Another example of "regional monitoring" is the Climate Prediction Center (CPC) of the National Weather Service (part of the National Oceanographic and Atmospheric Administration, NOAA). The CPC collects and produces daily and monthly data, time series, and maps for various climate parameters, such as precipitation, temperature, snow cover, and degree days for the United States, the Pacific islands, and other parts of the world. The CPC also compiles data on historical and current atmospheric and oceanic conditions, the El Niño-Southern Oscillation (ENSO) Index, and other climate patterns, such as the North Atlantic and Pacific Decadal Oscillations, as well as stratospheric ozone and temperatures.

- **U.K. Climate Research Unit**

A significant global center for compiling temperature and other climate data sets is the Climate Research Unit (CRU) of the University of East Anglia in the United Kingdom. Some of the data produced are available online, and other sets are available on request. CRU endeavors to update the majority of the data pages at timely intervals. Data sets are available in the following categories: temperature, precipitation, atmospheric pressure and circulation indices, climate indices for the United Kingdom, data for the Mediterranean and alpine areas, and high-resolution gridded data sets.

• World Data Center System

A good example of a "global center" is the World Data Center (WDC) system, which was created to archive and distribute data collected from the observational programs of the 1957-1958 International Geophysical Year (IGY). Originally established in the United States, Europe, Russia, and Japan, the WDC system has since expanded to fifty-two centers in twelve countries. Its holdings include a wide range of solar, geophysical, environmental, and human dimensions data. The WDC is maintained by Model and Data (M&D), which is hosted at the Max Planck Institute for Meteorology, located in Germany.

• Context

In terms of climate change, the monitoring of the climate is extremely important. A number of internationally recognized groups collect, analyze, and publish—mainly through Web sites—climate and other data for various areas of the world, including the globe as a whole, the land as a whole, the ocean as a whole, and regions such as the tropics and polar areas. In addition to the climate variables, a wide variety of other variables are monitored on a global or regional scale, such as the extent of sea ice, sea surface temperatures, carbon dioxide, and methane. All of these values, when correctly analyzed, provide important indicators of what changes have occurred during the past (weeks to many decades) in the broader atmospheric environment. Such information is essential if correct answers to questions relating to the changing climate are to be obtained.

Global surface temperature

- **Category:** Meteorology and atmospheric sciences

- **Definition**

Global surface temperature is an estimate of global mean air temperature at the Earth's surface, based on thermometer measurements made at land-based weather stations. Because about 70 percent of the Earth's surface is covered by water, land-based data are supplemented by sea-surface-temperature (SST) measurements. Estimates of air temperature are based on the assumption that there is a simple link between the SST and that of the air above. Usually, SST measurements are based on measurements of the temperature of sea-water that is taken aboard ships for use as an engine coolant. In the past, SST measurements were made of water taken from buckets tethered to ropes and thrown overboard. Supplementary SST data are gathered from data buoys, small island stations, and shipboard, nighttime measurements of marine air temperatures.

- **Significance for Climate Change**

Three agencies have taken responsibility for the combined global surface temperature record: the Climate Research Unit of the University of East Anglia; the U.S. National Aeronautics and Space Administration's Goddard Institute for Space Studies; and the Global Historical Climate Network of the U.S. National Oceanographic and Atmospheric Administration. To determine global surface temperature changes over time, these agencies locate and analyze anomalous departures from thirty-year temperature averages. These analyses are most commonly based on the area-weighted global average of sea-surface-temperature anomalies and land-surface-air-temperature anomalies. Based on these analyses, the mean global surface temperature of the Earth shows a warming in the range of 0.3°-0.7° Celsius over the past century, or a statistical average of about 0.003°-0.007° Celsius per year. Global data sets from the various agencies show slightly dissimilar trends, as the data are processed in different ways.

Deviations in Mean Global Surface Temperature

The following table lists deviations in average global surface temperature from the baseline temperature average set during the period between 1951 and 1980.

Year	*Deviation (in 0.01° Celsius)*	*Year*	*Deviation (in 0.01° Celsius)*
1880	−12	1960	−2
1890	−21	1970	+4
1900	−6	1980	+28
1910	−21	1990	+48
1920	−17	2000	+42
1930	−4	2005	+76
1940	+14	2008	+54
1950	−17		

Data from Goddard Institute for Space Studies, National Aeronautics and Space Administration.

Questions arise as to the representative nature of the data on which global surface temperature calculations have been based. These data come from weather stations unevenly distributed over the Earth's surface, mostly on land, close to towns and cities, and predominantly in the Northern Hemisphere. Land use can have significant effects on local climate. The best-documented examples of such effects are urban heat islands, which are significantly warmer than their rural surroundings. Cities replace natural vegetation with surfaces such as concrete and asphalt that can warm them by several degrees Celsius. Thus, a disproportionate number of weather stations being located in urban environments may skew data regarding global averages. Many weather stations are located at airports, which were originally located in rural areas that have since been developed. Thus, while the data collected at such stations remain reliable measurements of the local, urban environment, they may no longer be equally reliable indicators of global trends.

