluators (PEVs). All other accreditation activities, which were conducted previously by the CSAC, are now conducted by the ABET CAC.

The CSAB is governed by a Board of Directors whose members are appointed by the member societies. The current member societies of the CSAB, which include the ACM and the IEEE-CS, as well as its newest member, the Association for Information Systems (AIS), are the three largest technical, educational, and scientific societies in the computer and computer-related fields.

Since the incorporation of the CSAC into the ABET, computing programs have been accredited by the ABET CAC. The first programs accredited by the ABET CAC were in computer science (CS). In 2004, IS criteria were completed and partly funded by a National Science Foundation grant. With the addition of IS criteria, the scope of computing program accreditation was enlarged. This addition has been followed by the addition of information technology (IT), with criteria currently being piloted.

The CAC recognized a need to address the growing number of programs in emerging computing areas, which has resulted in even more revision of accreditation criteria, allowing such programs to apply for accreditation under computing general criteria. Thus, these areas can benefit from accreditation as well. We discuss these revisions in the next section.

THE AACSB AND ABET CAC ACCREDITATION CRITERIA

The AACSB Criteria

Although the AACSB does not accredit IS programs by themselves, the standards used support the concept of continuous quality improvement and require the use of a systematic process for curriculum management. Normally, the curriculum management process will result in an undergraduate degree program that includes learning experiences in such general knowledge and skill areas as follows (7):

- Communication abilities
- Ethical understanding and reasoning abilities
- Analytic skills
- Use of information technology
- Multicultural and diversity understanding
- Reflective thinking skills

Recent changes required of schools seeking accreditation include (8):

- Assessment activities are focused toward degree programs rather than toward the majors within a degree program (AACSB, 2006). In other words, recent criteria focus on learning goals applied to each degree rather than an separate majors.
- The requirements of direct measures measuring knowledge or skills that students will expected to attain by the time they graduate.
- The development of learning goals for the overall degree program.
- Involvement of faculty members to a far greater extent than under prior standards.
- The involvement of faculty to effect improvement.

The ABET Criteria

For several reasons, the ABET CAC revised significantly its accreditation criteria, a copy of which is available for inspection and comment from the ABET website (www.abet.org). The ABET is currently piloting the proposed criteria, which are expected to be officially in place for the 2008–2009 accreditation cycle.

Two significant revisions were made to the criteria. First, following the lead of, in particular, the ABET's Engineering Accreditation Commission (EAC), the criteria have been reorganized into a set of general criteria that apply to all programs in computing, and program-specific criteria for programs in CS, IS, and IT. For any program to be accredited in one of these specific disciplines, it must meet both the general and the associated program-specific criteria. However, programs in emerging areas of computing that are not strictly CS, IS or IT, such as programs in computer game design, or telecommunications, will be accredited under the ABET CAC's general criteria. The revision thus broadened the range of computing programs that can benefit from the ABET CAC accreditation.

Second, although criteria have required programs to establish program educational objectives and outcomes, and to set up an assessment and quality improvement process, it was not emphasized sufficiently. The revised criteria place greater emphasis on the need to set up a continuous improvement process.

The proposed CAC criteria for all computing programs are divided into nine major categories (9):

1. Students
2. Objectives
3. Outcomes
4. Continuous improvement
5. Curriculum
6. Faculty
7. Facilities
8. Support
9. Program criteria

The criteria are outcomes based, and it is expected that program outcomes are to be based on the needs of the program's constituencies. However, the criteria also will specify a minimum set of skills and knowledge that students must achieve by graduation. The general criteria specify that students must be able to demonstrate minimally the following (9):

(a) An ability to apply knowledge of computing and mathematics appropriate to the discipline

(b) An ability to analyze a problem and to identify and define the computing requirements appropriate to its solution

(c) An ability to design, implement, and evaluate a computer-based system, process, component, or program to meet desired needs

(d) An ability to function effectively on teams to accomplish a common goal

(e) An understanding of professional, ethical, legal, security, and social issues and responsibilities

(f) An ability to communicate effectively with a range of audiences

(g) An ability to analyze the local and global impact of computing on individuals, organizations, and society

(h) Recognition of the need for, and an ability to engage in, continuing professional development

(i) An ability to use current techniques, skills, and tools necessary for computing practice

To this criteria, computer science adds the following:

(j) An ability to apply mathematical foundations, algorithmic principles, and computer science theory in the modeling and design of computer-based systems in a way that demonstrates comprehension of the tradeoffs involved in design choices

(k) An ability to apply design and development principles in the construction of software systems of varying complexity

Information systems adds:

(j) An understanding of processes that support the delivery and management of information systems within a specific application environment

Whereas information technology adds:

(j) An ability to use and apply current technical concepts and practices in the core information technologies

(k) An ability to identify and analyze user needs and take them into account in the selection, creation, evaluation, and administration of computer-based systems

(l) An ability to effectively integrate IT-based solutions into the user environment

(m) An understanding of best practices and standards and their application

(n) An ability to assist in the creation of an effective project plan.

Similarities and Differences

Many similarities exist between accreditation criteria formulated by the ABET CAC and the AACSB. Both organizations stress the need for explicit learning outcomes for graduating students and for explicitly documented assessment and quality improvement processes. Both organizations also recognize the need for graduates to be well rounded with qualities beyond skills needed to understand specialized areas. Both accrediting bodies, as do many others, now require more than perceptions of constituents to determine the level of program accomplishments. A need for more direct assessment of knowledge and skills is required.

It should also be noted that IS programs offered through institutions accredited by the AACSB may also be accredited by the ABET. Indeed, a handful of ABET-accredited programs in IS are offered in AACSB-accredited business schools. Programs that are accredited by both organizations offer constituencies the added benefit of knowing that IS is offered within a high-quality business program and that it has a quality technology component integrated into the program.

Both agencies include in their accreditation criteria similar sets of attributes that they expect graduating students to achieve. For instance, the AACSB includes a management of curricula criterion that requires an undergraduate degree program to include learning experiences in specific general knowledge and skill areas as depicted above.

The difference in level of detail between the minimal learning outcomes in the ABET CAC accreditation criteria and those in the AACSB accreditation can be explained by the fact that the ABET CAC criteria are more focused. Both sets of evaluative rules promote continuous quality improvement. Rather than being designed for a class of programs, as the AACSB criteria are, the ABET CAC criteria focus on a single type of program. They can, therefore, be more specific about the expectations of graduates, especially in the technology area. Note, however, that both the ABET CAC and the AASCB merely formulate a minimal set of guidelines. Specific programs, whether they apply for accreditation under the ABET CAC criteria or under the AACSB criteria, are expected to formulate their own sets of objectives and learning goals (AACSB terminology) or outcomes (ABET terminology). Moreover, both insist that the specific objectives adopted be based on the needs of their specific constituencies rather than on the whims of faculty or other involved parties.

Although the ABET CAC is more specific in the specification of minimal outcomes, the AACSB is generally more specific when it comes to some other criteria. For example, the ABET CAC provides relatively general requirements for faculty. The faculty responsible for the program must have the required skills to deliver the program and to modify it, and some of them must also possess terminal degrees. The AACSB, on the other hand, provides a set of detailed guidelines that spell out the qualifications that faculty must have and what percentage of courses within a program must typically be covered by qualified faculty. However, such differences should not detract from the

fact that in both cases, continuous quality improvement is of central importance.

THE TYPICAL ACCREDITATION PROCESS

Program or Unit Being Accredited

The process of obtaining accreditation typically begins with the institution or program completing a self-analysis to determine whether the program meets the demands of the accrediting agency. Gorgone et al. (10) recommend that the accreditation process needs to begin at least a year before the time of an anticipated visit. Given that this step goes well, and the administration is supportive, a Request for Evaluation (RFE) begins the formal process. Figure 1 illustrates these and subsequent steps that include the preparation of a self-study, collection of materials for a review team, and the culminating accreditation visit. Most accreditation agencies prefer a program or institution to have completed its self-study before it applies for accreditation (and pays its fees).

Once the request for accreditation has been received by the accreditation agency, it appoints several program evaluators, typically in consultation with the program or institution seeking accreditation. Program evaluators are peers, often drawn from academia but not infrequently drawn from industry. The accreditation agency also appoints a team chair, again typically in consultation with the program or institution.

The remainder of the process is driven by the self-study. The visiting team will visit the program or institution. The primary purpose of the site visit is to verify the accuracy of the self-study and to make observations regarding issues that are hard to gauge from a self-study, such as faculty and staff morale and the students' view of the institution or program. The team writes a report of its findings, which is submitted to the accreditation agency. Generally, the institution or program is allowed to make comments on early drafts of the report, which may lead the visiting team to revise its report. Eventually, the accreditation agency will make its decision.

The Accrediting Agency

The accrediting agency has an enormous amount of responsibility. Typically a professional staff supports the accreditation process, and academic and industry volunteers in the areas being evaluated create the criteria. Associated tasks are summarized as (*1*) the identification of team chairs, (*2*) the selection and identification of institutions to visit, (*3*) the assignment and training of team chairs and a review team, and (*4*) the preparation of sample forms and reports (8).

CONCLUSION

Quality assurance in higher education has become an important issue for many. This article describes the primary quality assurance mechanism for higher education, namely accreditation. It has emphasized accreditation for programs in computing.

Programs or institutions that have voluntarily assented to the accreditation process and have achieved accreditation meet the quality that reasonable external stakeholders can expect them to have. Moreover, the emphasis on outcome-based criteria and the concomitant requirements that programs or institutions put in place for accreditation provides constituents with the assurance of quality and continuous quality improvement. Although we do dispute the fact that accreditation is the only way to assure quality in higher education, we do believe that accreditation is an excellent method for doing so and that every program or institution that has been accredited by a reputable accreditation agency is of high quality.

CYBERNETICS

The word cybernetics was coined by Norbert Wiener (1) and denotes a subject area that he indicated by the subtitle of his 1948 book: "control and communication in the animal and the machine." It is derived from the Greek word for "steersman," and the word "governor" comes from the same root. The word had been used in a related but more restricted sense by Ampère in the nineteenth century to denote a science of government, but Wiener initially was not aware of this. It also was used much earlier by Plato with a similar meaning.

The linking of "animal" and "machine" implies that these have properties in common that allow description in similar terms. At a simple level this view was not new, because nerves were identified as communication pathways by Descartes in the seventeenth century; however, later developments, especially during World War II and including the emergence of analog and digital electronic computers, allowed a deeper and more fruitful unified approach. It also was intended that "animal" should be understood to include organizations and societies, and later work increasingly has focused on them. A revised definition that has been suggested is: "communication and control within and between man, organizations and society."

HISTORY OF CYBERNETICS

The publication of the book by Wiener gave name and status to the subject area, but earlier origins can be traced. At the time of the publication, the ideas also were promoted vigorously by Warren McCulloch (2), and the emergence of cybernetics has been attributed to the meeting and collaboration of Wiener with McCulloch and Walter Pitts (3). McCulloch was a neurophysiologist who epitomized his own lifetime quest as the attempt to answer the question: "What is a number, that a man may know it, and a man, that he may know a number?" This question led him to study medicine and, particularly, neurophysiology. An international center for studies of what became known as cybernetics was planned by him in the 1920s but had to be abandoned for financial reasons in the 1930s.

Before the meeting with McCulloch, (2) a number of influences guided Wiener toward the initiative, a major one being his wartime work on the possibility of a predictor to extrapolate the curving path of an enemy aircraft so as to direct anti-aircraft gunfire more effectively. He had exposure to biological studies in a number of contexts, including introduction to electroencephalography by W. Grey Walter in the United Kingdom (4) and work on heart muscle with the Mexican physiologist Rosenblueth; he also had learned about biological homeostasis in discussions with Walter Cannon. He also had been involved with analog and digital computing.

The topic area, and its designation by name, were advanced greatly by a series of discussion meetings held in New York and sponsored by the Josiah Macy, Jr. Foundation between 1946 and 1953. Ten meetings took place, chaired by Warren McCulloch (2) and with the participation of scientists from different specializations, especially bringing together biological and nonbiological sciences. The first five meetings, which were not recorded in print, had various titles that referred to circular mechanisms and teleology. From the sixth meeting onward, the proceedings were edited by Heinz von Foerster and published. Wiener's book had appeared in the meantime, and in honor of his contribution, the reports on the last five meetings were entitled: *Cybernetics: Circular, Causal and Feedback Mechanisms in Biological and Social Systems*.

Relevant developments were not confined, however, to the United States. In Britain, an informal group called the Ratio Club was founded in 1949 and developed many of the basic ideas of cybernetics at first independently of the American work, although links were formed later. It also is noteworthy that the book by Wiener was published in French before the appearance of the English version and gave rise to a Circle of Cybernetic Studies in Paris. The Ratio Club was considered to have served its purpose, and the transatlantic separation ended by a conference in the National Physical Laboratory in Teddington, United Kingdom in 1958.

FEEDBACK AND SERVOMECHANISMS

What has been termed circular causation is a central characteristic of living systems as well as of many modern artifacts. The flow of effect, or causation, is not linear from input to output but has loops or feedbacks. The system is sensitive to what it, itself, influences, and it regulates its influence so as to achieve a desired result. Conscious muscular movement is an obvious example, where the actual movement is monitored by proprioceptors in joints and muscles and perhaps also visually and the force exerted by the muscles is regulated using this feedback so as to keep the movement close to what is wanted despite unknown weight to be lifted, friction, and inertia. The feedback that produces stability is negative feedback, which is to say that an excessive movement in the desired direction must cause diminution of muscular effort and conversely for insufficient movement.

Servomechanisms are artificial devices that similarly use negative feedback. They featured strongly in wartime applications, such as control of aircraft gun turrets, but were known much earlier, examples being the steering engines of ships and Watt's governor to regulate the speed of a steam engine. The use of the term "governor" here encouraged the later appellation of Wiener. Negative feedback also appears in a crude but effective form in the familiar ball-cock valve of the toilet cistern, which regulates inflow according to the sensed water level, and in thermostats in rooms, ovens, and refrigerators. Regulation of

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

temperature and many other variables by feedback from sensors also is a vital feature of biological systems.

Servomechanisms are required to respond rapidly to disturbances and, at the same time, to give stable control without large overshoots or oscillation. The achievement of this stability where the environment includes inertia and elasticity and viscous friction depends on the mathematical methods of Wiener and others, including Bode and Nyquist. One connection with biology noted by Wiener is that the tremors of a patient with Parkinson's disease are similar to the operation of a maladjusted servo. Negative feedback also is applied in electronic amplification and allows high-fidelity audio reproduction despite the nonlinear characteristics of the active components, whether vacuum tubes or transistors; important mathematical theory has been developed in this context.

NEUROPHYSIOLOGY AND DIGITAL COMPUTING

The nervous system is the most obvious and complex form of communication "in the animal," although the endocrine system also operates in a broadcast or "to whom it may concern" fashion and other forms are playing a part. McCulloch looked to neurophysiology for answers to the question he posed, and 5 years before the appearance of the book by Wiener, he and Walter Pitts published a mathematical proof of the computational capabilities of networks of model neurons that have some correspondence to the real kind. Much speculation was aroused by the apparent correspondence between the all-or-nothing response of neurons and the use of binary arithmetic and two-valued logic in digital computers.

In this and other ways, interest in cybernetics arose from advances in electronics, especially those stimulated by World War II. Young scientists who had worked on military projects wanted to turn their skills to something to help humanity, such as biological research. Ways were found of making micro electrodes that allowed recording from single neurons and stimulating them, and it looked as though the nervous system could be analyzed like an electronic device.

A great deal has been learned about the nervous system using microelectrodes, not least by a group around Warren McCulloch in the Massachusetts Institute of Technology in the 1950s and 1960s. Further insight came from theoretical treatments, including the idealization of neural nets as cellular automata by John von Neumann and the mathematical treatment of morphogenesis (the development of pattern or structure in living systems) pioneered by Alan Turing. Nevertheless, much of the working of the central nervous system remains mysterious, and in recent decades, the main focus of cybernetics has shifted to a higher-level view of thought processes and to examination of inter personal communication and organizations.

A recurring theme is that of self-organization, with several conferences in the 1950s and 1960s nominally devoted to discussion of self-organizing systems. The aim was to study learning in something like a neural net, associated with the spontaneous emergence of structure or at least a major structural change. Von Foerster treated the topic in terms of thermodynamics and pointed out that spontaneous emergence in an isolated system would be contrary to the second law. More recently, self-organization has been discussed rather differently with emphasis on the emergence of structure as such, independent of learning or goal-seeking.

Ilya Prigogine (5) and his followers have resolved the contradiction between the apparent implications of the second law of thermodynamics, that entropy or disorder can increase only, and the observed increase of order in biological evolution. The contradiction is resolved by observing that the second law applies to systems close to equilibrium, and living systems only exist far from equilibrium and can be termed "dissipative structures" as they receive energy and pass it to their environments. It has been shown that spontaneous emergence of structure is natural in such conditions. Implications for psychology and social systems, as well as cosmology, are drawn.

INFORMATION THEORY

An important part of cybernetics commonly is called information theory, although arguably more appropriately termed communication theory. It depends on the fact that information, in a certain sense of the word, can be measured and expressed in units. The amount of such information in a message is a measure of the difficulty of transmitting it from place to place or of storing it, not a measure of its significance. The unit of information is the "bit," the word being derived from "binary digit." It is the amount of information required to indicate a choice between two possibilities that previously were equally probable. The capacity of a communication channel can be expressed in bits per second. The principal author of the modern theory is Claude Shannon (6), although a similar measure of information was introduced by R. V. L. Hartley as early as 1928. The later work greatly extends the theory, particularly in taking account of noise.

In its simple form, with reference to discrete choices, the theory accounts nicely for some biological phenomena, for instance, the reaction times of subjects in multiple-choice experiments. It is extended to apply to continuous signals and to take account of corruption by random disturbances or "noise." The mathematical expressions then correspond, with a reversal of sign, to those expressions for the evaluation of entropy in thermodynamics. The theory applies to the detection of signals in noise and, therefore, to perception generally, and one notable treatment deals with its application to optimal recovery and detection of radar echoes in noise.

The effects of noise often can be overcome by exploiting redundancy, which is information (in the special quantitative sense) additional to that needed to convey the message in the absence of noise. Communication in natural language, whether spoken or written, has considerable redundancy, and meaning usually can be guessed with a fair degree of confidence when a substantial number of letters, syllables, or words effectively are lost because of noise, interference, and distortion. Much attention has been given to error-detecting and error-correcting coding that allow the introduction of redundancy in particularly effective ways. One theorem of information theory refers to the necessary capacity of an auxiliary channel to allow the correction of a corrupted message and corresponds to Ashby's (7) principle of requisite variety, which has found important application in management.

ARTIFICIAL INTELLIGENCE

In the attempt to understand the working of the brain in mechanistic terms, many attempts were made to model some aspect of its working, usually that of learning to perform a particular task. Often the task was a form of pattern classification, such as recognition of hand-blocked characters. An early assumption was that an intelligent artifact should model the nervous system and should consist of many relatively simple interacting units. Variations on such a scheme, indicated by the term "perceptron" devised by Frank Rosenblatt, could learn pattern classification but only of a simple kind without significant learned generalization. The outcomes of these early attempts to achieve "artificial intelligence" were not impressive, and at a conference in 1956 the term "Artificial Intelligence" (with capitals), or AI, was given a rather different meaning.

The aim of the new AI was to use the full power of computers, without restriction to a neural net or other prescribed architecture, to model human capability in areas that are accepted readily as demonstrating "intelligence." The main areas that have received attention are as follows:

Theorem Proving. The automatic proving of mathematical theorems has received much attention, and search methods developed have been applied in other areas, such as path planning for robots. They also are the basis of ways of programming computers declaratively, notably using the language PROLOG, rather than procedurally. In declarative programming, the required task is presented effectively as a mathematical theorem to be proved and, in some application areas, allows much faster program development than is possible by specifying procedures manually.

Game Playing. Chess has been seen as a classical challenge, and computers now can compete at an extremely high level, such that a computer beat the highest-scoring human chess player in history, Gary Kasparov. Important pioneering work was done using the game of checkers (or "draughts").

Pattern Recognition. Pattern recognition can refer to visual or auditory patterns; or patterns in other or mixed modalities; or in no particular modality, as when used to look for patterns in medical or weather data. Attention also has been given to the analysis of complete visual scenes, which presents special difficulty because, among other reasons, objects can have various orientations and can obscure each other partially. Scene analysis is necessary for advanced developments in robotics.

Use of Natural Language. Question-answering systems and mechanical translation have received attention, and practical systems for both have been implemented but leave much to be desired. Early optimistic predictions of computer performance in this area have not materialized fully. This lack is largely because the "understanding" of text depends on semantic as well as syntactical features and, therefore, on the huge amount of knowledge of the world that is accumulated by a person.

Robotics. Robotics has great practical importance in, for example, space research, undersea exploration, bomb disposal, and manufacturing. Many of its challenges are associated with processing sensory data, including video images, so as to navigate, recognize, and manipulate objects with dexterity and energy efficiency. Apart from their immediate use, these developments can be expected to throw light on corresponding biological mechanisms. Bipedal locomotion has been achieved only with great difficulty, which shows the complexity of the biological control of posture and balance. For practical mobile robots, wheeled or tracked locomotion is used instead. A topic area associated with advanced robotics projects is that of virtual reality, where a person is given sensory input and interactions that simulate a nonexistent environment. Flight simulators for pilot training were an early example, and computer games implement the effect to varying degrees.

Expert Systems. This term has been used to refer to systems that explicitly model the responses of a human "domain expert," either by questioning the expert about his/her methods or deriving rules from examples set to him/her. A favourite application area has been the medical diagnosis in various specializations, both for direct use and for training students. The general method has been applied to a very wide range of tasks in which human judgement is superior to any known analytic approach. Under the general heading of diagnosis, this range of topics includes fault finding in computers and other complex machinery or in organizations. Other applications are made to business decisions and military strategy.

A great deal has been achieved under the heading of AI. It has underlined the importance of heuristics, or rules that do not always "work" (in the sense of leading directly to a solution of a problem). Heuristics indicate where it may be useful to look for solutions and are certainly a feature of human, as well as machine, problem-solving. In this and other ways, studies of AI have contributed to the understanding of intelligence, not least by recognizing the complexity of many of the tasks studied. Apart from this, the influence of AI studies on computer programming practice has been profound; for example, the use of "list-processing," which has sometimes been seen as peculiar to AI programs, is used widely in compilers and operating systems.

Nevertheless, progress in AI is widely felt to have been disappointing. Mathematical theorem-proving and chess playing are forms of intellectual activity that people find difficult, and AI studies have produced machines proficient in them but unable to perform ordinary tasks like going round a house and emptying the ashtrays. Recognizing chairs, tables, ashtrays, and so forth in their almost infinite variety of shapes and colors is hard because it is hard to define these objects in a way that is "understandable" to a robot and because more problems arise in manipulation, trajectory planning, and balance. If the evolution of machine intelligence is to have correspondence to that of natural intelligence, then what are seen as low-level manifestations should appear first. The ultimate possibilities for machine intelligence were discussed comprehensively by Turing and more recently and sceptically using the parable of Searle's "Chinese Room" in which an operator manipulates symbols without understanding.

In relatively recent decades a revival of interest has grown in artificial neural nets (ANNs). This revival of interest is attributable partly to advances in computer technology that make feasible the representation and manipulation of large nets, but a more significant factor is the invention of useful ways of implementing learning in ANNs. The most powerful of these ways is "backpropagation," which depends on information pathways in the net that are additional to those serving its primary function, conducting in the opposite direction. Some applications are of a "control" or continuous-variable kind where the net provides a means of learning the continuous relation between a number of continuous variables, one of them a desired output that the net learns to compute from the others. Other application areas have an entirely different nature and include linguistics.

These relatively recent studies have been driven mainly by practical considerations, and the correspondence to biological processing often is controversial. The "backpropagation of error" algorithm, the basis of the majority of applications, has been argued to be unlikely to operate in biological processing. However, other forms of backpropagation probably do play a part, and biological considerations are invoked frequently in arguing the merits of schemes using ANNs.

CYBERNETIC MACHINES

Because a main aim of many cyberneticians is to understand biological learning, various demonstrations have involved "learning machines" realized either as computer programs or as special-purpose hardware. The various schemes for artificial neural nets are examples, and an earlier one was the "Homeostat" of Ross Ashby (7), which sought a stable equilibrium despite disturbances that could include alteration of its physical structure. A number of workers, starting with Grey Walter (4), made mobile robots or "tortoises" (land turtles) that showed remarkably lifelike behavior from simple internal control arrangements. They could avoid obstacles and would seek "food" (electric power) at charging stations when "hungry." The "Machina speculatrix" by Grey Walter did not learn, actually, but later developments implemented learning in various forms.

A task that has been used in a number of studies is pole-balancing, where the pole is an inverted pendulum constrained to pivot about a single axis and mounted on a trolley. The task is to control the trolley so that the pole does not fall and the trolley remains within a certain length of track. The input data to the learning controller are indications of the position of the trolley on the track and of the angle of the pendulum, and its output is a signal to drive the trolley. In one study, the controller was made to copy the responses of a human performing the task; in others, it developed its own control policy by trial.

Learning, unless purely imitative, requires feedback of success or failure, referred to as reinforcement. The term "reinforcement learning," however, has been given special significance as indicating methods that respond not only to an immediate return from actions but also to a potential return associated with the change of state of the environment. A means of estimating an ultimate expected return, or value, for any state has to exist. The most favorable action is chosen to maximize the sum of the immediate return and the change in expected subsequent return. The means of evaluating states is subject, itself to modification by learning.

This extension of the meaning of "reinforcement learning," having some correspondence to the "dynamic programming" of Richard Bellman, has led to powerful learning algorithms and has been applied successfully to the pole-balancing problem as well as to writing a program that learned to play a very powerful game of backgammon.

CYBERSPACE

Interactions using the Internet and other channels of ready computer communication are said to occur in, and to define, cyberspace. The new environment and resulting feeling of community are real and amenable to sociological examination. The prefix "cyber-" is applied rather indiscriminately to any entity strongly involving computer communication, so that a café offering its customers Internet access is termed a "cybercafé", the provision of bomb-making instructions on the Internet is described as "cyberterrorism," and so on. In science fiction, such terms as "cybermen" have been used to refer to humans who are subject to computer control. These uses of the prefix must be deprecated as supporting an erroneous interpretation of cybernetics.

SECOND-ORDER CYBERNETICS

The idea of the circular causality implicit in cybernetics has been extended, originally by Heinz von Foerster, to include the circle comprising an observed system and the observer. This extension is a departure from traditional Newtonian science and from earlier views of cybernetics where the observer is assumed to have autonomy that puts him or her outside any causal loop. The earlier version of cybernetics is termed "first-order"; the extension is called "second-order" or "cybernetics of cybernetics."

The extension is most clearly relevant to the observation of social systems and, hence also, to teaching and management. In these contexts, an observer must either be part of the observed system or have involvement with it. In other contexts, such as those of the so-called exact sciences, the involvement of the observer may be less obvious, but still, complete objectivity is impossible.

The impossibility of access to anything to be called reality also has been recognized under the heading of constructivism, a philosophical viewpoint that predates cybernetics. Clearly the construction formed by an individual has to allow effective interaction with the environment if he or she is to operate effectively and, indeed, to survive, but no precise image or model is implied by this construction.

MANAGEMENT

The application of cybernetics to management was pioneered by Stafford Beer (8,9) and is a major field of interest. In an early paper, he listed characteristics of a cybernetic, or viable, system that include internal complexity and the capability of self-organization, along with a means of interacting appropriately with its environment. He indicated points of similarity between the communications and control within a firm and a human or animal central nervous system. For example, he likened the exclusive pursuit of short-term profit by a firm to the behavior of a "spinal" dog deprived of cerebral function.

The view of human organizations as viable is supported by the observation that groups of people in contact spontaneously form a social structure. The viability of organizations has been described as "social autopoiesis," as part of sociocybernetics where autopoiesis is a principle originally used with reference to biological systems to indicate self-production.

The Beer "Viable System Model" (8,9) has found wide application in management studies and depends on his listing of a set of components that are essential for viability. Failures or inadequacies of management performance may be attributed to absence or weakness of one or more of these components. It is asserted that viable systems have recursive character in that they have other viable systems embedded in them and are themselves components of larger ones. The cells of the body are viable systems that are embedded in people, who in turn form organizations, and so on. Connections to higher and lower viable systems are part of the model.

An aspect emphasized by Beer (8,9) is the need for a rapid response to disturbances, achieved in the nervous system by local reflexes, which respond automatically but also are subject to higher-level control. His work also makes extensive use of the Ashby (7) principle of Requisite Variety, which corresponds to a theorem of the Shannon Information Theory and states that a disturbance of a system only can be corrected by a control action whose variety, or information content, is at least equal to that of the disturbance. This view has been epitomized as: "only variety can absorb variety." Beer (8,9) analyzed many management situations in terms of variety, alternatively termed complexity, and claimed to be practising "complexity engineering."

SYSTEMS SCIENCE

Cybernetics is concerned essentially with systems, and valuable discussions of the meaning of "system" appear in works of Ashby (7), Pask (10,11), and Beer (8,9). No firm distinction exists between cybernetics and systems science except for a difference of emphasis because of the essentially biological focus of cybernetics. However, the seminal work of Ludwig von Bertalanffy (12)on systems theory has very substantial biological content.

SOCIOCYBERNETICS

Cybernetics has social implications under two distinct headings. One is the social effect of the introduction of automation, including, with computers and advanced robots, the automation of tasks of intellectual and skilled nature. Norbert Wiener, in his book *The Human Use of Human Beings*(13), expressed his grave concern over these aspects.

The topic that has come to be termed sociocybernetics is not concerned primarily with these aspects but with the examination of social systems in terms of their control and informational features and with the use of concepts from cybernetics and systems theory to describe and model them. The need for second-order cybernetics became particularly clear in this context, and its use has allowed valuable analyses of, for example, international and inter faith tensions and aspects of the "war on terror."

The theory of autopoiesis, or self-production, developed originally by Humberto Maturana (14) and Francisco Varela with reference to living cells, has been applied to the self-maintenance of organizations in society as "social autopoiesis." This term is applied by Niklas Luhmann (15) to various entities, including the legal system. The autopoietic character is indicated by the reference to "organizational (or operative) closure." In management and social studies, the correspondence of a social entity to a living organism is emphasized frequently by reference to pathology and diagnosis. The theoretical treatment of self-organization due to Prigogine (5), mentioned earlier, has been applied in social studies.

A range of topics bearing on psychology and sociology were treated in cybernetic terms by Gregory Bateson (16) and his wife the anthropologist Margaret Mead, both participants in the Macy conference series. His insights were based on experience of anthropological fieldwork in Bali and New Guinea, as well as psychiatry among schizophrenics and alcoholics and the study of communication behavior in octopi and dophins. Another study that bears particularly on education is the "conversation theory" of Gordon Pask (10,11), with the aim of exteriorizing thought processes in managed conversations.

GAIA

In 1969 James Lovelock (17) advanced the suggestion that the totality of living things in the biosphere acts like one large animal to regulate environmental variables. This hypothesis has been termed the Gaia hypothesis, where the name Gaia was one given to the Greek earth goddess. It was assumed previously that environmental conditions on the earth (temperature, ocean salinity, oxygen concentration of the atmosphere, and so on) just happened to be compatible with life. Lovelock points out that these variables have remained remarkably steady despite disturbances, including a large change in the strength of solar radiation.

The environment is influenced by biological activity to a greater extent than usually is realized; for example, without life almost no atmosphere would exist. This influence makes regulation feasible, and the Lovelock theory (17) has given accurate predictions, including a gloomy view of the likely consequences of the effects of human activity on Gaia, especially with regard to carbon emissions and other factors that contribute to global warming. It is widely accepted, in fact, that the greatest threat to humanity is that the feedback mechanisms that regulate the temperature of the planet may be overwhelmed by the ignorant, selfish, and short-sighted behavior of humans and that a greater understanding of these issues urgently is required.

Lovelock (17) has suggested how regulation could have come into being, with the help of a parable called Daisyworld. Daisyworld is a simple model of a planet on which two species of plant ("daisies") grow, one species black and the other white. The dependence of growth rate on temperature is the same for both species. The spread of black daisies causes the planet to become warmer, and the spread of white daisies affects the planet conversely.

It has been shown that with reasonable assumptions about heat conductivity of the planet, such that black daisies are a little warmer than the planet generally and white ones a little cooler, effective regulation of temperature can result. Apart from its environmental significance, the mechanism is interesting as an example of control without an obvious set-point.

OTHER TOPICS

Other topics, among many, that impinge on cybernetics include the use of "fuzzy" methods to allow operation under uncertainty, based on the introduction of the fuzzy set theory by Lotfi Zadeh (18), as well as methods for the study of complex systems under headings of chaos and fractals and artificial life.

EDUCATION AND TRAINING IN SOFTWARE ENGINEERING

INTRODUCTION

Although the term “software engineering” has been used widely since the late 1960s, the question of whether to treat it as a distinct academic discipline has only been addressed during the past 15 years. The fact that a steadily increasing number of software engineering degree programs in colleges and universities exists throughout the world indicates a greater (although still far from unanimous) acceptance of software engineering as a separate discipline of study.

These software engineering degree programs emerged first at the master’s level, and then more recently at the bachelor’s and doctoral levels, in a process paralleling the development of computer science programs in the 1960s and 1970s. In both cases, the process began with the introduction of specialized elective courses in an existing curriculum. With computer science, as the body of knowledge grew, more courses were introduced, relationships among topics were better understood, textbooks were written, and better teaching methods were developed. Eventually, the fundamentals of computer science were codified in an undergraduate curriculum that provided the necessary skills to meet the increasing demand for computing practitioners, whereas the growth of computer science research and the demand for new faculty in the discipline led to doctoral programs in the field. Currently, software engineering is following this same pattern.

In addition, the evolution of software engineering has meant that industry and government both need to retrain workers from other fields as software engineer and to provide additional software engineering skills to current computing practitioners. Therefore, a variety of software engineering training courses and techniques has also been developed over the years.

This article contains:

- A history of software engineering in academia,
- The role of accreditation in various countries,
- Various curriculum models that have been proposed,
- The gap between academic education and professional knowledge required,
- An overview of software engineering training issues and academic certificate programs,
- University/industry collaborations in software engineering education,
- Distance learning and web-based education in software engineering,
- The role of professional issues in software engineering education, and
- Information on software engineering education conferences and publications.

HISTORY

In the spring of 1968, Douglas T. Ross taught a “special topics” graduate course on the topic of software engineering at the Massachusetts Institute of Technology (1). Ross claims that it is the first academic course with a title that used the term “software engineering”, James Tomayko, in his excellent article on the history of software engineering education (2), agrees that no apparent evidence exists to the contrary. This was several months before the now-famous first Conference on Software Engineering sponsored the North Atlantic Treaty Organization (NATO)!

The idea fostered by that first NATO conference of applying engineering concepts such as design, reliability, performance, and maintenance to software was revolutionary. As early as 1969, the software community began to recognize that the graduates of the fledgling computer science programs in universities were not prepared for industrial software development. In response, the industry started to ask for software engineering education rather than computer science education, including separate degree programs (3). Sketches of model curricula for software engineering programs also began to appear in the literature (4,5).

Early Software Engineering Courses

The most common form of software engineering education, even today, is a one-semester survey course, usually with a toy project built by groups of three students. In the extended decade between the first appearance of these courses and the establishment for the first software engineering degree programs, they became the mechanism for academia to experiment with teaching software engineering concepts.

Throughout the 1970s, industry continued to struggle to build larger and more complex software systems, and educators continued to create and teach the new discipline of computer science. Recognizing the problem of the divergence of these two communities, in 1976 Peter Freeman of the University of California, Irvine, and Anthony I. Wasserman of the University of California, San Francisco, organized the first U.S. workshop on software engineering education. The 40 participants represented academia, industry, and government, including companies involved in building large software systems. The workshop focused on the kind of work a professional software engineer actually did and on what the academic preparation for such a profession should be. The proceedings of the workshop (6) were published and distributed widely, and it still influences software engineering education today.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

ACM Curriculum 68 and 78 Recommendations

ACM Curriculum 68, the first major undergraduate computer science curriculum modeling effort (7), said little about learning how to develop complex software, except through work opportunities (e.g., through summer employment) or special individual project courses. (The latter became the basis for the "senior project" courses that are commonplace today of the undergraduate level, and the "software studio" courses in some graduate curricula.)

Later, ACM Curriculum 78 (8) listed a course in "software design and development"; however, it was not required in this undergraduate model. Therefore, although some growth occurred in software engineering undergraduate education, it remained limited to one or two semesters for the next 10 years. Meanwhile, software engineering as a graduate discipline would grow at a faster rate.

First Master's Degree Programs

Of course, one or two courses do not make a full curriculum. So, by the late 1970s, a few schools had started Master's degree programs in software engineering, primarily because of the pressure from local industry. To date, most graduate software engineering degree programs have used the model of a professional degree such as an MBA. (The degree title "Master of Software Engineering," or MSE, will be used here, although variations of this name are used.) A professional master's degree is a terminal degree, with graduates going into industry rather than academia. In particular, a software engineering master's degree has been a professional degree where the students in the program are already programmers or software developers in the workplace, with either a bachelor's degree in another computing discipline, or having completed sufficient undergraduate leveling to do the graduate coursework.

The first three U.S. MSE-type programs were developed at Seattle University, Texas Christian University, and the now-defunct Wang Institute of Graduate Studies in the late 1970s. Texas Christian University, located in Fort Worth, established a graduate degree program in software engineering in 1978 (9). The original curriculum was influenced greatly by the 1976 workshop. Because of external pressure prompted by the absence of an engineering college at the university, the program name was changed in 1980 to *Master of Software Design and Development*, and Texas Christian later discontinued the program.

In 1977, Seattle University initiated a series of discussions with representatives from local business and industry, during which software engineering emerged as a critical area of need for specialized educational programs. Leading software professionals were invited to assist in the development of an MSE program, which was initiated in 1979.

The Wang Institute of Graduate Studies was founded in 1979 by An Wang, founder and chairman of Wang Laboratories. It offered an MSE degree beginning in 1978. The Institute continued to depend heavily on Wang for financial support, because of the relatively low tuition income from the small student body (typically 20–30 students per year). Business declines at Wang Laboratories in the early 1980s reduced the ability to continue that support, and the institute closed in the summer of 1987. Its facilities in Tyngsboro, Massachusetts, were donated to Boston University, and its last few students were permitted to complete their degrees at that school. During its existence, the Wang program was considered to be the premier program of its kind.

According to Tomayko (2), by the mid-1980s, these three programs had similar curricula. The core courses at these institutions focused on various stages of the life cycle such as analysis, design, implementation, and testing, whereas each of the programs had a capstone project course lasting one or more semesters. These curricula were to have a large impact not only for future graduate programs, but for undergraduate curricula as well.

Academic Certificate Programs

Many higher education institutions around the world offer graduate-level academic certificates in software engineering. Although such certificate programs are targeted primarily toward those that received their undergraduate degrees in a non computing field, they differ from training programs in that they typically consist of several software engineering courses offered for graduate course credit at that institution. Typically, such graduate certificate programs typically the completion of a series of semester-long courses, constituting some portion of what might be required for a Bachelor's degree or Master's degree program. These academic certificate programs should not be confused with professional certification in software engineering, which will be addressed later in this article.

Development of Undergraduate Degree Programs

Undergraduate degree programs in software engineering have been slow to develop in most countries. One exception is the United Kingdom, where the British Computer Society (BCS) and the Institution of Electrical Engineers (IEE) have worked together to promote software engineering as a discipline. One of the oldest undergraduate software engineering degree programs in the world is at the University of Sheffield (10), which started in 1988.

Several Australian universities have also created bachelor's degree programs since the 1990 creation of an undergraduate program at the University of Melbourne.

The first undergraduate software engineering program in the United States started at the Rochester Institute of Technology in the fall of 1996, and now over 30 such programs exist (11).

Several software engineering undergraduate programs have been implemented in Canada. The program at McMaster University is probably the closest to a traditional engineering program of all those in software engineering, including requirements for courses in materials, thermodynamics, dynamics, and engineering economics, using a model outlined by its chair, David Lorge Parnas (12).

SOFTWARE ENGINEERING ACCREDITATION

Usually, accreditation of educational degree programs in a particular country is performed either by organizations in conjunction with professional societies or directly by the societies themselves. The mechanisms for software engineering accreditation in several different countries are provided below. More details are available in Ref. 13.

United States

Accreditation of engineering programs in the United States is conducted by the Engineering Accreditation Commission (EAC) of the Accreditation Board of Engineering and Technology (ABET) and until recently, accreditation of computer science programs had been conducted by a commission of the Computer Science Accreditation Board (CSAB).

In the late 1990s, the Institute of Electrical and Electronics Engineers (IEEE) developed criteria for the accreditation of software engineering programs by ABET/EAC (14). ABET and CSAB subsequently merged, with CSAB reinventing itself as a "participating society" of ABET. (As part of this change, ABET is not considered an acronym, and the organization bills itself as the accreditation body for applied science, computing, engineering, and technology education.) CSAB has lead responsibility for the accreditation of software engineering programs by ABET, which accredited its first programs during the 2002–2003 academic year, and as of October 2006 it has 13 schools accredited.

Canada

Canada had a legal dispute over the use of the term "engineering" by software engineers and in universities (15). The Association of Professional Engineers and Geoscientists of Newfoundland (APEGN) and the Canadian Council of Professional Engineers (CCPE) filed a Statement of Claim alleging trademark violation by Memorial University of Newfoundland (MUN) for using the name "software engineering" for a baccalaureate program. The APEGN and the CCPE claimed the program was not accreditable as an engineering program.

Subsequently, the parties came to an agreement: MUN dropped the use of the title "software engineering" for its program, APEGN and CCPE discontinued their lawsuit (with a five-year moratorium placed on new legal action), and the three organizations agreed to work together to define the appropriate uses of the term "software engineering" within Canadian universities (16). As a result of this action, the Canadian Engineering Accreditation Board (CEAB) began to develop criteria for accreditation of software engineering undergraduate degree programs. CEAB first accreditations were of three software engineering programs during the 2000–2001 academic year; nine programs are accredited as of 2007.

In part because of the five-year moratorium, the Computer Science Accreditation Council (CSAC), an accrediting body for computing programs in Canada sponsored by the Canadian Information Processing Society (CIPS), also started accrediting software engineering programs in 2000–2001, and also now has nine accredited schools (some schools are accredited by both CSAC and CEAB).

McCalla (17) claims that

> The difference between the CEAB and CSAC programs is substantial. The CEAB programs are offered as part of a standard engineering degree, with students highly constrained in their options and with the focus heavily on specific software engineering topics. The CSAC programs are offered as variations of standard computer science programs, with more flexibility for student choice and with the focus on a wider range of applied computer science topics than just software engineering.

Despite the end of the five-year moratorium in July 2005, both CEAB and CSAC continue to accredit software engineering degree programs.

United Kingdom

The BCS and the Institution of Engineering and Technology (IET) have accredited software engineering programs in the United Kingdom for several years. As of 2007, 64 schools with degree courses (programs) that have the words "software engineering" in their titles are accredited by BCS, according to their website at www.bcs.org.

Japan

In 2000, the Japan Board for Engineering Education (JABEE) applied a trial software engineering accreditation program (18). The Osaka Institute of Technology (OIT) was chosen for this trial, and was visited by a JABEE examination team in December 2000. The criteria used for examining the OIT program included the J97 curriculum model for Japanese computer science and software engineering programs and the IEEE-ACM Education Task Force recommended accreditation guidelines (both are discussed in the "Curriculum Models" section below).

Australia

The Institution of Engineers, Australia (IEAust) has been accrediting software engineering programs since 1993. A discussion of the IEAust accreditation process, and how the University of Melbourne developed an undergraduate software engineering degree program that was accredited in 1996, in described in Ref. 19.

CURRICULUM MODELS

Curriculum Development Issues

Below are some primary issues frequently addressed when developing or evaluating a software engineering curriculum model.

- Software engineering content
- Computer science content
- The role of calculus, laboratory sciences, and engineering sciences
- Application domain-specific topics
- Capstone experience
- Flexibility

The curriculum models below include some of the earliest, the most recent, and the most widely distributed in the field of software engineering.

Software Engineering Institute MSE Model

The mission of the Software Engineering Institute (SEI) at Carnegie Mellon University, in Pittsburgh, Pennsylvania is to provide leadership in advancing the state of the practice of software engineering to improve the quality of systems that depend on software. Recognizing the importance of education in the preparation of software professionals, the institute's charter required it to "influence software engineering curricula throughout the education community." Thus, the SEI Education Program began in 1985, only one year after the Institute's founding. This program emerged at the right time to play a key role in the development of software engineering education in the United States. The program was organized with a permanent staff of educators along with a rotating set of visiting professors.

Under the direction of Norman Gibbs (1985–1990) and Nancy Mead (1991–1994), the SEI Education Program accomplished a wide variety of tasks, including developing a detailed Graduate Curriculum Model, several curriculum modules on various topics, an outline of a undergraduate curriculum model; compiling a list of U.S. graduate software engineering degree programs; creating a directory of software engineering courses offered in U.S. institutions; developing educational videotape series for both academia and industry; and creating and initial sponsoring of the Conference on Software Engineering Education. Although the Education Program was phased out at SEI in 1994, its work is still influential today.

With regard to curriculum models, the SEI concentrated initially on master's level programs for two reasons. First, it is substantially easier within a university to develop and initiate a one-year master's program than a four-year bachelor's program. Second, the primary client population at the time was software professionals, nearly all of whom already have a bachelor's degree in some discipline. In 1987, 1989, and 1991, the SEI published model curricula for university MSE programs (described below) (20–22).

Because the goal of an MSE degree program is to produce a software engineer who can assume rapidly a position of substantial responsibility within an organization, SEI proposed a curriculum designed to give the student a body of knowledge that includes balanced coverage of the software engineering process activities, their aspects, and the products produced, along with sufficient experience to bridge the gap between undergraduate programming and professional software engineering. Basically, the program was broken into four parts: undergraduate prerequisites, core curriculum, the project experience component, and electives. The minimal undergraduate prerequisites were discrete mathematics, programming, data structures, assembly language, algorithm analysis, communication skills, and some calculus. Laboratory sciences were not required. The six core curriculum courses were:

Specification of Software Systems
Software Verification and Validation
Software Generation and Maintenance
Principles and Applications of Software Design
Software Systems Engineering
Software Project Management

The topics and content of these courses were in many ways an outgrowth of the common courses identified in the first MSE programs. These courses would likely be taken in the first year of a two-year MSE sequence. The bulk of the report consists of detailed syllabi and lecture suggestions for these six courses.

The project experience component took the form of the capstone project, and might require different prerequisites according to the project. The electives could be additional software engineering subjects, related computer science topics, system engineering courses, application domain courses, or engineering management topics.

Although the final version of the SEI model for an MSE was released almost 15 years ago, it remains today the most influential software engineering curriculum model for Master's degree programs.

BCS/IEE Undergraduate Model

As stated previously, the BCS and the IET have cooperated for many years in the development and accreditation of software engineering degree programs, dating back to the IEE, one of the two societies that merged to form the IET. Therefore, it is not surprising that the first major effort to develop a curriculum model for the discipline was a joint effort by these two societies (23).

The curriculum content defined in the report was "deliberately designed to be non-prescriptive and to encourage variety" (p. 27). Three types of skills are defined: central software engineering skills, supporting fundamental skills (technical communication, discrete math, and various computer science areas), and advanced skills.

At the end of the section on curriculum content, the authors state "the topics alone do not define a curriculum, since it is also necessary to define the depth to which they may be taught. The same topic may be taught in different disciplines with a different target result..." (p. 31). This reinforces the comments concerning the variety and non prescriptive nature of the recommendations at the beginning of that section.