Global warming potential

- **Category:** Pollution and waste

- **Definition**

Global warming potential (GWP) is an index based upon radiative (infrared-absorbing) properties of well-mixed greenhouse gases (GHGs). It can be used to estimate the relative potential future impacts of GHG emissions on the global climate. Specifically, the GWP of a given GHG is the time-integrated global mean radiative forcing from the instantaneous release of 1 kilogram of that GHG, relative to that of a reference GHG, usually carbon dioxide (CO_2). The GWP is a function of a gas's lifetime, concentration, and effectiveness at absorbing thermal infrared radiation.

- **Significance for Climate Change**

GWP is the index used by parties to the United Nations Framework Convention on Climate Change (UNFCCC) to quantify the greenhouse-enhancing potential of trace atmospheric gases. The GWP is used to evaluate the effects of anthropogenic interference in the climate system and of GHG emission reductions. GWP is a purely physical index and does not take into consideration the costs and benefits of climate policy initiatives, cost discounting, or the location of emissions or regional climates, among other factors. Thus, GWP does not measure economic, cultural, or regional factors useful in determining climate- and GHG-related policies.

Other limitations of the GWP index exist. The choice of time horizon for integration ranges from short-term changes (such as responses of cloud cover to surface temperature changes) to long-term effects (such as changes in ocean level). For purposes of the first commitment period under the Kyoto Protocol, the parties to the UNFCCC agreed to a one-hundred-year time horizon for integration of GWPs as a mid-term balance between long-term (five-hundred-year) and short-term (twenty-year) climate effects. The current one-hundred-year GWPs for select GHGs are listed in *Climate Change, 2007*, a report prepared by the Intergovernmental Panel on Climate Change (IPCC).

The mid-term time horizon favors reductions in GHGs whose GWP is greatest over one-hundred-year periods, while diminishing the importance of reducing short-lived GHG emissions in the near future and long-lived GHGs over the long term. For example, GWPs for methane over twenty-year, one-hundred-year, and five-hundred-year time horizons are 72, 25, and 7, respectively. The value of reducing methane under analyses based on the short-term time horizon is nearly three times that of reducing it according to analyses employing the mid-term time horizon. Short-term analyses, however, have motivated the United States to create the Methane to Markets initiative, which seeks to capture or reduce methane emissions to address near-term climate change cost-effectively.

Uncertainties in the GWP arise from assuming a linear radiative forcing function under a small emission pulse (1 kilogram). That is, GWP calculations assume that 100 kilograms of a GHG will have a GWP one hundred times that of 1 kilogram of that GHG. This is not necessarily the case, as emissions of a GHG may build on or interfere with each other, cause positive or negative feedback loops, or otherwise increase or decrease their effects on climate in a nonlinear manner. As more information on radiative forcing is gathered, confidence in GWP values will increase.

Gore, Al

American statesman and environmental activist

Born: March 31, 1948; Washington, D.C.

A longtime congressional and administrative governmental advocate for environmental issues, Gore was awarded the 2007 Nobel Peace Prize for his work in raising awareness about such issues, particularly global warming.

• Life

Al Gore was born on March 31, 1948, in Washington, D.C., the son of then-congressman, later U.S. senator, Albert Arnold Gore, Sr., of Carthage, Tennessee, and his wife, Pauline LaFon Gore. Gore attended Harvard University from 1965 to 1969, earning a bachelor of arts in government. He saw military service in Vietnam with the Twentieth Engineers from 1970 to 1971 and spent a year in the divinity school at Vanderbilt University before landing a position as a reporter for *The Tennessean*, Nashville's largest daily newspaper. After two years at Vanderbilt Law School, Gore was elected to the U.S. House of Representatives in 1976.

He was re-elected three times; in 1984, he ran successfully for the Senate, where he served until 1993. In 1988, he announced his intention to enter the race for the Democratic Party's presidential nomination. Failing to overtake front-runner and eventual nominee Michael Dukakis of Massachusetts, Gore dropped from the race after losing heavily in the New York State primary election. Apart from his environmental efforts, Gore's most notable legislative activity lay in the field of informational technology. As chair of the House Committee on Science and Technology, he was the most active legislative advocate for promoting the Internet. While in the Senate, he sponsored the High Performance Computing and Communication Act of 1991. His contribution in the crafting of this piece of legislation was so pervasive that it was dubbed the Gore Act.

Gore initially decided against involvement in the 1992 presidential campaign, citing family concerns arising from his son's near-fatal traffic accident and lengthy recuperation. However, when Democratic nominee Bill Clinton offered him the vice presidential slot on the party ticket, the Tennessee senator accepted. His strong performance in the television debate with Republican vice presidential candidate Dan Quayle and independent candidate Admiral James B. Stockdale is seen by some as a factor in the Democratic electoral victory in November, 1992. He served as vice president for the duration of the Clinton administration, 1993-2001.

Breaking somewhat with Clinton in the wake of the Monica Lewinsky scandal, Gore easily secured the Democratic presidential nomination in 2000, selecting U.S. senator Joseph Lieberman of Connecticut as his running mate. Though Gore won the popular vote over George W. Bush, it was the Republican candidate who took the presidency by tallying a margin of 271-266 votes in the Electoral College in a campaign marred by a ballot recount controversy in Florida.

• Climate Work

Gore himself attributes the genesis of his interest in the environment to listening to his mother reading from the groundbreaking book *Silent Spring* (1962) by Rachel Carson. Then, while studying at Harvard, he was much influenced by the lectures and research of Roger Revelle, one of the world's first academics to monitor atmospheric carbon dioxide levels scientifically and to tie them to global temperature increases. So active was Gore at taking the lead in advocating green causes during his congressional and senatorial tenures that he earned the nickname Mr. Ozone. In 1992, Gore published *Earth in the Balance*, wherein he pressed for what he termed a "global Marshall Plan" comprising a united effort by the more technologically advanced nations to set aside specific funding in order to assist underdeveloped countries in coping with their own ecological crises. However, apart from raising awareness about the global warming issue through committee hearings and publications, Gore was able to push through little in the way of far-reaching ecological legislation.

It would not be until his vice presidential term that some of his ideas would effectively permeate through higher governmental circles, generating some interest from the Clinton administration. Even at that, efforts in that direction would be hampered by conservative Republican electoral gains that resulted in Republican control of Congress. Increasingly focused on the 2000 presidential campaign, Gore began drawing criticism from environmental groups for his apparent inactivity. Even his greatest effort in the cause of alleviating the threat to global warming posed by greenhouse gases—his intervention to save the Kyoto Protocol on Climate Change—elicited mixed reactions. Negotiations almost broke down over the question of whether developing countries could be held to the same gas emission standards as the more technologically advanced nations. The U.S. Senate threatened to sabotage the treaty if Third World nations were not equally accountable. In December, 1997, Gore traveled personally to Kyoto and, probably putting his political career on the line, was able to devise a compromise calling for accountability, but also for lower emission standards.

During the course of his post-vice presidential years, Gore has worked for environmental policy change through the Alliance for Climate Protection, a nonprofit educational and lobbying organization dedicated to reversing global warming, and Generation Investment Management, a business corporation he founded in 2004 to encourage investment in firms that demonstrate environmental consciousness. In 2006, Gore gained his greatest international fame through the simultaneous release of a film and book titled *An Inconvenient Truth*. The DVD recording of the film, especially, in which Gore himself adroitly lectured upon and explained global warming at the popular level, was so acclaimed that it earned the former vice president the 2007 Nobel Peace Prize, which he shared with the Intergovernmental Panel on Climate Change, and a share of the credit for the 2006 Academy Award for Best Documentary Feature.

Raymond Pierre Hylton

Things Fall Apart

In Earth in the Balance, *Al Gore describes the societal breakdown that occurred in the early nineteenth century in response to climate anomalies caused by a volcanic eruption. He suggests that such breakdowns will be repeated and worsen as Earth's climate systematically alters.*

Beginning in 1816, "the year without a summer," widespread crop failures led to food riots in nearly every country of Europe, producing a revolutionary fervor that swept the continent for three years.

In France, for example, the existing government fell and the conservative Duc de Richelieu was asked to form a new one. Everywhere governments struggled to maintain social order as an unprecedented crime epidemic surged in the cities. The Swiss were stunned by the wave of criminal activity. Even the number of suicides increased dramatically, along with executions of women for infanticide. . . .

Although no one realized it at the time, the proximate cause of this suffering and social unrest was a change in the composition of the global atmosphere following an unusually large series of eruptions of the Tambora volcano, on the island of Sumbawa, Indonesia, in the spring of 1815. Scientists estimate that 10,000 people were killed in the initial eruption and approximately 82,000 more died of starvation and disease in the following months. However, the worst effects on the rest of the world were not felt until a year later, by which time the dust ejected into the sky had spread throughout the atmosphere and had begun to dramatically reduce the amount of sunlight reaching the surface of the earth and to force temperatures down.

Greenhouse effect

- **Category:** Meteorology and atmospheric sciences

• Definition

The greenhouse effect warms the lower portion of a planet's atmosphere when heat is trapped there by gases—such as water vapor, carbon dioxide (CO_2), methane, and nitrous oxides—that prevent it from escaping into space. As a result of their molecular structure, these gases are dominant absorbers and emitters of infrared radiation. They absorb infrared energy from a planet's surface and reemit it in all directions. A significant fraction of this reradiated energy is directed back to the planet's surface, resulting in an increase in average temperatures. This effect is somewhat analogous to the trapping of heat by a greenhouse, but the retention of heat in a greenhouse is due mostly to reduced cooling caused by the prevention of convection: Only a small amount is due to trapped infrared radiation.