It is interesting to note that the curriculum content does *not* include a need for skills in areas traditionally taught to engineers (e.g., calculus, differential equations, chemistry, physics, and most engineering sciences). It is remarkable that the computer scientists and electrical engineers on the working party that produced this report were able to agree on a curriculum that focused primarily on engineering process and computer science skills, and did not tie itself to traditional engineering courses.

SEI Undergraduate Model

In making undergraduate curriculum recommendations, Gary Ford (24) of SEI wanted a curriculum that would be compatible with the general requirements for ABET and CSAB and the core computing curriculum in the IEEE-CS/ ACM Curricula 91 (which was then in draft form). Also, although he was complimentary of the BCS/IEE recommendations, Ford was more precise in defining his model curriculum. The breakdown (for a standard 120 semester hour curriculum) was as follows:

Mathematics and Basic Sciences	27 semester hours
Software Engineering Sciences and Design	45 semester hours
Humanities and Social Sciences	30 semester hours
Electives	18 semester hours

The humanities & social sciences and electives were included to allow for maximum flexibility in implementing the curriculum. Mathematics and basic sciences consisted of two semesters of both discrete mathematics and calculus, and one semester of probability and statistics, numerical methods, physics, chemistry, and biology.

In designing the software engineering science and design component, Ford argues that the engineering sciences for software are primarily computer science, rather than sciences such as statics and thermodynamics (although for particular application domains, such knowledge may be useful). Four different software engineering areas are defined: software analysis, software architectures, computer systems, and software process.

Ford goes on to define 14 courses (totaling 42 semester hours; one elective is allowed), with 3 or 4 courses in each of these four areas, and places them (as well as the other aspects of the curriculum) in the context of a standard four-year curriculum. The four software process courses were placed in the last two years of the program, which allowed for the possibility of a senior project-type experience.

Thus, several similarities existed between the BCS/IEE and SEI recommended undergraduate models: they focused on similar software engineering skills, did not require standard engineering sciences, and (interestingly) did not require a capstone experience.

IEEE-ACM Education Task Force

The Education Task Force of an IEEE-ACM Joint Steering Committee for the Establishment of Software Engineering developed some recommended accreditation criteria for undergraduate programs in software engineering (25). Although no accreditation board has yet adopted these precise guidelines, it has influenced several accreditation and curriculum initiatives.

According to their accreditation guidelines, four areas exist (software engineering, computer science, and engineering, supporting areas suchc technical communication and mathematics, and advanced work in one or more area) that are each about three-sixteenths of the curriculum, which amounts to 21–24 semester hours for each area in a 120-hour degree plan. (The remaining hours were left open, to be used by, for instance, general education requirements in the United States). As in the SEI graduate guidelines, a capstone project is addressed explicitly.

Guidelines for Software Engineering Education

This project was created by a team within the Working Group for Software Engineering Education and Training (WGSEET). The Working Group was a “think tank” of about 30 members of the software engineering and training communities, who come together twice a year to work on major projects related to the discipline. WGSEET was established in 1995 in part to fill a void left by the demise of the SEI Education Program.

At the November 1997 Working Group meeting, work began on what was originally called the “Guidelines for Software Education.” A major difference in goals of the *Guidelines* with the previously discussed projects is that the latter developed computer science, computer engineering, and information systems curricula with software engineering concentrations in addition to making recommendations for an undergraduate software engineering curriculum. (This article will focus only on the software engineering model.)

Here are the recommended number of hours and courses for each topic area in the software engineering model, from Ref. 26.

Software Engineering – Required (24 of 120 Semester Hours)

Software Engineering Seminar (One hour course for first-semester students)
Introduction to Software Engineering
Formal Methods
Software Quality
Software Analysis and Design I and II
Professional Ethics
Senior Design Project (capstone experience)

Computer Science – Required (21 Semester Hours)

Introduction to Computer Science for Software Engineers 1 and 2
(Similar to first year computer science, but oriented to software engineering)
Data Structures and Algorithms
Computer Organization
Programming Languages
Software Systems 1 and 2
(Covers operating systems, databases, and other application areas)

Computer Science / Software Engineering – Electives (9 Semester Hours)

Various topics

Lab Sciences (12 Semester Hours)

Chemistry 1
Physics 1 and 2

Engineering Sciences (9 Semester Hours)

Engineering Economics
Engineering Science 1 and 2
(Provides an overview of the major engineering sciences)

Mathematics (24 Semester Hours)

Discrete Mathematics
Calculus 1, 2 and 3
Probability and Statistics
Linear Algebra
Differential Equations

Communication/Humanities/Social Sciences (18 Semester Hours)

Communications 1 and 2 (first year writing courses)
Technical Writing
Humanities/Social Sciences electives

Open Electives (3 Semester Hours)

Any course

This model is intended to be consistent with the IEEE-ACM Education Task Force recommendations and criteria for all engineering programs accredited by ABET. The nine hours of engineering sciences is less than for traditional engineering disciplines and that contained in the McMaster University degree program, but more than that is required in the other software engineering curriculum models.

Not much flexibility exists in this model, because only one technical elective outside of Computer Science/Software Engineering can be taken (using the open elective). However, note that the model is for a minimal number of semester hours (120), so additional hours could provide that flexibility.

Information Processing Society of Japan (IPSJ)

IPSJ has developed a core curriculum model for computer science and software engineering degree programs commonly called J97 (18). Unlike the other curriculum models discussed above, J97 defines a common core curriculum for every undergraduate computer science and software engineering program. This core curriculum includes the following learning units:

Computer Literacy Courses

Computer Science Fundamentals
Programming Fundamentals

Mathematics Courses

Discrete Mathematics
Computing Algorithms
Probability and Information Theory
Basic Logic

Computing Courses

Digital Logic
Formal Languages and Automata Theory
Data Structures
Computer Architecture
Programming Languages
Operating Systems
Compilers
Databases
Software Engineering
The Human-Computer Interface

Note that, unlike most computing curriculum models, basic programming skills are considered part of basic computer literacy, whereas algorithm analysis (computing algorithms) is treated as part of the mathematics component. The units listed above provide for a broad background in computer science as well as an education in basic computer engineering and software engineering fundamentals.

Computing Curricula – Software Engineering

Over the years, the ACM/IEEE-CS joint Education Task Force went through several changes, eventually aligning itself with similar projects being jointly pursued by the two societies. The Software Engineering 2004 (SE 2004) project (as it was eventually named) was created to provide detailed undergraduate software engineering curriculum guidelines which could serve as a model for higher education institutions across the world. The result of this project was an extensive and comprehensive document which has indeed become the leading model for software engineering undergraduate curricula (27). SE 2004 was defined using the following principles:

1. Computing is a broad field that extends well beyond the boundaries of any one computing discipline.
2. Software Engineering draws its foundations from a wide variety of disciplines.
3. The rapid evolution and the professional nature of software engineering require an ongoing review of the corresponding curriculum. The professional associations in this discipline.
4. Development of a software engineering curriculum must be sensitive to changes in technologies, practices, and applications, new developments in pedagogy, and the importance of lifelong learning. In a field that evolves as rapidly as software engineering, educational institutions must adopt explicit strategies for responding to change.
5. SE 2004 must go beyond knowledge elements to offer significant guidance in terms of individual curriculum components.

6. SE 2004 must support the identification of the fundamental skills and knowledge that all software engineering graduates must possess.
7. Guidance on software engineering curricula must be based on an appropriate definition of software engineering knowledge.
8. SE 2004 must strive to be international in scope.
9. The development of SE2004 must be broadly based.
10. SE 2004 must include exposure to aspects of professional practice as an integral component of the undergraduate curriculum.
11. SE 2004 must include discussions of strategies and tactics for implementation, along with high-level recommendations.

The SE 2004 document also defines student outcomes; that is, what is expected of graduates of a software engineering program using the curriculum guidelines contained within:

1. Show mastery of the software engineering knowledge and skills, and professional issues necessary to begin practice as a software engineer.
2. Work as an individual and as part of a team to develop and deliver quality software artifacts.
3. Reconcile conflicting project objectives, finding acceptable compromises within limitations of cost, time, knowledge, existing systems, and organizations.
4. Design appropriate solutions in one or more application domains using software engineering approaches that integrate ethical, social, legal, and economic concerns.
5. Demonstrate an understanding of and apply current theories, models, and techniques that provide a basis for problem identification and analysis, software design, development, implementation, verification, and documentation.
6. Demonstrate an understanding and appreciation for the importance of negotiation, effective work habits, leadership, and good communication with stakeholders in a typical software development environment.
7. Learn new models, techniques, and technologies as they emerge and appreciate the necessity of such continuing professional development.

The next step was to define Software Engineering Education Knowledge (SEEK), a collection of topics considered important in the education of software engineering students. SEEK was created and reviewed by volunteers in the software engineering education community. The SEEK body is a three-level hierarchy, initially divided into knowledge areas (KAs) as follows:

Computing essentials
Mathematical and engineering fundamentals
Professional practice
Software modeling and analysis
Software design
Software verification & validation
Software evolution
Software process
Software quality
Software management

Those KAs are then divided even more into units, and finally, those units are divided into *topics*. For example, DES.con.7 is a specific topic (Design Tradeoffs) in the Design Concepts unit of the Software Design knowledge area. Each topic in *SEEK* is also categorized for its importance: Essential, Desired, or Optional.

The SE 2004 document also contains recommendations for possible curricula and courses, tailored towards models for specific countries and specific kinds of institutions of higher-level education. Software engineering topics consisted of at least 20% of the overall curriculum in each case. Most of the models recommended for use in the United States included some type of introduction to software engineering during the first two years of study, followed by six SE courses, with a capstone project occurring throughout the fourth and final (senior) year of study.

THE GAP BETWEEN EDUCATION AND INDUSTRY

Tim Lethbridge of the University of Ottawa has done a considerable amount of work in attempting to determine what industry thinks is important knowledge for a software professional to receive through academic and other educational venues through a series of surveys (28). The results of these surveys show that a wide gap still exists between what is taught in education versus what is needed in industry. For instance, among the topics required of professionals that had to be learned on the job include negotiation skills, human-computer interaction methods, real-time system design methods, management and leadership skills, cost estimation methods, software metrics, software reliability and fault tolerance, ethics and professionalism practice guidelines, and requirements gathering and analysis skills. Among the topics taught in most educational programs but not considered important to industry included digital logic, analog systems, formal languages, automata theory, linear algebra, physics and chemistry. Industry and academia agreed that a few things were important, including data structures, algorithm design, and operating systems.

The survey results also demonstrate that it is essential for industry and academia to work together to create future software engineering curricula, for both groups to use their resources more wisely and effectively in the development of software professionals in the future.

Another excellent article outlining the industrial view was by Tockey (29). Besides stressing the need for software practitioners to be well-versed in computer science and discrete mathematics, he identified software engineering economics as an important “missing link” that current software professionals do not have when entering the workforce.

TRACKING SOFTWARE ENGINEERING DEGREE PROGRAMS

Over the years, several surveys have been attempted to determine what software engineering programs exist in a particular country or for a particular type of degree. By 1994, 25 graduate MSE-type programs existed in the United States, and 20 other programs with software engineering options were in their graduate catalogs, according to an SEI survey (30) that was revised slightly for final release in early 1996.

Thompson and Edwards' excellent article on software engineering education in the United Kingdom (31) provides an excellent list of 43 Bachelor's degree and 11 Master's programs in software engineering in the UK.

Doug Grant (32) of the Swinburne University of Technology reported that Bachelor's degree programs insoftware engineering were offered by at least 9 of Australia's 39 universities, with more being planned.

In June 2002, Fred Otto of CCPE provided the author with a list of 10 Canadian schools with undergraduate software engineering degree programs.

Bagert has in recent years published a list of 32 undergraduate (11) and 43 Master's level (33) SE programs in the United States, along with some information concerning those programs.

Currently, few doctoral programs in software engineering exist. In the late 1990s, the first Doctor of Philosophy (Ph.D.) programs in software engineering in the United States were approved at the Naval Postgraduate School (34) and at the Carnegie Mellon University (35). Also, in 1999, Auburn University changed its doctoral degree in Computer Science to "Computer Science and Software Engineering."

INDUSTRY/UNIVERSITY COLLABORATIONS

Collaborations between industry and higher education are common in engineering disciplines, where companies can give students experience with real-world problems through project courses. However, formal collaborations between university and industry have become more frequent in the last decade. Beckman et al. (36) discussed the benefits to industry and academia of such collaborations:

- Benefits to industry:
  - ◦Cost-effective, customized education and training
  - ◦Influence on academic programs
  - ◦Access to university software engineering research
  - ◦New revenue sources
- Benefits to academia:
  - ◦Placement of students
  - ◦Insight into corporate issues at the applied, practical level
  - ◦Research and continuing education opportunities for faculty
  - ◦Special funding from a corporate partner to the cooperating university

This paper also provided details on three successful formal university/industry partnerships in software engineering. Through evaluation of these and other evaluations, Beckman et al. (36), developed a model for a successful collaboration which included:

- Formation by the university of an advisory board made up of representatives of its industrial partners.
- A clear definition of the goals and expectations of the collaboration.
- Developing and executing a multiphase process for the collaboration project.
- Defining, measuring, and evaluating effectively metrics for project success.

WGSEET has documented several innovative formal industry-university collaborations in software engineering over the years; (37) Ref. 37 is the seventh and latest edition of their directory of such collaborations, providing details of 23 such formal partnerships, including the three described above. The initial results of an even more recent survey by this group can be found in Ref. 38.

TRAINING IN SOFTWARE ENGINEERING

To this point, this discussion has concentrated on academic education, as opposed to education within industry (training). The term *software engineering education and training* is used commonly to encompass both academic education and industrial training issues.

Starting over 20 years ago, several large companies involved in software development began to embrace the concept of software engineering. Faced with both a software development workforce mostly untrained in software engineering skills and paucity of academic coursework in software engineering available, many companies began developing an array of in-house courses to meet the need. Among the first of these companies was the IBM Software Engineering Education Program, which was started in the late 1970s. This program was influenced greatly by software engineering pioneer Harlan Mills, who worked for IBM from 1964 to 1987.

Also among the oldest software engineering training programs is that of the Texas Instruments Defense Systems and Electronics Group (DSEG), which is now part of Raytheon. Moore and Purvis (39) discussed the DSEG software training curriculum as it existed then. First, those engineers assigned to develop software would take a three-day "Software Engineering Workshop" for engineers, which would introduce the workers to DSEG software practices and standards, as well as DoD life cycle requirements. This workshop could be followed with courses such as software quality assurance, software configuration management, introduction to real-time systems, structured analysis, software design, software testing and software management.

Motorola is another example of a company that has invested considerably in the software engineering training of its employees. Sanders and Smith (40) estimated that its software engineering population at the time required 160,000 person-hours of training per year, which it provided both through its own Motorola University, as well as through collaborations with various universities (such as the one with Florida Atlantic University discussed in the previous section).

Over the years, several companies have offered a wide variety of software engineering training courses to both companies and individuals . Construx Software lists on its web page (41) a wide variety of training seminars. In addition, Construx has a significant professional development program for its own employees, employing readings, classes, discussion groups, mentoring, and so on.

Typically software engineering training courses offered by companies are of length anywhere from a half-day course associated with a meeting such as the International Conference on Software Engineering to a one or two-week stand-alone course. Generally, such courses cost $500–1000 U.S. per day for each registrant.

Software process improvement training has increased significantly over the past 10 years. For instance, several of companies offer training services to corporations that want their software divisions to obtain ISO 9000 registration or a certain level of the Capability Maturity Model Integration (registered in the U.S. Patent and Trademark office). In addition, also many training courses exist in both the Personal Software Process and the related Team Software Process (e.g., Ref. 42) (Personal Software Process and Team Software Process are service marks of Cargegie Mellon University, Pittsburgh, PA).

DISTANCE LEARNING AND WEB-BASED EDUCATION

Both software engineering academic and training courses have been available through various distance means over the years. A early example was the Software Engineering Institute's Video Dissemination Project begun the early 1990s, which provided two series of courses: one to support academic instruction and the other to continue education.

With the advent of the Internet and advanced multimedia technology, software engineering distance education has increased significantly. Synchronous and asynchronous distance education and training in software engineering allows for increased schedule flexibility for the participant, and it also helps to satisfy the demand for such courses despite the limited number of instructors available.

Carnegie Mellon offers its entire MSE degree online through the use various media. The first group of Carnegie Mellon students to graduate with an MSE without ever setting foot on campus was in August 2000 (43).

A survey of Master's level software engineering programs in the United States by Bagert and Mu (33) found that of the 43 schools that had "software engineering" as the name of the Master's degree, 24 schools deliver the programs only face-to-face, three only online, and 16 schools provide for both or have a curriculum that has both face-to-face and online courses.

THE ROLE OF PROFESSIONAL ISSUES

As software engineering has begun to evolve as a distinct discipline, various efforts have been related to professional issues in software engineering, including accreditation of degree programs, the identification of the software engineering body of knowledge, the licensing and certification of software engineers, and the development of a code of ethics and professional practices for software engineering. The software engineering education and training community, recognizing the impact of professional issues on their curricula, has begun to address such matters in education and training conferences and publications.

SOFTWARE ENGINEERING EDUCATION CONFERENCES AND PUBLICATIONS

Since 1987, the Conference on Software Engineering Education (CSEE&T) has become tremendously influential to the software engineering education and training community worldwide. Originally created and run by the SEI, the conference has in recent years been sponsored by the IEEE Computer Society. As the conference evolved, it grew to include training (hence the name change) and professional issues, and for a time was colocated with the ACM SIGCSE (Special Interest Group on Computer Science Education) Symposium on Computer Science Education, giving educators in computer science and software engineering an opportunity to meet together and discuss issues of common concern. Today, CSEE&T remains the world's premiere conference dedicated to software engineering education, training, and professional issues.

FASE (Forum for Advancing Software engineering Education) was started in 1991 by members of the software engineering education community to have an electronic forum for the dissemination and discussion of events related to software engineering education. The original acronym for *FASE* was Forum for Academic Software Engineering, but it was subsequently changed so that it was more inclusive to industrial and government training issues. In the last few years, FASE has also covered a wide variety of professional issues. During the last few years, FASE has limited its coverage mostly to announcements of upcoming events and faculty openings. An archive of all issues through February 2004 is available at http://cstl-csm.semo.edu/dbagert/fase.

Although currently no refereed journals are devoted exclusively to software engineering education, several publications have devoted special issues to the subject over the years, including *IEEE Software, IEEE Transactions on Software Engineering*, *Journal of Systems and Software*, *Information and Software Technology*, and *Computer Science Education*.

CONCLUSIONS AND FUTURE DIRECTIONS

Only a few years ago, the number of software engineering degree programs were consistently increasing, giving great hope for the future. However, the rate of increase of such programs has slowed [e.g., its status in the United States was discussed by Bagert and Chenoweth (11)]. A unique opportunity in software engineering education is before the computing and engineering disciplines, one that has the potential to open both to tremendous possibilities. However, this can be done only by a joint effort of the computing and engineering communities, just as BCS and IEE did in the United Kingdom almost 20 years ago. In other countries, the results of such attempted collaborations in other countries have been at best mixed.

Industrial education, both through training courses and from collaborations with academic institutions, will continue to expand as the demand for software engineers also continues to increase. This requires the continuing education of software professionals as well as the retraining of workers with backgrounds from related disciplines. The need for more collaboration between industry/university is especially important in the face of surveys that demonstrate a distinct gap between academic educational outcomes and the industrial knowledge required for software professionals.

It is likely that distance education will be impacting all academic and professional disciplines in the near future. In addition, distance learning will be especially important for the software engineering community as long as instructor shortages remain.

Finally, perhaps the most critical step required for the future of software engineering education and training is the need for a true internationalization of major initiatives. Many projects discussed in this article were successful efforts that were developed within a single country. The SE 2004 project was notable in part for the fact that it went to great lengths to be a document truly international in development and scope. Not enough communication of the successes of a particular country to the international community exists; for instance, the accomplishments of BCS and IEE regarding software engineering education in the United Kingdom over past dozen years is largely unknown in the United States even today. The challenge is to use the Internet, the World Wide Web, and other technological innovations (which were, after all, developed in large part by software professionals!) to advance the discipline itself even more by creating an effective and truly global software engineering education and training community.

ACKNOWLEDGMENTS

ETHICS AND PROFESSIONAL RESPONSIBILITY IN COMPUTING

INTRODUCTION

Computing professionals perform a variety of tasks: They write specifications for new computer systems, they design instruction pipelines for superscalar processors, they diagnose timing anomalies in embedded systems, they test and validate software systems, they restructure the back-end databases of inventory systems, they analyze packet traffic in local area networks, and they recommend security policies for medical information systems. Computing professionals are obligated to perform these tasks conscientiously because their decisions affect the performance and functionality of computer systems, which in turn affect the welfare of the systems' users directly and that of other people less directly. For example, the software that controls the automatic transmission of an automobile should minimize gasoline consumption and, more important, ensure the safety of the driver, any passengers, other drivers, and pedestrians.

The obligations of computing professionals are similar to the obligations of other technical professionals, such as civil engineers. Taken together, these professional obligations are called *professional ethics*. Ethical obligations have been studied by philosophers and have been articulated by religious leaders for many years. Within the discipline of philosophy, ethics encompasses the study of the actions that a responsible individual should choose, the values that an honorable individual should espouse, and the character that a virtuous individual should have. For example, everyone should be honest, fair, kind, civil, respectful, and trustworthy. Besides these general obligations that everyone shares, professionals have additional obligations that originate from the responsibilities of their professional work and their relationships with clients, employers, other professionals, and the public.

The ethical obligations of computing professionals go beyond complying with laws or regulations; laws often lag behind advances in technology. For example, before the passage of the Electronic Communications Privacy Act of 1986 in the United States, government officials did not require a search warrant to collect personal information transmitted over computer communication networks. Nevertheless, even in the absence of a privacy law before 1986, computing professionals should have been aware of the obligation to protect the privacy of personal information.

WHAT IS A PROFESSION?

Computing professionals include hardware designers, software engineers, database administrators, system analysts, and computer scientists. In what ways do these occupations resemble recognized professions such as medicine, law, engineering, counseling, and accounting? In what ways do computing professions resemble occupations that are not thought of traditionally as professions, such as plumbers, fashion models, and sales clerks?

Professions that exhibit certain characteristics are called *strongty differentiated* professions (1). These professions include physicians and lawyers, who have special rights and responsibilities. The defining characteristics of a strongly differentiated profession are specialized knowledge and skills, systematic research, professional autonomy, a robust professional association, and a well-defined social good associated with the profession.

Members of a strongly differentiated profession have specialized knowledge and skills, often called a "body of knowledge," gained through formal education and practical experience. Although plumbers also have special knowledge and skills, education in the trades such as plumbing emphasizes apprenticeship training rather than formal education. An educational program in a professional school teaches students the theoretical basis of a profession, which is difficult to learn without formal education. A professional school also socializes students to the values and practices of the profession. Engineering schools teach students to value efficiency and to reject shoddy work. Medical schools teach students to become physicians, and law schools teach future attorneys. Because professional work has a significant intellectual component, entry into a profession often requires a post-baccalaureate degree such as the M.S.W. (Master of Social Work) or the Psy.D. (Doctor of Psychology).

Professionals value the expansion of knowledge through systematic research; they do not rely exclusively on the transmission of craft traditions from one generation to the next. Research in a profession is conducted by academic members of the professioin and sometimes by practitioner members too- Academic physicians, for example, conduct medical research. Because professionals understand that professional knowledge always advances, professionals should also engage in continuing education by reading publications and attending conferences. Professionals should share general knowledge of their fields, rather than keeping secrets of a guild. Professionals are obligated, however, to keep specific information about clients confidential.

Professionals tend to have *clients*, not *customers*. Whereas a sales clerk should try to satisfy the customer's *desires*, the professional should try to meet the client's *needs* (consistent with the welfare of the client and the public). For example, a physician should not give a patient a prescription for barbiturates just because the patient wants the drugs but only if the patient's medical condition warrants the prescription.

Because professionals have specialized knowledge, clients cannot fully evaluate the quality of services provided by professionals. Only other members of a profession, the

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

professional's peers, can sufficiently determine the quality of professional work. The principle of peer review underlies accreditation and licensing activities: Members of a profession evaluate the quality of an educational program for accreditation, and they set the requirements for the licensing of individuals. For example, in the United States, a lawyer must pass a state's bar examination to be licensed to practice in that state. (Most states have reciprocity arrangements—a professional license granted by one state is recognized by other states.) The license gives professionals legal authority and privileges that are not available to unlicensed individuals. For example, a licensed physician may legitimately prescribe medications and perform surgery, which are activities that should not be performed by people who are not medical professionals.

Through accreditation and licensing, the public cedes control over a profession to members of the profession. In return for this autonomy, the profession promises to serve the public good. Medicine is devoted to advancing human health, law to the pursuit of justice, and engineering to the economical construction of safe and useful objects. As an example of promoting the public good over the pursuit of self-interest, professionals are expected to provide services to some indigent clients without charge. For instance, physicians volunteer at free clinics, and they serve in humanitarian missions to developing countries. Physicians and nurses are expected to render assistance in cases of medical emergency—for instance, when a train passenger suffers a heart attack. In sum, medical professionals have special obligations that those who are not medical professionals do not have.

The purposes and values of a profession, including its commitment to a public good, are expressed by its code of ethics. A fortiori, the creation of a code of ethics is one mark of the transformation of an occupation into a profession.

A profession's code of ethics is developed and updated by a national or international professional association. This association publishes periodicals and hosts conferences to enable professionals to continue their learning and to network with other members of the profession. The association typically organizes the accreditation of educational programs and the licensing of individual professionals.

Do computing professions measure up to these criteria for a strongly differentiated profession? To become a computing professional, an individual must acquire specialized knowledge about discrete algorithms and relational database theory and specialized skills such as software development techniques and digital system design. Computing professionals usually learn this knowledge and acquire these skills by earning a baccalaureate degree in computer science, computer engineering, information systems, or a related field. As in engineering, a bachelor's degree currently suffices for entry into the computing professions. The knowledge base for computing expands through research in computer science conducted in universities and in industrial and government laboratories.

Like electrical engineers, most computing professionals work for employers, who might not be the professionals' clients. For example, a software engineer might develop application software that controls a kitchen appliance; the engineer's employer might be different from the appliance manufacturer. Furthermore, the software engineer should prevent harm to the ultimate users of the appliance and to others who might be affected by the appliance. Thus, the computing professional's relationship with a client and with the public might be indirect.

The obligations of computing professionals to clients, employers, and the public are expressed in several codes of ethics. The later section on codes of ethics reviews two codes that apply to computing professionals.

Although the computing professions meet many criteria of other professions, they are deficient in significant ways. Unlike academic programs in engineering, relatively few academic programs in computing are accredited. Furthermore, in the United States, computing professionals cannot be licensed, except that software engineers can be licensed in Texas. As of this writing, the Association for Computing Machinery (ACM) has reaffirmed its opposition to state-sponsored licensing of individuals (2). Computing professionals may earn proprietary certifications offered by corporations such as Cisco, Novell, Sun, and Microsoft. In the United States, the American Medical Association dominates the medical profession, and the American Bar Association dominates the legal profession, but no single organization defines the computing profession. Instead, multiple distinct organizations exist, including the ACM, the Institute of Electrical and Electronics Engineers Computer Society (IEEE-CS), and the Association of Information Technology Professionals (AIPT). Although these organizations cooperate on some projects, they remain largely distinct, with separate publications and codes of ethics.

Regardless of whether computing professions are strongly differentiated, computing professionals have important ethical obligations, as explained in the remainder of this article.

WHAT IS MORAL RESPONSIBILITY IN COMPUTING?

In the early 1980s Atomic Energy of Canada Limited (AECL) manufactured and sold a cancer radiation treatment machine called the Therac 25, which relied on computer software to control its operation. Between 1985 and 1987, the Therac-25 caused the deaths of three patients and serious injuries to three others (3). Who was responsible for the accidents? The operator who administered the massive radiation overdoses, which produced severe burns? The software developers who wrote and tested the control software, which contained several serious errors? The system engineers who neglected to install the backup hardware safety mechanisms that had been used in previous versions of the machine? The manufacturer, AECL? Government agencies? We can use the Therac-25 case to distinguish among four different kinds of responsibility (4,5).

Causal Responsibility

Responsibility can be attributed to causes: For example, "the tornado was responsible for damaging the house." In the Therac-25 case, the proximate cause of each accident was the operator, who started the radiation treatment. But just as the weather cannot be blamed for a moral failing, the

Therac-25 operators cannot be blamed because they followed standard procedures, and the information displayed on the computer monitors was cryptic and misleading.

Role Responsibility

An individual who is assigned a task or function is considered the responsible person for that role. In this sense, a foreman in a chemical plant may be responsible for disposing of drums of toxic waste, even if a forklift operator actually transfers the drums from the plant to the truck. In the Therac-25 case, the software developers and system engineers were assigned the responsibility of designing the software and hardware of the machine. Insofar as their designs were deficient, they were responsible for those deficiencies because of their roles. Even if they had completed their assigned tasks, however, their role responsibility may not encompass the full extent of their professional responsibilities.

Legal Responsibility

An individual or an organization can be legally responsible, or liable, for a problem. That is, the individual could be charged with a crime, or the organization could be liable for damages in a civil lawsuit. Similarly, a physician can be sued for malpractice. In the Therac-25 case, AECL could have been sued. One kind of legal responsibility is *strict liability*: If a product injures someone, then the manufacturer of the product can be found liable for damages in a lawsuit, even if the product met all applicable safety standards and the manufacturer did nothing wrong. The principle of strict liability encourages manufacturers to be careful, and it provides a way to compensate victims of accidents.

Moral Responsibility

Causal, role, and legal responsibilities tend to be exclusive: If one individual is responsible, then another is not. In contrast, moral responsibility tends to be shared: many engineers are responsible for the safety of the products that they design, not just a designated safety engineer. Furthermore, rather than assign blame for a past event, moral responsibility focuses on what individuals should do in the future. In the moral sense, responsibility is a virtue: A "responsible person" is careful, considerate, and trustworthy; an "irresponsible person" is reckless, inconsiderate, and untrustworthy.

Responsibility is shared whenever multiple individuals collaborate as a group, such as a software development team. When moral responsibility is shared, responsibility is *not* atomized to the point at which no one in the group is responsible. Rather, each member of the group is accountable to the other members of the group and to those whom the group's work might affect, both for the individual's own actions and for the effects of their collective effort. For example, suppose a computer network monitoring team has made mistakes in a complicated statistical analysis of network traffic data, and that these mistakes have changed the interpretation of the reported results. If the team members do not reanalyze the data themselves, they have an obligation to seek the assistance of a statistician who can analyze the data correctly. Different team members might work with the statistician in different ways, but they should hold each other accountable for their individual roles in correcting the mistakes. Finally, the team has a collective moral responsibility to inform readers of the team's initial report about the mistakes and the correction.

Moral responsibility for recklessness and negligence is not mitigated by the presence of good intentions or by the absence of bad consequences. Suppose a software tester neglects to sufficiently test a new module for a telephone switching system, and the module fails. Although the subsequent telephone service outages are not intended, the software tester is morally responsible for the harms caused by the outages. Suppose a hacker installs a keystroke logging program in a deliberate attempt to steal passwords at a public computer. Even if the program fails to work, the hacker is still morally responsible for attempting to invade the privacy of users.

An individual can be held morally responsible both for acting and for failing to act. For example, a hardware engineer might notice a design flaw that could result in a severe electrical shock to someone who opens a personal computer system unit to replace a memory chip. Even if the engineer is not specifically assigned to check the electrical safety of the system unit, the engineer is morally responsible for calling attention to the design flaw, and the engineer can be held accountable for failing to act.

Computing systems often obscure accountability (5). In particular, in an embedded system such as the Therac-25, the computer that controls the device is hidden. Computer users seem resigned to accepting defects in computers and software that cause intermittent crashes and losses of data. Errors in code are called "bugs," regardless of whether they are minor deficiencies or major mistakes that could cause fatalities. In addition, because computers seem to act autonomously, people tend to blame the computers themselves for failing, instead of the professionals who designed, programmed, and deployed the computers.

WHAT ARE THE RESPONSIBILITIES OF COMPUTING PROFESSIONALS?

Responsibilities to Clients and Users

Whether a computing professional works as a consultant to an individual or as an employee in a large organization, the professional is obligated to perform assigned tasks competently, according to professional standards. These professional standards include not only attention to technical excellence but also concern for the social effects of computers on operators, users, and the public. When assessing the capabilities and risks of computer systems, the professional must be candid: The professional must report all relevant findings honestly and accurately. When designing a new computer system, the professional must consider not only the specifications of the client but also how the system might affect the quality of life of users and others. For example, a computing professional who designs an information system for a hospital and should allow speedy access by physicians and nurses and yet protect patients' medical records from unauthorized access; the technical requirement to provide fast access may conflict with the social obligation to ensure patients' privacy.

Computing professionals enjoy considerable freedom in deciding how to meet the specifications of a computer system. Provided that they meet the minimum performance requirements for speed, reliability, and functionality, within an overall budget, they may choose to invest resources to decrease the response time rather than to enhance a graphical user interface, or vice versa. Because choices involve tradeoffs between competing values, computing professionals should identify potential biases in their design choices (6). For example, the designer of a search engine for an online retailer might choose to display the most expensive items first. This choice might favor the interest of the retailer, to maximize profit, over the interest of the customer, to minimize cost.

Even moderately large software artifacts (computer programs) are inherently complex and error-prone. Furthermore, software is generally becoming more complex. It is therefore reasonable to assume that all software artifacts have errors. Even if a particular artifact does not contain errors, it is extremely difficult to prove its correctness. Faced with these realities, how can a responsible software engineer release software that is likely to fail sometime in the future? Other engineers confront the same problem, because all engineering artifacts eventually fail. Whereas most engineering artifacts fail because physical objects wear out, software artifacts are most likely to fail because of faults *designed into* the original artifact. The intrinsically faulty nature of software distinguishes it from light bulbs and I-beams, for example, whose failures are easier to predict statistically.

To acknowledge responsibilities for the failure of software artifacts, software developers should exercise due diligence in creating software, and they should be as candid as possible about both known and unknown faults in the software—particularly software for *safety-critical systems*, in which a failure can threaten the lives of people. Candor by software developers would give software consumers a better chance to make reasonable decisions about software before they buy it (7). Following an established tradition in medicine, Miller (8) advocates "software informed consent" as a way to formalize an ethical principle that requires openness from software developers. Software informed consent requires software developers to reveal, using explanations that are understandable to their customers, the risks of their software, including the likelihoods of known faults and the probabilities that undiscovered faults still exist. The idea of software informed consent motivates candor and requires continuing research into methods of discovering software faults and measuring risk.

Responsibilities to Employers

Most computing professionals work for employers. The employment relationship is contractual: The professional promises to work for the employer in return for a salary and benefits. Professionals often have access to the employer's proprietary information such as trade secrets, and the professional must keep this information confidential. Besides trade secrets, the professional must also honor other forms of *intellectual property* owned by the employer: The professional does not have the right to profit from independent sale or use of this intellectual property, including software developed with the employer's resources.

Every employee is expected to work loyally on behalf of the employer. In particular, professionals should be aware of potential conflicts of interest, in which loyalty might be owed to other parties besides the employer. A *conflict of interest* occurs when a professional is asked to render a judgment, but the professional has personal or financial interests that may interfere with the exercise of that judgment. For instance, a computing professional may be responsible for ordering computing equipment, and an equipment vendor owned by the professional's spouse might submit a bid. In this case, others would perceive that the marriage relationship might bias the professional's judgment. Even if the spouse's equipment would be the best choice, the professional's judgment would not be trustworthy. In a typical conflict of interest situation, the professional should *recuse* herself: that is, the professional should remove herself and ask another qualified person to make the decision.

Many computing professionals have managerial duties, and some are solely managers. Managerial roles complicate the responsibilities of computing professionals because managers have administrative responsibilities and interests within their organizations in addition to their professional responsibilities to clients and the public.

Responsibilities to Other Professionals

Although everyone deserves respect from everyone else, when professionals interact with each other, they should demonstrate a kind of respect called *collegiality*. For example, when one professional uses the ideas of a second professional, the first should credit the second. In a research article, an author gives credit by properly citing the sources of ideas from other authors in previously published articles. Using these ideas without attribution constitutes plagiarism. Academics consider plagiarism unethical because it represents the theft of ideas and the misrepresentation of those ideas as the plagiarist's own.

Because clients cannot adequately evaluate the quality of professional service, individual professionals know that their work must be evaluated by other members of the same profession. This evaluation, called *peer review* occurs in both practice and research. Research in computing is presented at conferences and is published in scholarly journals. Before a manuscript that reports a research project can be accepted for a conference or published in a journal, the manuscript must be reviewed by peer researchers who are experts in the subject of the manuscript.

Because computing professionals work together, they must observe *professional standards*. These standards of practice are created by members of the profession or within organizations. For example, in software development, one standard of practice is a convention for names of variables in code. By following coding standards, a software developer can facilitate the work of a software maintainer who subsequently modifies the code. For many important issues for which standards would be appropriate theoretically, however, “standards” in software engineering are controversial, informal, or nonexistent. An example of this problem is the difficulties encountered when the IEEE and the ACM attempted to standardize a body of knowledge for software engineering to enable the licensing of software engineers.

Senior professionals have an obligation to *mentor* junior professionals in the same field. Although professionals are highly educated, junior members of a profession require additional learning and experience to develop professional judgment. This learning is best accomplished under the tutelage of a senior professional. In engineering, to earn a P.E. license, a junior engineer must work under the supervision of a licensed engineer for at least four years. More generally, professionals should assist each other in continuing education and professional development, which are generally required for maintaining licensure.

Professionals can fulfill their obligations to contribute to the profession *volunteering*. The peer review of research publications depends heavily on volunteer reviewers and editors, and the activities of professional associations are conducted by committees of volunteers.

Responsibilities to the Public

According to engineering codes of ethics, the engineer’s most important obligation is to ensure the safety, health, and welfare of the public. Although everyone must avoid endangering others, engineers have a special obligation to ensure the safety of the objects that they produce. Computing professionals share this special obligation to guarantee the safety of the public and to improve the quality of life of those who use computers and information systems.

As part of this obligation, computing professionals should enhance the public’s understanding of computing. The responsibility to educate the public is a collective responsibility of the computing profession as a whole; individual professionals might fulfill this responsibility in their own ways. Examples of such public service include advising a church on the purchase of computing equipment and writing a letter to the editor of a newspaper about technical issues related to proposed legislation to regulate the Internet.

It is particularly important for computing professionals to contribute their technical knowledge to discussions about public policies regarding computing. Many communities are considering controversial measures such as the installation of Web filtering software on public access computers in libraries. Computing professionals can participate in communities’ decisions by providing technical facts. Technological controversies involving the social impacts of computers are covered in a separate article of this encyclopedia.

When a technical professional’s obligation of loyalty to the employer conflicts with the obligation to ensure the safety of the public, the professional may consider *whistlebhwing,* that is, alerting people outside the employer’s organization to a serious, imminent threat to public safety. Computer engineers blew the whistle during the development of the Bay Area Rapid Transit (BART) system near San Francisco (9). In the early 1970s, three BART engineers became alarmed by deficiencies in the design of the electronics and software for the automatic train control system, deficiencies that could have endangered passengers on BART trains. The engineers raised their concerns within the BART organization without success. Finally, they contacted a member of the BART board of directors, who passed their concerns to Bay Area newspapers. The three engineers were immediately fired for disloyalty. They were never reinstated, even when an accident proved their concerns were valid. When the engineers sued the BART managers, the IEEE filed an *amicus curiae* brief on the engineers’ behalf, stating that engineering codes of ethics required the three engineers to act to protect the safety of the public. The next section describes codes of ethics for computing professionals.

CODES OF ETHICS

For each profession, the professional’s obligations to clients, employers, other professionals, and the public are stated explicitly in the profession’s code of ethics or code of professional conduct. For computing professionals, such codes have been developed by ACM, the British Computer Society (BCS), the, IEEE-CS, the AITP, the Hong Kong Computer Society, the Systems Administrators Special Interest Group of USENEX (SAGE), and other associations. Two of these codes will be described briefly here: the ACM code and the Software Engineering Code jointly approved by the IEEE-CS and the ACM.

The ACM is one of the largest nonprofit scientific and educational organization devoted to computing. In 1966 and 1972, the ACM published codes of ethics for computing professionals. In 1992, the ACM adopted the current Code of Ethics and Professional Conduct (10), which appears in Appendix 1. Each statement of the code is accompanied by interpretive guidelines. For example, the guideline for statement 1.8, *Honor confidentiality*, indicates that other ethical imperatives such as complying with a law may take precedence. Unlike ethics codes for other professions, one section of the ACM code states the ethical obligations of “organizational leaders,” who are typically technical managers.

The ACM collaborated with the IEEE-CS to produce the Software Engineering Code of Ethics and Professional Practice (11). Like the ACM code, the Software Engineering Code also includes the obligations of technical managers. This code is notable in part because it was the first code to focus exclusively on software engineers, not on other computing professionals. This code is broken into a short version is composed of and a long version. The short version is composed of a preamble and eight short principles; this version appears in Appendix 2. The long version expands on the eight principles with multiple clauses that apply the principles to specific issues and situations.

Any code of ethics is necessarily incomplete—no document can address every possible situation. In addition, a code must be written in general language; each statement in a code requires interpretation to be applied in specific circumstances. Nevertheless, a code of ethics can serve multiple purposes (12,13). A code can inspire members of a profession to strive for the profession's ideals. A code can educate new members about their professional obligations, and tell nonmembers what they may expect members to do, A code can set standards of conduct for professionals and provide a basis for expelling members who violate these standards. Finally, a code may support individuals in making difficult decisions. For example, because all engineering codes of ethics prioritize the safety and welfare of the public, an engineer can object to unsafe practices not merely as a matter of individual conscience but also with the full support of the consensus of the profession. The application of a code of ethics for making decisions is highlighted in the next section.

ETHICAL DECISION MAKING FOR COMPUTING PROFESSIONALS

Every user of e-mail has received unsolicited bulk commercial e-mail messages, known in a general way as *spam*. (A precise definition of "spam" has proven elusive and is controversial; most people know spam when they see it, but legally and ethically a universally accepted definition has not yet emerged.) A single spam broadcast can initiate millions of messages. Senders of spam claim that they are exercising their free speech rights, and few laws have been attempted to restrict it. In the United States, no federal law prohibited spamming before the CAN-SPAM Act of 2003. Even now, the CAN-SPAM law does not apply to spam messages that originate in other countries. Although some prosecutions have occurred using the CAN-SPAM Act, most people still receive many e-mail messages that they consider spam.

Some spam messages are designed to be deceptive and include intentionally inaccurate information, but others include only accurate information. Although most spamming is not illegal, even honest spamming is considered unethical by many people, for the following reasons. First, spamming has bad consequences: It wastes the time of recipients who must delete junk e-mail messages, and these messages waste space on computers; in addition, spamming reduces users' trust in e-mail. Second, spamming is not reversible: Senders of spam do not want to receive spam. Third, spamming could not be allowed as a general practice: If everyone attempted to broadcast spam messages to wide audiences, computer networks would become clogged with unwanted e-mail messages, and no one could communicate via e-mail at all.

The three reasons advanced against spam correspond to three ways in which the morality of an action can be evaluated: first, whether on balance the action results in more good consequences than bad consequences; second, whether the actor would be willing to trade places with someone affected by the action: and third, whether everyone (in a similar situation) could choose the same action as a general rule. These three kinds of moral reasons correspond to three of the many traditions in philosophical ethics: consequentialism, the Golden Rule, and duty-based ethics.

Ethical issues in the use of computers can also be evaluated through the use of analogies to more familiar situations. For example, a hacker may try to justify gaining unauthorized access to unsecured data by reasoning that because the data are not protected, anyone should be able to read it. But by analogy, someone who finds the front door of a house unlocked is not justified in entering the house and snooping around. Entering an unlocked house is trespassing, and trespassing violates the privacy of the house's occupants.

When making ethical decisions, computing professionals can rely not only on general moral reasoning but also on specific guidance from codes of ethics, such as the ACM Code of Ethics (10). Here is a fictional example of that approach.

> ***Scenario:*** XYZ Corporation plans to monitor secretly the Web pages visited by its employees, using a data mining program to analyze the access records. Chris, an engineer at XYZ, recommends that XYZ purchase a data mining program from Robin, an independent contractor, without mentioning that Robin is Chris's domestic partner. Robin had developed this program while previously employed at UVW Corporation, without the awareness of anyone at UVW.
> ***Analysis:*** First, the monitoring of Web accesses intrudes on employees' privacy; it is analogous to eavesdropping on telephone calls. Professionals should respect the privacy of individuals (ACM Code 1.7, *Respect the privacy of others*, and 3.5, *Articulate and support policies that protect the dignity of users and others affected by a computing system).* Second, Chris has a conflict of interest because the sale would benefit Chris's domestic partner. By failing to mention this relationship, Chris was disingenuous (ACM Code 1.3, *Be honest and trustworthy).* Third, because Robin developed the program while working at UVW, some and perhaps all of the property rights belong to UVW. Robin probably signed an agreement that software developed while employed at UVW belongs to UVW. Professionals should honor property rights and contacts (ACM Code 1.5, *Honor property rights including copyrights and patent*, and 2.6, *Honor contracts, agreements, and assigned responsibilities).*

Applying a code of ethics might not yield a clear solution of an ethical problem because different principles in a code might conflict. For instance, the principles of honesty and confidentiality conflict when a professional who is questioned about the technical details of the employer's forthcoming product must choose between answering the question completely and keeping the information secret. Consequently, more sophisticated methods have been developed for solving ethical problems. Maner (14) has studied and collected what he calls "procedural ethics, step-by-step ethical reasoning procedures ... that may prove useful to computing professionals engaged in ethical decision-making." Maner's list includes a method specialized for business ethics (15), a paramedic method (16), and a procedure from the U.S. Department of Defense (17). These procedures appeal to the problem-solving ethos of engineering, and they help professionals avoid specific traps that might otherwise impair a professional's ethical judgment. No procedural ethics method should be interpreted as allowing complete objectivity or providing a mechanical algorithm for reaching a conclusion about an ethical problem, however, because all professional ethics issues of any complexity require subtle and subjective judgments.

COMPUTING AND THE STUDY OF ETHICS: THE ETHICAL CHALLENGES OF ARTIFICIAL INTELLIGENCE AND AUTONOMOUS AGENTS

Many ethical issues, such as conflict of interest, are common to different professions. In computing and engineering, however, unique ethical issues develop from the creation of machines whose outward behaviors resemble human behaviors that we consider "intelligent." As machines become more versatile and sophisticated, and as they increasingly take on tasks that were once assigned only to humans, computing professionals and engineers must rethink their relationship to the artifacts they design, develop, and then deploy.

For many years, ethical challenges have been part of discussions of artificial intelligence. Indeed, two classic references in the field are by Norbert Wiener in 1965 (18) and by Joseph Weizenbaum in 1976 (19). Since the 1990s, the emergence of sophisticated "autonomous agents," including Web "bots" and physical robots, has intensified the ethical debate. Two fundamental issues are of immediate concern: the responsibility of computing professionals who create these sophisticated machines, and the notion that the machines themselves will, if they have not already done so, become sufficiently sophisticated so that they will be considered themselves moral agents, capable of ethical praise or blame independent of the engineers and scientists who developed them. This area of ethics is controversial and actively researched. A full discussion of even some of the nuances is beyond the scope of this article. Recent essays by Floridi and Sanders (20) and Himma (21) are two examples of influential ideas in the area.

APPENDIX 1. ACM CODE OF ETHICS AND PROFESSIONAL CONDUCT

http://www.acm.org/about/code-of-ethics.

PREAMBLE

Commitment to ethical professional conduct is expected of every member (voting members, associate members, and student members) of the Association for Computing Machinery (ACM).