• Significance for Climate Change

The greenhouse effect is a natural phenomenon that has been occurring on Earth and other planets for millions of years. It allows Earth to support life. If heat were not trapped in Earth's atmosphere, the planet would be approximately 33° Celsius cooler than it is now. A large percentage of Earth's natural greenhouse warming is caused by water vapor. If the greenhouse effect were enhanced, the Earth would become warmer, which could cause problems for humans, plants, and animals.

In the mid-1950's, an enhanced greenhouse effect was recognized as a concern. As a result of anthropogenic (human-induced) activities, atmospheric concentrations of the greenhouse gases (GHGs) were on the rise. This trend was associated with an increasing global atmospheric temperature. Industrialization resulted in an increase in the use of fossil fuels, which increased GHG emissions. The global mean annual temperature rose by approximately 0.5° Celsius between 1890 and 2000. Most of that increase occurred after 1970.

In addition to rising global temperature, observations of glaciers indicate that more of them are retreating than are growing. For example, eight glaciers that were advancing on Mount Baker in the northern Cascades in 1976 were all melting back at their termini by 1990. Observed climate changes associated with rising global temperatures, retreating glaciers, and increased polar ice melting are consistent with the effects that might be produced by an enhanced greenhouse effect accelerated by burning more fossil fuels. Verification of this connection depends primarily on computer-generated climate models. Existing models must be improved by addressing the coupled, nonlinear, dynamic nature of climate and by expanding the climatological database to include additional factors that influence the greenhouse effect, such as volcanic production of GHGs and the emission of methane from landfills and melting tundra.

Greenhouse Gas Protocol

- **Category:** Economics, industries, and products
- **Date:** Published September, 2001; revised March, 2004

• Definition

Prior to 2001, there was not a tool for corporations to assess greenhouse gas (GHG) emissions. To remedy this void, the World Business Council for Sustainable Development (WBCSD) and the World Resources Institute (WRI) began work on a method for corporations to account for and report their GHG emissions. The result was the Greenhouse Gas Protocol. WBCSD is a coalition of 170 international companies whose shared interest is sustainable development guided by growth economically balanced with ecology and social progress. Members come from more than thirty-five countries. WRI is a nonprofit organization of over one hundred people from many different occupations who work toward protecting the Earth while improving people's lives. There were five ideals controlling the production of the protocol: relevance (that the program provide accurate information to those needing the information, both inside and external to the company), completeness (that the program account for all sources of emissions), consistency (that the program produce meaningful and useful data year after year), transparency (that the procedures be apparent to anyone interested), and accuracy (that emissions are measured correctly with the smallest possible degree of uncertainty). The protocol was published in September, 2001, and in March, 2004, a revised version was published.

• Significance for Climate Change

The accounting tool consists of three modules: The first one is for corporations to use in calculating and reporting GHG emissions, the second is for calculating indirect emissions, and the third is used to calculate the effect of reduction projects. The GHGs covered by this protocol are the gases covered by the Kyoto Protocol: carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), and sulfur hexafluoride (SF_6).

There were five objectives used in the design of this accounting tool. First, it would be a tool that would aid companies in making a true and accurate measure of their GHG emissions. Second, the procedure would be simpler and less expensive than current practices. Third, it would provide the means to acquire the information needed to control and reduce GHG emissions. Fourth, the protocol would provide the information to allow companies to join GHG programs, both voluntary and required. Fifth, the protocol is to increase communication between companies and provide a standard method to report emissions. The procedures are divided into three scopes. Scope 1 is derived from emissions that are produced by equipment or machinery owned or controlled by the company. Most of these emissions are direct emissions; some activity of the company causes the emission. Scope 2 is the electricity indirect GHG emissions. These are the emissions generated in producing the electricity used by the company in its equipment or machinery. This includes electricity that is lost during transport or distribution. Scope 3 is the emissions due to the exploration, production, and transportation of the fuel used to generate electricity.

The 2004 revised edition added more guidelines to the procedure, more case studies, and appendixes on indirect emissions. Information in the revised edition is also designed to aid companies in setting a target for future emissions now that they know their current values. The protocol is also set up to allow the companies to more easily evaluate and trade GHG offsets. Offsets increase the amounts of GHGs that can be emitted without breaking governmental rules. A company with low rates of emissions may sell offsets to a company with high output to allow the second company to stay within the rules.

The Greenhouse Gas Protocol is designed to allow companies to evaluate their current emissions and set targets for reduction of GHGs. It even allows a company to assess different reduction procedures to determine which might be best. Countries can now set standards for companies in an effort to control the emission of GHGs. By the use of this standard accounting system, one company will not have an advantage over another company when meeting the standards. It will also be easier for the government to monitor companies' emissions with the new accounting system.

Greenhouse gases

• Categories: Meteorology and atmospheric sciences; pollution and waste

GHGs are trace atmospheric gases that trap heat in the lower atmosphere, causing global warming. Such warming has been associated with droughts, tornadoes, ice melting, sea-level rise, saltwater intrusion, evaporation, and other climatic changes and effects.

• Key concepts

aerosols: small particles suspended in the atmosphere

anthropogenic: deriving from human sources or activities

fossil fuels: fuels (coal, oil, and natural gas) formed by the chemical alteration of plant and animal matter under geologic pressure over long periods of time

global dimming: reduction of the amount of sunlight reaching Earth's surface

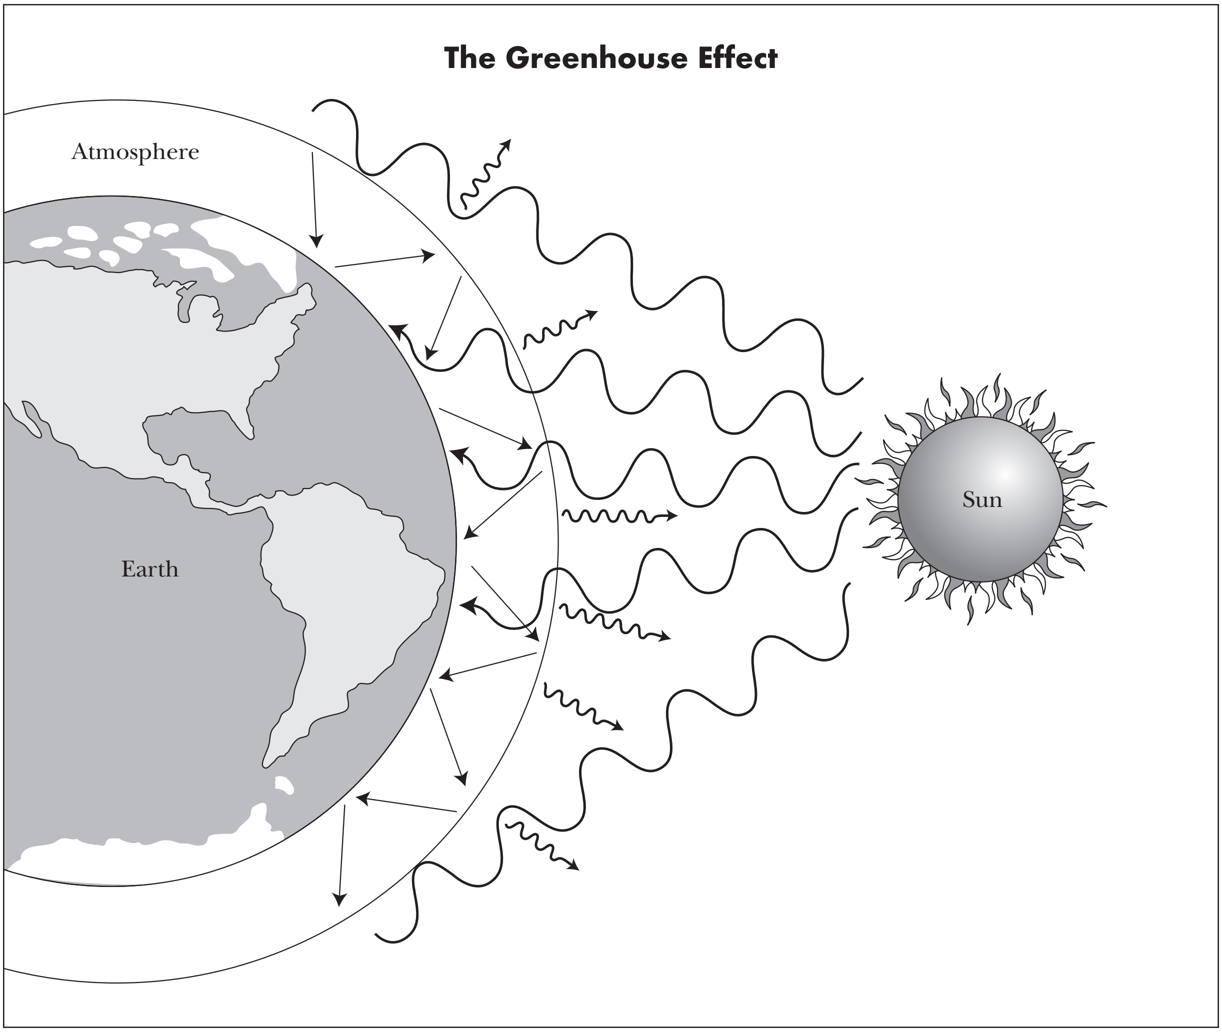
global warming: an overall increase in Earth's average temperature

greenhouse effect: absorption and emission of radiation by atmospheric gases, trapping heat energy within the atmosphere rather than allowing it to escape into space

greenhouse gases (GHGs): atmospheric trace gases that contribute to the greenhouse effect

• Background

Greenhouse gases (GHGs) have both natural and anthropogenic sources. They allow sunlight to pass through them and reach Earth's surface, but they trap the infrared radiation released by Earth's surface, preventing it from escaping into space. These trace atmospheric gases thus play an important role in the regulation of Earth's energy balance, raising the temperature of the lower atmosphere. GHG concentrations in the atmosphere have historically varied as a result of natural processes, such as volcanic activity. They have always been a small fraction of the overall atmosphere, however, exhibiting significant effects on the climate despite their low concentrations. Thus, small variations in GHG concentration may have disproportionate effects on



The greenhouse effect is aptly named: Some heat from the Sun is reflected back into space (squiggled arrows), but some becomes trapped by Earth's atmosphere and reradiates toward Earth (straight arrows), heating the planet just as heat is trapped inside a greenhouse.