This Code, consisting of 24 imperatives formulated as statements of personal responsibility, identifies the elements of such a commitment. It contains many, but not all, issues professionals are likely to face. Section 1 outlines fundamental ethical considerations, while Section 2 addresses additional, more specific considerations of professional conduct. Statements in Section 3 pertain more specifically to individuals who have a leadership role, whether in the workplace or in a volunteer capacity such as with organizations like ACM. Principles involving compliance with this Code are given in Section 4.

The Code shall be supplemented by a set of Guidelines, which provide explanation to assist members in dealing with the various issues contained in the Code. It is expected that the Guidelines will be changed more frequently than the Code.

The Code and its supplemented Guidelines are intended to serve as a basis for ethical decision making in the conduct of professional work. Secondarily, they may serve as a basis for judging the merit of a formal complaint pertaining to violation of professional ethical standards.

It should be noted that although computing is not mentioned in the imperatives of Section 1, the Code is concerned with how these fundamental imperatives apply to one's conduct as a computing professional. These imperatives are expressed in a general form to emphasize that ethical principles which apply to computer ethics are derived from more general ethical principles.

It is understood that some words and phrases in a code of ethics are subject to varying interpretations, and that any ethical principle may conflict with other ethical principles in specific situations. Questions related to ethical conflicts can best be answered by thoughtful consideration of fundamental principles, rather than reliance on detailed regulations.

1. GENERAL MORAL IMPERATIVES

As an ACM member I will . . . .

1.1 Contribute to society and human well-being

This principle concerning the quality of life of all people affirms an obligation to protect fundamental human rights and to respect the diversity of all cultures. An essential aim of computing professionals is to minimize negative consequences of computing systems, including threats to health and safety. When designing or implementing systems, computing professionals must attempt to ensure that the products of their efforts will be used in socially responsible ways, will meet social needs, and will avoid harmful effects to health and welfare.

In addition to a safe social environment, human well-being includes a safe natural environment. Therefore, computing professionals who design and develop systems must be alert to, and make others aware of, any potential damage to the local or global environment.

1.2 Avoid harm to others

"Harm" means injury or negative consequences, such as undesirable loss of information, loss of property, property damage, or unwanted environmental impacts. This principle prohibits use of computing technology in ways that result in harm to any of the following: users, the general public, employees, employers. Harmful actions include intentional destruction or modification of files and programs leading to serious loss of resources or unnecessary expenditure of human resources such as the time and effort required to purge systems of "computer viruses."

Well-intended actions, including those that accomplish assigned duties, may lead to harm unexpectedly. In such an event the responsible person or persons are obligated to undo or mitigate the negative consequences as much as possible. One way to avoid unintentional harm is to carefully consider potential impacts on all those affected by decisions made during design and implementation.

To minimize the possibility of indirectly harming others, computing professionals must minimize malfunctions by following generally accepted standards for system design and testing. Furthermore, it is often necessary to assess the social consequences of systems to project the likelihood of any serious harm to others. If system features are misrepresented to users, coworkers, or supervisors, the individual computing professional is responsible for any resulting injury.

In the work environment the computing professional has the additional obligation to report any signs of system dangers that might result in serious personal or social damage. If one's superiors do not act to curtail or mitigate such dangers, it may be necessary to "blow the whistle" to help correct the problem or reduce the risk. However, capricious or misguided reporting of violations can, itself, be harmful. Before reporting violations, all relevant aspects of the incident must be thoroughly assessed. In particular, the assessment of risk and responsibility must be credible. It is suggested that advice be sought from other computing professionals. See principle 2.5 regarding thorough evaluations.

1.3 Be honest and trustworthy

Honesty is an essential component of trust. Without trust an organization cannot function effectively. The honest computing professional will not make deliberately false or deceptive claims about a system or system design, but will instead provide full disclosure of all pertinent system limitations and problems.

A computer professional has a duty to be honest about his or her own qualifications, and about any circumstances that might lead to conflicts of interest.

Membership in volunteer organizations such as ACM may at times place individuals in situations where their statements or actions could be interpreted as carrying the "weight" of a larger group of professionals. An ACM member will exercise care to not misrepresent ACM or positions and policies of ACM or any ACM units.

1.4 Be fair and take action not to discriminate

The values of equality, tolerance, respect for others, and the principles of equal justice govern this imperative. Discrimination on the basis of race, sex, religion, age, disability, national origin, or other such factors is an explicit violation of ACM policy and will not be tolerated.

Inequities between different groups of people may result from the use or misuse of information and technology. In a fair society, all individuals would have equal opportunity to participate in, or benefit from, the use of computer resources regardless of race, sex, religion, age, disability, national origin or other such similar factors. However, these ideals do not justify unauthorized use of computer resources nor do they provide an adequate basis for violation of any other ethical imperatives of this code.

1.5 Honor property rights including copyrights and patent

Violation of copyrights, patents, trade secrets and the terms of license agreements is prohibited by law in most circumstances. Even when software is not so protected, such violations are contrary to professional behavior. Copies of software should be made only with proper authorization. Unauthorized duplication of materials must not be condoned

1.6 Give proper credit for intellectual property

Computing professionals are obligated to protect the integrity of intellectual property. Specifically, one must not take credit for other's ideas or work, even in cases where the work has not been explicitly protected by copyright, patent, etc.

1.7 Respect the privacy of others

Computing and communication technology enables the collection and exchange of personal information on a scale unprecedented in the history of civilization. Thus there is increased potential for violating the privacy of individuals and groups. It is the responsibility of professionals to maintain the privacy and integrity of data describing individuals. This includes taking precautions to ensure the accuracy of data, as well as protecting it from unauthorized access or accidental disclosure to inappropriate individuals. Furthermore, procedures must be established to allow individuals to review their records and correct inaccuracies.

This imperative implies that only the necessary amount of personal information be collected in a system, that retention and disposal periods for that information be clearly defined and enforced, and that personal information gathered for a specific purpose not be used for other purposes without consent of the individual(s). These principles apply to electronic communications, including electronic mail, and prohibit procedures that capture or monitor electronic user data, including messages, without the permission of users or bona fide authorization related to system operation and maintenance. User data observed during the normal duties of system operation and maintenance must be treated with strictest confidentiality, except in cases where it is evidence for the violation of law, organizational regulations, or this Code. In these cases, the nature or contents of that information must be disclosed only to proper authorities.

1.8 Honor confidentiality

The principle of honesty extends to issues of confidentiality of information whenever one has made an explicit promise to honor confidentiality or, implicitly, when private information not directly related to the performance of one's duties becomes available. The ethical concern is to respect all obligations of confidentiality to employers, clients, and users unless discharged from such obligations by requirements of the law or other principles of this Code.

2 MORE SPECIFIC PROFESSIONAL RESPONSIBILITIES

As an ACM computing professional I will . . ..

2.1 Strive to achieve the highest quality, effectiveness and dignity in both the process and products of professional work

Excellence is perhaps the most important obligation of a professional. The computing professional must strive to achieve quality and to be cognizant of the serious negative consequences that may result from poor quality in a system.

2.2 Acquire and maintain professional competence

Excellence depends on individuals who take responsibility for acquiring and maintaining professional competence. A professional must participate in setting standards for appropriate levels of competence, and strive to achieve those standards. Upgrading technical knowledge and competence can be achieved in several ways: doing independent study; attending seminars, conferences, or courses; and being involved in professional organizations.

2.3 Know and respect existing laws pertaining to professional work

ACM members must obey existing local, state, province, national, and international laws unless there is a compelling ethical basis not to do so. Policies and procedures of the organizations in which one participates must also be obeyed. But compliance must be balanced with the recognition that sometimes existing laws and rules may be immoral or inappropriate and, therefore, must be challenged. Violation of a law or regulation may be ethical when that law or rule has inadequate moral basis or when it conflicts with another law judged to be more important. If one decides to violate a law or rule because it is viewed as unethical, or for any other reason, one must fully accept responsibility for one's actions and for the consequences.

2.4 Accept and provide appropriate professional review

Quality professional work, especially in the computing profession, depends on professional reviewing and critiquing. Whenever appropriate, individual members should seek and utilize peer review as well as provide critical review of the work of others.

2.5 Give comprehensive and thorough evaluations of computer systems and their impacts, including analysis of possible risks

Computer professionals must strive to be perceptive, thorough, and objective when evaluating, recommending, and presenting system descriptions and alternatives. Computer professionals are in a position of special trust, and therefore have a special responsibility to provide objective, credible evaluations to employers, clients, users, and the public. When providing evaluations the professional must also identify any relevant conflicts of interest, as stated in imperative 1.3.

As noted in the discussion of principle 1.2 on avoiding harm, any signs of danger from systems must be reported to those who have opportunity and/or responsibility to resolve them. See the guidelines for imperative 1.2 for more details concerning harm, including the reporting of professional violations.

2.6 Honor contracts, agreements, and assigned responsibilities

Honoring one's commitments is a matter of integrity and honesty. For the computer professional this includes ensuring that system elements perform as intended. Also, when one contracts for work with another party, one has an obligation to keep that party properly informed about progress toward completing that work.

A computing professional has a responsibility to request a change in any assignment that he or she feels cannot be completed as defined. Only after serious consideration and with full disclosure of risks and concerns to the employer or client, should one accept the assignment. The major underlying principle here is the obligation to accept personal accountability for professional work. On some occasions other ethical principles may take greater priority.

A judgment that a specific assignment should not be performed may not be accepted. Having clearly identified one's concerns and reasons for that judgment, but failing to procure a change in that assignment, one may yet be obligated, by contract or by law, to proceed as directed. The computing professional's ethical judgment should be the final guide in deciding whether or not to proceed. Regardless of the decision, one must accept the responsibility for the consequences.

However, performing assignments "against one's own judgment" does not relieve the professional of responsibility for any negative consequences.

2.7 Improve public understanding of computing and its consequences

Computing professionals have a responsibility to share technical knowledge with the public by encouraging understanding of computing, including the impacts of computer systems and their limitations. This imperative implies an obligation to counter any false views related to computing.

2.8 Access computing and communication resources only when authorized to do so

Theft or destruction of tangible and electronic property is prohibited by imperative 1.2 - "Avoid harm to others." Trespassing and unauthorized use of a computer or communication system is addressed by this imperative. Trespassing includes accessing communication networks and computer systems, or accounts and/or files associated with those systems, without explicit authorization to do so. Individuals and organizations have the right to restrict access to their systems so long as they do not violate the discrimination principle (see 1.4), No one should enter or use another's computer system, software, or data files without permission. One must always have appropriate approval before using system resources, including communication ports, file space, other system peripherals, and computer time.

3. ORGANIZATIONAL LEADERSHIP IMPERATIVES

As an ACM member and an organizational leader, I will . . . .

BACKGROUND NOTE: This section draws extensively from the draft IFIP Code of Ethics, especially its sections on organizational ethics and international concerns. The ethical obligations of organizations tend to be neglected in most codes of professional conduct, perhaps because these codes are written from the perspective of the individual member. This dilemma is addressed by stating these imperatives from the perspective of the organizational leader. In this context "leader" is viewed as any organizational member who has leadership or educational responsibilities. These imperatives generally may apply to organizations as well as their leaders. In this context "organizations" are corporations, government agencies, and other "employers," as well as volunteer professional organizations.

3.1 Articulate social responsibilities of members of an organizational unit and encourage full acceptance of those responsibilities

Because organizations of all kinds have impacts on the public, they must accept responsibilities to society. Organizational procedures and attitudes oriented toward quality and the welfare of society will reduce harm to members of the public, thereby serving public interest and fulfilling social responsibility. Therefore, organizational leaders must encourage full participation in meeting social responsibilities as well as quality performance.

3.2 Manage personnel and resources to design and build information systems that enhance the quality of working life

Organizational leaders are responsible for ensuring that computer systems enhance, not degrade, the quality of working life. When implementing a computer system, organizations must consider the personal and professional development, physical safety, and human dignity of all workers. Appropriate human-computer ergonomic standards should be considered in system design and in the workplace.

3.3 Acknowledge and support proper and authorized uses of an organization's computing and communication resources

Because computer systems can become tools to harm as well as to benefit an organization, the leadership has the responsibility to clearly define appropriate and inappropriate uses of organizational computing resources. While the number and scope of such rules should be minimal, they should be fully enforced when established.

3.4 Ensure that users and those who will be affected by a system have their needs clearly articulated during the assessment and design of requirements; later the system must be validated to meet requirements

Current system users, potential users and other persons whose lives may be affected by a system must have their needs assessed and incorporated in the statement of requirements. System validation should ensure compliance with those requirements.

3.5 Articulate and support policies that protect the dignity of users and others affected by a computing system

Designing or implementing systems that deliberately or inadvertently demean individuals or groups is ethically unacceptable. Computer professionals who are in decision making positions should verify that systems are designed and implemented to protect personal privacy and enhance personal dignity.

3.6 Create opportunities for members of the organization to learn the principles and limitations of computer systems

This complements the imperative on public understanding (2.7). Educational opportunities are essential to facilitate optimal participation of all organizational members. Opportunities must be available to all members to help them improve their knowledge and skills in computing, including courses that familiarize them with the consequences and limitations of particular types of systems. In particular, professionals must be made aware of the dangers of building systems around oversimplified models, the improbability of anticipating and designing for every possible operating condition, and other issues related to the complexity of this profession.

4. COMPLIANCE WITH THE CODE

As an ACM member I will . . . .

4.1 Uphold and promote the principles of this code

The future of the computing profession depends on both technical and ethical excellence. Not only is it important for ACM computing professionals to adhere to the principles expressed in this Code, each member should encourage and support adherence by other members.

4.2 Treat violations of this code as inconsistent with membership in the ACM

Adherence of professionals to a code of ethics is largely a voluntary matter. However, if a member does not follow this code by engaging in gross misconduct, membership in ACM may be terminated.

APPENDIX 2: SOFTWARE ENGINEERING CODE OF ETHICS AND PROFESSIONAL PRACTICE (SHORT VERSION)

http://www.acm.org/about/se-code/
Short Version

PREAMBLE

The short version of the code summarizes aspirations at a high level of the abstraction; the clauses that are included in the full version give examples and details of how these aspirations change the way we act as software engineering professionals. Without the aspirations, the details can become legalistic and tedious; without the details, the aspirations can become high sounding but empty; together, the aspirations and the details form a cohesive code.

Software engineers shall commit themselves to making the analysis, specification, design, development, testing and maintenance of software a beneficial and respected profession. In accordance with their commitment to the health, safety and welfare of the public, software engineers shall adhere to the following Eight Principles:

1. PUBLIC - Software engineers shall act consistently with the public interest.
2. CLIENT AND EMPLOYER - Software engineers shall act in a manner that is in the best interests of their client and employer consistent with the public interest.
3. PRODUCT - Software engineers shall ensure that their products and related modifications meet the highest professional standards possible.
4. JUDGMENT - Software engineers shall maintain integrity and independence in their professional judgment.
5. MANAGEMENT - Software engineering managers and leaders shall subscribe to and promote an ethical approach to the management of software development and maintenance.
6. PROFESSION - Software engineers shall advance the integrity and reputation of the profession consistent with the public interest.
7. COLLEAGUES - Software engineers shall be fair to and supportive of their colleagues.
8. SELF - Software engineers shall participate in lifelong learning regarding the practice of their profession and shall promote an ethical approach to the practice of the profession.

FIXED-POINT COMPUTER ARITHMETIC

INTRODUCTION

This article begins with a brief discussion of the two's complement number system in the section on "Number Systems." The section on "Arithmetic Algorithms" provides examples of implementations of the four basic arithmetic operations (i.e., add, subtract, multiply, and divide).

Regarding notation, capital letters represent digital numbers (i.e., n-bit words), whereas subscripted lowercase letters represent bits of the corresponding word. The subscripts range from n – 1 to 0 to indicate the bit position within the word (x_{n-1} is the most significant bit of X, x_0 is the least significant bit of X, etc.). The logic designs presented in this chapter are based on positive logic with AND, OR, and INVERT operations. Depending on the technology used for implementation, different logical operations (such as NAND and NOR) or direct transistor realizations may be used, but the basic concepts do not change significantly.

NUMBER SYSTEMS

At the current time, fixed-point binary numbers are represented generally using the two's complement number system. This choice has prevailed over the sign magnitude and one's complement number systems, because the frequently performed operations of addition and subtraction are easiest to perform on two's complement numbers. Sign magnitude numbers are more efficient for multiplication, but the lower frequency of multiplication and the development of the efficient Booth's two's complement multiplication algorithm have resulted in the nearly universal selection of the two's complement number system for most implementations. The algorithms presented in this article assume the use of two's complement numbers.

Fixed-point number systems represent numbers, for example A, by n bits: a sign bit, and $n-1$ "data" bits. By convention, the most significant bit, a_{n-1}, is the sign bit, which is generally a ONE for negative numbers and a ZERO for positive numbers. The $n-1$ data bits are a_{n-2}, a_{n-3},. . ., a_1, a_0. In the two's complement fractional number system, the value of a number is the sum of $n-1$ positive binary fractional bits and a sign bit which has a weight of -1:

$$A = -a_{n-1} + \sum_{i=0}^{n-2} a_i 2^{i-n+1} \qquad (1)$$

Examples of 4-bit fractional two's complement fractions are shown in Table 1. Two points are evident from the table: First, only a single representation of zero exists (specifically 0000) and second, the system is not symmetric because a negative number exists, −1, (1000), for which no positive equivalent exists. The latter property means that taking the absolute value of, negating or squaring a valid number (−1) can produce a result that cannot be represented.

Table 1. 4-Bit fractional two's complement numbers

Decimal Fraction	Binary Representation
+7/8	0111
+3/4	0110
+5/8	0101
+1/2	0100
+3/8	0011
+1/4	0010
+1/8	0001
+0	0000
−1/8	1111
−1/4	1110
−3/8	1101
−1/2	1100
−5/8	1011
−3/4	1010
−7/8	1001
−1	1000

Two's complement numbers are negated by inverting all bits and adding a ONE to the least significant bit position. For example, to form −3/8:

```
          +3/8              = 0011

          invert all bits   = 1100

          add 1               0001
                              ----
                              1101     = –3/8

Check:    invert all bits   = 0010

          add 1               0001
                              ----
                              0011     = 3/8
```

Truncation of two's complement numbers never increases the value of the number. The truncated numbers have values that are either unchanged or shifted toward negative infinity. This shift may be seen from Equation (1), in which any truncated digits come from the least significant end of the word and have positive weight. Thus, to remove them will either leave the value of the number unchanged (if the bits that are removed are ZEROs) or reduce the value of the number. On average, a shift toward $-\infty$ of one-half the value of the least significant bit exists. Summing many truncated numbers (which may occur in scientific, matrix, and signal processing applications) can cause a significant accumulated error.

ARITHMETIC ALGORITHMS

This section presents a reasonable assortment of typical fixed-point algorithms for addition, subtraction, multiplication, and division.

Addition

Addition is performed by summing the corresponding bits of the two n-bit numbers, which includes the sign bit. Subtraction is performed by summing the corresponding bits of the minuend and the two's complement of the subtrahend.

Overflow is detected in a two's complement adder by comparing the carry signals into and out of the most significant adder stage (i.e., the stage which computes the sign bit). If the carries differ, the addition has overflowed and the result is invalid. Alternatively, if the sign of the sum differs from the signs of the two operands, the addition has overflowed.

ADDITION IMPLEMENTATION

A wide range of implementations exist for fixed point addition, which include ripple carry adders, carry lookahead adders, and carry select adders. All start with a full adder as the basic building block.

Full Adder

The full adder is the fundamental building block of most arithmetic circuits. The operation of a full adder is defined by the truth table shown in Table 2. The sum and carry outputs are described by the following equations:

$$\mathrm{s_k} = \mathrm{a_k} \oplus \mathrm{b_k} \oplus \mathrm{c_k} \tag{2}$$

$$\mathrm{c_{k+1}} = \mathrm{a_k b_k} + \mathrm{a_k c_k} + \mathrm{b_k c_k} \tag{3}$$

where $\mathrm{a_k}$, $\mathrm{b_k}$, and $\mathrm{c_k}$ are the inputs to the k-th full adder stage, and s_k and c_{k+1} are the sum and carry outputs, respectively, and $\oplus$ denotes the Exclusive-OR logic operation.

In evaluating the relative complexity of implementations, often it is convenient to assume a nine-gate realization of the full adder, as shown in Fig. 1. For this implementation, the delay from either $\mathrm{a_k}$ or $\mathrm{b_k}$ to $\mathrm{s_k}$ is six gate delays and the delay from $\mathrm{c_k}$ to $\mathrm{c_{k+1}}$ is two gate delays. Some technologies, such as CMOS, form inverting gates (e.g., NAND and NOR gates) more efficiently than the noninverting gates that are assumed in this article. Circuits with equivalent speed and complexity can be constructed with inverting gates.

Ripple Carry Adder

A ripple carry adder for n-bit numbers is implemented by concatenating n full adders, as shown in Fig. 2. At the k-th bit position, bits a_k and b_k of operands A and B and the carry signal from the preceding adder stage, c_k, are used to generate the kth bit of the sum, s_k, and the carry, c_{k+1}, to

Table 2. Full adder truth table

Inputs			Outputs	
$\mathrm{a_k}$	$\mathrm{b_k}$	$\mathrm{c_k}$	$\mathrm{c_{k+1}}$	$\mathrm{s_k}$
0	0	0	0	0
0	0	1	0	1
0	1	0	0	1
0	1	1	1	0
1	0	0	0	1
1	0	1	1	0
1	1	0	1	0
1	1	1	1	1

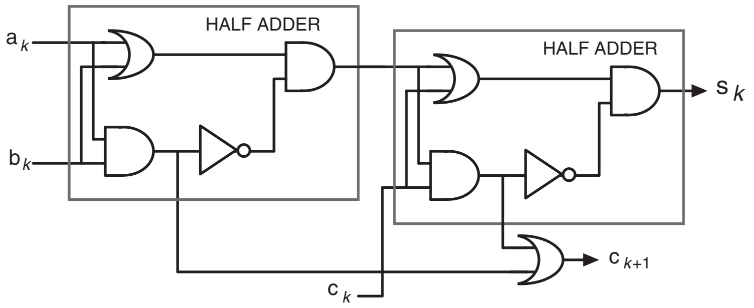

Figure 1. Nine gate full adder

.

the next adder stage. This adder is called a ripple carry adder, because the carry signals "ripple" from the least significant bit position to the most significant.

If the ripple carry adder is implemented by concatenating n of the nine gate full adders, which were shown in Fig. 1, an n-bit ripple carry adder requires $2n + 4$ gate delays to produce the most significant sum bit and $2n + 3$ gate delays to produce the carry output. A total of $9n$ logic gates are required to implement the n-bit ripple carry adder. In comparing the delay and complexity of adders, the delay from data input to most significant sum output denoted by DELAY and the gate count denoted by GATES will be used. These DELAY and GATES are subscripted by RCA to indicate ripple carry adder. Although these simple metrics are suitable for first-order comparisons, more accurate comparisons require more exact modeling because the implementations may be realized with transistor networks (as opposed to gates), which will have different delay and complexity characteristics.

$$\text{DELAY}_{\text{RCA}} = 2n + 4 \tag{4}$$

$$\text{GATES}_{\text{RCA}} = 9\text{n} \tag{5}$$

Carry Lookahead Adder

Another popular adder approach is the carry lookahead adder (1,2). Here, specialized logic computes the carries in parallel. The carry lookahead adder uses eight gate modified full adders that do not form a carry output for each bit position and lookahead modules, which form the carry outputs. The carry lookahead concept is best understood by rewriting Equation (3) with $\text{g}_k = \text{a}_k\text{b}_k$ and $\text{p}_k = \text{a}_k + \text{b}_k$.

$$\text{c}_{k+1} = \text{g}_k + \text{p}_k\text{c}_k \tag{6}$$

This equation helps to explain the concept of carry "generation" and "propagation": A bit position "generates" a carry regardless of whether there is a carry into that bit position if g_k is true (i.e., both a_k and b_k are ONEs), and a stage "propagates" an incoming carry to its output if p_k is true (i.e., either a_k or b_k is a ONE). The eight-gate modified full adder is based on the nine-gate full adder shown on Fig. 1. It has AND and OR gates that produce g_k and p_k with no additional complexity.

Extending Equation (6) to a second stage:

$$\begin{aligned} \text{c}_{k+2} &= \text{g}_{k+1} + \text{p}_{k+1}\text{c}_{k+1} \\ &= \text{g}_{k+1} + \text{p}_{k+1}(\text{g}_k + \text{p}_k\text{c}_k) \\ &= \text{g}_{k+1} + \text{p}_{k+1}\text{g}_k + \text{p}_{k+1}\text{p}_k\text{c}_k \end{aligned} \tag{7}$$

Equation (7) results from evaluating Equation (6) for the $(k + 1)$th stage and substituting c_{k+1} from Equation (6). Carry c_{k+2} exits from stage k+1 if: (*1*) a carry is generated there, (*2*) a carry is generated in stage k and propagates across stage k+1, or (*3*) a carry enters stage k and propagates across both stages k and k+1, etc. Extending to a third stage:

$$\begin{aligned} \text{c}_{k+3} &= \text{g}_{k+2} + \text{p}_{k+2}\text{c}_{k+2} \\ &= \text{g}_{k+2} + \text{p}_{k+2}(\text{g}_{k+1} + \text{p}_{k+1}\text{g}_k + \text{p}_{k+1}\text{p}_k\text{c}_k) \\ &= \text{g}_{k+2} + \text{p}_{k+2}\text{g}_{k+1} + \text{p}_{k+2}\text{p}_{k+1}\text{g}_k + \text{p}_{k+2}\text{p}_{k+1}\text{p}_k\text{c}_k \end{aligned} \tag{8}$$

Although it would be possible to continue this process indefinitely, each additional stage increases the fan-in (i.e., the number of inputs) of the logic gates. Four inputs [as required to implement Equation (8)] frequently are the maximum number of inputs per gate for current technologies. To continue the process, block generate and block propagate signals are defined over 4-bit blocks

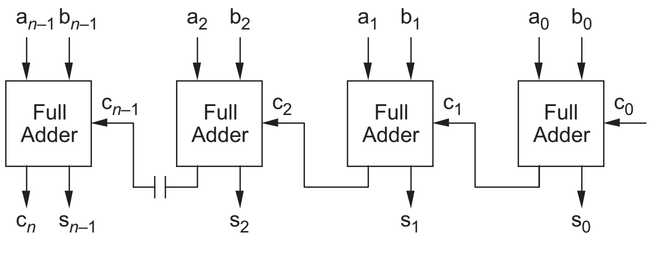

Figure 2. Ripple carry adder.

(stages k to k + 3), $g_{k:k+3}$ and $p_{k:k+3}$, respectively:

$$g_{k:k+3} = g_{k+3} + p_{k+3}g_{k+2} + p_{k+3}p_{k+2}g_{k+1} + p_{k+3}p_{k+2}p_{k+1}g_k \tag{9}$$

and

$$p_{k:k+3} = p_{k+3}p_{k+2}p_{k+1}p_k \tag{10}$$

Equation (6) can be expressed in terms of the 4-bit block generate and propagate signals:

$$c_{k+4} = g_{k:k+3} + p_{k:k+3}c_k \tag{11}$$

Thus, the carry out from a 4-bit wide block can be computed in only four gate delays [the first to compute p_i and g_i for i = k through k + 3, the second to evaluate $p_{k:k+3}$, the second and third to evaluate $g_{k:k+3}$, and the third and fourth to evaluate c_{k+4} using Equation (11)].

An n-bit carry lookahead adder requires $\lceil (n-1)/(r-1) \rceil$ lookahead logic blocks, where r is the width of the block. A 4-bit lookahead logic block is a direct implementation of Equations (6)–(10), with 14 logic gates. In general, an r-bit lookahead logic block requires $\frac{1}{2}(3r + r^2)$ logic gates. The Manchester carry chain (3) is an alternative switch-based technique to implement a lookahead logic block.

Figure 3 shows the interconnection of 16 adders and five lookahead logic blocks to realize a 16-bit carry lookahead adder. The events that occur during an add operation are:

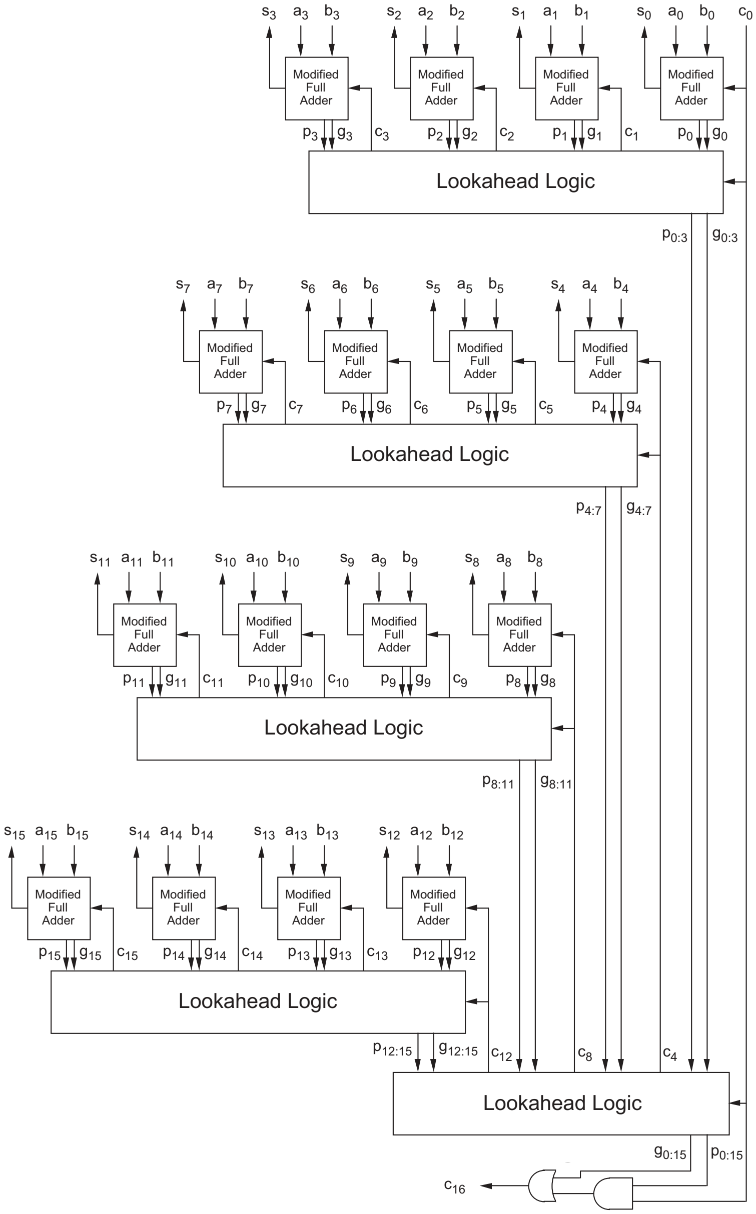

Figure 3. 16-bit carry lookahead adder.

(*1*) apply A, B, and carry in signals at time 0, (*2*) each modified full adder computes P and G, at time 1, (*3*) first level lookahead logic computes the 4-bit block propagate at time 2 and block generate signals by time 3, (*4*) second level lookahead logic computes c_4, c_8, and c_{12}, at time 5, (*5*) first level lookahead logic computes the individual carries at time 7, and (*6*) each modified full adder computes the sum outputs at time 10. This process may be extended to larger adders by subdividing the large adder into 16-bit blocks and by using additional levels of carry lookahead (e.g., a 64-bit adder requires three levels).

The delay of carry lookahead adders is evaluated by recognizing that an adder with a single level of carry lookahead (for r-bit words) has six gate delays, and that each additional level of lookahead increases the maximum word size by a factor of r and adds four gate delays. More generally, the number of lookahead levels for an n-bit adder is $\lceil \mathrm{Log}_r n \rceil$ where r is the "width" of the lookahead logic block (generally equal to the maximum number of inputs per logic gate). Because an r-bit carry lookahead adder has six gate delays and four additional gate delays exist per carry lookahead level after the first,

$$\mathrm{DELAY}_{\mathrm{CLA}} = 2 + 4\lceil \mathrm{Log}_r n \rceil \tag{12}$$

The complexity of an n-bit carry lookahead adder implemented with r-bit lookahead logic blocks is n modified full adders (each of which requires eight gates) and $\lceil (n-1)/(r-1) \rceil$ lookahead logic blocks (each of which requires $\frac{1}{2}(3r + r^2)$ gates). In addition, two gates are used to calculate the carry out from the adder, c_n, from $p_{0:n-1}$ and $g_{0:n-1}$.

$$\mathrm{GATES}_{\mathrm{CLA}} = 8\mathrm{n} + \tfrac{1}{2}(3\mathrm{r} + \mathrm{r}^2)\lceil (\mathrm{n}-1)/(\mathrm{r}-1) \rceil + 2 \tag{13}$$

If $r = 4$

$$\mathrm{GATES}_{\mathrm{CLA}} \approx 12\tfrac{2}{3}n - 2\tfrac{2}{3} \tag{14}$$

The carry lookahead approach reduces the delay of adders from increasing in proportion to the word size (as is the case for ripple carry adders) to increasing in proportion to the logarithm of the word size. As with ripple carry adders, the carry lookahead adder complexity grows linearly with the word size (for $r = 4$, the complexity of a carry lookahead adder is about 40% greater than the complexity of a ripple carry adder). It is important to realize that most carry lookahead adders require gates with up to 4 inputs, whereas ripple carry adders use only inverters and two input gates.

Carry Select Adder

The carry select adder divides the words to be added into blocks and forms two sums for each block in parallel (one with a carry in of ZERO and the other with a carry in of ONE). As shown for a 16-bit carry select adder in Fig. 4, the carry out from the previous block controls a multiplexer that selects the appropriate sum. The carry out is computed using Equation (11), because the block propagate signal is the carry out of an adder with a carry input of ONE, and the block generate signal is the carry out of an adder with a carry input of ZERO.

If a constant block width of k is used, $\lceil n/k \rceil$ blocks will exist and the delay to generate the sum is $2k + 3$ gate delays to form the carry out of the first block, two gate delays for each of the $\lceil n/k \rceil - 2$ intermediate blocks, and three gate delays (for the multiplexer) in the final block. To simplify the analysis, the ceiling function in the count of intermediate blocks is ignored. The total delay is thus

$$\mathrm{DELAY}_{\mathrm{C-SEL}} = 2k + 2n/k + 2 \tag{15}$$

where $\mathrm{DELAY}_{\mathrm{C-SEL}}$ is the total delay. The optimum block size is determined by taking the derivative of $\mathrm{DELAY}_{\mathrm{C-SEL}}$ with respect to k, setting it to zero, and solving for k. The result is

$$\mathrm{k} = \mathrm{n}^{.5} \tag{16}$$

$$\mathrm{DELAY}_{\mathrm{C-SEL}} = 2 + 4\mathrm{n}^{.5} \tag{17}$$

The complexity of the carry select adder is $2n - k$ ripple carry adder stages, the intermediate carry logic and $(\lceil n/k \rceil - 1)$ k-bit wide 2:1 multiplexers for the sum bits and one 1-bit wide multiplexer for the most significant carry output.

$$\mathrm{GATES}_{\mathrm{C-SEL}} = 21n - 12k + 3\lceil n/k \rceil - 2 \tag{18}$$

This result is somewhat more than twice the complexity of a ripple carry adder.

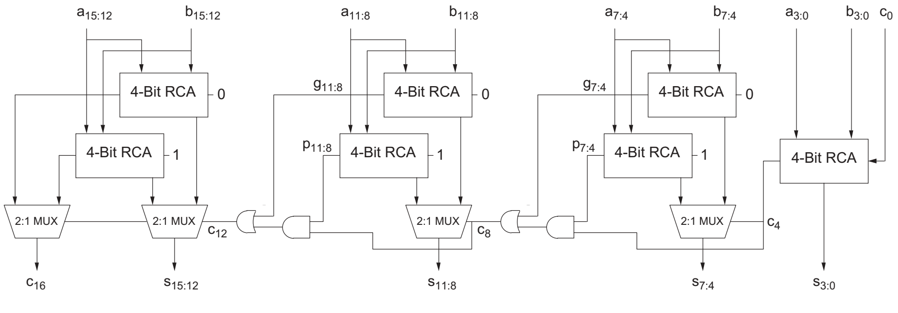

Figure 4. 16-bit carry select adder.

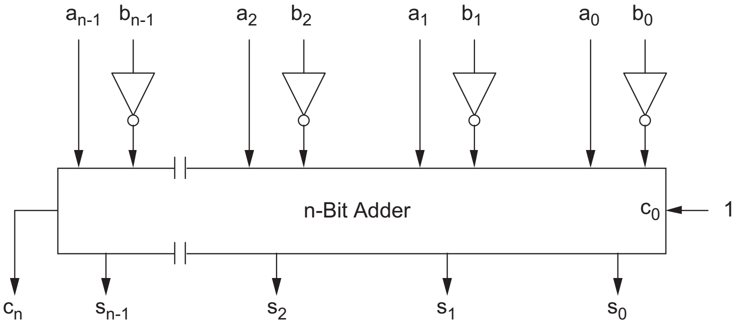

Figure 5. Two's complement subtracter.

Slightly better results can be obtained by varying the width of the blocks. The optimum is to make the two least significant blocks the same size and make each successively more significant block one bit larger than its predecessor. With four blocks, this gives an adder that is 3 bits wider than the conventional carry select adder.

SUBTRACTION

As noted previously, subtraction of two's complement numbers is accomplished by adding the minuend to the inverted bits of the subtrahend and adding a one at the least significant position. Figure 5 shows a two's complement subtracter that computes A – B. The inverters complement the bits of B; the formation of the two's complement is completed by setting the carry into the least significant adder stage to a ONE.

MULTIPLICATION

The bit product matrix of a 5-bit by 5-bit multiplier for unsigned operands is shown on Fig. 5. The two operands, A and B, are shown at the top, followed by n rows (each consisting of n bit products) that compose the bit product matrix. Finally, the product (2*n* bits wide) is at the bottom.

Several ways exist to implement a multiplier. One of the oldest techniques is to use an *n* bit wide adder to sum the rows of the bit product matrix in a row by row fashion. This process can be slow because $n - 1$ cycles (each long enough to complete an n bit addition) are required. If a ripple carry adder is used, the time to multiply two *n*-bit numbers is proportional to n^2. If a fast adder such as a carry lookahead adder is used, the time is proportional to $n \text{ Log}_2 (n)$.

Booth Multiplier

The Booth multiplier (4) and the modified Booth multiplier are attractive for two's complement multiplication, because they accept two's complement operands, produce a two's complement product, directly, and are easy to implement. The sequential Booth multiplier requires *n* cycles to form the product of a pair of *n*-bit numbers, where each cycle consists of an *n*-bit addition and a shift, an *n*-bit subtraction and a shift, or a shift without any other arithmetic operation. The radix-4 modified Booth multiplier (2) takes half as many cycles as the "standard" Booth multiplier, although the operations performed during each cycle are slightly more complex (because it is necessary to select one of five possible addends, namely, ±2B, ±B, or 0 instead of one of three).

Modified Booth Multiplier

To multiply A B, the radix-4 modified Booth multiplier [as described by MacSorley (2)] uses *n*/2 cycles where each cycle examines three adjacent bits of A, adds or subtracts 0, B, or 2B to the partial product and shifts the partial product two bits to the right. Figure 7 shows a flowchart for a radix-4 modified Booth multiplier. After an initialization step, there are *n*/2 passes through a loop where three bits of A are tested and the partial product P is modified. This algorithm takes half the number of cycles of the "standard" Booth multiplier (4), although the operations performed during a cycle are slightly more complex (because it is necessary to select one of four possible addends instead of one of two). Extensions to higher radices that examine more than three bits per cycle (5) are possible, but generally not attractive because the addition/subtraction operations involve nonpower of two

					b_4	b_3	b_2	b_1	b_0
					a_4	a_3	a_2	a_1	a_0
					$a_0 b_4$	$a_0 b_3$	$a_0 b_2$	$a_0 b_1$	$a_0 b_0$
				$a_1 b_4$	$a_1 b_3$	$a_1 b_2$	$a_1 b_1$	$a_1 b_0$	
			$a_2 b_4$	$a_2 b_3$	$a_2 b_2$	$a_2 b_1$	$a_2 b_0$		
		$a_3 b_4$	$a_3 b_3$	$a_3 b_2$	$a_3 b_1$	$a_3 b_0$			
	$a_4 b_4$	$a_4 b_3$	$a_4 b_2$	$a_4 b_1$	$a_4 b_0$				
p_9	p_8	p_7	p_6	p_5	p_4	p_3	p_2	p_1	p_0

Figure 6. 5-bit by 5-bit multiplier for unsigned operands.

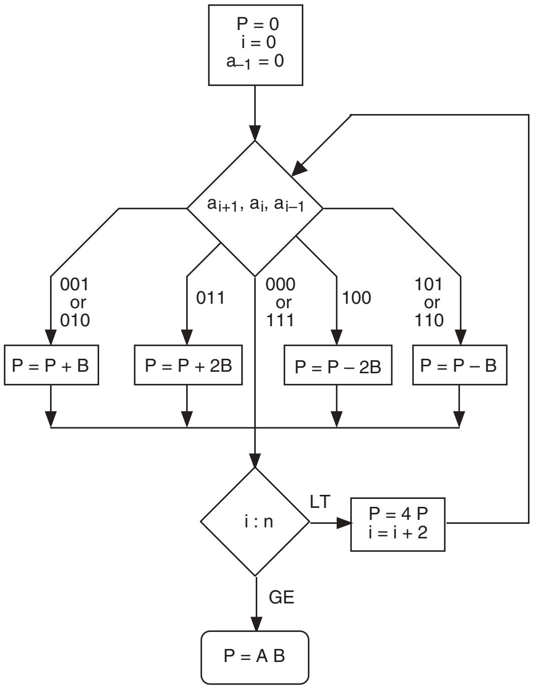

Figure 7. Flowchart of radix-4 modified booth multiplication.

multiples of B (such as 3B, 5B, etc.), which raises the complexity.

The delay of the radix-4 modified Booth multiplier is relatively high because an n-bit by n-bit multiplication requires $n/2$ cycles in which each cycle is long enough to perform an n-bit addition. It is low in complexity because it requires only a few registers, an n-bit 2:1 multiplexer, an n-bit adder/subtracter, and some simple control logic for its implementation.

Array Multipliers

A more hardware-intensive approach to multiplication involves the combinational generation of all bit products and their summation with an array of full adders. The bit product matrix of a 5-bit by 5-bit array multiplier for two's complement numbers (based on Ref. 6, p. 179) is shown in Fig. 8. It consists of a 5 by 5 array of bit product terms where most terms are of the form a_i AND b_j. The terms along the left edge and the bottom row are the complement of the normal terms (i.e., a_4 NAND b_0) as indicated by the over bar. The most significant term a_4b_4 is not complemented. Finally, ONEs are added at the sixth and tenth columns. In practice, the ONE at the tenth column is usually omitted.

Figure 9 shows an array multiplier that implements a 6-bit by 6-bit array multiplier realizing the algorithm shown on Fig. 8. It uses a 6 column by 6 row array of cells to form the bit products and do most of the summation and five adders (at the bottom of the array) to complete the evaluation of the product. Five types of cells are used in the square array: AND gate cells (marked G in Fig. 9) that form x_iy_j, NAND gate cells (marked NG) that form x_5 NAND y_j, half adder cells (marked HA) that sum the second input to the cell with x_iy_j, full adder cells (marked FA) that sum the second and third inputs to the cell with x_iy_j, and special full adder cells (marked NFA) that sum the second and third inputs to the cell with x_i NAND y_5. A special half adder, *HA, (that forms the sum of its two inputs and 1) and

\end{array}
$$

Figure 8. 5-bit by 5-bit multiplier for two's complement operands

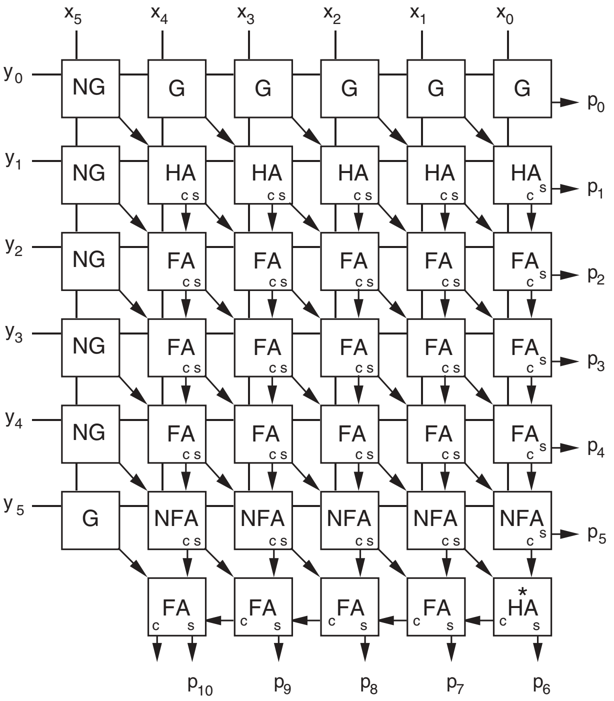

Figure 9. 6-bit by 6-bit two's complement array multiplier.

standard full adders are used in the five-cell strip at the bottom. The special half adder takes care of the extra 1 in the bit product matrix.

The delay of the array multiplier is evaluated by following the pathways from the inputs to the outputs. The longest path starts at the upper left corner, progresses to the lower right corner, and then progresses across the bottom to the lower left corner. If it is assumed that the delay from any adder input (for either half or full adders) to any adder output is k gate delays, then the total delay of an n-bit by n-bit array multiplier is:

$$\text{DELAY}_{\text{ARRAY MPY}} = k(2n - 2) + 1 \qquad (19)$$

The complexity of the array multiplier is n^2 AND and NAND gates, n half adders (one of which is a *half adder), and $n^2 - 2n$ full adders. If a half adder is realized with four gates and a full adder with nine gates, the total complexity of an n-bit by n-bit array multiplier is

$$\text{GATES}_{\text{ARRAY MPY}} = 10n^2 - 14n \qquad (20)$$

Array multipliers are laid out easily in a cellular fashion which makes them attractive for VLSI implementation, where minimizing the design effort may be more important than maximizing the speed.

Wallace/Dadda Fast Multiplier

A method for fast multiplication was developed by Wallace (7) and was refined by Dadda (8). With this method, a three-step process is used to multiply two numbers: (*1*) The bit products are formed, (*2*) the bit product matrix is "reduced" to a two row matrix whose sum equals the sum of the bit products, and (*3*) the two numbers are summed with a fast adder to produce the product. Although this may seem to be a complex process, it yields multipliers with delay proportional to the logarithm of the operand word size, which is "faster" than the array multiplier, which has delay proportional to the word size.

The second step in the fast multiplication process is shown for a 6-bit by 6-bit Dadda multiplier on Fig. 10. An input 6 by 6 matrix of dots (each dot represents a bit product) is shown as matrix 0. "Regular dots" are formed with an AND gate, and dots with an over bar are formed with a NAND gate. Columns that have more than four dots (or that will grow to more than four dots because of carries) are reduced by the use of half adders (each half adder takes in two dots and outputs one in the same column and one in the next more significant column) and full adders (each full adder takes in three dots from a column and outputs one in the same column and one in the next more significant column) so that no column in matrix 1 will have more than four dots. Half adders are shown by two dots connected by a "crossed" line in the succeeding matrix and full adders are shown by two dots connected by a line in the succeeding matrix. In each case, the right-most dot of the pair that are connected by a line is in the column from which the inputs were taken in the preceding matrix for the adder. A special half adder (that forms the sum of its two inputs and 1) is shown with a doubly crossed line. In the succeeding steps reduction to matrix 2, with no more than three dots per column, and finally matrix 3, with no more than two dots per column, is performed. The reduction shown on Fig. 10 (which requires three full adder delays) is followed by an 10-bit carry propagating adder. Traditionally, the carry propagating adder is realized with a carry lookahead adder.