Earth's climate. Since the Industrial Revolution, humans have added a significant amount of GHGs to the atmosphere by burning fossil fuels and cutting down trees. Scientists estimate that the Earth's average temperature has already increased by 0.3° to 0.6° Celsius since the beginning of the twentieth century.

- **GHG Sources and Atmospheric Physics**

The atmosphere comprises constant components and variable components. It is composed primarily of nitrogen (78 percent) and oxygen (21 percent). Its other constant components include argon, neon, krypton, and helium. Its variable components include carbon dioxide (CO_2), water vapor (H_2O), methane (CH_4), sulfur dioxide (SO_2), ozone (O_3), and nitrous oxide (N_2O). The variable components affect the weather and climate because they absorb heat emitted by Earth and thereby warm the atmosphere. In addition to the variable natural atmospheric GHGs, anthropogenic halocarbons, other chlorine- and bromine-containing substances, sulfur hexafluoride, hydrofluorocarbons, and perfluorocarbons contribute to the greenhouse effect.

CO_2, composed of two oxygen atoms and one carbon atom, is a colorless, odorless gas deriving from carbon burning in the presence of sufficient oxygen. It is released to the atmosphere by forest fires, fossil fuel combustion, volcanic eruptions, plant and animal decomposition, oceanic evaporation, and respiration. It is removed from the atmosphere by CO_2 sinks, seawater absorption, and photosynthesis.

Methane is a colorless, odorless, nontoxic gas consisting of four hydrogen atoms and one carbon atom. It is a constituent of natural gas and fossil fuel. It is released into the atmosphere when organic matter decomposes in oxygen-deficient environments. Natural sources include wetlands, swamps, marshes, termites, and oceans. Other sources are the mining and burning of fossil fuels, digestive processes in ruminant animals, and landfills. Methane reacts with hydroxyl radicals in the atmosphere, which break it down in the presence of sunlight, shortening its lifetime.

Nitrous oxide is a colorless, nonflammable gas with a sweetish odor. It is naturally produced by oceans and rain forests. Anthropogenic sources include nylon and nitric acid production, fertilizers, cars with catalytic converters, and the burning of organic matter. Nitrous oxide gas is consumed by microbial respiration in specific anoxic environments.

Sulfur dioxide is released during volcanic activities, combustion of fossil fuel, transportation, and industrial metal processing. This gas is more reactive than is CO_2, and it rapidly oxidizes to sulfate. It produces acidic gases and acid rain when it reacts with water and oxygen.

Ozone (triatomic oxygen) is a highly reactive, gaseous constituent of the atmosphere. A powerfully oxidizing, poisonous, blue gas with an unpleasant smell, it helps create smog. It is produced in chemical reactions of volatile organic compounds or nitrogen oxide with other atmospheric gases in the presence of sunlight. Oxygen and ozone absorb a critical range of the ultraviolet spectrum, preventing this dangerous radiation from reaching Earth's surface and making possible life on Earth.

Halocarbons have global warming potentials (GWPs) from three thousand to thirteen thousand times that of CO_2; they remain in the atmosphere for hundreds of years. These compounds were commonly used in refrigeration, air conditioning, and electrical systems, but their use has been regulated as a result of their environmental and climatic effects.

• Effect on Climate Change

The Working Groups of the Intergovernmental Panel on Climate Change (IPCC) presented a synthesis report in 2007, providing an integrated view of climate change from multiple perspectives. The report observed an increase of global air and ocean temperatures, melting of snows, and rising sea levels. The report estimated the one-hundred-year linear trend of Earth's average temperature between 1906 and 2005 at an increase of 0.74° Celsius, significantly greater than the trend from 1901 to 2000 (0.6° Celsius). The increase of temperature contributed to changes in wind patterns, affecting extratropical storm tracks and temperature patterns.

Global average sea level has risen between 1961 and 2001 at an average rate of 1.8 millimeters per year and between 1993 and 2008 at an average rate of 3.1 millimeters per year. The increase is due largely to melting glaciers and polar ice sheets. Satellite data between 1978 and 2008 show that average annual extent of Arctic sea ice shrank by an average of 2.7 percent per decade. The average summertime extent shrank far more, an average of 7.4 percent per decade.

Increases have been reported in the number and size of glacial lakes and the rate of change in some Arctic and Antarctic ecosystems. Runoff and earlier spring peak discharge in many glacier- and snow-fed rivers have also increased. These increases have in turn had effects on the thermal structure and water quality of the rivers and lakes fed by this runoff. Both marine and freshwater systems have been associated with rising water temperatures and with changes in ice cover, salinity, oxygen levels, and circulation patterns. These ecological changes have affected algal, plankton, and fish abundance.