The height of the matrices is determined by working back from the final (two row) matrix and limiting the height of each matrix to the largest integer that is no more than 1.5

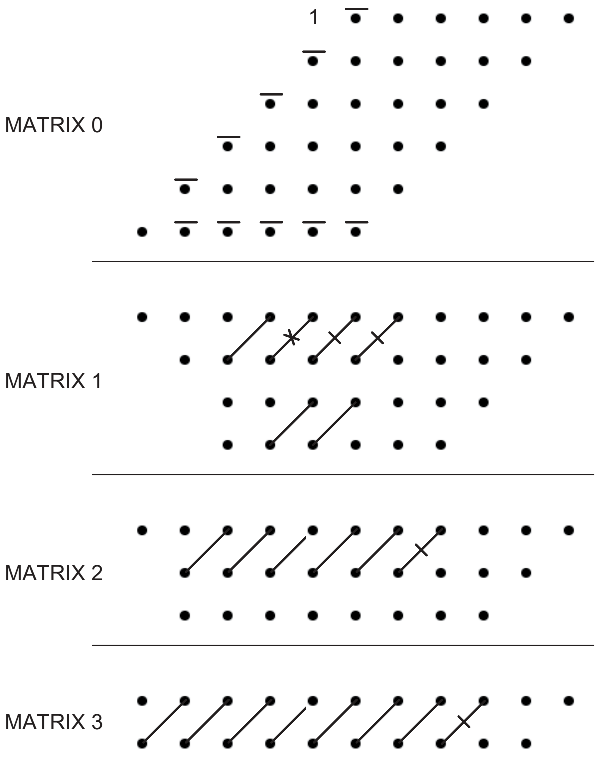

Figure 10. 6-bit by 6-bit two's complement Dadda multiplier.

times the height of its successor. Each matrix is produced from its predecessor in one adder delay. Because the number of matrices is related logarithmically to the number of rows in matrix 0, which is equal to the number of bits in the words to be multiplied, the delay of the matrix reduction process is proportional to log n. Because the adder that reduces the final two row matrix can be implemented as a carry lookahead adder (which also has logarithmic delay), the total delay for this multiplier is proportional to the logarithm of the word size.

The delay of a Dadda multiplier is evaluated by following the pathways from the inputs to the outputs. The longest path starts at the center column of bit products (which require one gate delay to be formed), progresses through the successive reduction matrices (which requires approximately $\text{Log}_{1.44}(n)$ full adder delays) and finally through the $2n-2$-bit carry propagate adder. If the delay from any adder input (for either half or full adders) to any adder output is k gate delays, and if the carry propagate adder is realized with a carry lookahead adder implemented with 4-bit lookahead logic blocks (with delay given by Equation (12), the total delay (in gate delays) of an n-bit by n-bit Dadda multiplier is:

$$\text{DELAY}_{\text{DADDA MPY}} = 1 + k\,\text{LOG}_{1.44}(n) + 2 + 4\lceil \text{Log}_r(2n-2)\rceil \qquad (21)$$

The complexity of a Dadda multiplier is determined by evaluating the complexity of its parts. n^2 gates ($2n-2$ are NAND gates, the rest are AND gates) to form the bit product matrix exist, $(\text{n}-2)^2$ full adders, $n-1$ half adders and one special half adder for the matrix reduction and a $2n-2$-bit carry propagate adder for the addition of the final two row matrix. If the carry propagate adder is realized with a carry lookahead adder (implemented with 4-bit lookahead logic blocks), and if the complexity of a full adder is nine gates and the complexity of a half adder (either regular or special) is four gates, then the total complexity is:

$$\text{GATES}_{\text{DADDA MPY}} = 10n^2 - 6\,\frac{2}{3}n - 26 \qquad (22)$$

The Wallace tree multiplier is very similar to the Dadda multiplier, except that it does more reduction in the first stages of the reduction process, it uses more half adders, and it uses a slightly smaller carry propagating adder. A dot diagram for a 6-bit by 6-bit Wallace tree multiplier for two's complement operands is shown on Fig. 11. This reduction (which requires three full adder delays) is followed by an 8-bit carry propagating adder. The total complexity of the Wallace tree multiplier is a bit greater than the total complexity of the Dadda multiplier. In most cases, the Wallace and Dadda multipliers have about the same delay.

DIVISION

Two types of division algorithms are in common use: digit recurrence and convergence methods. The digit recurrence approach computes the quotient on a digit-by-digit basis,

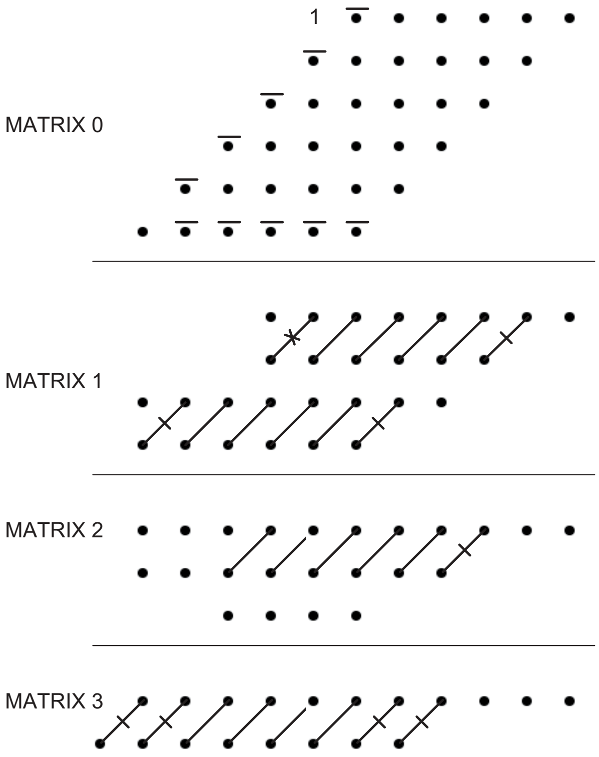

Figure 11. 6-bit by 6-bit Two's Complement Wallace Multiplier.

hence they have a delay proportional to the precision of the quotient. In contrast, the convergence methods compute an approximation that converges to the value of the quotient. For the common algorithms the convergence is quadratic, which means that the number of accurate bits approximately doubles on each iteration.

The digit recurrence methods that use a sequence of shift, add or subtract, and compare operations are relatively simple to implement. On the other hand, the convergence methods use multiplication on each cycle. This fact means higher hardware complexity, but if a fast multiplier is available, potentially a higher speed may result.

Digit Recurrent Division

The digit recurrent algorithms (9) are based on selecting digits of the quotient Q (where Q = N/D) to satisfy the following equation:

$$P_{k+1} = rP_k - q_{n-k-1}D \text{ for } k = 1, 2, \ldots, n-1 \qquad (23)$$

where P_k is the partial remainder after the selection of the kth quotient digit, $P_0 = N$ (subject to the constraint $|P_0| < |D|$), r is the radix, q_{n-k-1} is the kth quotient digit to the right of the binary point, and D is the divisor. In this subsection, it is assumed that both N and D are positive, see Ref. 10 for details on handling the general case.

Binary SRT Divider

The binary SRT division process (also known as radix-2 SRT division) selects the quotient from three candidate quotient digits {±1, 0}. The divisor is restricted to $.5 \leq D < 1$. A flowchart of the basic binary SRT scheme is shown in Fig. 12. Block 1 initializes the algorithm. In step 3, 2 P_k and the divisor are used to select the quotient digit. In step 4, $P_{k+1} = 2\ P_k - q\ D$. Step 5 tests whether all bits of the quotient have been formed and goes to step 2 if more need to be computed. Each pass through steps 2–5 forms one digit of the quotient. The result upon exiting from step 5 is a collection of n signed binary digits.

Step 6 converts the n digit signed digit number into an n-bit two's complement number by subtracting, N, which has a 1 for each bit position where $q_i = -1$ and 0 elsewhere from, P, which has a 1 for each bit position where $q_i = 1$ and 0 elsewhere. For example:

Q = 0 . 1 1 –1 0 1 = 21/32

P = 0 . 1 1 0 0 1

N = 0 . 0 0 1 0 0

Q = 0 . 1 1 0 0 1 – 0 . 0 0 1 0 0

Q = 0 . 1 1 0 0 1 + 1 . 1 1 1 0 0

Q = 0 . 1 0 1 0 1 = 21/32

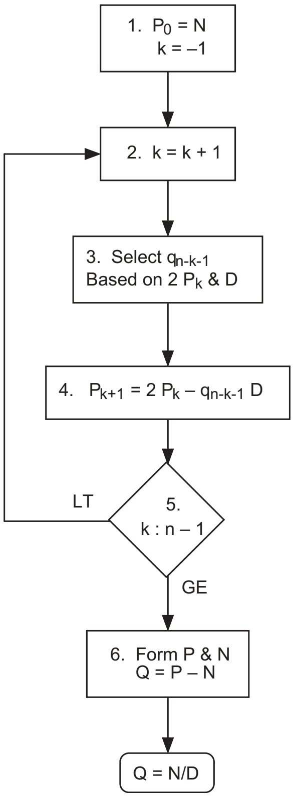

Figure 12. Flowchart of binary SRT division.

The selection of the quotient digit can be visualized with a P-D Plot such as the one shown in Fig. 13. The plot shows the divisor along the x axis and the shifted partial remainder (in this case 2 $\mathrm{P_k}$) along the y-axis. In the area where 0.5 $\le$ D $<$ 1, values of the quotient digit are shown as a function of the value of the shifted partial remainder. In this case, the relations are especially simple. The digit selection and resulting partial remainder are given for the k-th iteration by the following relations:

$$\text{If } \mathrm{P}_k > .5, \quad \mathrm{q}_{n-k-1} = 1 \quad \text{and } \mathrm{P}_{k+1} = 2\mathrm{P}_k - \mathrm{D} \tag{24}$$

$$\text{If } -.5 < P_k < .5, \quad q_{n-k-1} = 0 \quad \text{and } \mathrm{P}_{k+1} = 2P_k \tag{25}$$

$$\text{If } P_k \le -.5, \quad q_{n-k-1} = -1 \text{ and } P_{k+1} = 2P_k + \mathrm{D} \tag{26}$$

Computing an n-bit quotient will involve selecting n quotient digits and up to $n + 1$ additions.

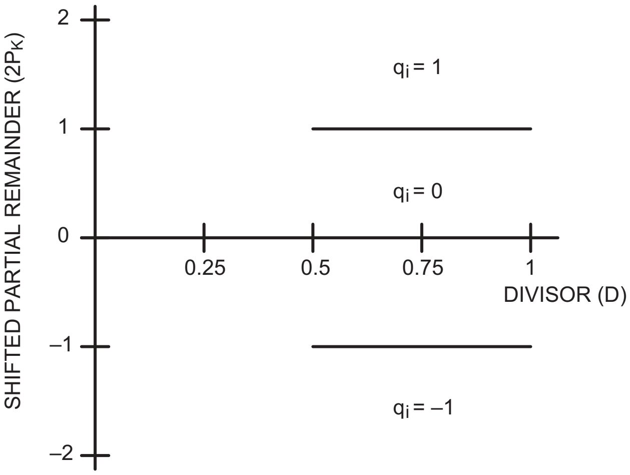

Figure 13. P-D plot for binary SRT division.

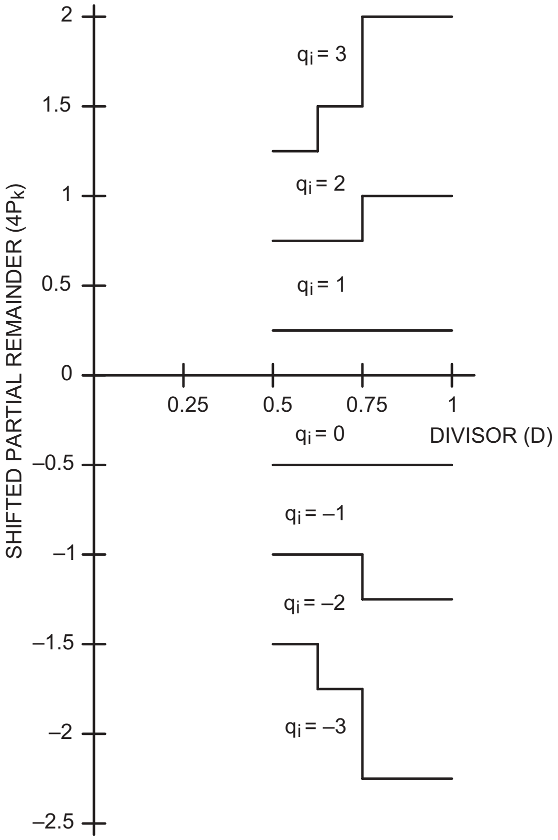

Figure 14. P-D Plot for radix-4 maximally redundant SRT division.

Radix-4 SRT Divider

The higher radix SRT division process is similar to the binary SRT algorithms. Radix 4 is the most common higher radix SRT division algorithm with either a minimally redundant digit set of {±2, ±1, 0} or the maximally redundant digit set of {±3, ±2, ±1, 0}. The operation of the algorithm is similar to the binary SRT algorithm shown on Fig. 12, except that in step 3, 4 P_k, and D are used to determine the quotient digit. A P-D Plot is shown on Fig. 14 for the maximum redundancy version of radix-4 SRT division. Seven values are possible for the quotient digit at each stage. The test for completion in step 5 becomes $k : \frac{n}{2} - 1$. Also the conversion to two's complement in step 6 is modified slightly because each quotient digit provides two bits of the P and N numbers that are used to form the two's complement number.

Newton–Raphson Divider

The second category of division techniques uses a multiplication-based iteration to compute a quadratically convergent approximation to the quotient. In systems that include a fast multiplier, this process may be faster than the digit recurrent methods. One popular approach is the Newton-Raphson algorithm that computes an approximation to the reciprocal of the divisor that is then multiplied by the dividend to produce the quotient. The process to compute Q = N/D consists of three steps:

1. Calculate a starting estimate of the reciprocal of the divisor, $R_{(0)}$. If the divisor, D, is normalized (i.e., $\frac{1}{2} \leq D < 1$), then $R_{(0)} = 3 - 2D$ exactly computes 1/ D at D = .5 and D = 1 and exhibits maximum error (of approximately 0.17) at $D = \frac{1}{2}^{.5}$. Adjusting $R_{(0)}$ downward to by half the maximum error gives

$$R_{(0)} = 2.915 - 2D \tag{27}$$

   This produces an initial estimate, that is within about 0.087 of the correct value for all points in the interval $\frac{1}{2} \leq D < 1$.

2. Compute successively more accurate estimates of the reciprocal by the following iterative procedure:

$$R_{(i+1)} = R_{(i)}(2 - D\,R_{(i)}) \text{ for } i = 0, 1, \ldots, k \tag{28}$$

3. Compute the quotient by multiplying the dividend times the reciprocal of the divisor.

$$Q = N\,R_{(k)} \tag{29}$$

where i is the iteration count and N is the numerator. Figure 15 illustrates the operation of the Newton–Raphson algorithm. For this example, three iterations (which involve a total of four subtractions and

$A = .625$
$B = .75$

$R_{(0)} = 2.915 - 2 \cdot B$ 1 Subtract
$= 2.915 - 2 \cdot .75$

$R_{(0)} = 1.415$

$R_{(1)} = R_{(0)}\,(2 - B \cdot R_{(0)})$ 2 Multiplies, 1 Subtract
$= 1.415\,(2 - .75 \cdot 1.415)$
$= 1.415 \cdot .95875$
$R_{(1)} = 1.32833125$

$R_{(2)} = R_{(1)}\,(2 - B \cdot R_{(1)})$ 2 Multiplies, 1 Subtract
$= 1.32833125\,(2 - .75 \cdot 1.32833125)$
$= 1.32833125 \cdot 1.00375156$
$R_{(2)} = 1.3333145677$

$R_{(3)} = R_{(2)}\,(2 - B \cdot R_{(2)})$ 2 Multiplies, 1 Subtract
$= 1.3333145677\,(2 - .75 \cdot 1.3333145677)$
$= 1.3333145677 \cdot 1.00001407$
$R_{(3)} = 1.3333333331$

$Q = A \cdot R_{(3)}$ 1 Multiply
$= .625 \cdot 1.3333333331$
$Q = .83333333319$

Figure 15. Example of Newton–Raphson division.

seven multiplications) produces an answer accurate to nine decimal digits (approximately 30 bits).

With this algorithm, the error decreases quadratically so that the number of correct bits in each approximation is roughly twice the number of correct bits on the previous iteration. Thus, from a 3.5-bit initial approximation, two iterations produce a reciprocal estimate accurate to 14-bits, four iterations produce a reciprocal estimate accurate to 56-bits, and so on.

The efficiency of this process is dependent on the availability of a fast multiplier, because each iteration of Equation (28) requires two multiplications and a subtraction. The complete process for the initial estimate, three iterations, and the final quotient determination requires four subtraction operations and seven multiplication operations to produce a 16-bit quotient. This process is faster than a conventional nonrestoring divider if multiplication is roughly as fast as addition, which is a condition that is satisfied for some systems that include a hardware multiplier.

CONCLUSIONS

This article has presented an overview of the two's complement number system and algorithms for the basic fixed-point arithmetic operations of addition, subtraction, multiplication, and division. When implementing arithmetic units, often an opportunity exists to optimize the performance and the complexity to match the requirements of the specific application. In general, faster algorithms require more area and power; often it is desirable to use the fastest algorithm that will fit the available area and power bugdets.

FLOATING-POINT COMPUTER ARITHMETIC

INTRODUCTION

The field of floating-point computer arithmetic is a subsection of computer engineering that concentrates on the development and execution of arithmetic in microprocessors. The floating-point sections of processor chips and coprocessors are the units in a microprocessor that perform most of the arithmetic operations for applications such as 3D graphics, multimedia, signal processing, Fourier transforms, etc.

The floating-point format is a form of scientific notation. A floating-point number may represent a vast range of real numbers, with values ranging from nearly infinitely large to nearly infinitely small, all in a finite bit-width. Although many floating-point formats have been used (1), this chapter is based on the IEEE-754 Standard (2) that is widely used at the current time.

This article begins with a brief review of the IEEE-754 floating-point format in the section on floating-point number systems. The next section provides implementation examples of the fundamental floating-point execution units: the floating-point adder and the floating-point multiplier. Other floating-point mathematical operations are derived from these two instructions, so most of the same hardware is used. Finally, the section on other IEEE-754 specifications covers miscellaneous other aspects of the IEEE-754 specifications, such as convert instructions, denormalized numbers, and the representation of special "numbers" infinity and zero.

FLOATING-POINT NUMBER SYSTEMS

The IEEE-754 standard sets down specific rules and formats for binary floating-point arithmetic. A processor that follows every rule in the specification is considered "IEEE-754 compliant." Although some specialized machines [such as DirectX graphics cards (3), CELL processors (4), etc.] are not fully compliant with all parts of the standard, the fundamentals of the specification are essentially universal and should be understood by any engineer or scientist developing a floating-point application.

The IEEE-754 standard defines a format that consists of three parts: a sign bit, a significand, and a biased exponent. Four standard formats are defined: single precision (stored as a 32-bit number), single extended (often realized as double precision), double precision (stored as a 64-bit number), and double extended (stored as greater than 78 bits). The significand, which is a mixed number with a leading 1 for its integer part, takes the place of the fractional mantissa or the integer coefficient of previous floating-point formats. The significand is a fixed point magnitude in the range $1 \leq \text{significand} < 2$. If the sign = 1, then the number is negative; if the sign = 0, then the number is positive. For single-precision numbers, the significand is a 24-bit magnitude, for double-precision numbers it is a 53-bit magnitude.

The biased exponent is an excess-127 integer for single precision and excess-1023 for double precision. The use of the word "biased" means that the stored integer value in the exponent bits actually represents that integer number minus the bias. The rationale behind biased exponents is to allow an equal range of positive and negative exponents (i.e., '127' is the midpoint of the linear range in an 8-bit unsigned binary field. Single-precision stored numbers above this bias represent positive exponents and those below are negative exponents).

With all bits combined, the value of a number, A, is given by:

$$A = (-1)^{\text{sign A}} \times \text{significand}_{\text{A}} \times 2^{\text{exponent A}-\text{bias}} \tag{1}$$

Numbers stored by the processor are "packed" by first normalizing the significand, which is done by removing the integer 1. The remaining fraction bits, the sign bit, and the biased exponent bits are then packed together into a single entity that is stored. This use of normalized significand packing and the removal of the "hidden one" for storage provide one extra (free) bit of precision.

Following the standard, "single precision" numbers that consist of 23 fraction bits, 8 biased exponent bits, and 1 sign bit are stored in a 32-bit register or memory location. The implicit "1" from the significand is not stored. Double-precision numbers that consist of 52 fraction bits, 11 biased exponent bits, and 1 sign bit are stored in a 64-bit register or memory location. Figure 1 shows the bit partitioning of the *stored* binary words.

To clarify the formats, consider the following example: The decimal number 7.25 is to be saved in memory as a single-precision number. As a fixed point number, it would be represented in binary as:

$$7.25 = 111;01$$

The ";" is used throughout this chapter to represent the binary point (i.e., the numeric split between the integers and fractions) in binary numbers. Meanwhile, the same decimal number stored as a single-precision floating-point number is:

S	Exp								Fraction																						
0	1	0	0	0	0	0	0	1	1	1	0	1	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0

Sign = 0 (sign = 0 means the number is positive)

Biased Exponent = 1000_0001 = 129

Fraction = 1101_0000_0000_0000_0000_000 (as stored in memory)

Significand = 1;1101_0000_0000_0000_0000_000 (as used in the processor)

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

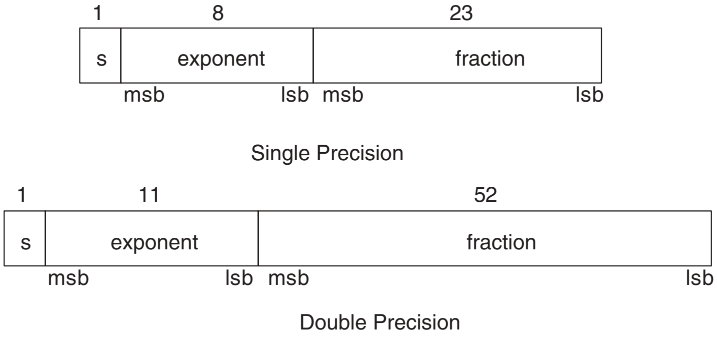

Figure 1. The IEEE-754 single and double precision floating-point data types (2).

Therefore

$$7.25 = (-1)^0 \times 2^{129-127} \times (1;1101) = 1;1101 \times 2^2$$
$$= 111;01 \times 2^0 = 111;01$$

Notice that the position of the binary point is a function of the biased exponent value, hence the term "floating-point." It should be noted that negative numbers in the IEEE floating-point format are identical to positive numbers except for the sign bit of '1.'

Arithmetic in Floating-Point Format

The IEEE-754 standard enumerates the required arithmetic functions that must be supported in a floating-point machine if it is to be identified as compliant to the standard. The following operations are required: add; subtract; multiply; divide; square root; remainder; round to integer in floating-point format; convert between floating-point formats; convert between floating-point and integer; convert binary to decimal; and compare. The operations may be implemented in hardware, software, or a combination of the two (2).

In practice, the key to floating-point arithmetic is simply keeping track of the various binary-point positions. For instance, floating-point addition requires that the binary points of each input number are normalized to the same exponential value before addition may occur. This task effectively aligns the binary points. Determining which direction and to what extent a fractional value must shift for this normalization is performed by a simple difference of biased exponents. In multiplications, the biased exponents must additively combine to produce the correct binary-point position. Each case is shown in examples below.

Floating-Point Addition Example

As an example, consider the addition of two single-precision floating-point numbers. Each number is stored in a 32-bit word in memory. The addition of the decimal numbers 7.25 and 1.75 is to be performed. The two numbers are stored in memory as shown in Fig. 2.

As the numbers are brought into the processor, they are "unpacked" revealing the hidden '1' bits:

$$1;1101\_0000\_0000\_0000\_0000\_000 \times 2^{129-127} = 1;1101 \times 2^2$$
$$1;1100\_0000\_0000\_0000\_0000\_000 \times 2^{127-127} = 1;1100 \times 2^0$$

Currently, the numbers cannot be directly added, as their exponents differ. The significand of the number with the smaller exponent needs to shifted down by two bit positions so that both numbers to have the same exponent. After alignment, the numbers may be correctly added:

$$\begin{array}{r} 1;1101\_0000\_0000\_0000\_0000\_000 \times 2^{129-127} = \ 1;1101 \times 2^2 \\ +\,0;0111\_0000\_0000\_0000\_0000\_000 \times 2^{129-127} = \ 0;0111 \times 2^2 \\ \hline 10;0100\_0000\_0000\_0000\_0000\_000 \times 2^{129-127} = 10;0100 \times 2^2 \end{array}$$

S			Exp																Fraction												
0	1	0	0	0	0	0	0	1	1	1	0	1	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0

Figure 3. The sum (= 9) as stored in the memory.

Before this result is stored back in the memory, the number must be "packed," by shifting the significand so that it is a mixed number with the integer portion being a 1. In this example, the addition caused an overflow, so the exponent must be incremented and the significand normalized:

$$10;0100\_0000\_0000\_0000\_0000\_000 \times 2^{129-127}$$
$$= 10;0100 \times 2^{2}$$

is normalized to

$$1;0010\_0000\_0000\_0000\_0000\_000 \times 2^{130-127}$$
$$= 1;0010 \times 2^{3}$$

The result is stored in the memory as observed in Fig. 3.

Floating-Point Multiplication Example

The only difference between fixed-point and floating-point multiplication is that the exponent values need to be combined. The significands of the floating-point numbers are multiplied as described in the chapter on fixed-point computer arithmetic.

Assume the same numerical values that were used for the adder example. The multiplication of the decimal numbers 7.25 and 1.75 is to be performed. The significands of each operand are multiplied:

$$\begin{array}{r} 1;1101\_0000\_0000\_0000\_0000\_000 \\ \times\ 1;1100\_0000\_0000\_0000\_0000\_000 \\ \hline 11;0010\_1100\_0000\_0000\_0000\_0000\_ \\ 0000\_0000\_0000\_0000\_0000\_00 \end{array}$$

The exponent values are summed and the bias value is adjusted. For the numerical example:

$$\begin{array}{r} 2^{129-127} = 2^{2} \\ \times\ 2^{127-127} = 2^{0} \\ \hline 2^{129+127-2(\text{BIAS})} = 2^{2} \end{array}$$

At this point, both the exponent and the significand have been multiplied. Because the significand requires no rounding, all that remains is to normalize the result to the correct format before passing it to memory.

$$11;0010\_1100\_0000\_0000\_0000\_000$$
$$\times 2^{\,129-127} = 11;0010\_1100 \times 2^{2}$$

is normalized to

$$1;1001\_0110\_0000\_0000\_0000\_000$$
$$\times 2^{130-127} \quad = \quad 1;1001\_0110 \times 2^{3}$$

The result is stored as shown in Fig. 4.

Floating-Point Rounding

If the significand of a calculation has too many bits for the given format (i.e., single precision, single extended precision, or double precision) the result must be rounded to the appropriate number of bits. The IEEE-754 standard requires the support of four rounding modes. These rounding modes provide numerical precision flexibility for application programmers.

In hardware designs that conform to this requirement, rounding is performed at the end of an execution block. IEEE-754 compliance in rounding is generally considered to be one of the more difficult and expensive requirements of the floating-point standard. This requirement is so hardware intensive that it is commonly the first rule ignored in applications that do not conform entirely to the IEEE-754 standard.

For instance, DirectX (3) compliant graphics cards allow a greater margin of error in their rounding, specifying that results must be within 1 least significant bit of an IEEE-754 compliant CPU. Although this change seems small, the hardware reductions are significant. Additionally, it is common in noncompliant implementations to ignore rounding in the case of massive cancellation (a special case in subtraction where two operands are nearly identical), as the hardware cost of maintaining full precision is too expensive.

The subject of rounding is too large to explain fully in a short article. This section only covers the basics and provides a simple example. The subject of floating-point rounding methods is quite important, and a more thorough explanation of corner cases, requirements, and methods may be found in Refs. 5-8.

The Four IEEE-754 Rounding Modes. The four IEEE-754 rounding modes are: round to nearest-even (RNE), round toward positive infinity (RPI), round toward negative infinity (RNI), and round toward zero (RTZ). The mathematical behavior required from each of the four rounding modes may be observed in Figs. 5–8. The figures show the real numerical number range centered around zero. Each tick of the graph represents a numerical value that may be represented by the result precision range.

S			Exp																Fraction

Figure 4. The product (= 12.6875) as stored in the memory.

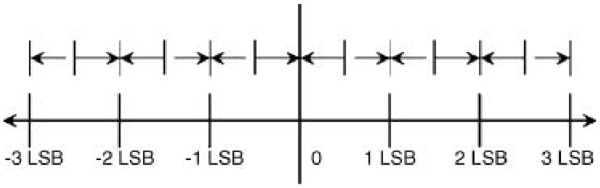

Figure 5. Round to nearest-even (RNE).

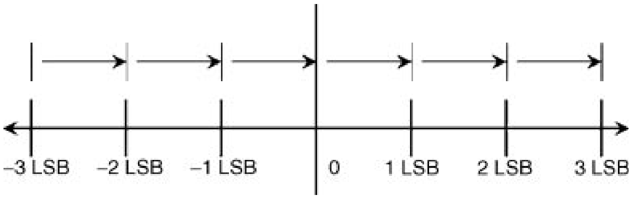

Figure 6. Round toward positive infinity (RPI).

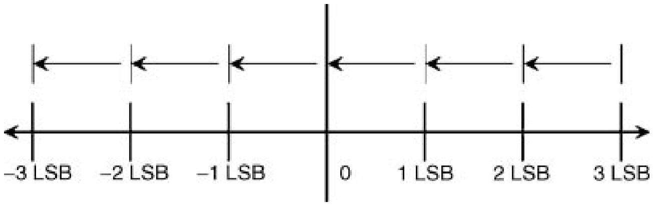

Figure 7. Round toward negative infinity (RNI).

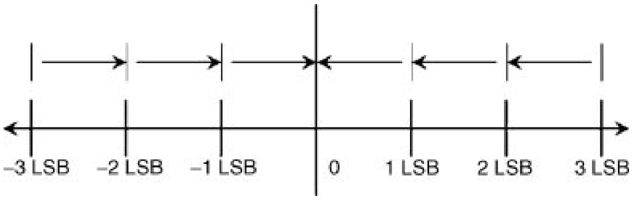

Figure 8. Round toward zero (RTZ).

The arrows represent the direction that all numbers between the possible number representations round to in the different modes. Finally, rounding methods and precisions generally refer to actions relative to the binary unit in the last place (ULP) also known as the least significant bit (LSB).

The most complex of the rounding schemes is round to nearest-even. The rules of RNE are as follows:

1. If the sum of the bits beyond the LSB is less than LSB/2, then truncate the bits.
2. If the sum of the bits beyond the LSB is more than LSB/2, then increment the LSB.
3. If the sum of the bits beyond the LSB is exactly LSB/2, then round to the nearest even number.

The round to infinity schemes, RPI and RNI, each either require an increment of the result to round-up or require a truncation should data exist beyond the desired precision. The decision to round-up or to truncate is based on which direction to infinity is specified and the sign of the number. For RPI, positive data that exceeds the desired precision require an increment of the least significant bit, whereas negative data only require truncation. For RNI, positive data require truncation whereas negative data require an increment of the least significant bit.

The simplest of the schemes, round to zero, is achieved by truncating all data beyond the range of the output result. Once a floating-point result is calculated and normalized back into the correct format, any bits that exceed the precision specified by the application are simply discarded. Positive results see the equivalent of a round-down, and negative results see the equivalent of a round-up after truncation.

The Rounding Bits. To perform the rounding required by the IEEE-754 standard, a series of bits called the "rounding bits" are commonly used. These bits include the "guard bit" (G), the "round bit" (R), the "carry bit" (C), and the "sticky bit" (S). Because these bits are not explicitly identified in the IEEE-754 specification, the naming conventions vary, but the concepts remain the same.

For floating-point addition and related instructions, the guard, round, and sticky bits are used for rounding. These three bits are typically included in order at the end of an intermediate result. Figure 9 shows the guard bit, G, is in the bit position directly following the LSB of the intermediate result. The round bit, R, is adjacent to the guard bit, and the sticky bit, S, completes the set.

The first bit to understand is the sticky bit. This bit is a logical OR of all bits in its position and smaller. Figure 10 shows formation of the sticky bit. If the sticky bit is a 0, then the intermediate result up to the round bit is exact.

The guard and round bits are primarily included to help determine what action to perform in the RNE mode. Specifically, in a normal addition, if G = 1, then the result has

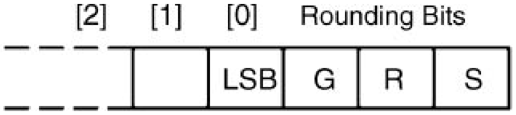

Figure 9. Rounding bits for floating-point addition.

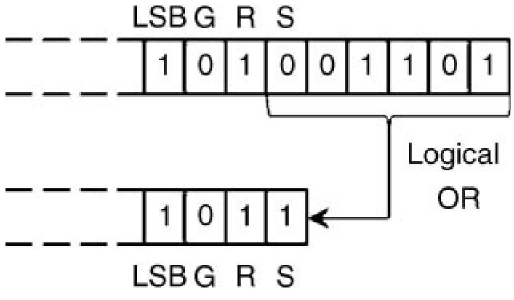

Figure 10. Creation of the sticky bit.

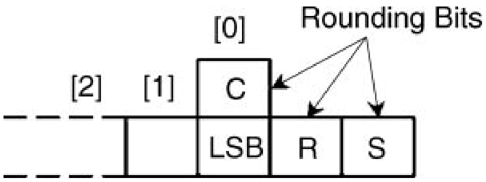

Figure 11. Floating-point multiplication rounding bits.

the value of LSB/2 exceeding the output range. In this case, if the R = 0 and S = 0, then the final result should round to nearest even. If G = 1 and either R = 1 or S = 1, then the result needs to be rounded up. Finally, if G = 0, then the R and S bits serve no function, and the result is rounded down.

In floating-point subtractions, several cases can occur in which the final result needs to be shifted one position to the left (i.e., when the result after the subtraction is in the form 0;1XXX...). In these cases, the result is shifted and the guard bit becomes the LSB, which leave the R and S bits to perform rounding. If the round bit were not present then the sticky bit would be all that is left to determine rounding, and an incorrect rounding decision might be made.

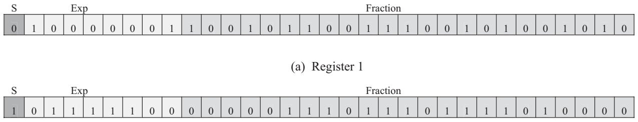
Floating-point multiplication shares a similar rounding scheme for RNE modes, but with slightly different (and more difficult to calculate) rounding bits. Figure 11 shows that floating-point multiplication uses a, C, a R, and an S. No guard bit is needed, as no subtractions are required in multiplication.

The carry bit is a carry-in from the partial product combination of all bits below the range of the output result. Calculating the sticky bit of all out-of-range bits is not enough for a correctly rounded multiplication, as a partial product combination that incorrectly kills a carry can cause a rounding error greater than LSB/2. Because every multiplication results in an intermediate result twice as wide as the original operands, the carry bit requires an adder structure large enough to propagate a carry all the way to the upper-half of the result. Because the carry may cause a carry out of the original MSB of the product, the carry must be propagated upward before the round and sticky bit are calculated to determine the final rounded result.

Rounding Example. Assume a 32-bit single-precision subtraction in RNE mode between the following two data in memory, as shown in Fig. 12.

The numerical representation of these two numbers is as follows:

$$\begin{array}{rl} & 1;1001\_0110\_0111\_0010\_1001\_010 \times 2^{129-127=2} \\ (-) & 1;0000\_0111\_0111\_0111\_1010\_000 \times 2^{124-127=-3} \end{array}$$



S			Exp																Fraction												
0	1	0	0	0	0	0	0	1	1	0	0	1	0	1	1	0	0	1	1	1	0	0	1	0	1	0	0	1	0	1	0

(a) Register 1

S			Exp																Fraction												
1	0	1	1	1	1	1	0	0	0	0	0	0	0	1	1	1	0	1	1	1	0	1	1	1	1	0	1	0	0	0	0

(b) Register 2

Figure 12. The operands as stored in the memory.

S			Exp																Fraction												
0	1	0	0	0	0	0	0	1	1	0	0	1	1	1	1	0	1	0	1	0	1	1	1	0	0	1	0	1	0	0	0

Figure 13. The RNE rounded result.

The smaller fraction is aligned so that the exponent values of each operand match and the subtraction may occur. However, observing that the sign bit of the smaller operand is a 1, the second operand is a negative number. Therefore, the subtraction of a negative number is a "true addition," which results in the following:

$$\begin{array}{rl} & 1;1001\_0110\_0111\_0010\_1001\_010\_\overset{\text{GRS}}{000} \times 2^2 \\ -\quad(-) & 0;0000\_1000\_0011\_1011\_1011\_110\_100 \times 2^2 \\ \hline & 1;1001\_1110\_1010\_1110\_0101\_000\_\overset{\text{GRS}}{100} \times 2^2 \end{array}$$

At this point, because the instruction is in RNE mode, the G, R, and S bits are observed. G = 1, R = 0, and S = 0. This finding means the intermediate result's rounding bits sum to exactly LSB/2. This specific case requires a round to nearest even. Because the closest even result is a round-down, the final result truncates the rounding bits and is stored in memory as:

$$1;1001\_1110\_1010\_1110\_0101\_000 \times 2^{129-127=2}$$

Or more formally as is shown in Fig. 13.

FLOATING-POINT HARDWARE

The hardware required to support floating-point operations can vary widely. As stated in the IEEE-754 specification, compliant floating-point systems may support the requirements in hardware, software, or a combination of both. Therefore, the actual implementation of the floating-point arithmetic is at the discretion of the designer.

However, high-performance IEEE-754 compliant machines typically are implemented mostly in hardware for performance reasons. Floating-point units (FPUs) are usually built as co-processors. The first of these by Intel were off-chip devices that communicated to the central processing unit (CPU) with an external bus. Because the original coprocessor and its derivatives were named as some version of the 8087, the suffix of "x87" to describe floating-point logic stuck. Modern FPU coprocessors embedded on the same silicon as the CPU are still referred to as "x87" devices.

A modern x87 FPU typically comprises a scheduler, register file, load and store units, convert units, MMX units and floating-point execution units. Although all the pieces of the x87 coprocessor are necessary and important, the most critical are the execution units: the floating-point adder (FPA) and the floating-point multiplier (FPM).

FPA Hardware

The FPA is one of the most fundamental units used in x87 coprocessors. It performs floating-point additions in the way described by the addition examples in the previous sections. The unit takes two input floating-point addends and performs an addition, subtraction, or any derivative of the fundamental addition instruction. The floating-point result is rounded according to the IEEE-754 specifications and passed out of the block. In some designs, more common in the x86 market, the floating-point adder also produces an unrounded result so that the control units may detect special cases, denormals, exceptions, and various other data for trap handling.

A modern floating-point adder is nearly always designed using the Farmwald dual-path architecture (9). This general scheme, which has also been selected as the floating-point adder example shown here, splits the addition datapath into two separate parallel cases. The reason for this is that the hardware required to handle data for operands with large exponent differences is very different than that for exponents that are equal or nearly equal. Floating-point adders now build two paths to handle these different data ranges, which are commonly known as the "far path" and the "close path."

It is important to first identify the two general addition/subtraction cases possible in floating-point addition. First, in cases with large exponent differences (i.e., the far path case), the significands must be aligned via a large shifter before addition or subtraction may occur. This behavior has already been demonstrated in the earlier floating-point addition examples: Given two addends with different exponents, the significand of the addend with the smaller exponent must be shifted until the exponents are equal before the significands are added.

However the second close path case was not covered in the examples. In certain subtraction cases with equal exponents, subtraction of nearly equal significands may result in what is called "massive cancellation," in which the final significand may be much smaller than the original and must be normalized via a large shift. Such cases use specialized hardware in the close path.

For example, two floating-point operands are to be subtracted. The two numbers themselves also happen to be nearly identical to one another, say decimal 1.000000 and 1.000001. When the two are subtracted, the result before normalization is decimal 0.000001. Normalization requires a large left-shift of the significand and a significant reduction in the value of the exponent. Cases like these use a completely different set of hardware than normal additions and subtractions. Older floating-point adder units used to handle all of these cases in a single serial path, but modern x87 units gain performance by splitting and parallelizing these mutually exclusive cases in a "dual-path" FPA.

Figure 14 shows the top-view architecture of a dual-path floating-point adder. The design is for the IEEE-754 double-precision format with 64-bit buses for inputs and outputs. The example architecture uses the Farmwald split, which employs a far path and close path in parallel. When the correct path is chosen by the exponent logic, the selected path sends its data to a combined add/round stage (5,6), where performance is gained by combining addition and rounding logic, and both an unrounded and rounded result are produced.

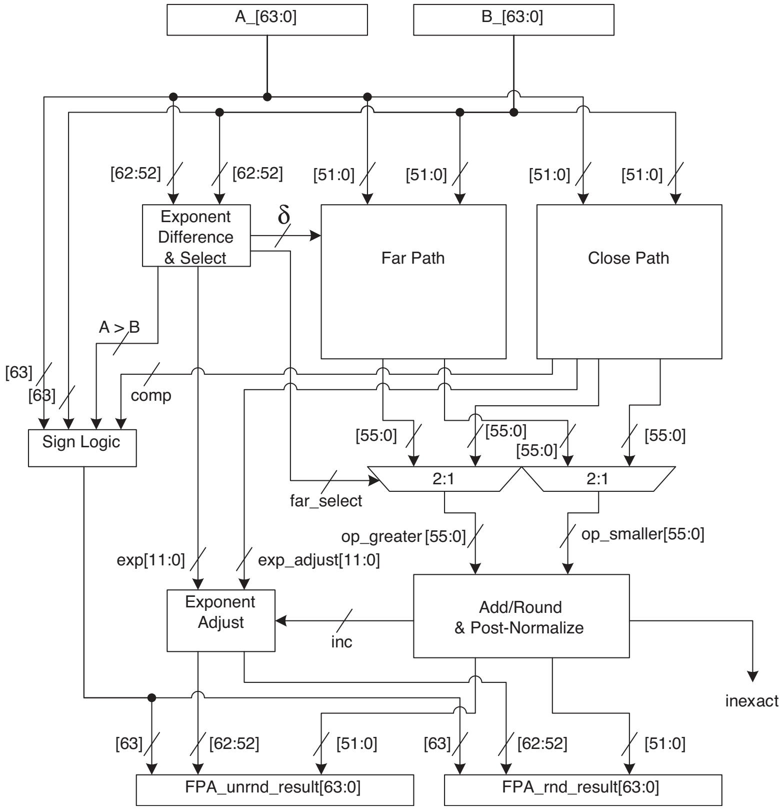


Figure 14. Top view of double-precision floating-point adder.

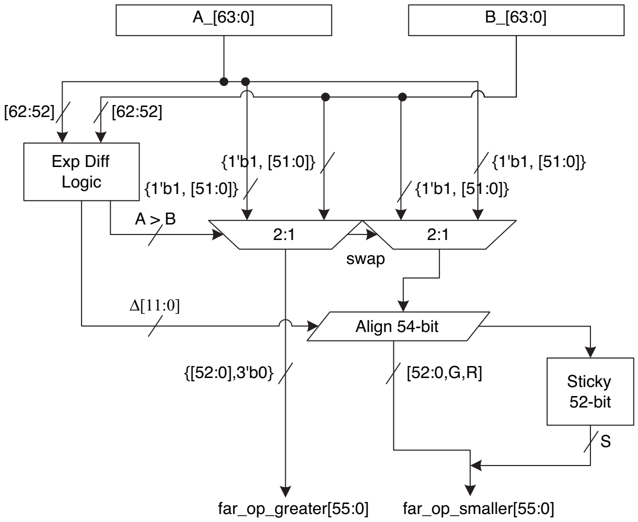

Figure 15. Far path of floating-point adder.

The FPA Far Path. A floating-point adder far path is the significand datapath for all additions and for all subtractions when exponents differ by more than two. The exponent difference of two is selected based on mathematical analysis of floating-point subtraction cases (10). This far path, shown in Fig. 15, is set up to determine how far apart the operand exponents are and to align the significands so that correct floating-point addition/subtraction occurs. Additionally, if the smaller operand is out of the range of what these designs refer to as the "anchor," or the larger operand, which has a static position, then the smaller operand's significand is collected in a sticky bit for rounding.

The implementation of the far path scheme uses a comparator in the exponent logic to determine which operand is larger. When the large operand is identified, the significands of the inputs pass through the "swap" multiplexer stage, which chooses which input is the anchor and which is the one for alignment. In double precision, the smaller operand enters a 54-bit aligner and passes any bits that exceed 54-bits to the sticky tree. The stage is complete when the smaller operand is aligned to the anchor, and the far path results are passed out of the block.

The FPA Close Path. The floating-point adder close path is the significand data path for all subtractions with operand exponents within the difference range of {−1,0,1}. In this data range, a subtraction may cause massive cancellation, which requires a large normalization before the result may be correctly rounded. Massive cancellation cases, like the floating-point adder design presented here, are commonly handled by leading zero anticipator blocks (LZAs).

The LZA is a specialized piece of hardware designed to detect the number of ZEROs above the first ONE in the significand of the result. The LZA logical block runs in parallel with the subtraction itself (and sometimes ahead of it, as seen in this design), calculating only the number of leading ZEROs, which indicates how many bits of normalization are required. This parallel execution allows for an immediate normalization after (or before) the subtraction occurs. The mathematics involved in the construction of an LZA are complex (11).

The close-path architecture is shown in Fig. 16. The input significands are passed to a swap block, a comparator, and three leading-ONEs predictors (LOPs, part of the LZA algorithm). The block begins by determining which exponent, if any, is greater. Once the exponent difference is determined, the operands are swapped, putting the greater

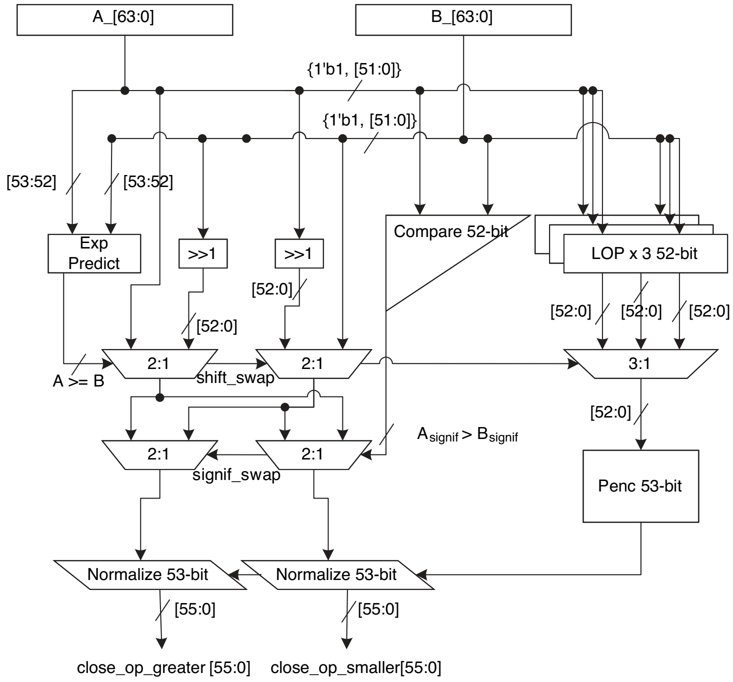

Figure 16. Close path of floating-point adder.

exponent in the "greater operand" path. Three LOPs are used: one for A > B, one for A = B, and one for A < B. The exponent control selects the correct LOP at the same time as the shift swap. The operands are sorted and the LOP result is sent to a priority encoder (the second half of a LZA).