Precipitation has increased in the eastern parts of North and South America, northern Europe, and northern and central Asia. It has decreased in the Mediterranean and southern Africa. These patterns also have affected algal, plankton, and fish abundance. Globally, since 1970, a greater area of Earth's surface has been affected by drought.

Changes in atmospheric GHG and aerosol concentration, as well as solar radiation levels, affect the energy balance of Earth's climate system. Global GHG emissions increased by 70 percent over preindustrial levels between 1970 and 2004. CO_2 emissions increased by 80 percent, but they began to decline after 2000. The global increase in CO_2 and methane emissions is due to fossil fuel and land use, particularly agriculture.

Coastlines are particularly vulnerable to the consequences of climate change, such as sea-level rise and extreme weather. Around 120 million people on Earth are exposed to tropical cyclone hazards. During the twentieth century, global sea-level rises contributed to increased coastal inundation, erosion, ecosystem losses, loss of sea ice, thawing of permafrost, coastal retreat, and more frequent coral bleaching.

Anticipated future climate-related changes include a rise in sea level of up to 0.6 meter by 2100, a rise in sea surface temperatures by up to 3° Celsius, an intensification of tropical cyclones, larger waves and storms, changes in precipitation and runoff patterns, and ocean acidification. These phenomena will vary on regional and local scales. Increased flooding and the degradation of freshwater, fisheries, and other resources could impact hundreds of millions of people, with significant socioeconomic costs. Degradation of coastal ecosystems, especially wetlands and coral reefs, affects the well-being of societies dependent on coastal ecosystems for goods and services.

• Context

In response to global warming, changes are being implemented to reduce GHG emissions. The United Nations Framework Convention on Climate Change prepared the 1997 Kyoto Protocol. Under the protocol, thirty-six states, including highly industrialized countries and countries undergoing transitions to a market economy, entered into legally binding agreements to limit and reduce GHG emissions. Developing countries assumed nonbinding obligations to limit their emissions as well.

In the energy sector, fuel use is slowly transitioning from coal to natural gas and renewable energy (hydropower, solar, wind, geothermal, tidal, wave, and bioenergy). In the transport sector, fuel-efficient, hybrid, and fully electric vehicles are being designed and marketed, and governments are attempting to motivate commuters to use mass-transit systems. More efficient uses of energy, including low-energy lightbulbs, day lighting, and efficient electrical, heating, and cooling appliances are being developed and deployed.

Industrial manufacturers have implemented electrical efficiency measures as well, and they have begun recycling, as well as capturing and storing CO_2. Crop and land management techniques have also improved, leading to an increase in soil carbon storage and the restoration of peaty soils and degraded land. Rice cultivation techniques have been improved, and livestock management techniques are being developed to reduce methane and nitrogen emissions. More controversially, dedicated energy crops are being grown to replace fossil fuels.

Afforestation, reforestation, forest management, reduced deforestation, and harvested wood product management are also being geared toward reducing GHG emissions. Forestry products are in use for bioenenergy to replace fossil fuels. Improvements are being made in tree species, remote sensing for analyses of vegetation and soil carbon, and mapping of land use. In the waste industry, methane is being recovered from landfills and energy is being recovered from waste incineration. Organic waste is more widely used for composting, wastewater is minimized, and the wastewater produced is treated and recycled. Biocovers and biofilters are being developed to optimize methane oxidation.

Greening Earth Society

- **Category:** Organizations and agencies
- **Date:** Established 1998
- **Web address:** http://www.greeningearthsociety.org/ (deactivated)

• Mission

The Greening Earth Society (GES), created by the Western Fuels Association, is a public relations organization promoting the idea that higher levels of greenhouse gases (GHGs), particularly of carbon dioxide (CO_2), are beneficial because they promote plant growth. GES was founded on Earth Day, 1998, by Frederick Palmer, chief executive officer of the Western Fuels Association, a group of coal-based rural electric cooperatives and municipal utilities. The purpose of GES is to promote the benefits of "moderate" global warming. The group is based in Arlington, Virginia, where both Palmer and Ned Leonard, director of communications and government affairs of GES and of the Western Fuels Association, worked as registered lobbyists. After 2000, Bob Norrgard, general manager of Western Fuels, assumed the directorship of GES. Its scientific advisers include Patrick J. Michael, professor of environmental sciences at the University of Virginia; Robert E. Davis, professor of climatology at the University of Virginia's Department of Environmental Sciences; Robert C. Balling, director of the Laboratory of Climatology at Arizona State University; and Sallie Baliunas and Willie Soon of the Harvard-Smithsonian Center for Astrophysics.