In the case when the exponents are equal, the greater operand is still unknown. To resolve this problem, a second swap stage uses a significand compare select to determine the greater operand. When the swap stages are over, the LZA priority encoder prenormalizes both operands, and the results are passed to the round stage. Prenormalization (or normalization before actual subtraction occurs) is valid because cases of massive cancellation will wipe out any leading ONE bits when the numbers are subtracted, so shifting them out early saves a stage after the actual subtraction occurs.

The FPA Add/Round Stage. Following the parallel processing of the floating-point adder far and close path, the greater and smaller operands from each adder merge paths in two parallel multiplexers. Exponent control has by this point determined the correct numerical path, and the operands from the selection are passed to the combined addition and rounding stage.

The add/round stage architectures used in the floating-point adder are shown in Fig. 17. Two adders are used in parallel, one unbiased and one with a constant, to compute both a rounded and an unrounded result similar to the suggestions by Quach and colleagues (5,6), and the implementation of the SPARC-64 (12). The scheme uses the concept that a correct IEEE-754 rounded result may be obtained by operating on the LSB in an adder sum or an adder sum + 2.

In this implementation, the two input operands are passed to dual 59-bit adders. One of the adders precombines the two operands with a constant: a +2 constant for additions and a +1 constant for subtractions. The MSBs and LSBs of both results are sent to a rounding table, where the correct rounding decision is made based on rounding control. The final rounded significand is selected by the final multiplexer, and both the rounded and un-rounded results are passed out of the block.

FPM Hardware

The FPM is generally the largest block in a floating-point unit, which is built to take two input operands and provide a multiplied and rounded result. The unit itself, when compared with a floating-point adder, has a simpler overall architecture, but it contains components that use a lot of area and power.

Adding to the floating-point multiplier's size and latency is an array of complex arithmetic functions beyond simple multiplication. A common floating-point unit uses the multiplier to process transcendental, divide, and square root algorithms that use ROM tables and multiplicative iterations. Without this additional burden, the floating-point multiplier has a very fast performance with low latency. However, with the additional instructions that must be handled by the unit, the latency increases and the delay becomes similar to that of a floating-point adder.

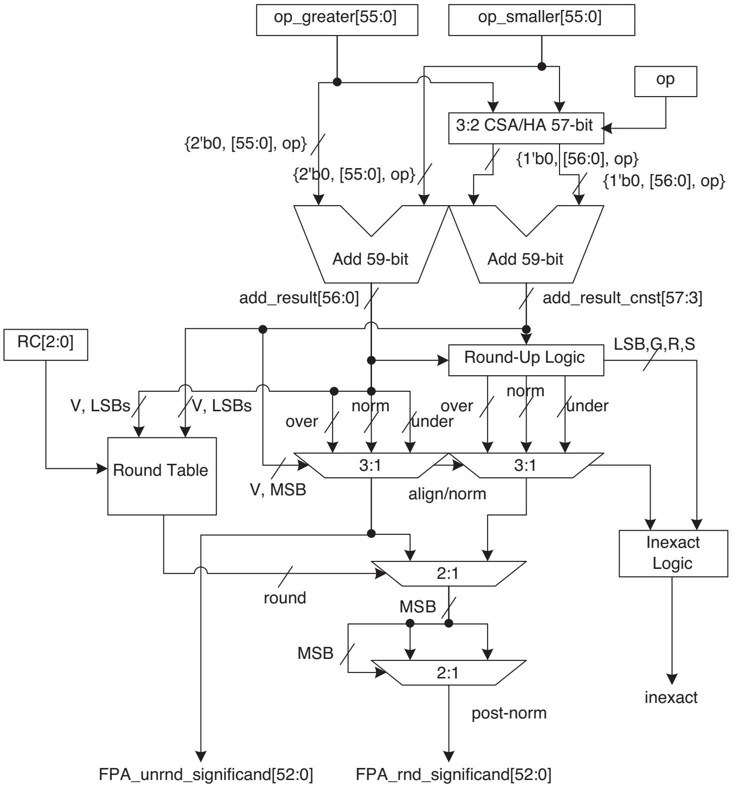

Figure 17. Floating-point adder add/round stage.

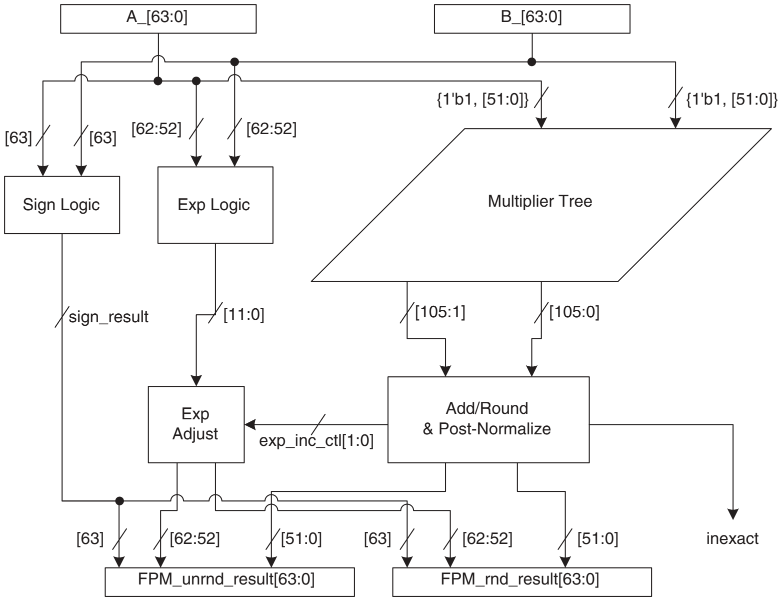

Figure 18. Top view of the floating-point multiplier.

The floating-point multiplier described here has been designed without the transcendental, square root, or division algorithms. Although these algorithms are necessary in a floating-point unit that complies with the IEEE-754 standard, the design is intended to provide the implementation details of a pure floating-point multiplication instruction.

The floating-point multiplier implemented architecture is shown in Fig. 18. The multiplier tree product result passes to a combined add/round stage, where the carry/save product is combined and rounded. The stage outputs both an unrounded and rounded result, and the floating-point multiplication is complete. Both the sign logic and the exponent datapath run in parallel to the significand processing.

The FPM Add/Round Stage. The addition and rounding stage in a floating-point multiplier requires a rounding stage more complex than that of a floating-point adder. As briefly described in earlier sections, the calculation of the rounding bits for FPM units is not simple. Specifically, this multiplier needs unique hardware to produce a rounded result that is the same size as its input operands, all while correctly propagating carries from the lower half of the double precision product.

The floating-point multiplier add/round stage, shown in Fig. 19, uses an architecture similar to those suggested by the authors of Refs. 7 and 8. The upper half of the input carry/save product is passed to two half-adder (HA) stages, where the LSB from each stage is stripped off and sent to a constant 2-bit adder. The remaining upper half enters a compound adder, where the sum and augmented sum (sum + 1) are calculated.

The lower half of the add/round stage input is sent to a carry and sticky tree, where the LSB, C, R, and S bits are produced. These bits combine with rounding control and select the correct increment of the final result's lower 2-bits. Depending on the bit sequence selection of the lower 2-bit constant adder output, the upper half of the result will either be ready for post-normalization or will require the augmented selection. Both the lower 2-bits and the selected compound adder output are postnormalized, and the product is complete.

OTHER IEEE-754 SPECIFICATIONS

The IEEE-754 standard includes far more than precision specifications and descriptions of addition, multiplication, and rounding. The standard identifies several other required mathematical functions, such as divide, square root, reciprocal, as well as convert instructions to pass data between fixed point and floating point. Also included are specifications on reserved values for infinity, not-a-number (NaN), zero, and denormalized numbers, which are frequently referred to as denormals. Each of these items is briefly touched on in this section.

The other functions required by the standard are handled by different x87 machines in different ways. Performance-intensive applications commonly map these other mathematical operations to the floating-point adder and floating-point multiplier hardware. For instance, division can be mapped to either the FPA or FPM, because digit-recurrence (13), Goldschmidt, and Newton-Raphson division require either adders, multipliers, or both in their algorithms (see the chapter on fixed-point computer arithmetic). Reciprocal and square-root estimates may be mapped to a FPM that employs iterative multiplication based on bipartite ROM initial estimations (14). Transcendentals and CORDIC algorithms may be realized with combinations of FPA and FPM hardware. Convert instructions that involve float-to-float, fixed-to-float, and float-to-fixed translations are special

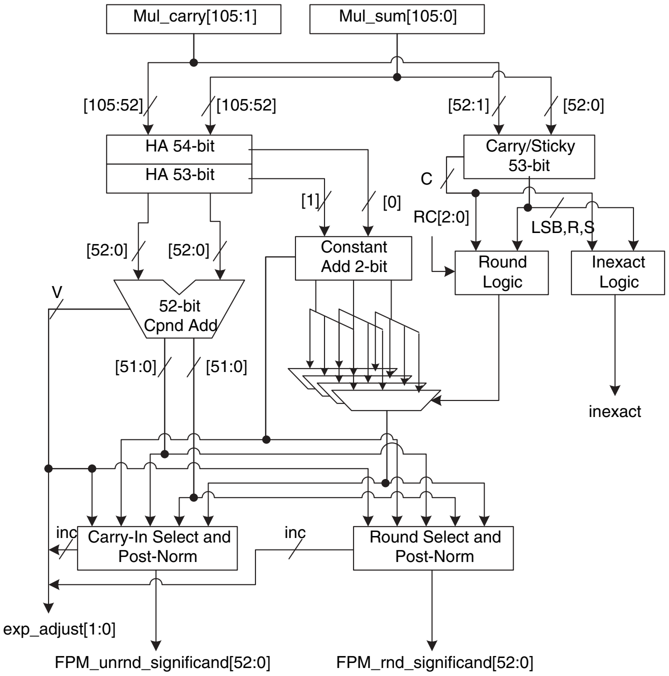

Figure 19. Floating-point multiplier add/round stage.

cases of floating-point addition in which one of the operands is a constant. Depending on the application, convert instructions may be mapped to the FPA or implemented with a separate store-convert unit, which is in essence just a simplified version of the FPA. In any case, most IEEE-754 mathematical operations are subsets of the FPA and FPM operations.

The IEEE-754 specification reserves two exponent fields for special numbers, specifically the largest and the smallest exponent values. For example, in single-precision, the exponent value of 1111_1111 is reserved for ± infinity and NaN, whereas the exponent value of 0000_0000 is reserved for ± zero and denormals.

When the exponent is the lowest value (i.e., 0000_0000 for single precision), if the significand is all 0s, then the number is interpreted as either positive or negative zero,If the significand is non-zero, then the result is a valid number, called a "denormal."

Denormals are special numbers that fill the space between N_{min} (i.e., exp = 0000_0001 and a minimum significand of 1.0000.... for single-precision) and zero. In the normalized floating-point format, no values exist between N_{min} and zero, but rather, the lowest floating-point value would simply jump from N_{min} directly to zero. Denormals solve this problem by holding a numerical value and indicating to the machine that underflow has occurred. Figure 20 shows graphical representations of the range of floating-point values possible with and without denormal numbers, respectively.

Denormals in the IEEE-754 specification are used to express values between N_{min} and zero. If a number is less than N_{min}, then without denormals the number would be rounded to either to zero or to N_{min}. Instead, denormals allow the x87 machine to save the denormalized result. In this fashion, no data are lost.

Actual denormal values are represented in a slightly different format than normal floating-point numbers. Specifically, when the exponent value of a number is all 0s, the significand does NOT have an implicit integer 1. Instead, the significand is assumed to begin with a '0' (i.e., $0;XXX\ldots \times 2^{N_{min}}$). For a better understanding of denormals and how they are handled in x87 machines, refer to Ref. 15.

CONCLUSIONS

This article presents an overview of the IEEE-754 specification for floating-point numbers and how they are used in arithmetic operations, such as addition and multiplication. It then follows with a brief look at floating-point addition and floating-point multiplication via double-precision hardware implementations that convey the fundamentals of an x87 execution unit design. Finally, the article briefly discusses the various special "numbers" required by the standard such as denormals, infinites, zeros, and conversions.

Although many modern processors do not necessarily comply entirely with all elements of the IEEE-754 floating-point standard, the fundamentals of all floating-point systems are similar. This brief introduction should provide a useful starting point. More details are available in Refs. 16-19 .

FLUENCY WITH INFORMATION TECHNOLOGY

Fluency with Information Technology specifies a degree of competency with computers and information in which users possess the skills, concepts, and capabilities needed to apply Information Technology (IT) confidently and effectively and can acquire new knowledge independently. Fluency with Information Technology transcends computer literacy and prepares students for lifelong learning of IT.

The concept of *Fluency with Information Technology* derives from a National Research Council (NRC) study initiated in 1997 and funded by the National Science Foundation (NSF). The study focused on defining "what everyone should know about Information Technology." For the purposes of the study, "everyone" meant the population at large, and IT was defined broadly to include computers, networking, software and applications, as well as information resources—virtually anything one would encounter using a network-connected personal computer.

The NSF motivation for requesting the study was driven by the belief that much of the United States population is already "computer literate," but that literacy is not enough. With more knowledge, people would make greater use of IT, and doing so would generally be beneficial. Specifically, the NSF noted these points:

- Most users have had no formal training in the use of IT because of the relatively brief period during which it has entered our society; more complete knowledge could be useful.
- Many users seem to have only a limited understanding of the applications they use and (probably correctly) assume they are underutilizing them.
- Many users are not confident nor do they feel in control when confronted with Information Technology opportunities or problems.
- Extravagant claims have been made about the potential benefits of IT, but most citizens do not enjoy them; they want to apply IT to personally relevant goals.
- Informed participation in certain contemporary social and political discussions—strong encryption, copyright, spam, privacy, and so forth—requires a sound understanding of IT.

What knowledge would address these concerns?

The NRC, under the auspices of the Computer Science and Telecommunication board, appointed seven experts to the ad hoc Committee on Information Technology Literacy:

Lawrence Snyder, University of Washington, Chair
Alfred V. Aho, Lucent Technologies
Marcia Linn, University of California at Berkeley
Arnold Packer, The Johns Hopkins University
Allen Tucker, Bowdoin College
Jeffrey Ullman, Stanford University
Andries Van Dam, Brown University

Herbert Lin of the NRC staff assisted the committee.

Meeting over a two-year period, the committee broadly solicited information, using invited testimony from various stakeholders, electronic queries to the community at large, and a public forum. The broad range of views expressed indicated that *computer literacy*, which currently is understood to teach students how to use specific applications, does not have the "staying power" to prepare people for the continual change that is so familiar in IT. Users must be trained to be more adaptive and ready and willing to change. The committee decided that a deeper, more foundational understanding was needed that would allow people to respond to change through a process of lifelong learning. The term *fluency*, suggested by Yasmin Kafai of UCLA, became the moniker for that deeper, foundational knowledge.

The committee issued its report, *Being Fluent with Information Technology*, in June 1999, published by the National Academy Press (1). The report attracted considerable interest, and some schools immediately began offering college-level classes. By July 2002 Addison Wesley published the first textbook *Fluency with Information Technology*. And in the fall of 2003, an online course to teach the content was launched with NSF funding.

CONTENT OF FLUENCY WITH INFORMATION TECHNOLOGY

To provide the necessary foundation to support lifelong learning in IT, the committee recommended a tripartite body of knowledge that covers contemporary skills, fundamental concepts, and intellectual capabilities:

Skills—the ability to use contemporary computer applications. Skills knowledge makes computers and information resources useful immediately; it provides valuable employment training and supports the other aspects of *fluency* education. Examples include word processing, web searching, and so forth.

Concepts—the fundamental information about IT drawn from its supporting fields. Concepts knowledge includes both "general science" knowledge, such as how a computer works, that educated citizens should know and directly applicable knowledge, such as algorithmic thinking, that underpins future applications of IT by users.

Capabilities—the higher-level thinking skills needed for everything from finding new ways to exploit IT to

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

recovering from errors. Capabilities—reasoning, debugging, problem solving, and so forth—apply in everyday life as well as in IT. However, because they occur often and intensively in IT, it is essential that users be accomplished with them.

Notice that *skills* generally align with traditional computer literacy, so *fluency* includes literacy as a component.

The committee, charged with developing the content, chose not to enumerate every conceivable skill, concept or capability but rather to identify the top ten most important items in each category. Their recommendation (1, p. 4) is shown in the companion table. NRC Recommended Fluency Topics

Skills –

- Set up a personal computer
- Use basic operating system facilities
- Use a word processor
- Use a graphics/artwork/presentation tool
- Connect a PC to a network
- Search the Internet to locate information
- Send and receive e-mail
- Use a spreadsheet
- Query a database
- Use online help and tutorial facilities

Concepts –

- Principles of computer operation
- Enterprise information systems
- Networking
- Digital representation of information
- Information structure and assessment
- Modeling the world with computers
- Algorithmic thinking and programming
- Universality of computers
- Limitations of computers
- Information and society

Capabilities –

- Engage in sustained reasoning
- Manage complexity
- Test a solution
- Locate bugs in an IT solution
- Organize and navigate information structures
- Collaborate using IT
- Communicate an IT solution to others
- Expect the unexpected
- Anticipate technological change
- Think technologically

An important aspect of the recommended topics is that the *skills*, built around contemporary software and systems, can be expected to change over time. The *concepts* and *capabilities*, focused on fundamental ideas and intellectual processes, are generally time-invariant.

PROJECTS AS AN INTEGRATING MECHANISM

The committee asserted that *skills*, *concepts*, and *capabilities* are separate but interdependent types of knowledge. Furthermore, because most nontrivial applications of information technology rely on applying all three kinds of knowledge seamlessly, it is best not to teach them in isolation. Rather, the material should be integrated using projects. Projects—multi week activities that produce a specific IT "product" such as a web page or database—can be designed to use several components from each list to give students an experience that approximates realistic IT situations. Through the projects, *fluency* becomes a coherent body of knowledge rather than a set of 30 disparate topics.

An example of a project might be to build a database to support patient processing at a storefront medical clinic. Students would set up the database tables, define the queries, and design the user interfaces to track patients through processing at the clinic. In addition to a record of the visit, documents would be generated for follow-up actions such as referral letters, labels for specimens for laboratory tests, prescriptions, (possibly) payment invoices and receipts, and so foth.

The medical database example combines the use of several *skills*, *concepts*, and *capabilities*. Among the *skills* applied might be Web searching to find out privacy requirements, database querying, using basic operating system facilities, using online help facilities, and probably others. Among the *concepts* applied might be fundamentals of database design, information representation, information structure and organization, social implications of computing, and probably others. Among the *capabilities* applied might be sustained logical reasoning, debugging, solution testing, communicating a technological solution, and probably others. When working on a project, a student is focused on solving the problem, not on which of the curricular components he or she is applying at the moment. As a result, projects produce an integrated application of IT that conforms closely to how it is used under non academic circumstances. Furthermore, successful completion of such substantial efforts can give students a greater degree of confidence as computer users than can exercises specialized to a particular topic.

Appendix A of the report (1, pp. 67–77) gives a listing of other sample projects.

ALGORITHMIC THINKING AND PROGRAMMING

Since the introduction of the first computer courses for non specialists in the 1970s, the question has been debated whether programming should be a component of the computing knowledge of the general population. The subject is complex and often has been divisive. Fair-minded commentators have offered thoughtful and substantive arguments on both sides, but no clear resolution has emerged. Curricula have been developed taking each position.

The NRC committee was confronted with the question, too: Should programming be listed among the *skills*, *concepts*, and *capabilities*? The matter took on a crisp form in the testimony presented to the committee. Most contributors recommended that *algorithmic thinking* be a part of "what everyone should know about Information Technology." They asserted that educated people should be able to formulate procedural solutions to problems with sufficient precision that someone (or something) else could implement them. It also was common for the committee to be advised not to include *programming* as a requirement for the general population. Programming embodies professional knowledge that is too advanced and too detail-oriented to be of value to users. That is, the committee was told that algorithmic thinking was essential and programming was not.

Although algorithmic thinking and programming are distinct, they overlap substantially. The committee wrestled with how to interpret these largely contradictory inputs. Was the committee being told to prescribe those aspects of algorithmic thinking that do not involve programming in any way? Or was it being told to prescribe algorithmic thinking in full but to include programming only to support it, not a full, professional-level programming course? In addition to the algorithmic thinking/programming question, related issues existed: What were those individuals who recommended programming including in their recommendation, passing familiarity to programming or deep knowledge? Also, because programming is a challenging engineering discipline, how much aptitude for learning programming does the general population possess?

The committee finally resolved these difficult issues by including algorithmic thinking and programming as item # 7 among the *concepts*. In explaining the recommendation (1, pp. 41–48), the committee stated that programming is included to the extent necessary to support a thorough development of algorithmic thinking. It did not recommend "majors" -level programming knowledge. Specifically, the committee identified a small list of programming concepts that it regarded as sufficiently fundamental and generally accessible to be considered part of that programming content. These concepts include name and value, assignment, conditional execution, and repeated execution. It supported the choice by presenting examples where the ideas occur both within and beyond IT. Since the publication of the report, its wide distribution has exposed the approach to considerable scrutiny. Because the *fluency* concept has been embraced widely and its algorithmic thinking/programming resolution has engendered almost no comment of any kind, it must be concluded that the committee recommendation settles—yes, but only a little—the longstanding programming question.

IMPLEMENTING FLUENCY WITH INFORMATION TECHNOLOGY

The charge of the NRC committee was to specify only the content that "everyone should know about Information Technology." The implementation of FITness—the term used by the committee to identify those who are fluent with information technology—education would be left until later. But the committee was composed of academics, so, inevitably, teaching *fluency* at the college level was addressed.

The committee began by noting the desirability of FITness as a post condition of college, that is, knowledge with which students leave college. Eventually, the report stated, FITness should be a pre condition of college, like basic knowledge of science, math, and foreign languages. Although appropriate for pre-college, the challenges are so great for implementing fluency instruction in K–12 that it will be years before FITness can be an entrance requirement. Therefore, teaching *fluency* in college is essential in the short run. Also, compared with K–12 public instruction, post secondary institutions are far more flexible in terms of their ability to develop curricula and infrastructure for new pedagogical endeavors.

The NRC committee did not define a curriculum, only the content. Curriculum development began in the spring term of 1999 with the offering of the first FITness class, CSE100 *Fluency with Information Technology* at the University of Washington. The goal of this class is to teach the recommended *skills*, *concepts* and *capabilities* to freshmen in one 10-week quarter. The class has three lectures and two labs per week, each of 50 minutes. *Skills* are taught primarily in the labs, *capabilities* are presented primarily as lecture demonstrations, and *concepts* are learned primarily through reading. [Course notes from early offerings of this program became the textbook, *Fluency with Information Technology*, published by Addison Wesley (2).] Three projects integrate the material. Other universities, colleges, and community colleges have developed FITness curricula since then.

Because the *skills*, *concepts*, and *capabilities* are such different kinds of knowledge, teaching *fluency* requires a varied strategy.

Skills material—word processing, browsing, processing e-mail, and so on—is best taught in a lab with a video projector connected to the computer of the instructor. In the lab, students "learn through doing," and, because an important part of learning an application is familiarity with the GUI, the video display facilitates demonstrations. Furthermore, the detailed "click here, click there" instruction should give way quickly to more generic instruction that describes general properties of PC applications. This process allows students to learn how to learn an application, which makes them more independent.

Concepts material—computer operation, database principles, network protocols, and so forth—is effectively science and can be learned most efficiently through a combination of textbook reading and lectures that amplify and illustrate the ideas. Because computers are so fast and the common applications are built with millions of lines of software, students will not be able to recognize the instruction interpretation cycle of a computer or TCP/IP in their direct experience. So, the goal is simply to explain, as is done in physics or biology, how basic processes work.

Capabilities material—logical reasoning, complexity management, debugging, and so forth—is higher-level thinking that often is learned through life experience. Because *capabilities* generally are non algorithmic, they are somewhat more challenging to teach. Lecture demonstrations are effective because the class can, say, debug a problem together, which illustrates the process and provides a context for commentary on alternative techniques. The *capabilities*, being instances of thinking, are not learned entirely in a FITness course; students will continue to hone their knowledge throughout life.

As noted, projects provide the opportunity to apply and integrate these three kinds of knowledge.

The committee recommended that the ideal case would be for *fluency* instruction to be incorporated into discipline-specific IT instruction when possible. That is, as architecture students, business majors, and pharmacists learn the technology that supports their specialties, they also learn the recommended *skills*, *concepts*, and *capabilities*. Projects could be specialized to their area of study, and problem solving could incorporate discipline-specific methodologies. Although it has advantages, the recommendation implies that students learn FITness relatively late in their college career, that is, after choosing a major. Because the material applies across the curriculum, it is advantageous to learn it much earlier, for example, freshman year or before college, so that it can support the whole academic program. A compromise would be to offer generic FITness, as described above, as early as possible, and then to give further instruction on the *capabilities* in a research methods or career tools class once students have specialized in a major.

NEXT STEPS FOR FLUENCY

Universities, colleges, and community colleges are adopting *fluency* courses at a rapid rate, and schools outside the United States are beginning to promote FITness. These courses typically replace traditional computer literacy classes both because *fluency* provides a more useful body of knowledge and because a majority of students are computer literate when they enter post secondary schools. So, *college-age* students are becoming FIT, but what about the remainder of the population?

The original NSF question asked what the population at large should know about IT. Enrolled college students are only a small part of that, which raises the question of how the adult population not in school is to become *fluent*. This problem remains unsolved. One small contribution to the effort is a free, online, self-study version of the University of Washington Fluency with Information Technology course, called BeneFIT100. Any person with a computer and Internet connection who speaks basic English, is computer literate enough to browse to the University of Washington Website, is disciplined enough to take an online class, and is motivated to become *fluent* can use BeneFIT100 to do so. Although many people doubtless meet those five qualifications, still they are a minority. Expanding access to *fluency* instruction likely will remain a difficult problem and the main challenge for the foreseeable future.

INFORMATION TECHNOLOGY

This article provides a brief account of information technology. The purpose of information technology is discussed and a brief account is given of its historical evolution. Then the many profound influences that information technology has had, is having, and will have on organizations, and the way in which this effect will strongly affect the engineering of information technology products and services will be discussed. A presentation of 10 major challenges for information technology in the 21st century concludes the article.

Fundamentally, information technology (IT) is concerned with improvements in a variety of human problem-solving endeavors through the design, development, and use of technologically based systems and processes that enhance the efficiency and effectiveness of information and associated knowledge in a variety of strategic, tactical, and operational situations. Ideally, this is accomplished through critical attention to the information needs of humans in problem-solving tasks and in the provision of technological aids, including computer-based systems of hardware and software and associated processes, that assist in these tasks. Information technology activities complement and enhance, as well as transcend, the boundaries of traditional engineering through emphasis on the information basis for engineering as contrasted with the physical science basis for traditional engineering endeavors.

Information technology is composed of hardware and software that enable the acquisition, representation, storage, transmission, and use of information. Success in information technology is dependent upon being able to cope with the overall architecture of systems, their interfaces with humans and organizations, and their relations with external environments. It is also very critically dependent upon the ability to successfully convert information into knowledge.

The initial efforts at provision of information technology based systems concerned implementation and use of new technologies to support office functions. These have evolved from electric typewriters and electronic accounting systems to include very advanced technological hardware, such as facsimile machines and personal computers to perform such important functions as electronic file processing, accounting, and word processing. Now networking is a major facet of information technology.

It is neither possible nor desirable to provide a detailed discussion of the present IT based devices and products, or the many possible future developments in this exciting area. There are a plethora of relevant articles in this encyclopedia that discuss these in some detail.

HISTORICAL EVOLUTION OF INFORMATION TECHNOLOGY

In the early days of human civilization, development was made possible primarily through the use of human effort, or labor. Human ability to use natural resources led to the ability to develop based not only on labor, but also on the availability of natural resources. Natural resources are usually denoted land as the classic economic term that implies natural physical resources. At that time, most organizations were composed of small proprietorships. The availability of financial capital during the Industrial Revolution led to this being a third fundamental economic resource, and also to the development of large, hierarchical corporations. This period is generally associated with centralization, mass production, and standardization.

In the latter part of the industrial revolution, electricity was discovered, and later the semiconductor. This has led to the information age, or the information technology age. Among the many potentially critical information technology based tools are: data base machines, E-mail, artificial intelligence tools, facsimile transmission (fax) devices, fourth-generation programming languages, local area networks (LAN), integrated service digital networks (ISDN), optical disk storage (CD-ROM) devices, personal computers, parallel processing algorithms, word processing software, computer-aided software engineering packages, word processing and accounting software, and a variety of algorithmically based software packages. Virtually anything that supports information acquisition, representation, transmission, and use can be called an information technology product.

Easy availability of technologies for information capture, storage, and processing has led to information, as well as the product of information in context or knowledge, as a fourth fundamental economic resource for development. This is the era of total quality management, mass customization of products and services, reengineering at the level of product and process, and decentralization and horizontalization of organizations, and systems management. While information technology has enabled these changes, much more than just information technology is needed to bring them about satisfactorily. In this article, attention will be primarily focused upon information technology and its use by individuals and organizations to improve productivity and the human condition.

Commentators such as Bell (1), Toffler (2,3), and Zuboff (4) have long predicted the coming of the information age. The characteristics of the information age are described in a number of contemporary writings as well (5,6). Alvin Toffler writes of three waves: the agriculture, industrial, and

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

information or knowledge ages. Within these ages are numerous subdivisions. For example, the information age could be partitioned into the era of vertically integrated and stand-alone systems, process reengineering, total quality management, and knowledge and enterprise integration. Information and knowledge are now fundamental resources that augment the traditional economic resources: land or natural resources, human labor, and financial capital. Critical success factors for success in the third wave, or information age, have been identified (7) and include: strategy, customer value, knowledge management, business organization, market focus, management accounting, measurement and control, shareholder value, productivity, and transformation to the third-wave model for success.

There are numerous other methods of partition of these "ages." The information age could be partitioned into the age of mainframe computers, minicomputers, microcomputers, networked and client–server computers, and the age of knowledge management.

Major growth in the power of systems for computing and communicating, and associated networking is quite fundamental and has changed relationships among people, organizations, and technology. These capabilities allow us to study much more complex issues than was formerly possible. They provide a foundation for dramatic increases in learning and in both individual and organizational effectiveness. In large part, this is due to the networking capability that enables enhanced coordination and communications among humans in organizations. It is also due to the vastly increased potential availability of knowledge to support individuals and organizations in their efforts. However, information technologies need to be appropriately integrated within organizational frameworks if they are to be broadly useful. This poses a transdisciplinary challenge of unprecedented magnitude if we are to move from high-performance information technologies to high-performance organizations.

In years past, broadly available capabilities never seemed to match the visions offered, especially in terms of the time frame of their availability. Consequently, despite compelling predictions, traditional methods of information access and utilization continued their dominance. As a result, comments that go something like "computers are everywhere except in productivity statistics" have often been made ((8)). In just the past few years, the pace has quickened quite substantially and the need for integration of information technology issues with organizational issues has led to the creation of a field of study sometimes called "organizational informatics" or, more recently, "knowledge management," the objectives of which generally include:

- Capturing human information and knowledge needs in the form of system requirements and specifications
- Developing and deploying systems that satisfy these requirements
- Supporting the role of cross-functional teams in work
- Overcoming behavioral and social impediments to the introduction of information technology systems in organizations
- Enhancing human communication and coordination for effective and efficient workflow through knowledge management

Networks in general and the internet and World Wide Web in particular (9,10) have become ubiquitous in supporting these endeavors. Almost everyone is growing up digital (5), searching for designs for living in the information age, and going on line to communicate with one another and to use digital libraries. It also seems that hardware and software become obsolete as soon as they are unboxed. Indeed, with current trends, boxes themselves may become quaint collectibles. However, organizational productivity is not necessarily enhanced unless attention is paid to the human side of developing and managing technological innovation (11) to ensure that systems are designed for human interaction.

Because of the importance of information and knowledge to an organization, two related areas of study have arisen. The first of these is concerned with technologies associated with the effective and efficient acquisition, transmission, and use of information, or information technology. When associated with organizational use, this is sometimes called organizational intelligence, or organizational informatics. The second area, known as knowledge management, refers to an organization's capacity to gather information, generate knowledge, and act effectively and in an innovative manner on the basis of that knowledge. This provides the capacity for success in the rapidly changing or highly competitive environments of knowledge organizations. Developing and leveraging organizational knowledge is a key competency and, as noted, it requires information technology and much more than information technology capabilities. Thus, it can be seen that information technology has led to organizational informatics, and in this has led to knowledge management.

It would be very difficult to capture the state of information technology in an encyclopedia article without the article being hopelessly out of date even before the encyclopedia emerged from the publisher. Consequently, the goal of this article is to consider several broad trends, which we feel will persist regardless of the specific technologies that enable them. In particular, we focus on effects of information technology and on the organizational implications of these effects.

INFORMATION TECHNOLOGY AND INFORMATION TECHNOLOGY TRENDS

There are several ways in which one can define information technology. The US Bureau of Economic Analysis appears to define it in terms of office, computing, and accounting machinery. Others consider information technology as equivalent to information-processing equipment, which includes communications equipment, computers, software, and related office automation equipment. Still others speak about the technologies of the information revolution (12) and identify such technologies as advanced semiconductors, advanced computers, fiber optics, cellular technology, satellite technology, advanced networking, improved human–computer interaction, and digital transmission and digital compression. We would not quarrel with the content in this list, although we would certainly add software and middleware technology. It could be argued that software is intimately associated with advanced computers and communications. This is doubtlessly correct; however, there is still software associated with the integration of these various technologies of hardware and software to comprise the many information technology based systems in evidence today and which will be in use in the future.

Several trends transcend debates about technology alternatives—currently alternatives such as PCs versus Net PCs or ISDN versus cable. These overriding trends concern directions of computer and communications technologies, and the impacts of these directions on knowledge management and organizations.

The information revolution is driven by technology and market considerations and by market demand and pull for tools to support transaction processing, information warehousing, and knowledge formation. Market pull has been shown to exert a much stronger effect on the success of an emerging technology than technology push. There is hardly any conclusion that can be drawn other than that society shapes technology (13) or, perhaps more accurately stated, technology and the modern world shape each other in that only those technologies which are appropriate for society will ultimately survive.

The potential result of this mutual shaping of information technology and society is knowledge capital, and this creates needs for knowledge management. The costs of the information technology needed to provide a given level of functionality have declined dramatically over the past decade—especially within the last very few years—due to the use of such technologies as broadband fiber optics, spectrum management, and data compression. A transatlantic communication link today costs one tenth of the price that it did a decade ago, and may well decline by another order of magnitude within the next three or four years. The power of computers continues to increase and the cost of computing has declined by a factor of 10,000 or so over the past 25 years. Large central mainframe computers have been augmented, and in many cases replaced, by smaller, more powerful, and much more user-friendly personal computers. There has, in effect, been a merger of the computer and telecommunications industries into the information technology industry and it now is possible to store, manipulate, process, and transmit voice, digitized data, and images at very little cost.

Current industrial and management efforts are strongly dependent on access to information and associated knowledge. The world economy is in a process of globalization and it is possible to detect several important changes. The contemporary and evolving world is much more service oriented, especially in the more developed nations. The service economy is much more information- and knowledge-dependent and much more competitive. Further, the necessary mix of job skills for high-level employment is changing. The geographic distance between manufacturers and consumers, and between buyers and sellers, is often of little concern today. Consequently, organizations from diverse locations compete in efforts to provide products and services. Consumers potentially benefit as economies become more transnational.

The information technology revolution is associated with an explosive increase of data and information, with the potential for equally explosive growth of knowledge. Information technology and communication technology have the capacity to change radically the production and distribution of products and services and, thereby to bring about fundamental socioeconomic changes. In part, this potential for change is due to progressively lowered costs of computer hardware. This is associated with reduction in the size of the hardware and, therefore, to dematerialization of systems. This results in the ability to use these systems in locations and under conditions that would have been impossible just a few years ago. Software developments are similarly astonishing. The capabilities of software increase steadily, the costs of production decrease, reliability increases, functional capabilities can be established and changed rapidly, and the resulting systems are ideally and often user friendly through systems integration and design for user interaction. The potential for change is also brought about due to the use of information technology systems as virtual machines, and the almost unlimited potential for decentralization and global networking due to simultaneous progress in optical fiber and communication satellite technology (10).

The life cycle of information technology development is quite short and the technology transfer time in the new "postindustrial," or knowledge-based, society brought about by the information revolution is usually much less than in the Industrial Revolution. Information technology is used to aid problem-solving endeavors by using technologically based systems and processes and effective systems management. Ideally, this is accomplished through:

- Critical attention to the information needs of humans in problem-solving and decision-making tasks
- Provision of technological aids, including computer-based systems of hardware and software and associated processes, to assist in these tasks

Success in information technology and engineering-based efforts depends on a broad understanding of the interactions and interrelations that occur among the components of large systems of humans and machines. Moreover, a successful information technology strategy also seeks to meaningfully evolve the overall architecture of systems, the systems' interfaces with humans and organizations, and their relations with external environments.

As just discussed, the most dominant recent trend in information technology has been more and more computer power in less and less space. Gordon Moore, a founder of Intel, noted that since the 1950s the density of transistors on processing chips has doubled every 18 to 24 months. This observation is often called "Moore's Law." He projected that doubling would continue at this rate. Put differently, Moore's Law projects a doubling of computer performance every 18 months within the same physical volume. Schaller (14) discusses the basis for Moore's Law and suggests that this relationship should hold through at least 2010. The implication is that computers will provide increasingly impressive processing power. The key question, of course, is what we will be able to accomplish with this power.

Advances in computer technology have been paralleled by trends in communications technology. The Advanced Research Projects Agency Network, or ARPAnet as it is commonly called, emerged in the 1960s, led to the Internet Protocol in the 1970s, and the Internet in the 1980s. Connectivity, or the ability to connect to almost any destination, is now on most desktops, E-mail has become a "must have" business capability, and the World Wide Web is on the verge of becoming a thriving business channel. The result is an emerging networking market. Business publications are investing heavily to attract readers—or browsers—of their on-line publications (15). Telecommunications companies are trying to both avoid the obsolescence that this technology portends and to figure out how to generate revenues and profits from this channel. The result has been a flurry of mergers and acquisitions in this industry.

These strong trends present mixed blessings for end-users. The dramatic increases of processing power on desktops is quickly consumed by operating systems, browsers, multimedia demos, and so on. The escalating availability of data and information often does not provide the knowledge that users of this information need in order to answer questions, solve problems, and make decisions. The notion of "data smog" has become very real to many users (16). Not surprisingly, data smog possibilities encourage opportunities for technologies for coping with data smog. For example, "push" technology enables information to find users (17,18). Another possibility is "intelligent agent" technology whereby users can instruct autonomous programs to search for relevant data and information (19,20). While these types of capabilities are far from mature, they appear quite promising. The specifics of the above trends will surely change—probably by the time this article appears in print. However, the overall phenomenon of greater and greater processing power, connectivity, and information will be an underlying constant.

That the price of computing has dropped in half approximately every two years since the early 1980s is nothing short of astounding. Had the rest of the economy matched this decline in prices, the price of an automobile would be in the vicinity of $10. Organizational investments in information technologies have increased dramatically and now account for approximately 10% of new capital equipment investments by US organizations. Roughly half of the labor force is employed in information related activities. On the other hand, productivity growth seems to have continually declined since the early 1970s, especially in the service sector that comprises about 80% of information technology investments (8). This situation implies the need to effectively measure how IT contributes to productivity, to identify optimal investment strategies in IT, and to enhance IT effectiveness through knowledge management for enhanced productivity.

On the basis of a definitive study of IT and productivity, Brynjolfsson and Yang (8) draw a number of useful conclusions. They suggest that the simple relationship between decreases of productivity growth in the US economy and the rapid growth of computer capital is too general to draw meaningful conclusions. In particular, poor input and output data quality are responsible for many difficulties. Many of the studies they review suggest that the US economy would not be enjoying the boom that it is enjoying in the latter half of the 1990s without information technology contributions. Their study suggests improvements in accounting and statistical record keeping to enable better determination of costs and benefits due to IT. They support the often expressed notion that information technology helps us perform familiar tasks better and more productively, but that the greatest improvement is in enabling us to perform entirely new activities that would not be possible without these new information technologies. One of these, for example, is the ability to make major new product introductions into the world economy with no macro-level inventory changes being needed. They indicate some of the new economic and accounting approaches that are needed to provide improved measures for performance evaluation, such as activity based costing and activity based management (21,22).

Although information technology does indeed potentially support improvement of the designs of existing organizations and systems, it is also enables the creation of fundamentally new ones, such as virtual corporations and major expansions of organizational intelligence and knowledge. It does so not only by allowing for interactivity in working with clients to satisfy present needs, but also through proactivity in planning and plan execution. An ideal organizational knowledge strategy accounts for future technological, organizational, and human concerns, to support the graceful evolution of products and services that aid clients. Today, we realize that human and organizational considerations are vital to the success of information technology.

This is clearly the network age of information and knowledge. One of the major challenges we face today is that of capturing value in the network age (23). Associated with these changes are a wide range of new organizational models. Distributed collaboration across organizations and time zones is becoming increasingly common. The motivation for such collaboration is the desire to access sources of knowledge and skills not usually available in one place. The result of such new developments in information technology as network computing, open systems architectures, and major new software advances has been a paradigm shift that has prompted the reengineering of organizations; the development of high-performance business teams, integrated organizations, and extended virtual enterprises (24); the emergence of loosely-structured organizations (25) and has enabled the United States to regain the productive edge (26) that it once had but lost in the 1980s and early 1990s.

INFORMATION TECHNOLOGY CHALLENGES

There are a number of substantial challenges associated with use of information technology in terms of enhancing the productive efforts of an individual, a group, and an organization. Many of these are challenges that affect managing both people and knowledge. The command-and-control model of leadership is a poor fit for managing organizations where the participants are not bound to the organization by traditional incentive and reward systems (27). A collaborative effort has to continue to make sense and to provide value to participants for it to be sustained. Otherwise, knowledge and skills are quite portable and the loss of knowledgeable workers is a major potential downside risk for organizations today.

There are three keys to organizations prospering in this type of environment: (1) speed, (2) flexibility, and (3) discretion (25). Speed means understanding a situation (e.g., a market opportunity), formulating a plan for pursuing this opportunity (e.g., a joint venture for a new product), and executing this plan (e.g., product available in stores) quickly, in this case all within a few weeks at most. The need for flexibility is obvious; otherwise, there would not be any advantage to speed. However, flexibility is also crucial for reconfiguring and redesigning organizations, and consequently reallocating resources. Functional walls must be quite portable, if they exist at all.

Discretion is what transforms flexibility into speed. Distributed organizations must be free to act. While they may have to conform to established protocols, or play by the rules of the game—at least the rules of the moment—they need to be able to avoid having to wait unnecessarily for permission to proceed. Similarly, they need to be able to alter courses of action, or pull the plug, when things are not working. In this way, resources are deployed quickly and results are monitored just as quickly. Resource investments that are not paying off in the expected time frame can be quickly redeployed elsewhere.

A major determinant of these organizational abilities is the extent to which an organization possesses intellectual capital, or knowledge capital, such that it can create and use innovative ideas to produce productive results (28–30) and the ability to manage in a time of great change (31). We would add communications, collaboration, and courage to the formulation of Ulrick (32) representing intellectual capital to yield:

$$\begin{aligned}\text{Intellectual capital} = {} & \text{Competence} \times \text{Commitment} \\ & \times \text{Communications} \times \text{Collaboration} \\ & \times \text{Courage}\end{aligned}$$

What matters very much today is the ability to make sense of market and technology trends, to quickly decide how to take advantage of these trends, and to act faster than competitors, or other players. Sustaining competitive advantage requires redefining market-driven value propositions and quickly leading in providing value in appropriate new ways. Accomplishing this in an increasingly information-rich environment is a major challenge, both for organizations experiencing these environments and for those who devise and provide systems engineering and management methods and tools for supporting these new ways of doing business. Thus we see that the network age of information and knowledge is an integrated age in which the mutually reinforcing influences of information technology, organizations, and people have led to major challenges and major opportunities in which the new integrated system takes on global proportions.

A key issue now is how systems engineering and management can support business, government, and academia to address these major issues associated with productive use of information technology innovations in a successful manner. The remainder of this article discusses ten challenges, discussed in more depth in Ref. (33), that this integrative discipline must pursue and resolve if we are to support continued progress through information technology. Addressing these challenges will require much continued effort.

1. *Systems Modeling*
   Our methods and tools for modeling, optimization, and control depend heavily on exploiting problem structure. However, for loosely structured systems, behavior does not emerge from fixed structures. Instead, structure emerges from collective behaviors of agents. The distributed, collaborative, and virtual organizations that information technology enables are such that the system elements are quite fluid. Distinctions between what is inside and outside the system depend on time-varying behaviors and consequences. Satisfying this need will significantly challenge typical modeling methods and tools.
2. *Emergent and Complex Phenomena*
   Meeting this modeling challenge is complicated by the fact that not all critical phenomena cannot be fully understood, or even anticipated, based on analysis of the decomposed elements of the overall system. Complexity not only arises from there being many elements of the system, but also from the possibility of collective behaviors that even the participants in the system could not have anticipated (34). An excellent example is the process of technological innovation. Despite the focused intentions and immense efforts of the plethora of inventors and investors attracted by new technologies, the ultimate market success of these technologies almost always is other than what these people expect (35) and new technologies often cause great firms to fail (36). In other words, many critical phenomena can only be studied once they emerge and the only way to identify such phenomena is to let them happen, or to create ways to recognize the emergence of unanticipated phenomena through modeling and simulation. An important emergent phenomena is that of path dependence (37). The essence of this phenomenon begins with a supposedly minor advantage or inconsequential head start in the marketplace for some technology, product, or

standard. This minor advantage can have important and irreversible influences on the ultimate market allocation of resources even if market participants make voluntary decisions and attempt to maximize their individual benefits. One of the potential characteristics of information technology products, especially software, is that of increasing returns to scale. Also, there may be a network effect, or "network externality," which occurs because the value of a product for an individual consumer may increase with increased adoption of that product by other consumers and this, in turn, raises the potential value for additional users. An example is the telephone, which is only useful if at least one other person has one, and for which the utility of the product becomes increasingly higher as the number of potential users increases. These are major issues concerning information technology today and are at the heart of the concern in the late 1990s with respect to the Windows operating system and Internet Explorer, each from Microsoft.

3. *Uncertainties and Control*
   Information technology enables systems in which the interactions of many loosely structured elements can produce unpredictable and uncertain responses that may be difficult to control. The challenge is to understand such systems at a higher level and success in doing this may depend much more on efficient experimentation and simulation than on mathematical optimization due to the inherent complexities that are involved.
4. *Access and Utilization of Information and Knowledge*
   Information access and utilization, as well as management of the knowledge resulting from this process, are complicated in a world with high levels of connectivity and a wealth of data, information, and knowledge. Ubiquitous networks and data warehouses are touted as the information technology based means to taking advantage of this situation. However, providers of such "IT solutions" seldom address the basic issue of what information users really need, how this information should be processed and presented, and how it should be subsumed into knowledge that reflects context and experiential awareness of related issues. The result is an effort to obtain massive amounts of data and information, and associated large investments in information technology with negligible improvements of productivity (38). One of the major needs in this regard is for organizations to develop the capacity to become learning organizations (39,40) and to support bilateral transformations between tacit and explicit knowledge (41). Addressing these dilemmas should begin with the recognition that information is only a means to gaining knowledge and that information must be associated with the contingency task structure to become knowledge. This knowledge is the source of desired advantages in the marketplace or versus adversaries. Thus understanding and supporting the transformations from information to knowledge to advantage are central challenges to enhancing information access and utilization in organizations. This requires the contingency task structure of experiential familiarity with previous situations and understanding the environmental context for the present situation.
5. *Information and Knowledge Requirements*
   Beyond adopting a knowledge management perspective, one must deal with the tremendous challenge of specifying information requirements in a highly information-rich environment. Users can have access to virtually any information they want through modern information technology, regardless of whether they know what to do with it or how to utilize the information as knowledge. While information technology has evolved quite rapidly in recent decades, human information processing abilities have not evolved significantly (8). These limited abilities become bottlenecks as users attempt to digest the wealth of information they have requested. The result is sluggish and hesitant decision making, in a sense due to being overinformed.
6. *Information and Knowledge Support Systems*
   Information technology based support systems, including decision support and expert systems, can potentially provide the means to help users cope with information-rich environments. However, these support systems are difficult to define, develop, and deploy in today's highly networked and loosely structured organizations due to inherently less well-defined contexts and associated tasks and decisions. Effective definition, development, deployment, and use of these systems are also complicated by continually evolving information sources and organizational needs to respond to new opportunities and threats. In part, these difficulties can be overcome by adopting a human-centered approach to information and knowledge support system design (42,43). This approach begins with understanding the goals, needs, and preferences of system users and other stakeholders—for example, system maintainers. This approach focuses on stakeholders' abilities, limitations, and preferences, and attempts to synthesize solutions that enhance abilities, overcome limitations, and foster acceptance. From this perspective, information technology and alternative sources of information and knowledge are enablers rather than ends in themselves.
7. *Inductive Reasoning*
   Prior to the development of agent-based simulation models and complexity theory, most studies involved use of linear models and assumed time-invariant processes (i.e., ergodicity). Most studies also assumed that humans use deductive reasoning and techno-economic rationality to reach conclusions. But information imperfections and limits on available time often suggest that rationality must be bounded. Other forms of rationality and inductive reasoning are necessary. We interpret knowledge in terms of context and experience by sensing situations and

recognizing patterns. We recognize features similar to previously recognized situations. We simplify the problem by using these to construct internal models, hypotheses, or schemata to use on a temporary basis. We attempt simplified deductions based on these hypotheses and act accordingly. Feedback of results from these interactions enables us to learn more about the environment and the nature of the task at hand. We revise our hypotheses, reinforcing appropriate ones and discarding poor ones. This use of simplified models is a central part of inductive behavior (44).

8. *Learning Organizations*
Realizing the full value of the information obtained from an IT system, and the ability to interpret this as knowledge is strongly related to an organization's abilities to learn and its ability to become a learning organization. Learning involves the use of observations of the relationships between activities and outcomes, often obtained in an experiential manner, to improve behavior through the incorporation of appropriate changes in processes and products. Two types of organizational learning are defined by Argyris and Schon (40). Single-loop learning is learning which does not question the fundamental objectives or actions of an organization. It enables the use of present policies to achieve present objectives. The organization may well improve but this will be with respect to the current way of doing things. Organizational purpose, and perhaps even process, are seldom questioned. Often, they need to be. Double-loop learning involves identification of potential changes in organizational goals and approaches to inquiry that allow confrontation with and resolution of conflicts, rather than continued pursuit of incompatible objectives which usually leads to increased conflict. Double-loop learning is the result of organizational inquiry which resolves incompatible organizational objectives through the setting of new priorities and objectives. New understanding is developed which results in updated cognitive maps and scripts of organizational behavior. Studies show that poorly performing organizations learn primarily on the basis of single-loop learning and rarely engage in double-loop learning in which the underlying organizational purposes and objectives are questioned. Peter Senge (39) has discussed extensively the nature of learning organizations. He describes learning organizations as "organizations where people continually expand their capacity to create the results they truly desire, where new and expansive patterns of thinking are nurtured, where collective aspiration is set free, and where people are continually learning how to learn together." Five component technologies, or disciplines, enable this type of learning: (1) systems thinking; (2) personal mastery through proficiency and commitment to lifelong learning; (3) shared mental models of the organization markets, and competitors; (4) shared vision for the future of the organization; and (5) team learning. Systems thinking is denoted as the "fifth discipline." It is the catalyst and cornerstone of the learning organization that enables success through the other four dimensions. Lack of organizational capacity in any of these disciplines is called a learning disability. It is important to emphasize that the extended discussion of learning organizations in this section is central to understanding how to create organizations that can gain full benefits of information technology and knowledge management. This is crucial if we are to transform data to information to insights to meaningful and effective programs of action.

9. *Planning*
Dealing successfully with the above challenges requires that approaches to planning and its effect on the other systems life cycles be reconsidered. Traditionally, planning is an activity that occurs before engineering production and before systems are placed into operation. However, for loosely structured systems, systems planning must be transformed to something done in an interactive and integrative manner that considers each of the other life-cycles.

10. *Measurement and Evaluation*
Successfully addressing and resolving the many issues associated with the information technology challenges described in this article requires that a variety of measurement challenges be understood and resolved. Systems associated with access and utilization of information, and knowledge management, present particular measurement difficulties because the ways in which information and knowledge affect behaviors are often rather indirect. For this and a variety of related reasons, it can be quite difficult to evaluate the impact of information technology and knowledge management. Numerous studies have failed to identify measurable productivity improvements as the result of investments in these technologies. The difficulty is that the impact of information and knowledge is not usually directly related to numbers of products sold, manufactured, or shipped. Successful measurement requires understanding the often extended causal chain from information to knowledge to actions and results. Transformations from information to knowledge also present measurement problems. Information about the physical properties of a phenomena are usually constant across applications. In contrast, knowledge about the context-specific implications of these properties depends on human intentions relative to these implications. Consequently, the ways in which information is best transformed to knowledge depends on the intentions of the humans involved. The overall measurement problem involves inferring—or otherwise determining—the intentions of users of information technology based systems, both products and processes.

CONCLUSION

Ongoing trends in information technology and knowledge management pose substantial challenges for electrical and electronics engineering as implementation technologies enable enhanced physical system capabilities. Addressing the ten key challenges elaborated here requires utilizing many of concepts, principles, methods, and tools discussed elsewhere in this encyclopedia, especially those associated with systems engineering and management. In addition, it requires a new, broader perspective on the nature of information access and utilization, as well as knowledge management. Despite these challenges, there are many potential applications of information technology. Such studies as that on integrated manufacturing (45) and the role of information technology in conflict situations (46) are continually appearing. That this subject is a most relevant one for electrical engineering today can hardly be overemphasized.

KERNEL

The kernel is the subset of an operating system's functions that must be executed in privileged or supervisor mode, so that they might properly protect users and allocate resources among them. The privileged mode gives those programs unrestricted memory access and the right to executive sensitive instructions. Kernel functions typically include:

1. **Basic Input/Output System (BIOS).** Routines giving a process access to the essential I/O devices connected to the system—the display, keyboard, mouse, hard disks, and network. BIOS starts those devices and responds to their interrupts when they are done.
2. **Interrupt Management.** Routines for transferring the processor to a high priority task shortly after a signal indicates the need for the task. The names of interrupt handling routines are in an "interrupt vector." The actual routines are elsewhere; for example, the page fault handler is part of the memory manager (see below), and the network packet received handler is part of the interprocess communication manager (see below).
3. **Process Management.** Routines for switching processors among processes; using the clock interrupt for round-robin scheduling; sending semaphore signals among processes; creating and removing processes; and controlling entry to supervisor state.
4. **Memory Management.** Routines for mapping virtual to real addresses; transferring pages between main memory and secondary memory; controlling multiprogramming load; and handling page fault and protection violations.
5. **Interprocess Communication.** Routines for opening and closing connections between processes; transferring data over open connections; handling network protocols and routing; and processing name service.
6. **Security.** Routines for enforcing the access and information-flow control policies of the system, changing protection domains, and encapsulating programs.

The kernels of early operating systems were constrained by memory limitations to be small. MIT's Compatible Time Sharing System (1960) had a total of 256 kilobytes of main memory, of which half was allocated to the kernel. Early Unix systems (1972) also had small kernels. By the early 1980s, system such as Berkeley Unix grew their kernels to take advantage of larger main memory. However, large kernels were more error prone, less secure, and slow.

Operating systems designers introduced the microkernel as a way to minimize the operating system code that had to be main-memory resident and operate in supervisor mode. Only the bare essentials were included; all other routines were executed outside the kernel in the user's memory space. For example, a device driver can be executed in user mode; only the instructions that invoke it and receive its interrupts are privileged. Also, file access control lists are stored in the file system; the microkernel security manager simply verifies that a requested access is permitted by the access list. This strategy has led to very efficient, fast, and compact microkernels for many operating systems.

M

MONITOR

The term *monitor* denotes a control program that oversees the allocation of resources among a set of user programs. Along with *supervisor* and *executive*, it was an early synonym for operating system. An old example was the Fortran Monitor System (FMS), which appeared on the IBM 709 series beginning in the late 1950s to provide run-time support for Fortran programs. A later example was the Conversational Monitor System (CMS), a single-user interactive system that ran on a virtual machine within the IBM VM/370. Beginning in the early 1970s, the term *monitor* was slowly dissociated from operating systems and associated with object-class managers. The first such use was in secure operating systems: The *reference monitor* was an object-class manager that enforced an access policy among the users of those objects (1).

In 1974, Hoare (2) proposed programming language structures that simplified operating systems by providing a separate scheduler for each class of resources. The monitor maintains records of queues and resource states, and it gives external processes access through a high-level interface consisting of monitor procedures (today called methods). As with abstract data types, the monitor's methods restrict the caller to a few well-defined operations on the monitor's resources, hiding most details. Unlike abstract data types, monitors have internal locks that permit only one process to execute monitor instructions at a time, thereby permitting concurrent operations on the objects. Other processes must wait in a queue to enter the monitor. If a process in the monitor stops to wait for a resource to become available, the monitor must be unlocked so that another process (notably one that will release the desired resource) can gain access.

An example of a resource monitor is given below in Java, a modern language that supports the concept. With this monitor, a process can request that it be allocated a unit from a pool of resources; it can use that unit exclusively for a period of time, and then release it back to the pool. To set this up, a programmer includes these statements to declare a monitor for printers and to initialize it with a vector containing the names of all available printers:

```
ResourceMonitor printers;
printers = new ResourceMonitor(...);
```

Thereafter, the programmer can cause a thread (process) to acquire, use, and release a printer with this pattern:

```
myPrinter = printers.acquire();
  ...
  (use of printer)
  ...
  printers.release(myPrinter);
```

The Java code for the resource monitor is as follows:

```
class ResourceMonitor{
   Vector pool;
   /* initialization */
    ResourceMonitor(Vector initialResources){
        pool = initialResources;
    }
   /* acquire an available resource; wait if none
     available */
    public synchronized Object acquire(){
        Object out;
        while (pool.isEmpty()) wait();
        out = pool.firstElement();
        pool.removeElement(out);
        return out;
    }
   /* return a resource to the pool */
    public synchronized void release(Object in){
        pool.addElement(in);
        notify();
    }
   }
```

The methods `acquire()` and `release()` are declared as *public*, meaning that any process can call them, and *synchronized*, meaning that they are executed atomically. This implements the central feature of a monitor, which is that the operations are mutually exclusive and that their component steps cannot be interleaved. This feature is implemented by locks inserted by the compiler.

The Java operation `wait()` suspends the calling thread (process), releases the mutual exclusion lock on the methods (acquire, release), and records the process identifier in a waiting queue; `notify()` signals one of those. The signaled thread is removed from the queue and resumes its operation after relocking the monitor. Note that in this example, the call to `wait()` appears in a loop; it is possible that the thread may find the pool empty by the time it reenters the monitor; in which case, it will call `wait()` again. This can occur if another thread overtakes the signaled one.

Monitors are also useful in structuring distributed systems. The monitor operations can be called via remote procedure calls (RPCs). Most RPC mechanisms have built-in error controls to guard against lost messages; a lost message could cause a deadlock when a thread called the release method but the monitor did not receive the release message.

A monitor callable via RPC must be organized to avoid deadlock when network connections fail. When a remote call message arrives at the monitor, the method to be executed is given to a "proxy thread" running on the server housing the monitor. Meanwhile, the client application thread that issued the RPC is suspended on its host computer until

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

the proxy thread completes and returns the result. Even if the connection or the caller's host crashes, the proxy thread will complete and unlock the monitor, allowing other threads on other computers to call the monitor.

The programmer of the application that called the remote monitor sees some complications. They originate from the dynamic bindings between the programmer's computer and the server housing the monitor. The complications show up as new exceptions from the RPC system—e.g., unknown host, failed or hung connection, parameter marshaling error, no such remote procedure, no such object, and no response within the time-out period. The responses to these exceptions will depend on the application.

OVERHEAD

Overhead in computer systems is like overhead in organizations—shared functions that benefit everyone but that cannot be conveniently associated with any one activity. In organizations, rent, furnishings, electricity, telephones, utilities, supplies, auditing, accounting, general clerical support, and management are counted as overhead. In computer systems, allocation of resources, scheduling, conflict resolution, error correction, exceptional conditions, protection, security, performance monitoring, auditing, accounting, input–output control, caching, distributed functions, and network protocols are all counted as overhead. As in organizations, excessive overhead diminishes capacity and increases cost without increasing productivity. Overhead in computer systems manifests as slower processing, less memory, less network bandwidth, or bigger latencies than expected.

Overhead is not always easy to measure. The time an operating system spends in supervisor state is not pure overhead because many important operations requested by user tasks are implemented as system functions that run in supervisor state, for example, input–output, file operations, and message-passing. A measurement that an operating system spends 80% of its time in supervisor state does not mean that the system spends only 20% of its time doing useful work: We need to know what portion of the 80% is spent responding to requests from user tasks. Moreover, many operating systems use special coprocessors to perform important overhead tasks such as authentication, virtual memory control, external communications, or peripheral device management; these coprocessors do not diminish processor capacity, memory capacity, or bandwidth available to user tasks. When coprocessors perform system functions, a measurement that a processor spends 90% of the time running user tasks does not mean that overhead is low.

Listed below are the main functions that usually count as overhead. Each one has a cost in processing time, memory space, network bandwidth, and latency (response time).

Allocation of Resources. Many resources such as CPU cycles, disk sectors, main-memory page frames, local-network packet slots, and shared files can be used by only one task at a time. To prevent conflicts and deadlocks, operating systems implement schedulers for these resources. The time spent running a scheduler and the memory occupied by a scheduler's queues count as overhead.

Error Correction. Data are stored and transmitted with redundant bits that permit detecting and correcting errors. These bits consume some space and bandwidth.

Exceptional Conditions. Most system functions have normal and error returns; the instructions that test for and respond to errors consume some space and processing time. Examples are arithmetic contingencies, data transmission failures, addressing snags, and illegal actions.

Protection and Security. Monitors, firewalls, authenticators, backup systems, virus detectors, and other means of securing systems against unauthorized use, denial of service, and intruders are necessary but often expensive.

Performance Monitoring, Auditing and Accounting. Recording key actions and events, logging each task's usage of resources, figuring costs and billings to users of the system, and generating statistics on resource usage and performance cost.

Input–Output Control. Many I/O operations are easy to specify at the user level—for example, open or read a file. But the device spoolers and drivers can be complex because they must queue up requests from multiple tasks, translate each request into the low-level instruction sets of the devices, automatically work around known problems such as bad disk sectors, and handle interrupt conditions from their devices.

Caching. The speed of operations on secondary storage devices or remote servers can often be significantly improved by keeping a copy of the data in a local memory. Microcomputer register-windows, virtual memories, disk drivers, open-file managers, network browsers, and Internet edge servers are among the many prominent examples of caching. Caching consumes memory and processing time to locate and load copies of items into the cache and to maintain consistency with the originals.

Distributed Functions. Modern operating systems distribute their functions transparently over a collection of servers and workstations connected by a high-speed local network. Examples are file servers, printing servers, compute servers, authentication servers, and workstations. Maintaining the appearance that files, printers, processors, and login-sites are location independent significantly improves usability but is not cheap.

Network Protocols. Protocols for opening connections, transferring data, obtaining encryption keys, routing, and authenticating access all cost processing time, memory, and bandwidth.

Mainframe operating systems often charge users for processor, memory, and disk usage. In these systems, overhead will be charged back to users as percentage increases in each of these components. In personal computer networks and time-shared research computing systems, users are not charged for resource usage or overhead.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

Overhead detracts from system performance only to the extent that the overhead functions do not add to the productivity of user tasks. Many services are provided by the system to relieve programmers from having to provide these functions themselves or to prevent expensive breakdowns. As long as the system can provide these functions more efficiently than its users, the resulting increases in overhead are offset by better service, improved performance, and lower overall costs.

QUALITY IN COMPUTER SCIENCE AND COMPUTER ENGINEERING EDUCATION

INTRODUCTION

Any attempt to define the concept of quality, as it exists in higher education, tends to reveal the fact that in some sense it is elusive; on the other hand, "you know it when you see it". In his article, Peter Knight (1) articulates some of the dilemmas such as efficiency or effectiveness, emphasis on measurement or emphasis on process, and well-specified procedures or well-rehearsed goals. In some sense, one must achieve a proper balance. Of necessity, students themselves must be active, engaged, with and committed to the educational process. Given the current recognition of the phenomenon of the globalization of the workforce, it is very important for students to be competitive in the international workplace by the time they graduate.

The approaches to quality are many and varied, with different mechanisms and approaches. In turn these approaches produce different emphases, and inevitably, these tend to condition the behavior of those involved. Invariably, the mechanisms should place an emphasis on improvement or enhancement, although judgements inevitably have some role when it comes to assessing quality either through accreditation or through some other process.

The purpose of this article is to focus on the quality issues within computer science and computer engineering degree programs. In some countries, program quality is fostered through an accreditation process, whereas in others, slightly different approaches are employed. Here we attempt to span that spectrum.

THE CONCEPT OF QUALITY

Many definitions of the term *quality* exist as it applies in the context of higher education. Even in the context of individual programs of study, Different ways exist to define in the concept. In the United Kingdom, for instance, many different interpretations exist. Earlier definitions proved excessively complex to manage and to operate. A relatively recent document outlines certain principles that auditors should use during the review of programs of study (see Ref. 2). In this document, only seven aspects are most important, which include the following:

1. Aims and outcomes. What are the intended learning outcomes of the program and how were these obtained (e.g., from guidance from benchmarking standards, professional body requirements, local needs)? How do these out comes relate to the overall aims of the provision? Are staff and students familiar with these outcomes?
2. Curricula. Does the design and content of the curriculum encourage achievement of the full range of learning outcomes? Do modern approaches to learning and teaching by current developments and scholarship influence the discipline?
3. Assessment. Does the assessment process enable students to demonstrate acquisition of the full range of intended learning objectives? Does criteria exist to define different levels of achievement? Are full security and integrity associated with the assessment processes? Does the program require formative as well as summative assessment? Does the program meet benchmarking standards?
4. Enhancement. Does the program use an activity that seeks to improve standards regularly, (e.g., via internal or external reviews, appropriate communication with the external examiner(s), accreditation activity) and how deep and thorough is that activity? Are data analyzed regularly and are appropriate actions taken?
5. Teaching and learning. Are the breadth, depth, and challenge of the teaching of the full range of skills as well as the pace of teaching appropriate? Does the program implement a suitable variety of appropriate methods? If so, do these methods truly engage and motivate the students? Are the learning materials of high quality? Are the students participating in learning?
6. Student progression. Does the program have an appropriate strategy for academic support? Is admissions information clear and does it reflect the course of study faithfully? Are supervision arrangements in place? Do students receive appropriate induction throughout their course?
7. Learning resources. Are the teaching staff appropriately qualified to teach the given program of study and do they have the opportunity to keep teaching materials as well as their competences up-to-date? is effective support provided in laboratories and for practical activity? How does the institution use resources for the purposes of learning? Is the student working space attractive and is the general atmosphere in the department conducive to learning?

PARTICULAR APPROACHES

The U.S. Situation—ABET and CC2001

Within the United States, ABET, Inc. (formerly known as the Accreditation Board for Engineering and Technology, established in 1932) undertakes accreditation in the field of applied sciences, computing, engineering, and technology. In this capacity, it undertakes the accreditation of individual programs of study. It recognizes accreditation that is a process whereby programs are scrutinized to ascertain whether they meet quality standards estab-

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

lished by the professions. The view is that accreditation benefits:

- Students who choose programs of study with careers in mind
- Employers to enable them to recognize graduates who will meet these standards
- Institutions that are provided with feedback and even guidance on their courses.

Within ABET, CSAB, Inc. (formerly known as the Computing Sciences Accreditation Board) is a *participating body* and it is the lead society to represent programs in computer science, information systems, software engineering, and information technology. It is also a cooperating society (with the IEEE as the lead society) that represents programs in computer engineering. However, within ABET, its computing accrediting commission (CAC) is responsible to conduct the accreditation process for programs in computer science, information systems, and information technology. engineering accreditation commission (EAC) is responsible for the accreditation of programs in software engineering and in computer engineering.

Criteria for Accrediting Computer Science Programs. The ABET criteria for computer science programs may be found in Ref. 3. What follows is based directly on that publication.

Each program of study will possess some published overall set of objectives that aim to capture the philosophy of the program. Typically, these objective might address now students are prepare for a variety of possible careers in computer science or possible advanced study in that field.

A program of study, as defined by the individual modules, must be consistent with these objectives. Beyond this, the program requires additional elements phrased in terms of a general component, a technical computer science component, a mathematics and science component, and a component that addresses additional areas of study. The requirements themselves stipulate minimum times to devote to particular areas and issues that rate to content.

To quantify the time element, a typical academic year consists of two semester terms (though three quarter terms are also possible). A semester consists of 15 weeks and one semester hour is equivalent to meeting a class for 50 minutes one time a week for 15 weeks; that is, it is equivalent to 750 minutes of class time during a semester. Students take courses minimally worth 30 semester hours per year for four years; this is equivalent to 120 semester hours for a baccalaureate degree.

General Component. The general component of the accreditation criteria stipulates that a degree in computer science must contain at least 40 semester hours of appropriate and up-to-date topics in computer science. In addition, the degree program must contain 30 semester hours of mathematics and science, 30 hours of study in the humanities, social sciences, and the arts to provide a broadening education.

Computer Science Component. Specifically, the study of computer science must include a broad-based core of computer science topics and should have at least 16 semester hours; the program should have at least 16 hours of advanced material that builds on that core. Core material must cover algorithms, data structures, software design, concepts in programming languages, and computer architecture and organization. The program must stress theoretical considerations and an ethos of problem solving and design must exist. In addition, students require exposure to a variety of programming languages and systems and they must become proficient in at least one high-level programming language.

Mathematics and Science Component. The program must contain at least 15 semester hours of mathematics; the mathematical content must include discrete mathematics, differential and integral calculus, as well as probability and statistics. In addition, the program must contain at least 12 semester hours of science to include an appropriate two-semester sequence of a science course.

Additional Areas of Study. Oral and written communication skills must be well developed and be applied throughout the program. Additionally, students must be knowledgeable about legal, ethical, and professional issues. Beyond these matters of a technical nature, the program is also required to have laboratories and general facilities of a high standard; moreover, the institution must have sufficient resources (interpreted in the broadest sense) to provide a good environment that is aligned with the objectives of the program.

Criteria for Accrediting Computer Engineering Programs. The ABET criteria for computer engineering programs can be found in Ref. 4. What follows is based directly on that publication.

The criteria here take a different form from those outlined above for computer science; they are phrased in terms of general criteria that are applicable to all engineering programs followed by criteria that are specific to computer engineering. Thus, the general criteria mention students, program educational objectives, associated outcomes and assessment, and a professional component. We now describe these four areas.

Students. The quality and performance of students is an important measure of the health of the program. Of course, appropriate advice and guidance must be available to enhance that quality. Mechanisms must be in place to ensure that all students meet the stated learning objectives of the program. Firther more, it is imperative that institutions not only have policies to accept students from elsewhere (and recognizing credit gained) but also to validate courses taken in other institutions.

Program Educational Objectives. The criteria indicate that detailed published objectives (validated and reviewed at regular intervals) must exist for each program of study and these objectives must be consistent with the mission of the institution. The educational programs must provide classes whose successful completion implies that the broad program meets its aims and objectives.

Program Outcomes and Assessment. This aspect of the criteria relates to the expected profile of a student when program of study is completed successfully. Thus, successful completion of the individual classes should produce a graduate who possesses a range of skill or attributes. These attributes include appropriate knowledge and skills, the ability to design and conduct experiments, the ability to work in multi-disciplinary teams, the ability to communicate effectively, the understanding of professional and ethical issues, and the ability to apply their skills to undertake effective engineering practice.

Professional Component. This aspect relates to the inclusion of one year of a combination of mathematics and basic science, one and a half years of relevant engineering topics, and a general education program that complements the technical aspects of the program.

Additional Criteria. Beyond the previous criteria, additional requirements exist concerning the setting in which the program is based. Thus, the teaching staff must have an appropriate background, the facilities must be of high quality, and the institution must have the general resources to provide an environment in which successful and fruitful study can take place.

The specific computer engineering criteria include the requirement that the program should exhibit both the breadth and depth across a range of engineering topics in the area of the program of study. This range must include knowledge of probability and statistics, mathematics, including the integral and differential calculus, computer science, and the relevant engineering sciences needed to design and develop complex devices.

Computing Curricula 2001. Within the ABET criteria, core, advanced topics, and so on are mentioned. To provide a meaning for these terms, several professional societies, such as the ACM and the IEEE Computer Society, have worked together to produce curriculum guidance that includes mention of these terms.

We refer to this recent guidance as *Computing Curricula 2001* (or CC 2001 for short). Earlier documents were published as single volumes and they tended to focus on computer science programs. The expansion in the field of computing resulted in an effort to culminate the publishing of five volumes that cover computer science, information systems, computer engineering, software engineering, as well as information technology (see Refs. 5–8). A sixth volume is intended to provide an overview of the entire field (see Ref. 9). These references should provide up-to-date guidance on curriculum development and extends to detailed outlines for particular programs of study and classes within these programs. The intent is that these works will receive updates at regular intervals (e.g., perhaps every five years) to provide the community with up-to-date information and advice on these matters.

The System in the United Kingdom

In the United Kingdom, the *benchmarking standards* capture important aspects of the quality of programs of study in individual disciplines. Representative groups from the individual subject communities have developed these standards. In the context of computing, the relevant document (included in Ref. 10) the Quality Assurance Agency (the government body with general responsibility for quality in higher education is published in the united kingdom by). This document also forms the basis for the accreditation of computing programs in the United Kingdom, an activity to ensure that institutions provide within their courses the basic elements or foundations for professionalism.

The benchmarking document in computing is a very general outline in the sense that it must accommodate a wide range of existing degree programs; at the time of its development, an important consideration was that it had not to stifle, but rather facilitate, the development of new degree programs. The approach adopted was not to be dogmatic about content but to place a duty on institutions to explain how they met certain requirements.

The benchmarking document contains a set of requirements that must be met by all honors degrees in computing offered by U.K. institutions of higher education. This document defines minimal criteria for the award of an honors degree, but it also addresses the criteria expected from an average honors student; in addition, it indicates that criteria should exist to challenge the higher achieving students (e.g., the top 10%) and it provides guidance on possible programs.

The benchmarking document addresses knowledge and understanding, cognitive skills, and practical and transferable skills; it views professional, legal, and ethical issues as important. It recognizes these aspects as interrelated delicately but intimately. Several aspects of the requirements contained within the benchmarking document require mentioning these because indicate requirements fundamental thinking.

First, all degree programs should include some theory that acts as underpinning and institutions are required to defend their position on this matter. The theory need not be mathematical (e.g., it might be based on psychology), but it will serve to identify the fundamentals on which the program of study is based. This requirement should guarantee some level of permanence to benefit the educational provision.

Furthermore, all degree programs must take students to the frontiers of the subject. Institutions must identify themes developed throughout the course of study, from the basics through to the frontiers of current knowledge. In addition, all students should undertake, usually in their final year, an activity that demonstrates an ability to tackle a challenging problem within their sphere of study and to solve this problem using the disciplines of the subject. The essence of this activity is to demonstrate an ability to take ideas from several classes or modules and explore their integration by solving a major problem.

Finally, from the point of view of the accreditation carried out by the British Computer Society (BCS), the standards impose some additional requirements beyond those of the benchmarking standard to allow for some specific interpretations. For instance, the major final year activity must be a practical problem-solving activity that involves implementation.

The Australian Approach

The Australian Universities Quality Agency, AUQA for short, has a key overarching role in relation to the quality in Australian Universities (and beyond). Its objectives that relate primarily to course accreditation appear in Ref. 11.

The objectives specify two main points. First, the need to arrange and to manage a system of periodic audits of the quality assurance arrangements of the activities of Australian universities, other self-accrediting institutions, and state and territory higher education accreditation bodies is specified. In addition, the domument sitpulates that institutions must monitor, review, analyze, and provide public reports on quality assurance arrangements in self-accrediting institutions, on processes and procedures of state and territory accreditation authorities, and on the impact of these processes on the quality of programs.

The AUQA places a great emphasis on the self-review carried out by each institution. This self review will use a set of internal quality processes, procedures, and practices that must be robust and effective, with an emphasis on improvement. These internal mechanisms should accommodate accreditation and other such activities carried out by professional bodies and must imply peer judgement.

The AUQA itself seeks to encourage improvement and enhancement through the publication of good practice, as well as providing advice, and where desirable, consultation. The possibility of inter-institutional discussion also exists.

The Swedish System

In 1995, the National Agency for Higher Education in Sweden initiated a set of quality audits of institutions of higher education. In this audit, institutions were required to produce a self-evaluation of their provision; to sustain a team visit of auditors; and to conduct meetings and discussions; After the visit, auditors would discuss their findings amongst themselves. Although this process had value, most have deemed it to be less than satisfactory because it failed to drill down to departmental activity (see Ref. 12).

In December 1999, the Swedish government passed a bill that placed the student at the very heart of quality and at the heart of developments in higher education. Since 2002, quality assessment activities would be conducted by the agency on a six-year cycle. The process would involve self-assessment, visits from peer review teams, and the publication of reports. Four main purposes in the new system (see Ref. 12) are as follows:

- Ensure that students are offered equivalent education of good quality, regardless of their home institution
- Ensure that assessments place a premium on improvement
- Provide both students and potential students with information regarding the quality of degree programs
- Allow stakeholders to make comparisons on the aspect of provision, which should include international comparisons

The new activity has improved the level of education greatly in Sweden.

ADDITIONAL OBSERVATIONS

Bloom's Taxonomy and Educational Objectives

The seminal work of Bloom et al. (13) has conditioned heavily current thinking on educational objectives. Since its publication in 1956, this area has attracted extensive interest. More recently, the preoccupation with standards of achievement and more general quality concerns have resulted in attempts to clarify and to reformulate the underlying principles. One such reference is Ref. 14, which forms the basis of the discussion here, see Table 1.

Table 1. The cognitive process dimension (from Ref. 14 with permission)

Process Categories	Definitions	Illustrations of Cognitive Processes
1. Remember	Retrieve knowledge from memory	Recognize, recall, define, describe, repeat
2. Understand	Construct meaning from	Interpret, give examples, place in already defined categories, summarize, infer, compare, explain, discuss, indicate, interpret, extrapolate
3. Apply	Perform a known procedure in a given situation	Execute, implement, illustrate, solve, demonstrate, measure
4. Analyze	Break material into constituent parts and determine the relationships between these parts and how they contribute to the whole	Discriminate, distinguish, organize, attribute, criticize, compare, contrast, examine, question, test
5. Evaluate	Make judgments based on criteria and on standards	Check, compare and contrast, critique, defend, estimate, judge, predict, select, assess, argue
6. Create	Put elements together to form a coherent and/or functional entity	Design, compose, construct, produce, plan, generate, innovate; introduce new classifications; introduce new procedures

The typical form of a learning objective is a verb (which implies an activity that provides evidence of learning and therefore enhanced behavior) applied to some area of knowledge. Txpically, The verbs capture what students must be able to do. The objective must imply the acquisition of cognitive skills such as the ability to carry out some activity, or the acquisition of some knowledge.

In its original formulation, Bloom's taxonomy paid little attention to the underlying knowledge. Yet, we can identify different types of knowledge. Within any discipline, of course, the community will classify knowledge as elementary and as advanced.

The Knowledge Dimension. We now recognize that different kinds of knowledge exist. In Ref. 14, four different kinds of knowledge are identified, and these are captured within Table 1.

The Cognitive Dimension. We base this on a set of levels that claim to identify key skills in an increasing order of difficulty. These skills have been refined over the years but again a recent version taken from Ref. 14 appears in Table 2.

Of course, one can apply learning objectives at different levels. For example, learning objectives can exist at the level of:

- A program of study—hence, program objectives
- A module or a class—hence, module or class objectives
- Some knowledge unit—hence, instructional objectives

These objectives range from the general to the particular. Their role and function are different at these levels. However, within a particular program of study, the attainment of the lower-level objectives should be consistent with, and indeed contribute to, the attainment of the higher-level objectives. A question is generated about consistency; that is, to determine whether the attainment of the lower-level learning objectives implies attainment of the higher-level objectives.

It is now widely recognized in higher education circles that these levels from Bloom's taxonomy are most effective when combined with levels of difficulty and the currency of the knowledge within the discipline.

Keeping Up-To-Date

Especially for the computing profession, keeping up-to-date is essentially an attitude of mind. It involves regular update of technical developments to ensure the maintenance of knowledge as well as skill levels at the forefront of developments. Doing this requires discipline and support. Where changes in attitude and/or changes of a fundamental kind are required, a period of intense study must take place.

Technological change can herald opportunities for creativity and innovation. This change can lead to advances that result in improvements such as greater efficiency, greater functionality, and greater reliability with enhanced products or even new products that emerge as a result. Novel devices and new ways of thinking are especially cherished.

Higher education must to prepare students for challenges and opportunities. We can achieve this through imaginative approaches to teaching as well as through imaginative assignments and projects. Promoting innovation and creativity is important in computing courses. The concept of a final-year project in the united kingdom—similar to a capstone project in U.S. parlance—is an important vehicle from this perspective. More generally, it provides the opportunity for students to demonstrate their ability to apply the disciplines and techniques of a program of study by solving a substantial problem. Such exercises should open up opportunities for the demonstration of novelty.

We can identify a number of basic strategies to ensure a stimulating and an up-to-date provision. First, the curriculum itself must be up-to-date, the equipment has to be up-to-date, and faculty need to engage in relevant scholarship. Teachers can highlight relevant references (textbooks, software, websites, case studies, illustrations, etc.) with the by

Table 2. The knowledge dimension (taken from Ref. 14 with permission)

Knowledge Types	Definitions	Knowledge Subtypes
Factual knowledge	Basic terminology and elements of the discipline	a) Terminology b) Specific details and elements
Conceptual knowledge	Inter-relationships among different elements of the discipline, structures and classifications, theories, and principles	a) Classifications and categories b) Principles and generalizations c) Theories, models, and structures
Procedural knowledge	Algorithms, methods, methodologies,techniques, skills, as well as methods of enquiry and processes	a) Subject-specific skills and algorithms b) Techniques and methods c) Criteria for selection of approach
Meta-cognitive knowledge	Knowledge of cognition in general and self-awareness in this regard	a) Strategic knowledge b) Knowledge about cognitive tasks, includinginfluences of context and constraints c) Self-knowledge

Table 3. (See Ref. 15)

Stage	Student	Instructor	Instructional Example
1	Dependent	Authority/coach	Lecturing, coaching
2	Interested	Motivator/guide	Inspirational lecture, discussion group
3	Involved	Facilitator	Discussion lead by instructor Who participates as equal
4	Self-directed	Consultant	Internships, dissertations, self-directed study group

identifying sources of up-to-date and interesting information. However, more fundamental considerations must be addressed.

We already mentioned that keeping up-to-date is essentially an attitude of mind. Institutions can foster this attitude by implementing new approaches to teaching and learning that continually question and challenge and by highlighting opportunities for advances. Teachers can challenge students by developing assessments and exercises that seek to explore new avenues. It is also essential to see learning as an aspect that merits attention throughout the curriculum. For instance, four stages are identified in Table 3 (15).

Basic Requirements of Assessment and Confidence Building

Certain basic requirements of assessment exist. Assessment must be fair and reliable, of course, and it should address the true learning objectives of the classes. In addition, however, appropriate assessment should be enjoyable and rewarding, but all too often institutions do not follow these geidelines.

Overall, numerous and different skills require assessment such as transferable skills, technical skills, and cognitive skills. An over-emphasis on assessment, however, can create an avalanche of anxiety and the normal trade-offs that are often "fun" become sacrificed, which makes the situation highly undesirable. Imaginative ways of assessing are needed and should be the subject of continual change and exploration whereby assessors can discover better and more enjoyable approaches.

Of course, self-assessment should be encouraged. This can take (at least) one of two forms, which depend on whether the student supplies the questions. However, where students formulate their own assessments, these tend to be useful at one level, but they tend not to challenge usefully or extend the horizons of individuals.

One of the important goals of higher education is to extend the horizons and the capabilities of students and to build up their confidence. That confidence should to be well-founded and based on what students have managed to accomplish and to achieve throughout their study. Accordingly, finding imaginative ways of assessing is important. Assessment should

- Seek to address a range of issues in terms of skills
- Build on the work of the class in a reasonable and meaningful manner
- Challenge students whose confidence is enhanced by successful completion of the work
- Extend the horizons of individuals
- Encourage attention to interesting and stimulating applications
- Address international issues of interest and relevance to the students and their future careers
- Encourage excellence through appropriate assessment guidance

As part of the preparation for such activity, students should understand what teachers expect of them and how they can achieve the higher, even the highest, grades.

CONCLUDING REMARKS

Ultimately, it is very important not to lose sight of the very real benefits gained when the teaching staff interacts with students. Thus, quality is what happens between students and the teachers of an institution. Often, aspects of bureaucracy can tend to mask this important observation, and metrics and heavy paperwork take over. Fundamentally, the quality of education is about:

- Teachers who have an interest in students have an interest in teaching well and in motivating their students so that they can be proud of their achievements, and they have an interest in their subject and its applications. This often means teachers will adapt to particular audiences without compromising important standards.
- Students who feel welcomed and integrated into the ways of their department, who enjoy learning, and whose ability to learn is developing so that the process becomes ever more efficient and effective find their studies stimulating and interesting, find the material of the program of study relevant and meeting their needs, and feel themselves developing and their confidence increasing.
- The provision of induction to give guidance on course options as well as guidance of what is expected in terms of achieving the highest standards in particular areas.
- An environment that is supportive with good levels of up-to-date equipment and resources, with case studies, and lecture material all being readily available to inform, stimulate, and motivate.

Q

QUEUEING NETWORKS*

A major airline has set up a computerized transaction system used by its ticket agents to sell seats on its aircraft. The airline has authorized 1000 agents around the country to make reservations from their workstations. A "disk farm"—a large collection of magnetic-disk storage devices—in New York contains all the records of flights, routes, and reservations. On average, each agent issues a transaction against this database once every 60 seconds. One disk contains a directory that is consulted during every transaction to locate other disks that contain the actual data; on average, each transaction accesses the directory disk 10 times. The directory disk takes an average of five milliseconds to service each request, and it is busy 80% of the time.

On the basis of this information, can we calculate the throughput and response time of this system? Can we find the bottlenecks? Can we say what happens to the response time if we reduce directory disk visits by half or doubled the number of agents?

These performance questions are typical. The answers help analysts decide whether a system can perform well under the load offered, and where to add capacity if it is too slow. Most people think that no meaningful answers can be given without detailed knowledge of the system structure—the locations and types of the agents' workstations, the communication bandwidth between each workstation and the disk farm, the number and types of disks in the farm, access patterns for the disks, local processors and random-access memory within the farm, the type of operating system, the types of transactions, and more. It may come as a surprise, therefore, that the first two questions—concerning throughput, response time, and bottlenecks—can be answered precisely from the information given. The second two questions—concerning effects of configuration changes—can be answered with reasonable estimates made from the information given and a few plausible assumptions.

These questions illustrate the two important types of performance questions: calculation and prediction. Calculation questions seek metrics in the same observation period where parameters were measured. Prediction questions provide metrics in a different (future) observation period from when parameters were measured.

OPERATIONAL LAWS

A computer network is composed of interconnected servers. Servers include workstations, disks, processors, databases, printers, displays, and any other devices that can carry out computational tasks. Each server receives and queues up messages from other servers that specify tasks for the server to carry out; a typical message might ask a server to run a computationally intensive program, to perform an input-output transaction, or to access a database. A transaction is a specified sequence of tasks submitted to the network; when a server completes a particular task, it deletes the request from its queue and sends a request to another server to perform the next task in the same transaction.

Measurements of servers are always made during a definite observation period. Basic measures typically include event counters and timers. These and other measures derived from them are called operational quantities. Invariant relations among operations quantities that hold in every observation period are called operational laws.

By counting outgoing messages and by measuring the time that a server's queue is nonempty, it is easy to measure the output rate X, the mean service time S, and the utilization U of a server. These three empirical quantities satisfy the relation $U = SX$, known as the utilization law (Fig. 1). Similarly, by measuring the "space-time" accumulated by queued tasks, it is easy to determine the mean queue length Q and the mean response time R: These quantities satisfy the relation $Q = RX$, which is known as Little's Law (Fig. 2).

The utilization law and Little's law are counterparts of well-known limit theorems for stochastic queueing systems in a steady state. These theorems will usually be verified in actual measurements, not because a steady state has been attained, but because the measured quantities obey the operational laws (1, 2).

The tasks that make up a transaction can be regarded as a sequence of visits by the transaction to the servers of the network. The average number of visits per transaction to a particular server i is called the visit ratio V_i for that server; the server's output rate X_i and the system's output rate X_0 satisfy the relation $X_i = V_i\mathrm{X}_0$, which is known as the forced-flow law (Fig. 3). This remarkable law shows that knowledge of the visit ratios and the output rate of any one server is sufficient to determine the output rates of every other server and of the system itself. Moreover, any two networks with the same visit ratios have the same flows, no matter what is the interconnection structure among their servers.

In a network, a server's output is a portion of another server's input or of the system's output. It simplifies an analysis to assume that the input and output flows of a server are identical—a condition known as flow balance. Strictly speaking, "throughput" refers to the rate of a flow-balanced server. The definitions do not imply flow balance. In most real systems, a bound is placed on the number of tasks that can be in the system at once; as long as the number of completions at every server is large

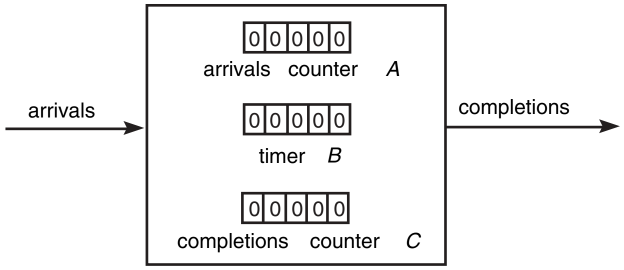

Figure 1. The task-processing server is the basic element of a network of computers. Over an observation period of length T, the counter A records the number of tasks that arrive at the server, the counter C records the number of tasks completed, and the timer B measures the total busy time (time when tasks are present). The utilization of the server is $U = B / T$, the output rate is $X = C / T$, and the mean service time per completed task is $S = B / C$. The identity $B/T = (C/T)(B/C)$ translates to the utilization law: $U = XS$. Because utilization cannot exceed 1, the output rate cannot exceed the saturation rate of $1/S$.

compared with this bound, the error introduced by assuming flow balance will be negligible. For this reason, flow balance does not generally introduce much error into the models.

When a network of servers receives all of its requests from a finite population of N users who each delay an average of Z seconds until submitting a new transaction, the response time for a request in the network satisfies the response-time formula $R = N/X_0 - Z$ (Fig. 4). This formula is exact for flow balance.

These formulas are sufficient to answer the throughput and response-time calculation questions posed earlier for the airline reservation network. We are given that each transaction generates an average of 10 directory-disk requests, and so $V_i = 10$ for the server represented by the directory disk. The mean service time at the directory disk is five milliseconds, so that $S_i = 0.005$ second. The directory disk's utilization is 80%: $U_i = 0.8$. Combining the forced-flow law and the utilization law, we have for total system throughput:

$$X_0 = U_i/V_iS_i = 0.8/(10^*0.005) = 16 \text{ transactions per second}$$

Thus, the entire airline reservation system is processing 57,600 transactions per hour. The response time experienced by any one of the 1000 agents is:

$$R = N/X_0 - Z = (1000/16) - 60 = 2.5 \text{ seconds.}$$

BOTTLENECKS

Every network has a bottleneck: A server that is slower than all the others and limits the overall throughput. Speeding up a bottleneck can yield a significant improvement in system throughput. Speeding up a nonbottleneck may hardly affect throughput. Our performance predictions will depend our knowledge of the bottlenecks.

Finding the bottleneck is easy. Suppose that the visit ratios and mean service times do not vary with N. Each server generates a potential bottleneck that would limit the system throughput to $1/V_iS_i$ and would give a lower bound to the response time of $NV_iS_i - Z$. Obviously, the server with the largest value of V_iS_i gives the tightest limit and is the real bottleneck. The products V_iS_i are sufficient to determine lower bounds on the response time as a function of N (Fig. 5).

The operational laws coupled with bottleneck analysis offer a simple but powerful method for performance analysis. For systems whose visit ratios and service times do not vary with overall load, the products V_iS_i—the total service time requirement for each server—are sufficient to answer these questions.

CHANGING THE CONFIGURATION

Consider the two prediction questions we asked at the beginning. They ask about the future effect of reducing directory-disk visit ratio or doubling the number of agents. The operational laws, which deal only with relations among quantities observed in a single measurement period, are

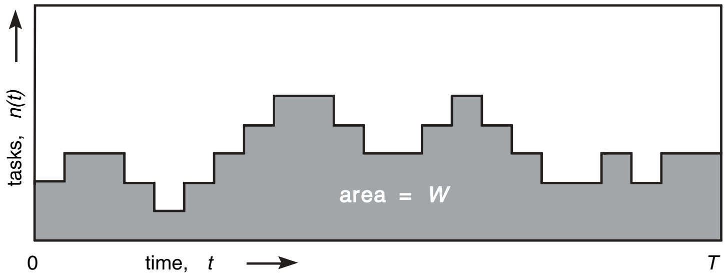

Figure 2. The average response time of a server can be calculated from just a few measurements. Let (nt) denote the number of tasks in the server at time t. Let W denote the area under the graph of $n(t)$ in the interval from time 0 to time T; W is the number of task-seconds of accumulated waiting. The mean number of tasks at the server is $Q = W / T$, and the mean response time per completed task is $R = W / C$. The identity $W / T = (C / T)(W / C)$ translates to Little's law: $Q = XR$. The mean service time S and the mean response time R are not the same; R includes queueing delay as well as service time.

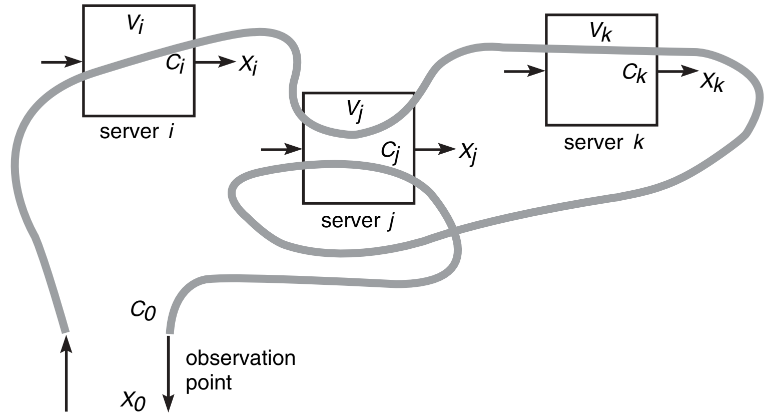

Figure 3. Flow of transactions through a network of servers can be calculated from a few selected measurements. Over an observation period T, the system completes C_0 transactions. The average number of tasks per transaction for server i is $V_i = C_i / C_0$; V_i is called the visit ratio because each task is regarded as a "visit" by the transaction to the server. Here the transaction visits servers i and k once and server j twice. The identity $C/T = (C_i/C_0)(C_0/T)$ translates to the forced-flow law: $X_i = V_iX_0$. This law says that the task flow at one point in the system determines the task flows everywhere. This law holds regardless of the interconnections among the servers; any two networks with the same visit ratios will have the same flows. The local throughput constraint $X_{\mathrm{i}} \leq 1 / S_i$ translates to a system throughput constraint $X_0 \leq 1/V_iS_i$.

not sufficient for making predictions. We must introduce additional forecasting assumptions that extrapolate measured parameter values from the past observation period into the future observation period; the laws can then be used to calculate the response time expected in that future period.

The most common type of forecasting assumption is that, unless otherwise specified, the visit ratios V_i, mean service times S_i, think time Z, and overall load N will be the same. When we change the workload or the strategy for processing data, or the electrical, mechanical, parallelism of a server, we alter only the affected parameters.

Our first prediction question asks what happens when the demand for the directory disk is cut in half (its speed is

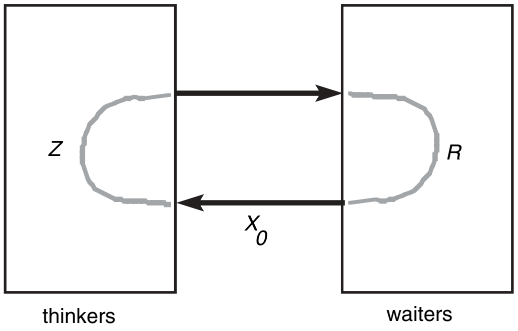

Figure 4. Users of a transaction system alternate between periods of "thinking" and "waiting" when using the system. The total number of thinkers and waiters is the number of users N. The average (waiting) response time per transaction is R and the average thinking time is Z. Little's law says that the mean number of active users in an entire system is equal to the mean cycle time of the system multiplied by the flow through the system. These three quantities are, respectively, N, $R+Z$, and X_0. Solving $N = (R+Z)X_0$ for the response time, we obtain the response-time formula: $R = N/X_0 - Z$. In the extreme case of response time almost zero—because all the servers are ultra-fast—the system throughput would be $X_0 = N/Z$ because transactions are flowing at the rate individual users complete their thinking intervals.

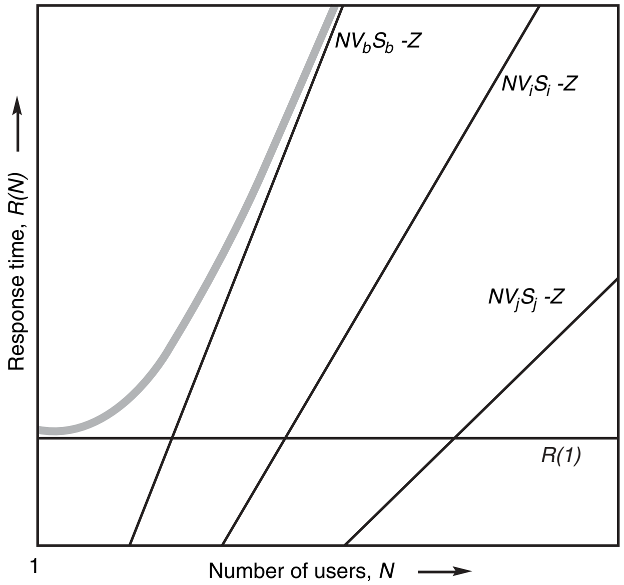

Figure 5. Bottleneck analysis shows how the response time changes as a function of N. When $N = 1$, the single user's transactions encounter no queueing delays from other transactions, whence $R(1) = V_1S_1 + \cdots + V_KS_K$, where K is the number of servers. Combining the utilization and forced-flow laws, $X_0 = X_i/V_i = U_i/V_iS_i < 1/V_iS_i$ because $U_i < 1$. Thus $R(N) > NV_iS_i - Z$ for all i. Each of the lines defined by these relations is a potential asymptote for $R(N)$ with large N. The actual asymptote is determined by the largest of the potential asymptotes. Taking server b (for bottleneck) to be the one with the largest V_iS_i, we have $R(N) > NV_bS_b - Z$. The bottleneck analysis assumes that the products V_iS_i do not vary with N.

doubled). The answer depends on whether the directory disk is the bottleneck:

1. If another server is the bottleneck, then speeding up the directory disk will not change the limit on system throughput.
2. If the directory disk is initially the bottleneck, but is no longer the bottleneck after its speed is doubled, then the throughput improves to the limit imposed by the second-slowest server.
3. If the directory disk is still the bottleneck after its speed is increased, then the system throughput improves to the new limit imposed by the directory disk.

The limits of cases 2 and 3 may be superseded by a think-time-imposed limit. No matter how fast the servers are, the maximum rate at which users submit transactions is N/Z; therefore, N/Z is also a limit on the system throughput. Cases 2 and 3 cannot improve beyond that limit.

The operational laws can yield nonsense if the bottleneck effects are ignored. For example, if we assume that doubling the directory disk speed will also double the system throughput, we would change the throughput from 16 to 32 in the response time formula and calculate an absurdity:

$$R = N/X_0 - Z = (1000/32) - 60 = -28.75\,\text{seconds},$$

The think-time constraint on throughput is $N/Z = 1000/60 = 16.7$ transactions per second. If we hypothesize that throughput X_0 can be larger, the response time law tells us that $R = N/X_0 - Z$ is less than zero. That is impossible.

All we can say with the given information and the given forecasting assumptions is that halving the demand for the directory disk will reduce the response time from 2.5 seconds to some small but still nonzero value. If the 2.5-second response time is acceptable, then this proposed change in directory search strategy would not be cost effective.

Consider the second configuration question: What happens to the response time if the number of agents is doubled? Again, we are limited by the lack of knowledge of the other disks. If the directory disk is the bottleneck, then doubling the number of agents is likely to increase its utilization to 100 %, giving a saturation value of throughput:

$$X_0 = 1/V_i S_i = 1/(10^* 0.005) = 20\,\text{transaction per second}$$

with corresponding response time,

$$R = N/X_0 - Z = (2000/20) - 60 = 40\,\text{second}$$

If the directory disk is not the bottleneck, then some other server will have a smaller saturation throughput, which forces response time to be longer than 40 seconds. Thus, doubling the number of agents will produce a response time that is likely to be unacceptably high.

COMPUTATIONAL ALGORITHMS

The simple methods described above cannot answer the more complex question of how throughput and response vary with the load N on the system. These questions can be answered with very simple algorithms that can be programmed easily on a spreadsheet or hand-held calculator.

The networks-of-queue model was first proposed by Jackson in 1957 (3), and mathematical expressions for its steady-state probabilities were presented by Gordon and Newell in 1967 (4). Their expressions were, unfortunately, exceedingly complex. To calculate a simple quantity such as central processing unit (CPU) usage required summations over enormous state spaces whose size grew exponentially with N. The computational algorithms for these models thus seemed to be intractable. Consequently, these models were not taken seriously, even though a few sporadic experimental studies showed they worked well. In 1973, Jeffrey Buzen presented a breakthrough: an algorithm that computed performance metrics from the Gordon-Newell model in time $O(N^2)$(5). Buzen's algorithm led to many studies that validated the models and extended them to many new cases and systems. Performance evaluation became the focus of a large and flourishing industry. One of the important extensions was Mean Value Analysis from Martin Reiser and Steve Lavenberg in 1980 (6), which eventually became the industry standard.

The Mean Value Algorithm is so named because it computes a set of means for a closed network (fixed load N)—the response times $R_i(N)$, queue lengths $Q_i(N)$, throughputs $X_i(N)$, and the system throughput $X(N)$ and response time $R(N)$. (Note that we have dropped the subscript "0" from the system throughput notation.) It does this iteratively for $N = 1, 2, 3, \ldots$ starting with the observation that the queue lengths are all 0 when $N = 0$.

The box below summaries the equations that the algorithm uses to obtain the mean values for load N once the mean values for load $N-1$ have been calculated. Following is an explanation for each of the equations.

Mean Value Equations

(1)	$R_i(N) = S_i(1 + Q_i(N-1))$	for all i
(2)	$R(N) = \sum_{i=1}^{K} V_i R_i(N)$	
(3)	$X(N) = \dfrac{N}{R(N) + Z}$	
(4)	$Q_i(N) = X(N) V_i R_i(N)$	for all i

1. When a job arrives at server i, it waits in the queue. That queue's length just before the arrival is approximated as the overall mean queue length

when the arriving job is not present (load $N-1$). Just after the arrival, that queue's length is one larger. The arriving job's response time is one service time S_i for each job in the queue just after its arrival. (We will discuss the accuracy of this approximation shortly.)

2. The overall response time is the sum of all per-visit server response times over all visits. This sum is actually an operational law. Multiply both sides by $X(N)$, apply Little's law to reduce the left side to N, and apply both the forced-flow law and Little's law to convert each term $X(N)V_iR_i(N)$ to $X_i(N)R_i(N)$ and then to the mean queue $Q_i(N)$. The result is the identity that N is the sum of the queue lengths of all the servers.
3. This equation is the response-time law solved for $X(N)$.
4. This equation is Little's law applied at each server.

Figure 6 is a very simple version of the airline reservation system. Figure 7 illustrates what the Mean Value Algorithm yields when applied to this model. It is easy to answer the two prediction questions simply by altering the parameters to their new values and applying the algorithm.

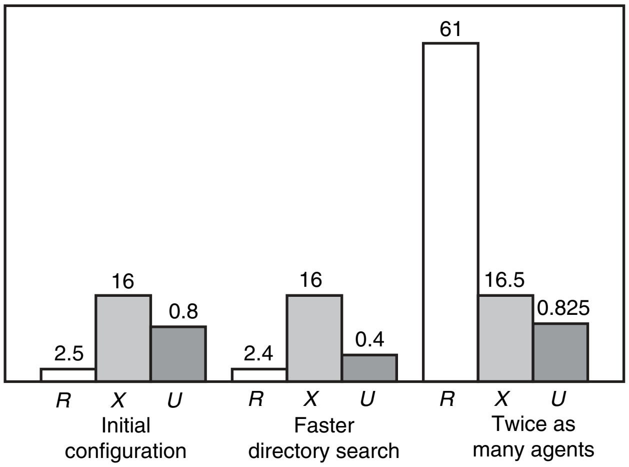

Figure 7. The bar graphs show the results of three network analyses. The original system has an average response time (R) of 2.5 seconds and a throughput (X) of 16 transactions per second; the directory, which seems likely to be the bottleneck, has a utilization (U) of 0.8. If the directory accesses are halved, the utilization of the directory disk falls to 0.4, but the improvement in response time is imperceptible. If the number of agents is doubled, then the response time jumps to 61 seconds.

THE RANDOM ARRIVAL ASSUMPTION

Our explanation for the Mean Value equations shows that only the first equation contains an approximation; the other three equations are operational laws. Let us consider the nature of this approximation. Whatever errors exist between values calculated from the model and values measured in a system develop from this approximation.

The approximation has two parts: (*1*) the arriving job observes the same queue length as a random outside observer would with one less job in the system, and (*2*) all jobs in the queue require the average service time to complete. These assumptions are not necessarily good assumptions. Here's why.

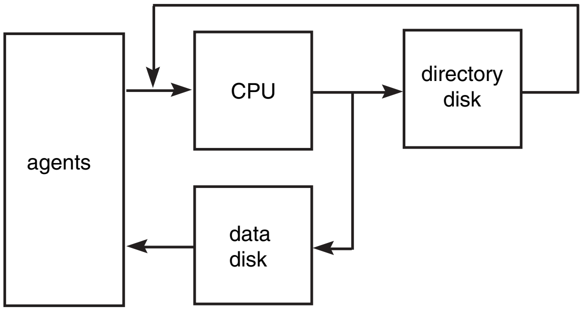

Figure 6. The hypothetical airline reservation system serves as an example of a computer network subject to mathematical performance analysis. In the initial configuration, 1000 agents access a database at the airline's central computing facility. Each agent thinks an average of 60 seconds between transactions. A typical transaction requires 10 lookups on the directory disk to locate the information requested, and then one lookup on the data disk to deliver the result. Each of these 11 disk accesses also requires service from the CPU. The total CPU time of a transaction averages 50 milliseconds. The directory disk service time is 5 milliseconds, and the data disk service time is 60.7 milliseconds.

In violation of part 1, the system may have a scheduling algorithm that admits new jobs to active status only when another job leaves. It synchronizes job arrivals with departures. In this case, the arrivals do not act as random outside observers. The arriving job may observe a queue that is shorter than what the random outside observer sees.

In violation of part 2, when a job arrives at a busy server, there is already a job in progress when it arrives. We know from queueing theory that the expected time until the job-in-progress completes is equal to S_i only if the distribution of service times is exponential. If the service times have a long-tail distribution (not unusual), then the expected time until the job-in-progress completes may be considerably larger than S_i. Thus, the assumption that every job in queue needs S_i time to complete may not hold for servers with long-tailed distributions. The arriving job may observe a response time that is longer than the approximation implies.

In both cases, Mean Value Equation (1) will underestimate the true response time. The underestimate may be considerable for long-tailed service distributions.

Few real systems exactly satisfy the assumption behind Equation (1). Yet extensive experiment studies have demonstrated that the models based on it are nonetheless robust: It is almost always possible to construct a model whose estimates of throughput and utilization are within 5% of the true values and whose estimates of response time are within 25% of the true values.

This is quite a remarkable track record for such a simple algorithm.

EXTENDING THE MEAN VALUE EQUATIONS

The Mean Value Equation [Equation (1)] is not the only way to approximate the response time. Yon Bard introduced another approximation in consultation with Paul Schweitzer in 1979 (7). The idea was to approximate the mean queue observed by the arriving job as a simple downward proration of the current mean queue length:

$$Q_i(N-1) = \frac{N-1}{N} Q_i(N)$$

After this subsitution, all the mean values mentioned in the equations are functions only of the load N, which can be dropped as an explicit parameter. The result is the simplified equations in the box below.

Bard-Schwetizer Equations for load N

(5)	$R_i = S_i\left(1 + \frac{N-1}{N} Q_i\right)$	for all i
(6)	$R = \sum_{i=1}^{K} V_i R_i$	
(7)	$X = \frac{N}{R+Z}$	
(8)	$Q_i = X V_i R_i$	for all i

For a given N, these equations are solved iteratively. The algorithm starts with any guess for the mean queue lengths, for example all 1. It then cycles through the Equations (5)–(8), which produces successive new guesses for mean queue lengths. The sequence of guesses converges to a set of values that solve the equations. Those mean values are the estimates of response time, throughput, and queue lengths for the system at load N.

Experimental validations have confirmed that the Bard-Schweitzer equations give good approximations in practice, usually with the same errors as the original Mean Value equations.

Another approximation addresses one problem mentioned earlier, that the actual response time is much larger than the Mean Value Equation [Equation (1)] assumes for long-tailed service distributions. It borrows from queueing theory the Pollaczek-Khintchine formula, which says

$$R_i = S_i\left(1 + \frac{U_i}{1-U_i}\,\frac{1+C_i^2}{2}\right)$$

where C_i is the coefficient of variation, namely the ratio of service time standard deviation to mean. This formula can replace Equation (5) in the Bard-Schweizer equations, with $U_i = X_i S_i$. Exponential service time distributions have $C_i = 1$, simplifying the formula to $R_i = S_i/(1-U_i)$ for those servers.

OPERATIONAL ANALYSIS

The discussion above is couched in operational terms: All parameters are taken directly from measured data, and all computed metrics represent measured metrics. For this reason, the analytic approach outlined above is called operational analysis. It begins with the laws and relationships among quantities observable in a system over a time period. It uses these laws to determine the limits bottlenecks impose on throughput and response time. With the additional assumptions of flow balance and random arrivals, it leads to the Mean Value Equations for calculating the throughput, response times, and mean queues. Operational analysis allows the measurement of errors caused by assumptions such as flow balance or random arrivals.

Traditional queueing theory assumes that stochastic (random) processes govern the performance quantities. Its more powerful methods allow calculation of metrics based on entire service distributions, not just the means. Many steady-state limit theorems of queueing theory turn into operational laws or formulas that hold for flow-balanced networks.

Operational analysis is more intuitive and easier to understand in the most common performance evaluation cases than traditional queueing theory. It gives more credibility to performance models because its assumptions are verifiable. It is commonly used in performance evaluation textbooks to introduce the basic ideas of queueing theory for computing systems and networks (8). Operational analysis, however, is not a replacement for traditional queueing theory.

The genesis of the operational interpretation was in the mid-1970s, when performance analysts were discovering that the formulas of Markovian queueing systems worked very well to predict utilizations, throughputs, and response times in real networks of computers, even though the Markovian assumptions themselves were grossly violated. Jeffrey Buzen proposed the operational hypothesis: Many traditional steady-state queueing formulas are also relations among observable quantities under simple, general conditions (9). This hypothesis has been substantiated in practice and has underpinned many computer programs that accurately calculate performance measures for network-of-server models of computer systems, computer networks, and manufacturing lines.

SWAPPING

Swapping is a general term for exchanging blocks of program code or data between main and secondary memory. An executing program encounters swapping in three ways:

- Swapping in: Moving the entire program into main memory at the start of execution.
- Swapping out: Moving the entire program out of main memory at the completion of execution.
- Page swapping: Moving individual pages of the program in or out of main memory during execution of a program.

The time to complete a swap is typically 10,000 to 100,000 times the basic instruction time. Since swapping is so expensive compared with instruction execution, system designers have always sought ways to minimize and mask it.

The term originated in the time-sharing systems of the early 1960s. These systems had insufficient memory to allow more than one program to be loaded (swapped in) for execution at a time. At the end of a time slice or stop for input/output, their operating systems swapped out the executing program and then swapped in another program. A single program could be swapped many times during its execution. Swapping was a perfect description of the main work of time-sharing—switching the CPU from one program to another.

In those early systems, swapping and CPU execution were disjoint activities. The operating system controlled the swapping overhead by setting time slices to be multiples of the average swapping time. MIT's CTSS was able to guarantee that the CPU would be executing programs about 50% of the time with this strategy (1).

To improve CPU efficiency to near 100%, operating systems of the late 1960s incorporated multiprogramming. Swapping was limited to swapping in and swapping out. The CPU could be switched among loaded programs without further swapping. Swaps were masked by performing them in parallel with CPU execution, without interrupting or slowing the CPU.

Multiprogramming is often combined with virtual memory. In that case, the operating system may allocate fewer pages of memory to a program than the size of its address space. There will be page swapping during execution. The operating system maintains a complete copy of the address space in a swap file on the disk; each page fault swaps a page from that file with a page from main memory. The paging algorithm attempts to minimize page swapping.

Modern operating systems use swapping in all these forms. Windows XP and Vista, Mac OS 10, and Linux all combine multiprogramming and virtual memory. They allow users the option of turning off virtual memory; in which case, the operating system will swap in a program's full address space at the beginning and then execute without page swapping.

THRASHING

Thrashing is an unstable collapse of throughput of a system as the load is increased. It violates the intuition that throughput should increase smoothly toward a saturation level as load increases. Thrashing occurs when contention for a critical resource prevents most jobs from actually using the resource.

Thrashing was first observed in the first-generation multiprogrammed virtual memory computing systems of the 1960s. Designers expected system throughput to increase toward a saturation level as the load (level of multiprogramming) increased. To their great surprise, throughput dropped suddenly after a critical load (see Fig. 1). Moreover, throughput would not return to its former high until the load was reduced below the critical value that triggered the thrashing — a form of hysteresis. The system did not crash, but it did slow to an imperceptible crawl. The engineers called it "paging to death" because all the jobs were constantly queued up waiting for the paging disk to satisfy their page faults.

Thrashing was a serious problem. It made the new generation of operating systems look like multi-million-dollar liabilities. Who would purchase such a system?

Thrashing was explained in 1968 (1). Increasing load in a fixed size memory causes the average partition to decrease, forcing an increase in the rate of page faults. The load at which the mean CPU time between page faults equals the disk service time is a tipping point: At higher loads, most jobs are queued at the paging disk, which becomes the system bottleneck.

As an example, consider a job that requires 1 second of CPU time on a system with a page fault service time of 10 milliseconds. At a small load, the job gets a large partition and generates (say) 20 page faults, which require a total of 0.2 seconds of disk time; this job's CPU efficiency is 1/(1 + 0.2) = 0.83. At an intermediate load, the job's partition has been squeezed a little and it generates (say) 100 page faults; the CPU efficiency drops to 0.5. At a large system load, the job's partition has been squeezed a lot and it generates (say) 1000 page faults; its efficiency drops to 0.09. At the small loads, the job is CPU-bound; at the large loads, it is disk-bound. At the tipping point (efficiency 0.5), the average CPU time between page faults equals the disk service time.

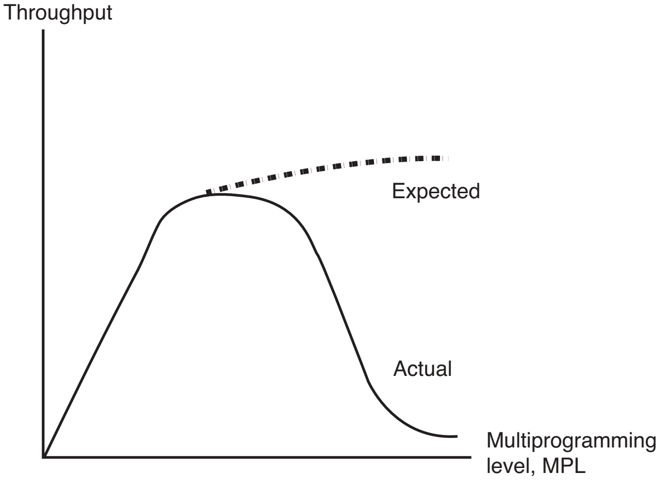

Figure 1. Thrashing in a multiprogrammed computer system.

The solution to thrashing is a load controller that allows all jobs enough memory space to keep their CPU efficiencies at 0.5 or higher. To accomplish this, a load controller separates submitted jobs into two sets: active and waiting. The active jobs are allowed to hold space in main memory. All other jobs are waiting. The working-set criterion is the ideal for deciding when to activate a waiting job. A job's working set is the set of pages required to allow the job to have a CPU efficiency above 0.5. If all active jobs have efficiencies above 0.5, the system will be below its thrashing tipping point. As long as every job gets enough space for its working set, it is impossible to activate enough jobs to push the system past its thrashing tipping point (2). The working-set criterion was found empirically not only to be optimal but to be more robust than other load-control criteria (3).

Within a decade after these early analyses, queueing network models were routinely used to quantify the relationship between throughput and the total demands for devices, and to help design load controllers to prevent thrashing (4).

Thrashing has been observed in other systems as well. Early packet networks provided examples. In unregulated networks, many servers vie for bandwidth in a common medium such as a satellite channel or Ethernet cable. When a server has a packet to transmit, it transmits into the medium. If another server jams it before completing, it stops transmitting, and tries again. This simple protocol works well for low loads, and system throughput increases with load. However, when the load gets high enough, there is a good chance that two or more servers will get into a loop where they start to transmit, detect a jam, stop, and repeat. Thereafter no one gets to transmit and throughput suddenly drops. This behavior was first observed in the ALOHA satellite communication network in the late 1960s (5).

Again, a properly designed load controller prevents the thrashing. In this case, the control is on the time interval from when a server drops out (it detected a jam) until it retries. It picks a random number for the first wait period; if that gets jammed, it waits twice as long; if that gets jammed, it waits twice as long again; and so on. This increasing-backoff protocol is used in Ethernets and cell phone networks.

Another instance of thrashing occurs from lock contention in database systems. A transaction requests and locks

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

all records it needs, but if a requested record is already locked by another transaction, it releases all its locks and tries again. Again, the doubling of successive backoff intervals prevents thrashing, a condition in which lock contention prevents anyone from locking anything.

The common features of these systems are as follows: (*1*) A shared resource for which there can be many requests, and (*2*) a contention resolution protocol whose delay increases with the number of contenders. As the number of contenders increases, more and more time is spent on contention resolution and few jobs get through to the resource.

T

THROUGHPUT

The throughput of a system is the number of jobs, tasks, or transactions the system completes per unit time. If during an observation period of length T the system completes C jobs, throughput X is measured as C/T. Throughput is often used as a figure of merit, with higher values indicating better performance. System engineers use analytic or simulation models to help determine a system configuration and server capacities that enable the system to meet throughput and response-time targets.

The term "throughput" suggests a stream of jobs flowing *through* a system. A through job would arrive and depart during the observation period. Completing jobs that were already in the system at the start of the observation period would not be counted. Therefore, counting all completions in the observation period overestimates throughput. However, in most systems, there is an upper limit N on the number of jobs in the system, reflecting the system capacity or the size of the user population. Therefore, the number of completions C is within N of the number of through jobs. For a long observation period, C is large compared with N, and throughput measured as $X = C/T$ is negligibly different from "true" throughput.

Throughput considered alone is often a deceptive measure of performance. One common deception is a server with a long queue: Its throughput is at saturation. Although the saturation throughput may be acceptable, the server's response time would be unacceptably high. Acceptable throughput does not guarantee acceptable response time.

Another deception can occur in a multiserver system. At a high load, the system's bottleneck saturates and produces its maximum possible throughput. In turn that limits the throughput at every other server in the system. If a nonbottleneck is used as the throughput reference point, the unacceptable throughput there will be due to the bottleneck, not to that server. Increasing the speed of the nonbottleneck server will not increase saturation throughput.

The subtle relationships among throughput, response time, and bottlenecks can be understood with the help of four fundamental laws of networked systems (1). The parameters are as follows:

Vi = number of visits per job to server i
Si = service time per visit at server i
N = number of users in the system
Z = think time of a user before making a new request of the system

The laws are as follows:

- *Utilization Law*: A server's utilization (fraction of time busy) is the product of its service time and throughput: $Ui = Si \times Xi$.
- *Little's Law*: A server's mean queue length is the product of its response time per visit and throughput: $Qi = Ri \times Xi$.
- *Forced Flow Law*: A server's throughput is the product of the system throughput and visit ratio: $Xi = X \times Vi$.
- *Response Time Law*: System response time per job plus think time is the number of jobs divided by the system throughput: $R + Z = N/X$.

A system bottleneck analysis follows immediately from these laws.

- Define demand $Di = Vi \times Si$ as the total expected job service required over all visits to a server.
- Since utilization cannot exceed 1, the utilization law implies $Xi \leq Vi/Di$.
- Combining with the forced flow law, the system throughput $X \leq 1/Di$ for all servers.
- Therefore, the server with largest Di limits the system throughput and is the bottleneck.
- Combining with the response time law, the mean response time cannot be smaller than $Di \times N - Z$.

An example will help illustrate these concepts. Consider a two-server system in which a job's total CPU demand is 2 seconds, a typical job visits a DISK server 100 times for 50 milliseconds each, and there are 10 users with an average think time of 20 seconds. The CPU demand is $D1 = 2$ seconds, and the DISK demand is $D2 = 5$ seconds. The DISK is the bottleneck, and system throughput is limited to 1/5 job per second. The CPU utilization cannot be higher than $D1/D2 = 2/5$. A faster CPU will have a smaller D1—speeding it up will only *reduce* its utilization. Speeding up the DISK will increase system throughput and CPU utilization. The system response time is at least $5\times10-20 = 30$ seconds. A response time of less than 30 seconds for 10 users is impossible.

The bottleneck analysis sketched above is for systems in which the parameters Vi and Si are independent of the load N in the system. If one Vi depends on N, then the upper bound on throughput may depend on N. An example of this occurs in multiprogrammed virtual memories: As load N

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

increases, job memory allocations are squeezed and paging traffic (Vi for the paging disk) increases. As load N increases, the total demand for the paging disk eventually exceeds all others and the paging disk becomes the bottleneck, forcing throughput down from a peak. (See "Thrashing" article.)

These simple relationships can be extended to systems with multiple job classes and variable rate servers (2).

V

VIRTUAL MEMORY

Virtual memory is the simulation of a storage space so large that users do not need to recompile their works when the capacity of a local memory or the configuration of a network changes. The name, borrowed from optics, recalls the virtual images formed in mirrors and lenses—images that are not there but behave as if they are. The designers of the Atlas Computer at the University of Manchester invented paged virtual memory in the 1950s to eliminate two looming problems: planning and scheduling data transfers between main and secondary memory and recompiling programs for each change of size of main memory.

For the first decade after its invention, virtual memory was the subject of intense controversies (1). It significantly improved programming productivity and ease of use, but its performance was unpredictable and it thrashed under multiprogramming. These problems were solved by the 1980s (2). Virtual memory is now so ordinary that few people think much about it. It is one of the engineering triumphs of the computer age.

One of the early lines of virtual memory accommodated objects of various sizes, stored in distinct storage segments. This line produced the first proposal for an object-oriented operating system (3), which led to a class of machines called capability machines (4,5), and even to a computer architecture for general object programming (6). The development of RISC produced such speeds that the special hardware in capability machines and their successors was not needed. However, all the methods used in these systems for mapping objects to their locations, protecting objects, and partitioning memory are at the heart of modern object-oriented runtime systems. We will therefore discuss virtual memory from an object point of view.

Virtual memory is ubiquitous in networked systems, which have many things to hide—on-chip caches, separate RAM chips, local disk storage, network file servers, many separately compiled program modules, multiple computers on the network, and the Internet.

MAPPING

The heart of virtual memory is a mapping between an address space and the real memory. The address space is a set of addresses sufficient to name all components of a program independent of their locations in the memory hierarchy. Virtual addresses do not change as objects are moved dynamically to various real addresses within the memory system. Programmers and users see only the virtual address space; the details of the real memory system are hidden.

Most early virtual memories were based on paging. A page is a fixed-size block or program code or data. Main and secondary memory are divided in slots of the same fixed size. Pages can then be moved from any memory slot to any other. Paging yields the simplest form of mapping but wastes storage in the last page assigned to the object.

Some early virtual memories were based on segmentation. A segment is a set of contiguous storage locations of any length. Segments could be sized as exact matches to objects such as procedures and arrays, but they are more difficult than pages to place. Segmentation has become common with object-oriented programming.

The method of mapping virtual addresses to real addresses is basically the same for both fixed and variable sized objects (paging and segmentation). The associations between virtual and real addresses are held in mapping tables; the hardware looks up the current real address for any virtual address generated by the processor. A schematic diagram is shown in Fig. 1.

Figure 1 shows the processor on the left and the memory system on the right. The processor generates virtual addresses from the address space of the process it is running. Virtual addresses are of the form (s,b), meaning byte b within segment s. Objects are stored as contiguous segments in the main and secondary memories. Figure 1 shows a segment of k bytes stored at real address c.

Between the processor and the memory is a device called a mapper. Its job is to translate virtual addresses into their current real addresses. For objects already loaded into main memory, translation consists of table lookups that yield the real address. For objects not loaded, the mapper first issues an "up" command to move it from its secondary memory file to an unused segment of main memory; and then it performs the translation. If main memory is full, the mapper will also issue "down" commands as needed to copy loaded objects back to their files and free up their space.

The mapper employs two types of tables, the Descriptor Table (DT) and the Object Tables (OT). Consider first the Descriptor Table. It has one entry for each object. Each object has a unique, system-wide name x. The entry for object x in this table consists of four parts:

- *Presence Bit*: P=1 means the object is loaded in main memory; P=0 means not.
- *Usage Bit*: U=1 means the object has been modified since being loaded; U=0 means not. Modified objects need to be copied back to their secondary files before their space can be released.
- *Base*: The base address of the segment in main memory.
- *Length*: The length of the segment in main memory.

The descriptor table is the only table in the system containing information about the physical locations of objects. When an object is moved, only the descriptor table must be updated.

The second table used by the mapper is an Object Table. There are actually multiple object tables, one for each process. A process's address space is called its "domain," and each address space has a unique domain identifier d. A

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

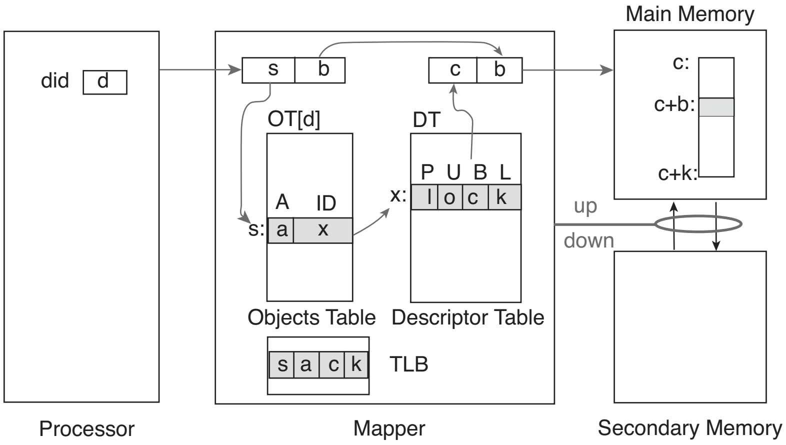

Figure 1. Object-oriented virtual memory.

register in the processor displays the domain of the current process. When the processor switches to a different process, its domain identifier register (did) is automatically changed. Thus, the processor always directs its addresses only to the objects of the currently executing process.

An object table has an entry for each segment s of its address space. That entry contains a handle of two parts:

- *Access Code*: A designates the allowable types of access, for example, read or write.
- *Identifier*: ID contains the unique system identifier x for the object.

The translation of a virtual address (s,b) to the real address containing the byte is straightforward:

1. From OT[d], get the handle for s and extract its identifier x.
2. From DT, get the base c from the descriptor for x.
3. Pass the real address c+b to the memory. (If b $\leq$ k, stop with an error.)

The object and descriptor tables are actually stored in a reserved area of main memory belonging to the mapper. Therefore, the table lookups require extra memory accesses. Those extra accesses could slow the system down a fraction of the speed without the mapper.

To bypass the table lookups whenever possible, the mapper contains a device called the Translation Lookaside Buffer (TLB) or address cache. It is a small very high-speed associative memory that holds the most recently used mapping paths. If segment s has been addressed recently, there will be an entry (s,A,B,L) in the TLB. It is built from the A-field of OT[d] plus the B- and L-fields of DT. The two table lookups are bypassed and are replaced with one ultrafast TLB lookup.

The mapper's basic cycle is as follows:

```
processor places (s,b) in address register
if ((a,c,k)=LOOKUP_TLB(s) undefined)
  then
       (a,x):=OT[d,s]
       (p,c,k):=DT[x]
       if p=0 then MISSING FAULT
       DT[x] .U:=1
       LOAD_TLB(s,a,c,k)
endif
if (b•k) then BOUNDS FAULT
if (request not allowed by a) then PROTECTION
FAULT place c+b in memory address register
```

The operation LOOKUP_TLB(s) scans all the TLB cells in parallel and returns the contents of the cell whose key matches s. The operation LOAD_TLB replaces the least-recently-used cell of TLB with (s,a,c,k). The mapper sets the usage bit U to 1 whenever the entry is accessed.

If the TLB already contains the path requested, the mapper bypasses the lookups in the object and descriptor tables. In practice, small TLBs (e.g., 64 or 128 cells) give high enough hit ratios that address-translation efficiency goals are easy to meet (7). The TLB is a powerful and cost-effective accelerator.

FAULTS

A fault is a condition that prevents additional processing. The mapper can generate three faults: missing object, out of bounds, and protection violation. Those three fault signals trigger the operating system to execute corresponding fault-handler routines that take corrective action.

The bounds fault and protection fault are fatal. References outside a segment are prohibited because they might read or write memory allocated to other objects. Unauthorized references of the wrong kind are also prohibited—for example attempting to write into a read-only object. The fault handlers for these two faults generally abort the running process.

The missing object fault occurs when the mapper encounters a not-present bit (P=0). The operating system interrupts with a missing object fault routine that

1. Locates the needed object in the secondary memory.
2. Selects a region of main memory to put that object in.
3. Empties that region by copying its contents to the secondary memory.
4. Copies the needed object into that region.
5. Updates the descriptor table.
6. Restarts the interrupted program, allowing it to complete its reference.

PERFORMANCE

The replacement policy is invoked by the missing object handler at step 2. The performance of virtual memory depends critically on the success of the replacement policy. Each missing object fault carries a huge cost: Accessing the object in main memory might take 10 nanoseconds while retrieving it from secondary memory might take 10 milliseconds—a speed differential of 100,000. It does not take very many missing object faults to seriously slow a process running in a virtual memory.

The ultimate objective of the replacement policy is to minimize the number of missing object faults. To do this, it seeks to minimize "mistakes"—replacements that are quickly undone when the process refers to those objects again. This objective is met ideally when the object selected for replacement will not be used again for the longest time among all the loaded objects. Unfortunately, the ideal cannot be realized because we have no way to look ahead into the future. A variety of non-lookahead replacement policies have been studied extensively to see how close they come to this ideal in practice. When the memory space allocated to a process is fixed in size, this usually is LRU (least recently used); when space can vary, it is WS (working set) (2).

The operating system can adjust the size of the main memory region allocated to a process so that the rate of missing object faults stays within acceptable limits. System throughput will be near-optimal when the virtual memory guarantees each active process just enough space to hold its working set (2).

PROTECTION

This structure provides the memory partitioning needed for multiprogramming. A process can refer *only* to the objects listed in its object table. It is impossible for a process to accidentally (or intentionally) read or write objects in another address space.

This structure also allows the operating system to restrict every process to a domain of least privilege. Only the objects listed in a domain's object table can be accessed by a process in that domain, and only then in accord with the access codes stored in the object's handle. In effect, the operating system walls each process off, giving it no chance to read or write the private objects of any other process. This has important benefits for system reliability. Should a process run amok, it can damage only its own objects: A program crash does not imply a system crash. This benefit is so important that many systems use virtual memory even if they allocate enough main memory to hold a process's entire address space.

THE WWW: VIRTUALIZING THE INTERNET

The World Wide Web extends virtual memory to the Internet. The Web allows an author to embed, anywhere in a document, a "universal resource locator" (URL), which is an Internet address of a file. By clicking the mouse on a URL string, the user triggers the operating system to map the URL to the file and then bring a copy of that file from the remote server to the local workstation for viewing. The URLs thus act as virtual addresses, and the combination of a server's IP address and a local file path name is the real address.

A URL is invalidated when the object's owner moves or renames the object. This can present operational problems to people who link to that object and depend on its presence. To overcome this problem, Kahn and Wilensky proposed a scheme that refers to mobile objects by location-independent "handles" and, with special servers, tracks the correspondence between handles and object locations (8). Their method is equivalent to that described earlier in Fig. 1: First it maps a URL to a handle, and then it maps the handle to the Internet location of the object.

CONCLUSION

Virtual memory is one of the great engineering triumphs of the computing age. Virtual memory systems meet one or more of the following needs:

Automatic Storage Allocation: Solving the overlay problem that originates when a program exceeds the size of the main memory available to it. Also solves the relocation and partitioning problems that develop with multiprogramming.

Protection: Each process is given access to a limited set of objects—its protection domain. The operating system enforces the rights granted in a protection domain by restricting references to the memory regions in which objects are stored and by permitting only the types of reference stated for each object (e.g., read or write). These constraints are easily checked by the hardware in parallel with the main computation. The same principles are used for efficient implementations of object-oriented programs.

Modular Programs: Programmers prepare codes as separately compiled, reusable, and sharable components into programs; their internal structure is hidden behind a public interface. Linker programs combine separate modules into a single address space.

Object-Oriented Programs: Programmers should be able to define managers of classes of objects and be assured that only the manager can access and modify the internal structures of objects (6). Objects should be freely sharable and reusable throughout a distributed system (9,10). Virtual memory mappings are designed for these objectives.

Data-Centered Programming: Computations in the World Wide Web tend to consist of many processes navigating through a space of shared, mobile objects. Objects can be bound to a computation only on demand.

Parallel Computations on Multicomputers: Scaleable algorithms that can be configured at run time for any number of processors are essential to mastery of highly parallel computations on clusters of computers. Virtual memory can join the memories of the component computers into a single address space and can reduce communication costs by eliminating some of the copying inherent in message-passing. This is known as distributed virtual memory (10).

WORKING SET

The working set is a dynamic subset of a process's address space that must be loaded in main memory to ensure acceptable processing efficiency. In the early days of computing, this intuitive idea enabled programmers to plan their memory usage over time in a constrained main memory. Later it turned into a formal definition of the ideal subset of address space to be loaded in main memory. Eventually the formal definition became the reference standard for all virtual memory replacement policies.

In early computing systems, programmers built overlay strategies for their programs. They made maps showing computational phases on the time axis and instruction or data block on the vertical axis. They checked off the blocks that needed to be loaded in main memory for each phase. They adjusted computational strategies and block contents until the blocks needed for each phase would fit. Then at the phase transitions, they programmed "down" and "up" commands. Down commands moved blocks from main to secondary memory when they were no longer needed in the next phase. Up commands moved blocks from secondary and main memory in time for the next phase. The set of blocks checked in the map was called the "working set" of a phase. The memory usage of the program could be characterized as a sequence

$$(\mathrm{L1}, \mathrm{T1})(\mathrm{L2}, \mathrm{T2})(\mathrm{L3}, \mathrm{T3})\ldots$$

in which each Li is the set of blocks loaded in phase i and Ti is the duration of the phase.

System designers were concerned that this process, already tedious and time consuming for small programs, would become unmanageable for large programs. In the late 1950s, the designers of the Atlas Computer at the University of Manchester invented virtual memory to automate this process. Their system broke program code and data into fixed size pages. It issued "up" commands at the moments that the program attempted to access a page not loaded. They invented a replacement algorithm that decided which loaded page to move "down" to make way for incoming "up" pages. Their algorithm assumed that each page was in a cycle of use and nonuse; by measuring the most recent use and nonuse periods, they predicted when each page would be used again. They selected for replacement the page not needed for the longest time.

Many people were attracted to the idea of virtual memory because of its big boost for programming productivity. But they were put off by the unpredictability of the replacement algorithms, which worked well for some programs and poorly for others. There were numerous contradictory experimental studies, but no one found a replacement algorithm that worked consistently well for all programs. In 1966 Les Belady (1) published an extensive study of replacement algorithms in which he demonstrated that replacement policies with usage bits performed better than those without. He suggested that this is due to "program locality," a tendency of programs to cluster references into subsets of their pages. He suggested that under multiprogramming a program should be given enough space to hold its "parachor," which was roughly the space at which the replacement algorithm's mean time between page faults equaled the page fault service time from the secondary memory.

In 1967, Denning (2) offered a precise definition of a working set. He defined it as the set of pages referenced in a virtual time window looking backwards for time T into the past. The working set dynamically varied as more or fewer pages appeared in the window. It was important to measure in virtual time—that is, not counting any interruptions—so as to get an intrinsic measure of the program's favored pages. He was able to show the somewhat surprising property that the paging rate and mean working set size could be computed easily from a histogram of the times between repeated references to the same page. It was then a simple matter to choose the window size T so that the mean time between page faults would always be larger than the mean page fault service time—that is, the CPU efficiency of the program would be at least 0.5.

Denning also showed that a multiprogrammed memory managed by a working set policy could not thrash. In later experiments with students and others, he established that the working set policy would produce system throughput within 5% to 10% of optimal, where optimal was defined in terms of perfect knowledge of the future (3). Thus, the working set policy became an ideal for other memory management policies.

The true working set would require measurements in a sliding window looking backwards from the current time. Although it worked perfectly (4), the cost of the mechanism was high. Many simpler software approximations were tried and tested, the most successful being the "WS Clock" (5).

Denning interpreted this definition of working set as a measure of the program's intrinsic memory demand. He hypothesized that programs have inherent tendencies to cluster their references into small subsets for extended periods, an idea he called "locality" after Belady. In numerous experiments with students and others, he concluded that the dynamic locality processes of programs consisted of phases and transitions; phases were periods of stability, with all references concentrated in a "locality set," and transitions were short periods of instability. In other words, every program has a natural sequence of locality sets and phases,

$$(\mathrm{L1}, \mathrm{T1})(\mathrm{L2}, \mathrm{T2})(\mathrm{L3}, \mathrm{T3})\ldots$$

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

A memory policy that loads exactly the locality set for each phase will achieve optimal paging behavior. As long as most phases are longer than the working set window T, the working set will be a very close measurement of these actual locality sets of varying sizes. Locality is the reason working sets work.

The locality behavior so painstakingly planned by early programmers is a natural property of programs anyway! It arises from the way that the human brain solves problems and pays attention.

In some systems, working sets can be deduced from a program's structure rather than by measurement of usage bits. For example, on machines using block-structured programming languages such as Ada, the working set can be defined as the current procedure segment, the stack, and all other data structures accessible from activated procedures.

In paging systems, it can be advantageous to "restructure" a program by clustering small, logical segments of the same locality on large pages. By preserving in the page references the locality originally present in the segment references, this strategy can yield the small working sets and efficient performance in systems with large page size. Restructuring is less important in systems with smaller page sizes.

ACTIVE DATABASE SYSTEMS

INTRODUCTION AND MOTIVATION

Traditionally, the database management system (DBMS) has been viewed as a passive repository of large quantities of data that are of interest for a particular application, which can be accessed/retrieved in an efficient manner. The typical commands for insertion of data records, deletion of existing ones, and updating of the particular attribute values for a selected set of items are executed by the DBMS upon the user's request and are specified via a proper interface or by an application program. Basic units of changes in the DBMS are the *transactions,* which correspond to executions of user programs/requests, and are perceived as a sequence of *reads* and/or *writes* to the database objects, which either *commit* successfully in their entirety or *abort*. One of the main benefits of the DBMS is the ability to optimize the processing of various queries while ensuring the consistency of the database and enabling a concurrent processing of multiple users transactions.

However, many applications that require management of large data volumes also have some behavioral aspects as part of their problem domain which, in turn, may require an ability to *react* to particular stimuli. Traditional exemplary settings, which were used as motivational scenarios for the early research works on this type of behavior in the DBMS, were focusing on monitoring and enforcing the integrity constraints in databases (1–4). Subsequently, it was recognized that this functionality is useful for a wider range of applications of DBMS. For example, a database that manages business portfolios may need to react to updates from a particular stock market to purchase or sell particular stocks (5), a database that stores users preferences/profiles may need to react to a location-update detected by some type of a sensor to deliver the right information content to a user that is in the proximity of a location of interest (e.g., deliver e-coupons when within 1 mile from a particular store) (6).

An active database system (ADBS) (1,7) extends the traditional database with the capability to *react* to various events, which can be either internal—generated by the DBMS (e.g., an insertion of a new tuple as part of a given transaction), or external—generated by an outside DBMS source (e.g., a RFID-like location sensor). Originally, the research to develop the reactive capabilities of the active databases was motivated by problems related to the maintenance of various declarative constraints (views, integrity constraints) (2,3). However, with the evolution of the DBMS technologies, novel application domains for data management, such as data streams (8), continuous queries processing (9), sensor data management, location-based services, and event notification systems (ENS) (10), have emerged, in which the efficient management of the reactive behavior is a paramount. The typical executional paradigm adopted by the ADBS is the so-called *event-condition-action* (ECA) (1,7) which describes the behavior of the form:

```
ON Event Detection
IF Condition Holds
THEN Execute Action
```

The basic tools to specify this type of behavior in commercially available DBMS are *triggers*—statements that the database automatically executes upon certain modifications. The *event* commonly specifies the occurrence of (an instance of) a phenomenon of interest. The *condition*, on the other hand, is a query posed to the database. Observe that both the detection of the event and the evaluation of the condition may require access not only to the current instance of the database but also to its history. The *action* part of the trigger specifies the activities that the DBMS needs to execute—either a (sequence of) SQL statement(s) or stored procedure calls. As a motivational example to illustrate the ECA paradigm, consider a scenario in which a particular enterprise would like to enforce the constraint that the average salary is maintained below 65K. The undesired modifications to the average salary value can occur upon: (1) an insertion of a new employee with above-average salary, (2) an update that increases the salaries of a set of employees, and (3) a deletion of employees with below-average salary. Hence, one may set up triggers that will react to these types of modifications (event) and, when necessary (condition satisfied), will perform corrective actions. In particular, let us assume that we have a relation whose schema is Employee(Name, ID, Department, Job-Title, Salary) and that, if an insertion of a new employee causes the average salary-cap to be exceeded, then the corrective action is to decrease everyone's salary by 5%. The specification of the respective trigger[1] in a typical DBMS, using syntax similar to the one proposed by the SQL-standard (11), would be:

```
CREATE TRIGGER New-Employee-Salary-Check
ON INSERT TO Employee
IF (SELECT AVG Employee.Salary) > 65,000
UPDATE Set Employee.
Salary = 0.95*Employee.Salary
```

This seemingly straightforward paradigm has generated a large body of research, both academic and industrial, which resulted in several prototype systems as well as its acceptance as a part of the SQL99 (11) standard that, in turn, has made triggers part of the commercially available DBMS. In the rest of this article, we will present some of the important aspects of the management of reactive behavior in ADBS and discuss their distinct features. In particular, in the section on formalizing and reasoning, we

[1] Observe that to fully capture the behavior described in this scenario, other triggers are needed—ones that would react to the UPDATE and DELETE of tuples in the Employee relation.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

motivate the need to formalize the active database behavior. In the section on semantic dimensions, we discuss the various parameters and the impact of the choice of their possible values, as they have been identified in the literature. In the overview section we present the main features of some prototype ADBS briefly, along with the discussion of some commercially available DBMS that provide the triggers capability. Finally, in the last section, we outline some of the current research trends related to the reactive behavior in novel application domains for data management, such as workflows (12), data streams (8,9), moving objects databases (13,14), and sensor networks (6).

FORMALIZING AND REASONING ABOUT THE ACTIVE BEHAVIOR

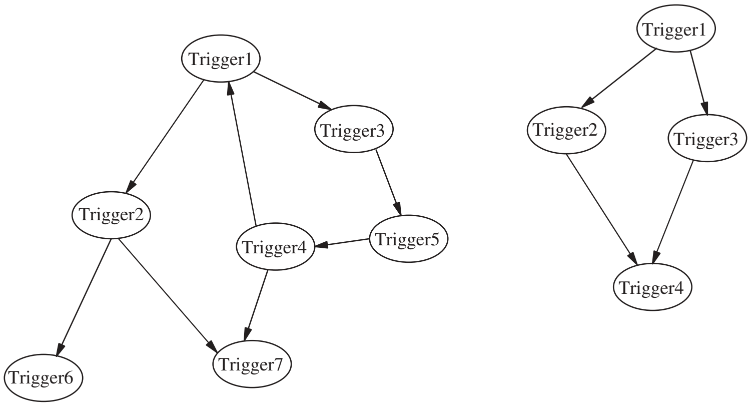
Historically, the reactive behavior expressed as a set of *condition* → *action* rules (IF *condition* holds, THEN execute *action*) was introduced in the Expert Systems literature [e.g., OPS5 (15)]. Basically, the inference engine of the system would "cycle" through the set of such rules and, whenever a left-hand side of a rule is encountered that matches the current status of the knowledge base (KB), the action of the right-hand side of that rule would be executed. From the perspective of the ECA paradigm of ADBS, this system can be viewed as one extreme point: CA rules, without an explicit event. Clearly, some kind of implicit event, along with a corresponding formalism, is needed so that the "C"-part (condition) can reflect properly and monitor/evaluate the desired behavior along the evolution of the database. Observe that, in general, the very concept of an *evolution* of the database must be defined clearly for example, the *state* of the data in a given instance together with the *activities log* (e.g., an SQL query will not change the data; however, the administrator may need to know which user queried which dataset). A particular approach to specify such conditions in database triggers, assuming that the "clock-tick" is the elementary implicit event, was presented by Sistla and Wolfson (16) and is based on temporal logic as an underlying mechanism to evaluate and to detect the satisfiability of the condition.

As another extreme, one may consider the EA type of rules, with a missing condition part. In this case, the detection of events must be empowered with the evaluation of a particular set of facts in a given state of the database [i.e., the evaluation of the "C"-part must be embedded within the detection of the events (5)]. A noteworthy observation is that even outside the context of the ADBS, the event management has spurred a large amount of research. An example is the field known as event notification systems in which various users can, in a sense, "subscribe" for notifications that, in turn, are generated by entities that have a role of "publishers"—all in distributed settings (10). Researchers have proposed various algebras to specify a set of *composite* events, based on the *operators* that are applied to the basic/primitive events (5,17). For example, the expression $E = E1 \wedge E2$ specifies that an instance of the event E should be detected in a state of the ADBS in which both *E1* and *E2* are present. On the other hand, $E = E1;E2$ specifies that an instance of the event E should be detected in a state in which the prior detection of *E1* is followed by a detection of *E2* (in that order). Clearly, one also needs an underlying detection mechanism for the expressions, for example, Petri Nets (17) or tree-like structures (5). Philosophically, the reason to incorporate both "E" and "C" parts of the ECA rules in ADBS is twofold: (1) It is intuitive to state that certain conditions should not always be checked but only upon the detection of certain events and (2) it is more cost-effective in actual implementations, as opposed to constant cycling through the set of rules.[2] Incorporating both events and conditions in the triggers has generated a plethora of different problems, such as the management of database state(s) during the execution of the triggers (18) and the binding of the detected events with the state(s) of the ADBS for the purpose of condition evaluation (19).

The need for formal characterization of the active rules (triggers) was recognized by the research community in the early 1990s. One motivation was caused by the observation that in different prototype systems [e.g., Postgres (4) vs. Starburst (2)], triggers with very similar syntactic structure would yield different executional behavior. Along with this was the need to perform some type of *reasoning* about the evolution of an active database system and to predict (certain aspects of) their behavior. As a simple example, given a set of triggers and a particular state of the DBMS, a database/application designer may wish to know whether a certain fact will hold in the database after a sequence of modifications (e.g., insertions, deletions, updates) have been performed. In the context of our example, one may be interested in the query *"will the average salary of the employees in the 'Shipping' department exceed 55K in any valid state which results via salary updates*." A translation of the active database specification into a logic program was proposed as a foundation for this type of reasoning in Ref. (20).

Two global properties that have been identified as desirable for any application of an ADBS are the *termination* and the *confluence* of a given set of triggers (21,22). The termination property ensures that for a given set of triggers in any initial state of the database and for any initial modification, the firing of the triggers cannot proceed indefinitely. On the other hand, the confluence property ensures that for a given set of triggers, in any initial state of the database and for any initial modification, the final state of the database is the same, regardless of the order of executing the (enabled) triggers. The main question is, given the specifications of a set of triggers, can one *statically*, (i.e., by applying some algorithmic techniques only to the triggers' specification) determine whether the properties of termination and/or confluence hold? To give a simple motivation, in many systems, the number of cascaded/recursive invocations of the triggers is bounded by a predefined constant to avoid infinite sequences of firing the triggers because of a particular event. Clearly, this behavior is undesirable, if the termination could have been achieved in a few more recursive executions of the triggers. Although run-time

[2] A noteworthy observation here is that the *occurrence* of a particular event is, strictly speaking, different from its *detection*, which is associated with a run-time processing cost.



(a) Non terminating cascading triggers

(b) Confluent triggers

Figure 1. Triggering graphs for termination and confluence.

termination analysis is a possible option, it is preferable to have static tools. In the earlier draft of the SQL3 standard, compile-time syntactic restrictions were placed on the triggers specifications to ensure termination/confluence. However, it was observed that these specifications may put excessive limitations on the expressive power on the triggers language, which is undesirable for many applications, and they were removed from the subsequent SQL99 draft.

For the most part, the techniques to analyze the termination and the confluence properties are based on labeled graph-based techniques, such as the triggering hyper graphs (22). For a simplified example, Fig. 1a illustrates a triggering graph in which the nodes denote the particular triggers, and the edge between two nodes indicates that the modifications generated by the action part of a given trigger node may generate the event that enables the trigger represented by the other node. If the graph contains a cycle, then it is possible for the set of triggers along that cycle to enable each other indefinitely through a cascaded sequence of invocations. In the example, the cycle is formed among Trigger1, Trigger3, Trigger4, and Trigger5. Hence, should Trigger1 ever become enabled because of the occurrence of its event, these four triggers could loop perpetually in a sequence of cascading firings. On the other hand, figure 1b illustrates a simple example of a confluent behavior of a set of triggers. When Trigger1 executes its action, both Trigger2 and Trigger3 are enabled. However, regardless of which one is selected for an execution, Trigger4 will be the next one that is enabled. Algorithms for static analysis of the ECA rules are presented in Ref. (21), which addresses their application to the triggers that conform to the SQL99 standard.

SEMANTIC DIMENSIONS OF ACTIVE DATABASES

Many of the distinctions among the various systems stem from the differences in the values chosen for a particular parameter (23). In some cases, the choice of that value is an integral part of the implementation (“hard wired”), whereas in other cases the ADBS provide a declarative syntax for the users to select a desired value. To better understand this concept, recall again our average salary maintenance scenario from the introduction. One of the possible sources that can cause the database to arrive at an undesired state is an update that increases the salary of a set of employees. We already illustrated the case of an insertion, now assume that the trigger that would correspond to the second case is specified as follows:

```
CREATE TRIGGER Update-Salary-Check
ON UPDATE OF Employee.Salary
IF (SELECT AVG Employee.Salary) > 65,000
UPDATE Employee
SET Employee.Salary = 0.95*Employee.Salary
```

Assume that it was decided to increase the salary of every employee in the “Maintenance” department by 10%, which would correspond to the following SQL statement:

```
UPDATE Employee
SET Employee.Salary = 1.10*Employee.Salary
WHERE Employee.Department = ‘Maintenance’
```

For the sake of illustration, assume that three employees are in the “Maintenance” department, Bob, Sam, and Tom, whose salaries need to be updated. Strictly speaking, an update is essentially a sequence of a deletion of an old tuple followed by an insertion of that tuple with the updated values for the respective attribute(s); however, for the purpose of this illustration, we can assume that the updates execute atomically. Now, some obvious behavioral options for this simple scenario are:

- An individual instance of the trigger Update-Salary-Check may be fired immediately, for every single update of a particular employee, as shown in Fig. 2a.
- The DBMS may wait until all the updates are completed, and then execute the Update-Salary-Check, as illustrated in Fig. 2b.

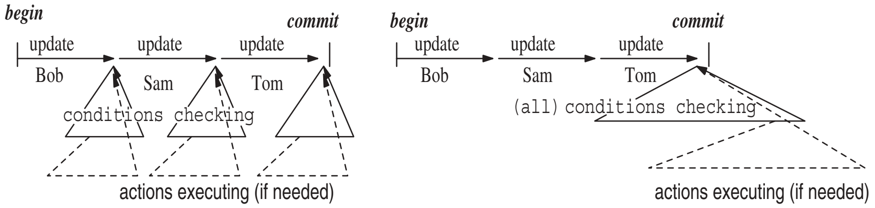


Figure 2. Different options for triggers execution.

- The DBMS waits for the completion of all the updates and the evaluation of the condition. If satisfied, the execution of the action for the instances of the Update-Salary-Check trigger may be performed either within the same transaction as the UPDATE Employee statement or in a different/subsequent transaction.

These issues illustrate some aspects that have motivated the researchers to identify various *semantic dimensions*, a term used to collectively identify the various parameters whose values may influence the executional behavior of ADBS. Strictly speaking, the model of the triggers' processing is coupled closely with the properties of the underlying DBMS, such as the data model, the transaction manager, and the query optimizer. However, some identifiable stages exist for every underlying DBMS:

- *Detection of events:* Events can be either *internal*, caused by a DBMS-invoked modification, transaction command, or, more generally, by any server-based action (e.g., clicking a mouse button on the display); or *external*, which report an occurrence of something outside the DBMS server (e.g., a humidity reading of a particular sensor, a location of a particular user detected by an RFID-based sensor, etc). Recall that (c.f. formalizing and reasoning), the events can be *primitive* or *composite*, defined in terms of the primitive events.
- *Detection of affected triggers:* This stage identifies the subset of the specified triggers, whose enabling events are among the detected events. Typically, this stage is also called the *instantiation* of the triggers.
- *Conditions evaluation:* Given the set of instantiated triggers, the DBMS evaluates their respective conditions and decides which ones are eligible for execution. Observe that the evaluation of the conditions may sometimes require a comparison between the values in the OLD (e.g., pretransaction state, or the state just before the occurence of the instantiating event) with the NEW (or current) state of the database.
- *Scheduling and execution:* Given the set of instantiated triggers, whose condition part is satisfied, this stage carries out their respective action-parts. In some systems [e.g., Starburst (2)] the users are allowed to specify a priority-based ordering among the triggers explicitly for this purpose. However, in the SQL standard (11), and in many commercially available DBMSs, the ordering is based on the time stamp of the creation of the trigger, and even this may not be enforced strictly at run-time. Recall (c.f. formalizing and reasoning) that the execution of the actions of the triggers may generate events that enable some other triggers, which causes a cascaded firing of triggers.

In the rest of this section, we present a detailed discussion of some of the semantic dimensions of the triggers.

Granularity of the Modifications

In relational database systems, a particular modification (insertion, deletion, update) may be applied to a single tuple or to a set of tuples. Similarly, in an object-oriented database system, the modifications may be applied to a single object or to a collection of objects—instances of a given class. Based on this distinction, the active rules can be made to react in a *tuple/instance* manner or in a *set-oriented* manner. An important observation is that this type of granularity is applicable in two different places in the active rules: (1) the events to which a particular rule reacts (is "awoken" by) and (2) the modifications executed by the action part of the rules. Typically, in the DBMS that complies with the SQL standard, this distinction is specified by using FOR EACH ROW (tuple-oriented) or FOR EACH STATEMENT (set-oriented) specification in the respective triggers. In our motivational scenario, if one would like the trigger Update-Salary to react to the modifications of the individual tuples, which correspond to the behavior illustrated in Fig. 2a, its specification should be:

```
CREATE TRIGGER Update-Salary-Check
ON UPDATE OF Employee.Salary
FOR EACH ROW
IF SELECT(...)
...
```

Coupling Among Trigger's Components

Because each trigger that conforms to the ECA paradigm has three distinct parts—the Event, Condition, and Action—one of the important questions is how they are synchronized. This synchronization is often called the *coupling* among the triggers components.

- *E-C coupling:* This dimension describes the temporal relationship among the events that enable certain triggers and the time of evaluating their conditions parts, with respect to the transaction in which the events were generated. With *immediate coupling*, the conditions are evaluated as soon as the basic modification that produced the events is completed. Under the *delayed coupling* mode, the evaluation of the conditions is delayed until a specific point (e.g., a special "event" takes place such as an explicit rule-processing point in the transaction). Specifically, if this special event is the attempt to *commit* the transaction, then the coupling is also called *deferred*.
- *C-A coupling:* Similarly, for a particular trigger, a temporal relationship exists between the evaluation of its condition and (if satisfied) the instant its action is executed. The options are the same as for the *E-C* coupling: *immediate*, in which case the action is executed as soon as the condition-evaluation is completed (in case it evaluates to true); *delayed,* which executes the action at some special point/event; and *deferred*, which is the case when the actions are executed at the end (just before *commit*) of the transaction in which the condition is evaluated.

A noteworthy observation at this point is that the semantic dimensions should not be understood as isolated completely from each other but, to the contrary, their values may be correlated. Among the other reasons, this correlation exists because the triggers manager cannot be implemented in isolation from the query optimizer and the transaction manager. In particular, the coupling modes discussed above are not independent from the transaction processing model and its relationship with the individual parts of the triggers. As another semantic dimension in this context, one may consider whether the conditions evaluation and the actions executions should be executed in the same transaction in which the triggering events have occurred (note that the particular transaction may be aborted because of the effects of the triggers processing). In a typical DBMS setting, in which the ACID (atomicity, consistency, isolation, and durability) properties of the transactions must be ensured, one would like to maintain the conditions evaluations and actions executions within the same transaction in which the triggering event originated. However, if a more sophisticated transaction management is available [e.g., nested transactions (24)] they may be processed in a separate subtransaction(s), in which the failure of a subtransaction may cause the failure of a parent transaction in which the events originated, or in two different transactions. This transaction is known commonly as a *detached* coupling mode.

Events Consumption and Composition

These dimensions describe how a particular event is treated when processing a particular trigger that is enabled due to its occurrence, as well as how the impact of the net effect of a set of events is considered.

One of the differences in the behavior of a particular ADBS is caused by the selection of the *scope*(23) of the event consumptions:

- *NO consumption:* the evaluation and the execution of the conditions part of the enabled/instantiated triggers have no impact on the triggering event. In essence, this means that the same event can enable a particular trigger over and over again. Typically, such behavior is found in the production rule systems used in expert systems (15).
- *Local consumption:* once an instantiated trigger has proceeded with its condition part evaluation, that trigger can no longer be enabled by the same event. However, that particular event remains eligible for evaluation of the condition the other triggers that it has enabled. This feature is the most common in the existing active database systems. In the setting of our motivational scenario, assume that we have another trigger, for example, Maintain-Statistics, which also reacts to an insertion of new employees by increasing properly the total number of the hired employees in the respective departmental relations. Upon insertion of a set of new employees, both New-Employee-Salary-Check and Maintain-Statistics triggers will be enabled. Under the local consumption mode, in case the New-Employee-Salary-Check trigger executes first, it is no longer enabled by the same insertion. The Maintain-Statistics trigger, however, is left enabled and will check its condition and/or execute its action.
- *Global consumption:* Essentially, global consumption means that once the first trigger has been selected for its processing, a particular event can no longer be used to enable any other triggers. In the settings of our motivational scenario, once the given trigger New-Employee-Salary-Check has been selected for evaluation of its condition, it would also disable the Maintain-Statistics despite that it never had its condition checked. In general, this type of consumption is appropriate for the settings in which one can distinguish among "regular" rules and "exception" rules that are enabled by the same event. The "exception" not only has a higher priority, but it also disables the processing of the "regular" rule.

A particular kind of event composition, which is encountered in practice, frequently is the *event net effect*. The basic distinction is whether the system should consider the impact of the occurrence of a particular event, regardless of what are the subsequent events in the transaction, or consider the possibility of invalidating some of the events that have occurred earlier. As a particular example, the following intuitive policy for computing the net effects has been formalized and implemented in the Starburst system (2):

- If a particular tuple is created (and possibly updated) in a transaction, and subsequently deleted within that same transaction, the net effect is *null.*

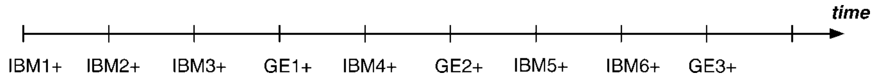

Figure 3. Composite events and consumption.

- If a particular tuple is created (respectively, updated) in a transaction, and that tuple is updated subsequently several times, the net effect is the creation of the final version of that tuple (respectively, the single update equivalent to the final value).
- If a particular tuple is updated and deleted subsequently in a given transaction, then the net effect is the deletion of the original tuple.

Combining the computation of the net effects in systems that allow specification of composite events via an event algebra (5,17) is a very complex problem. The main reason is that in a given algebra, the detection of a particular composite event may be in a state in which several different instances of one of its constituent events have occurred. Now, the question becomes what is the policy for *consuming* the primitive events upon a detection of a composite one. An illustrative example is provided in Fig. 3. Assume that the elementary (primitive) events correspond to tickers from the stockmarket and the user is interested in the composite event: *CE = (two consecutive increases of the IBM stock) AND (two consecutive increases of the General Electric [GE] stock).* Given the timeline for the sequence of events illustrated in Fig. 3, upon the second occurrence of the GE stock increase (GE2+), the desired composite event CE can be detected. However, now the question becomes *which* of the primitive events should be used for the detection of CE (6 ways exist to couple IBM-based events), and *how* should the rest of the events from the history be consumed for the future (e.g., if GE2+ is not consumed upon the detection of CE, then when GE3+ occurs, the system will be able to detect another instance of CE). Chakravarthy et al. (5) have identified four different contexts (*recent, chronicle, continuous,* and *cumulative*) of consuming the earlier occurrences of the primitive constituent events which enabled the detection of a given composite event.

Data Evolution

In many ADBSs, it is important to query the history concerning the execution of the transaction(s). For example, in our motivational scenario, one may envision a modified constraint that states that the average salary increase in the enterprise should not exceed 5% from its previous value when new employees are and/or inserted when the salaries of the existing employees are updated. Clearly, in such settings, the conditions part of the respective triggers should compare the current state of the database with the older state.

When it comes to past database states, a special syntax is required to specify properly the queries that will retrieve the correct information that pertains to the prior database states. It can be speculated that every single state that starts from the *begin* point of a particular transaction should be available for inspection; however, in practice, only a few such states are available (c.f. Ref. (23)):

- *Pretransaction state:* the state of the database just before the execution of the transaction that generated the enabling event.
- *Last consideration state:* given a particular trigger, the state of the database after the last time that trigger has been considered (i.e., for its condition evaluation).
- *Pre-event state:* given a particular trigger, the state of the database just before the occurrence of the event that enabled that trigger.

Typically, in the existing commercially available DBMS that offers active capabilities, the ability to query the past states refers to the pretransaction state. The users are given the keywords OLD and NEW to specify declaratively which part needs to be queried when specifying the condition part of the triggers (11).

Another option for inspecting the history of the active database system is to query explicitly the set of occurred events. The main benefit of this option is the increased flexibility to specify the desired behavioral aspects of a given application. For example, one may wish to query not all the items affected by a particular transaction, but only the ones that participated in the generation of the given composite event that enabled a particular trigger (5). Some prototype systems, [e.g., Chimera (25) offer this extended functionality, however, the triggers in the commercially available DBMS that conform to the SQL standard are restricted to querying the database states only (c.f., the OLD and NEW above).

Recent works (26) have addressed the issues of extending the capabilities of the commercially available ORDBMS Oracle 10g (27) with features that add a flexibility for accessing various portions (states) of interest throughout the evolution of the ADBS, which enable sophisticated management of events for wide variety of application domains.

Effects Ordering

We assumed that the execution of the action part of a particular trigger occurs not only *after* the occurrence of the event, but also after the effects of executing the modifications that generated that event have been incorporated. In other words, the effects of executing a particular trigger were adding to the effects of the modifications that were performed by its enabling event. Although this seems to be the most intuitive approach, in some applications, such as alerting or security monitoring, it may be desirable to have the action part of the corresponding trigger execute *before* the modifications of the events take place, or even *instead* of the modifications.

Typical example is a trigger that detects when an unauthorized user has attempted to update the value of a particular tuple in a given relation. Before executing the user's request, the respective log-file needs to be updated properly. Subsequently, the user-initiated transaction must be aborted; instead, an alert must be issued to the database administrator. Commercially available DBMS offer the flexibility of stating the BEFORE, AFTER, and INSTEAD preferences in the specification of the triggers.

Conflict Resolution and Atomicity of Actions

We already mentioned that if more than one trigger is enabled by the occurrence of a particular event, some selection must be performed to evaluate the respective conditions and/or execute the actions part. From the most global perspective, one may distinguish between the *serial* execution, which selects a single rule according to a predefined policy, and a *parallel* execution of all the enabled triggers. The latter was envisioned in the HiPAC active database systems (c.f. Ref. (28)) and requires sophisticated techniques for concurrency management. The former one can vary from specifying the total priority ordering completely by the designer, as done in the Postgres system (4), to partial ordering, which specifies an incomplete precedence relationship among the triggers, as is the case in the Starburst system (20). Although the total ordering among the triggers may enable a deterministic behavior of the active database, it may be too demanding on the designer, who always is expected to know exactly the intended behavior of all the available rules (23). Commercial systems that conform with the SQL99 standard do not offer the flexibility of specifying an ordering among the triggers. Instead, the default ordering is by the timestamp of their creation.

When executing the action part of a given trigger, a particular modification may constitute an enabling event for some other trigger, or even for a new instance of the same trigger whose action's execution generated that event. One option is to interrupt the action of the currently executing trigger and process the triggers that were "awoken" by it, which could result in cascaded invocation where the execution of the trigger that produced the event is suspended temporarily. Another option is to ignore the occurrence of the generated event temporarily, until the action part of the currently executing trigger is completed (atomic execution). This action illustrates that the values in different semantic dimensions are indeed correlated. Namely, the choice of the atomicity of the execution will impact the value of the E-C/C-A coupling modes: one cannot expect an immediate coupling if the execution of the actions is to be atomic.

Expressiveness Issues

As we illustrated, the choice of values for a particular semantic dimension, especially when it comes to the relationship with the transaction model, may yield different outcomes of the execution of a particular transaction by the DBMS (e.g., deferred coupling will yield different behavior from the immediate coupling). However, another subtle aspect of the active database systems is dependent strongly on their chosen semantic dimensions – the expressive power. Picouet and Vianu (29) introduced a broad model for active databases based on the unified framework of relational Turing machines. By restricting some of the values of the subset of the semantic dimensions and thus capturing the interactions between the sequence of the modifications and the triggers, one can establish a yardstick to compare the expressive powers of the various ADBSs. For example, it can be demonstrated that:

- The A-RDL system (30) under the immediate coupling mode is equivalent to the Postgres system (4) on ordered databases.
- The Starburst system (2) is incomparable to the Postgres system (4).
- The HiPAC system (28) subsumes strictly the Starburst (2) and the Postgres (4) systems.

Although this type of analysis is extremely theoretical in nature, it is important because it provides some insights that may have an impact on the overall application design. Namely, when the requirements of a given application of interest are formalized, the knowledge of the expressive power of the set of available systems may be a crucial factor to decide which particular platform should be used in the implementation of that particular application.

OVERVIEW OF ACTIVE DATABASE SYSTEMS

In this section, we outline briefly some of the distinct features of the existing ADBS—both prototypes as well as commercially available systems. A detailed discussion of the properties of some systems will also provide an insight of the historic development of the research in the field of ADBS, can be found in Refs. (1) and (7).

Relational Systems

A number of systems have been proposed to extend the functionality of relational DBMS with active rules. Typically, the events in such systems are mostly database modifications (insert, delete, update) and the language to specify the triggers is based on the SQL.

- *Ariel* (31): The Ariel system resembles closely the traditional *Condition* → *Action* rules from expert systems literature (15), because the specification of the Event part is optional. Therefore, in general, NO event consumption exists, and the coupling modes are immediate.
- *Starburst* (2): This system has been used extensively for database-internal applications, such as integrity constraints and views maintenance. Its most notable features include the set-based execution model and the introduction of the net effects when considering the modifications that have led to the occurrence of a particular event. Another particular feature

introduced by the Starburst system is the concept of *rule processing points*, which may be specified to occur during the execution of a particular transaction or at its end. The execution of the action part is atomic.

- *Postgres* (4): The key distinction of Postgres is that the granularity of the modifications to which the triggers react is tuple (row) oriented. The coupling modes between the E-C and the C-A parts of the triggers are immediate and the execution of the actions part is interruptable, which means that the recursive enabling of the triggers is an option. Another notable feature of the Postgres system is that it allows for INSTEAD OF specification in its active rules.

Object-Oriented Systems

One of the distinct features of object-oriented DBMS (OODBMS) is that it has *methods* that are coupled with the definition of the classes that specify the structure of the data objects stored in the database. This feature justifies the preference for using OODBMS for advanced application domains that include extended behavior management. Thus, the implementation of active behavior in these systems is coupled tightly with a richer source of events for the triggers (e.g., the execution of any method).

- *ODE* (32): The ODE system was envisioned as an extension of the C++ language with database capabilities. The active rules are of the C-A type and are divided into constraints and triggers for the efficiency of the implementations. Constraints and triggers are both defined at a class level and are considered a property of a given class. Consequently, they can be inherited. One restriction is that the updates of the individual objects, caused by private member functions, cannot be monitored by constraints and triggers. The system allows for both immediate coupling (called *hard constraints*) and deferred coupling (called *soft constraints*), and the triggers can be declared as executing once-only or perpetually (reactivated).
- *HiPAC* (28): The HiPAC project has pioneered many of the ideas that were used subsequently in various research results on active database systems. Some of the most important contributions were the introduction of the coupling modes and the concept of composite events. Another important feature of the HiPAC system was the extension that provided the so called *delta-relation*, which monitors the net effect of a set of modifications and made it available as a part of the querying language. HiPAC also introduced the visionary features of parallel execution of multiple triggers as subtransactions of the original transaction that generated their enabling events.
- *Sentinel* (5): The Sentinel project provided an active extension of the OODBMS, which represented the active rules as database objects and focused on the efficient integration of the rule processing module within the transaction manager. One of the main novelties discovered this particular research project was the introduction of a rich mechanism for to specify and to detect composite events.
- *SAMOS* (18): The SAMOS active database prototype introduced the concept of an *interval* as part of the functionality needed to manage composite events. A particular novelty was the ability to include the monitoring intervals of interest as part of the specification of the triggers. The underlying mechanism to detect the composite events was based on Colored Petri-Nets.
- *Chimera* (25): The Chimera system was envisioned as a tool that would seamlessly integrate the aspects of object orientation, deductive rules, and active rules into a unified paradigm. Its model has strict underlying logical semantics (fixpoint based) and very intuitive syntax to specify the active rules. It is based on the EECA (Extended-ECA) paradigm, specified in Ref. (23), and it provides the flexibility to specify a wide spectrum of behavioral aspects (e.g., semantic dimensions). The language consists of two main components: (1) declarative, which is used to specify queries, deductive rules, and conditions of the active rules; and (2) procedural, which is used to specify the nonelementary operations to the database, as well as the action parts of the triggers.

Commercially Available Systems

One of the earliest commercially available active database systems was DB2 (3), which integrated trigger processing with the evaluation and maintenance of declarative constraints in a manner fully compatible with the SQL92 standard. At the time it served as a foundation model for the draft of the SQL3 standard. Subsequently, the standard has migrated to the SQL99 version (11), in which the specification of the triggers is as follows:

```
<trigger definition> ::=
  CREATE TRIGGER <trigger name>
  {BEFORE | AFTER} <trigger event> ON
    <table name>
  [REFERENCING <old or new values alias list>]
  [FOR EACH {ROW | STATEMENT}]
  [<trigger condition>]
  <trigger action>
<trigger event> ::= INSERT | DELETE | UPDATE
    [OF <column name list>]
<old or new values alias list> ::= {OLD | NEW}
    [AS] <identifier> | {OLD_TABLE |
        NEW_TABLE} [AS] <identifier>
```

The condition part in the SQL99 triggers is optional and, if omitted, it is considered to be true; otherwise, it can be any arbitrarily complex SQL query. The action part, on the other hand, is any sequence of SQL statements, which includes the invocation of stored procedures, embedded within a single BEGIN – END block. The only statements that are excluded from the available actions pertain to connections, sessions, and transactions processing.

Commercially available DBMS, with minor variations, follow the guidelines of the SQL99 standards.

In particular, the Oracle 10g (27), an object-relational DBMS (ORDBMS), not only adheres to the syntax specifications of the SQL standard for triggers (28), but also provides some additions: The triggering event can be specified as a logical disjunction (ON INSERT OR UPDATE) and the INSTEAD OF option is provided for the action's execution. Also, some system events (startup/shutdown, server error messages), as well as user events (logon/logoff and DDL/DML commands), can be used as enabling events in the triggers specification. Just like in the SQL standard, if more than one trigger is enabled by the same event, the Oracle server will attempt to assign a priority for their execution based on the timestamps of their creation. However, it is not guarantees that this case will actually occur at run time. When it comes to dependency management, Oracle 10g server treats triggers in a similar manner to the stored procedures: they are inserted automatically into the data dictionary and linked with the referenced objects (e.g., the ones which are referenced by the action part of the trigger). In the presence of integrity constraints, the typical executional behavior of the Oracle 10g server is as follows:

1. Run all BEFORE *statement* triggers that apply to the statement.
2. Loop for each row affected by the SQL statement.
   a. Run all BEFORE *row* triggers that apply to the statement.
   b. Lock and change row, and perform integrity constraint checking. (The lock is not released until the transaction is committed.)
   c. Run all AFTER *row* triggers that apply to the statement.
3. Complete deferred integrity constraint checking.
4. Run all AFTER *statement* triggers that apply to the statement.

The Microsoft Server MS-SQL also follows closely the syntax prescribed by the SQL99 standard. However, it has its own additions; for example, it provides the INSTEAD OF option for triggers execution, as well as a specification of a restricted form of composite events to enable the particular trigger. Typically, the statements execute in a tuple-oriented manner for each row. A particular trigger is associated with a single table and, upon its definition, the server generates a virtual table automatically for to access the old data items. For example, if a particular trigger is supposed to react to INSERT on the table Employee, then upon insertion to Employee, a virtual relation called Inserted is maintained for that trigger.

NOVEL CHALLENGES FOR ACTIVE RULES

We conclude this article with a brief description of some challenges for the ADBSs in novel application domains, and with a look at an extended paradigm for declaratively specifying reactive behavior.

Application Domains

Workflow management systems (WfMS) provide tools to manage (modeling, executing, and monitoring) *workflows*, which are viewed commonly as processes that coordinate various cooperative activities to achieve a desired goal. Workflow systems often combine the *data centric* view of the applications, which is typical for information systems, with their *process centric* behavioral view. It has already been indicated (12) that WfMS could benefit greatly by a full use of the tools and techniques available in the DBMS when managing large volumes of data. In particular, Shankar et al. (12) have applied active rules to the WfMS settings, which demonstrates that data-intensive scientific workflows can benefit from the concept of *active tables* associated with the programs. One typical feature of workflows is that many of the activities may need to be executed by distributed agents (*actors* of particular *roles*), which need to be synchronized to optimize the concurrent execution. A particular challenge, from the perspective of triggers management in such distributed settings, is to establish a common (e.g., transaction-like) context for their main components—events, conditions, and actions. As a consequence, the corresponding triggers must execute in a detached mode, which poses problems related not only to the consistency, but also to their efficient scheduling and execution (33).

Unlike traditional database applications, many novel domains that require the management of large quantities of information are characterized by the high volumes of data that arrive very fast in a stream-like fashion (8). One of the main features of such systems is that the queries are no longer instantaneous; they become *continuous*/*persistent* in the sense that users expect the answers to be updated properly to reflect the current state of the streamed-in values. Clearly, one of the main aspects of the continuous queries (CQ) management systems is the ability to react quickly to the changes caused by the variation of the streams and process efficiently the modification of the answers. As such, the implementation of CQ systems may benefit from the usage of the triggers as was demonstrated in the Niagara project (9). One issue related to the scalability of the CQ systems is the very scalability of the triggers management (i.e., many instances of various triggers may be enabled). Although it is arguable that the problem of the scalable execution of a large number of triggers may be coupled closely with the nature of the particular application domain, it has been observed that some general aspects of the scalability are applicable universally. Namely, one can identify similar predicates (e.g., in the conditions) across many triggers and group them into equivalence classes that can be indexed on those predicates. This project may require a more involved system catalog (34), but the payoff is a much more efficient execution of a set of triggers. Recent research has also demonstrated that, to capture the intended semantics of the application domain in dynamic environments, the events may have to be assigned an interval-based semantics (i.e., duration may need to be associated with their detection). In particular, in Ref. (35), the authors have demonstrated that if the commonly accepted instantaneous semantics for events occurrence is used in traffic management settings, one may obtain an unintended meaning for the composite events.

Moving objects databases (MODs) are concerned with the management of large volumes of data that pertain to the location-in-time information of the moving entities, as well as efficient processing of the spatio-temporal queries that pertain to that information (13). By nature, MOD queries are continuous and the answers to the pending queries change because of the changes in the location of the mobile objects, which is another natural setting for exploiting an efficient form of a reactive behavior. In particular, Ref. (14) proposed a framework based on the existing triggers in commercially available systems to maintain the correctness of the continuous queries for trajectories. The problem of the scalable execution of the triggers in these settings occurs when a traffic abnormality in a geographically small region may cause changes to the trajectories that pass through that region and, in turn, invalidate the answers to spatio-temporal queries that pertain to a much larger geographic area. The nature of the continuous queries' maintenance is dependent largely on the model adopted for the mobility representation, and the MOD-field is still very active in devising efficient approaches for the queries management which, in one way or another, do require some form of active rules management.

Recently, the wireless sensor networks (WSNs) have opened a wide range of possibilities for novel applications domains in which the whole process of gathering and managing the information of interest requires new ways of perceiving the data management problems (36). WSN consist of hundreds, possibly thousands, of low-cost devices (sensors) that are capable of measuring the values of a particular physical phenomenon (e.g., temperature, humidity) and of performing some elementary calculations. In addition, the WSNs are also capable of communicating and self-organizing into a network in which the information can be gathered, processed, and disseminated to a desired location. As an illustrative example of the benefits of the ECA-like rules in WSN settings, consider the following scenario (c.f. Ref. (6)): whenever the sensors deployed in a given geographic area of interest have detected that the average level of carbon monoxide in the air over any region larger than 1200 ft^2 exceeds 22%, an alarm should be activated. Observe that here the event corresponds to the updates of the (readings of the) individual sensors; the condition is a continuous query evaluated over the entire geographic zone of interest, and with a nested sub-query of identifying the potentially-dangerous regions. At intuitive level, this seems like a straightforward application of the ECA paradigm. Numerous factors in sensor networks affect the efficient implementation of this type of behavior: the energy resource of the individual nodes is very limited, the communication between nodes drains more current from the battery than the sensing and local calculations, and unlike the traditional systems where there are few vantage points to generate new events, in WSN settings, any sensor node can be an event-generator. The detection of composite events, as well as the evaluation of the conditions, must to be integrated in a fully distributed environment under severe constraints (e.g., energy-efficient routing is a paramount). Efficient implementation of the reactive behavior in a WSN-based databases is an ongoing research effort.

The $(ECA)^2$ Paradigm

Given the constantly evolving nature of the streaming or moving objects data, along with the consideration that it may be managed by distributed and heterogeneous sources, it is important to offer a declarative tool in which the users can actually specify how the triggers themselves should evolve. Users can adjust the events that they monitor, the conditions that they need to evaluate, and the action that they execute. Consider, for example, a scenario in which a set of motion sensors deployed around a region of interest is supposed to monitor whether an object is moving continuously toward that region for a given time interval. Aside from the issues of efficient detection of such an event, the application may require an alert to be issued when the status of the closest air field is such that fewer than a certain number of fighter jets are available. In this setting, both the event detection and the condition evaluation are done in distributed manner and are continuous in nature. Aside from the need of their efficient synchronization, the application demands that when a particular object ceases to move continuously toward the region, the condition should not be monitored any further for that object. However, if the object in question is closer than a certain distance (after moving continuously toward the region of interest for a given time), in turn, another trigger may be enabled, which will notify the infantry personnel. An approach for declarative specification of triggers for such behavior was presented in Ref. (37) where the $(ECA)^2$ paradigm (evolving and context-aware event-condition-action) was introduced. Under this paradigm, for a given trigger, the users can embed children triggers in the specifications, which will become enabled upon the occurrences of certain events in the environment, and only when their respective parent triggers are no longer of interest. The children triggers may consume their parents either completely, by eliminating them from any consideration in the future or partially, by eliminating only the particular instance from the future consideration, but allowing a creation of subsequent instances of the parent trigger. Obviously, in these settings, the coupling modes among the E-C and C-A components of the triggers must to be detached, and for the purpose of their synchronization the concept of meta-triggers was proposed in Ref. (37). The efficient processing of such triggers is still an open challenge.

ALGEBRAIC CODING THEORY

INTRODUCTION

In computers and digital communication systems, information almost always is represented in a binary form as a sequence of bits each having the values 0 or 1. This sequence of bits is transmitted over a *channel* from a sender to a receiver. In some applications the channel is a storage medium like a DVD, where the information is written to the medium at a certain time and retrieved at a later time. Because of the physical limitations of the channel, some transmitted bits may be corrupted (the channel is *noisy*) and thus make it difficult for the receiver to reconstruct the information correctly.

In algebraic coding theory, we are concerned mainly with developing methods to detect and correct errors that typically occur during transmission of information over a noisy channel. The basic technique to detect and correct errors is by introducing redundancy in the data that is to be transmitted. This technique is similar to communicating in a natural language in daily life. One can understand the information while listening to a noisy radio or talking on a bad telephone line, because of the redundancy in the language.

For example, suppose the sender wants to communicate one of 16 different messages to a receiver. Each message m can then be represented as a binary quadruple (c_0, c_1, c_2, c_3). If the message (0101) is transmitted and the first position is corrupted such that (1101) is received, this leads to an uncorrectable error because this quadruple represents a different valid message than the message that was sent across the channel. The receiver will have no way to detect and to correct a corrupted message in general, because any quadruple represents a valid message.

Therefore, to combat errors the sender *encodes* the data by introducing redundancy into the transmitted information. If M messages are to be transmitted, the sender selects a subset of M binary n-tuples, where $M < 2^n$. Each of the M messages is encoded into an n-tuple. The set consisting of the M n-tuples obtained after encoding is called a binary (n, M) *code*, and the elements are called *codewords*. The codewords are sent over the channel.

It is customary for many applications to let $M = 2^k$, such that each message can be represented uniquely by a k-tuple of information bits. To encode each message the sender can append $n - k$ parity bits depending on the message bits and use the resulting n bit codeword to represent the corresponding message.

A binary code C is called a linear code if the sum (modulo 2) of two codewords is again a codeword. This is always the case when the parity bits are linear combinations of the information bits. In this case, the code C is a vector space of dimension k over the binary field of two elements, containing $M = 2^k$ codewords, and is called an $[n, k]$ code. The main reason for using linear codes is that these codes have more algebraic structure and are therefore often easier to analyze and to decode in practical applications.

The simplest example of a linear code is the $[n, n - 1]$ *even-weight code* (or parity-check code). The encoding consists of appending a single parity bit to the $n - 1$ information bits so that the codeword has an even number of ones. Thus, the code consists of all 2^{n-1} possible n-tuples of even weight, where the *weight* of a vector is the total number of ones in its components. This code can detect all errors in an odd number of positions, because if such an error occurs, the received vector also will have odd weight. The even-weight code, however, can only detect errors. For example, if (000…0) is sent and the first bit is corrupted, then (100…0) is received. Also, if (110…0) was sent and the second bit was corrupted, then (100…0) is received. Hence, the receiver cannot correct this single error or, in fact, any other error.

An illustration of a code that can correct any single error is shown in Fig. 1. The three circles intersect and divide the plane into seven finite areas and one infinite area. Each finite area contains a bit c_i for $i = 0, 1,\ldots, 6$. Each of the 16 possible messages, denoted by (c_0, c_1, c_2, c_3), is encoded into a codeword $(c_0, c_1, c_2, c_3, c_4, c_5, c_6)$, in such a way that the sum of the bits in each circle has an even parity.

In Fig. 2, an example is shown of encoding the message (0011) into the codeword (0011110). Because the sum of two codewords also obeys the parity-checks and thus is a codeword, the code is a linear [7, 4] code.

Suppose, for example, that the transmitted codeword is corrupted in the bit c_1 such that the received word is (0111110). Then, calculating the parity of each of the three circles, we see that the parity fails for the upper circle as well as for the leftmost circle, whereas the parity of the rightmost circle is correct. Hence, from the received vector, indeed we can conclude that bit c_1 is in error and should be corrected. In the same way, any single error can be corrected by this code.

LINEAR CODES

An (n, M) code is simply a set of M vectors of length n with components from a finite field $F_2 = \{0, 1\}$, where addition and multiplication are done modulo 2. For practical applications it is desirable to provide the code with more structure. Therefore, linear codes often are preferred. A linear $[n, k]$ code C is a k-dimensional subspace C of F_2^n, where F_2^n is the vector space of n-tuples with coefficients from the finite field F_2.

A linear code C usually is described in terms of a generator matrix or a parity-check matrix. A *generator matrix* G of C is a $k \times n$ matrix whose row space is the code C; i.e.,

$$C = \{\mathbf{x}G | \mathbf{x} \in F_2^k\}$$

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

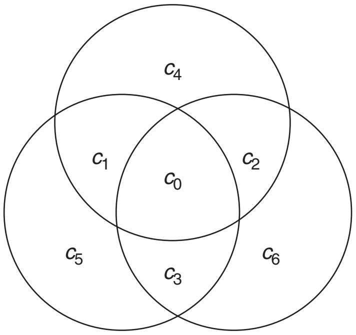

Figure 1. The message (c_0, c_1, c_2, c_3) is encoded into the codeword $(c_0, c_1, c_2, c_3, c_4, c_5, c_6)$, where c_4, c_5, c_6 are chosen such that there is an even number of ones within each circle.

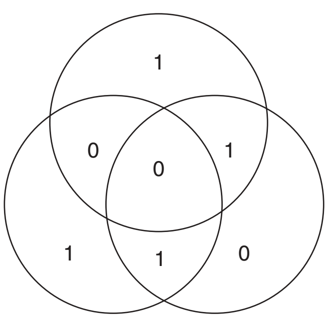

Figure 2. Example of the encoding procedure given in Fig. 1. The message (0011) is encoded into (0011110). Note that there is an even number of ones within each circle.

A *parity-check matrix* H is an $(n - k) \times n$ matrix such that

$$C = \{c \in F_2^n | cH^{tr} = 0\}$$

where H^{tr} denotes the transpose of H.

Example. The codewords in the code in the previous section are the vectors $(c_0, c_1, c_2, c_3, c_4, c_5, c_6)$ that satisfy the following system of *parity-check equations*:

$$\begin{array}{ccccccccc} c_0 & + & c_1 & + & c_2 & + & c_4 & = & 0 \\ c_0 & + & c_1 & + & c_3 & + & c_5 & = & 0 \\ c_0 & + & c_2 & + & c_3 & + & c_6 & = & 0 \end{array}$$

where all additions are modulo 2. Each of the three parity-check equations corresponds to one of the three circles.

The coefficient matrix of the parity-check equations is the *parity-check matrix*

$$H = \begin{pmatrix} 1 & 1 & 1 & 0 & 1 & 0 & 0 \\ 1 & 1 & 0 & 1 & 0 & 1 & 0 \\ 1 & 0 & 1 & 1 & 0 & 0 & 1 \end{pmatrix} \qquad (1)$$

The code C is therefore given by

$$C = \{\mathbf{c} = (c_0, c_1, \ldots, c_6) | cH^{tr} = 0\}$$

A generator matrix for the code in the previous example is given by

$$G = \begin{pmatrix} 1 & 0 & 0 & 0 & 1 & 1 & 1 \\ 0 & 1 & 0 & 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 & 1 & 1 \end{pmatrix}$$

Two codes are *equivalent* if the codewords in one of the codes can be obtained by a fixed permutation of the positions in the codewords in the other code. If G (respectively, H) is a generator (respectively, parity-check) matrix of a code, then the matrices obtained by permuting the columns of these matrices in the same way give the generator matrix (respectively, parity-check) matrix of the permuted code.

The *Hamming distance* between $\mathbf{x} = (x_0, x_1, \ldots, x_{n-1})$ and $\mathbf{y} = (y_0, y_1, \ldots, y_{n-1})$ in F_2^n is the number of positions in which they differ. That is,

$$d(\mathbf{x}, \mathbf{y}) = |\{i | x_i \neq y_i, 0 \leq i \leq n - 1\}|$$

The Hamming distance has the properties required to be a metric:

1. $d(\mathbf{x}, \mathbf{y}) \geq 0$ for all $\mathbf{x}, \mathbf{y} \in F_2^n$ and equality holds if and only if $\mathbf{x} = \mathbf{y}$.