GES was founded in response to attempts by the Environmental Protection Agency to regulate CO_2 as a pollutant. Higher concentrations of CO_2, GES argues, not only are not harmful, but also at moderate levels actually "increase plant productivity, water use efficiency, and their resistance to a variety of environmental stresses including heat, drought, cold, pests, deficient nutrients, and air pollution." In a 1999 ad in *The Washington Post*, GES articulated its position that CO_2 is a nutrient, not a pollutant, explaining,

> Carbon Dioxide (CO_2) levels have risen in direct proportion to human population since the 15th century. The good news is that today's higher CO_2 levels are producing more abundant plant life and greater agricultural yields. Unfortunately, good news like this doesn't command the same attention as news about catastrophic climate change.

According to GES, there is no scientific consensus about the anthropogenic causes of climate change, contrary to media reports. Environmentalists who argue that global warming represents a looming catastrophe, it argues, are merely alarmists who either misunderstand or intentionally misrepresent scientific data.

• Significance for Climate Change

Until 2003, GES published the *World Climate Report*, a biweekly newsletter intended to point out "the weaknesses and outright fallacies in the science that is being touted as 'proof' of disastrous warming." The group's Web site described the newsletter as "the perfect antidote against those who argue for proposed changes to the Rio Climate Treaty, such as the Kyoto Protocol, which are aimed at limiting carbon emissions from the United States." Since 2004, the newsletter has been published by New Hope Environmental Services, still under the direction of editors Michael, Davis, and Balling. The international science journal *Nature* recognized *World Climate Report* as presenting a "mainstream skeptic" view of global warming.

From 2000 to 2003, GES also issued Virtual Climate Alerts, brief press releases whose titles included "Emissions Trend Doesn't Support Claim of Ecological and Economic Disaster," "More Cold Truth Dispels Hot Air," and "How Popular Coverage of Melting Arctic Sea Ice Overlooks Relevant Long-Term Research." In addition, GES issued annual State of the Climate Reports; scientific reports, including "In Defense of Carbon Dioxide: A Comprehensive Review of Carbon Dioxide's Effect on Human Health, Welfare, and the Environment" (1998) and "The Internet Begins with Coal: A Preliminary Exploration of the Impact of the Internet on Electricity Consumption" (1999); and the videos *The Greening of Planet Earth* (1992) and *The Greening of Planet Earth Continues* (1998). The group is named as a sponsor of the Web site www.co2and climate.org, an annotated collection of links, and it has funded research through the Arizona State University Climate Data Task Force. By the end of 2008, the Greening Earth Society Web site had been suspended, many of its publications were available only on other sites, and the Western Fuels Association Web site no longer provided a link to GES.

Greenland ice cap

• Category: Cryology and glaciology

The largest mass of ice in the Northern Hemisphere resides atop Greenland, which is home to 10 percent of the world's ice. This ice has been melting at an accelerating rate, especially in coastal areas.

• Key concepts

albedo: the fraction of radiation reflected by a surface

ice cores: cylindrical samples of ice taken from glaciers or ice caps that are used by scientists to determine atmospheric composition in the past

Jakobshavn glacier: a major outlet glacier in Greenland whose movement toward the sea has been accelerating

tipping point: point at which feedbacks take control and propel a climatic forcing past a point where control or mitigation is possible

upwelling: a rising of warm water to the surface, displacing colder water and potentially melting coastal ice

• Background

Greenland's ice is only a fraction of Antarctica's, but it is melting more rapidly, in part because summers are warmer, allowing for more rapid runoff. The amount of ice lost by Greenland during 2007 was equivalent to two times all the ice in the Alps, or a layer of water more than 0.8 kilometer deep covering Washington, D.C., according to Konrad Steffen, a professor of geography at the University of Colorado, who also directs the Cooperative Institute for Research in Environmental Sciences.

• Six Meters of Sea-Level Rise

Philippe Huybrechts, a glaciologist and ice-sheet modeler at the Free University of Brussels, has modeled the behavior of Greenland's ice sheet, finding that, with an anticipated annual temperature increase of 8° Celsius, the ice sheet would shrink to a small glaciated area far inland and the worldwide sea level would rise by 6 meters. Erosion of the Greenland ice sheet due to prolonged warming would be irreversible.

Upon close examination of paleoclimatic proxies, scientists examining ice cores from Greenland have found that its climate can change very quickly. The island's climate altered to a different state within one to three years at the onset of the present interglacial period, for example. Other scientists have found evidence that Greenland's surface has been covered with pine forests within a few hundred thousand years of the present, with the ice mass a fraction of today's size.

Ice melt in Greenland has accelerated significantly since 1990, according to a report in the *Journal of Climate* coauthored by Steffen. A scientific team surveyed the rate of summer melting there between 1958 and 2006, and found that the five largest melting years occurred after 1995. The year 1998 was the biggest (454 cubic kilometers), followed by 2003, 2006, 1995, and 2002. Melting in

A section of the Greenland ice cap. (AP/Wide World Photos)

2007 exceeded that of all previous years. Scientists have been keeping close watch on many glaciers, one of the most notable being the Jakobshavn glacier (the probable source of the iceberg that sank the *Titanic*), which has been accelerating toward the ocean.

• Melting Acceleration

Greenland is largely an artifact of the last ice age, held in place by the albedo (reflectivity) of its massive ice sheet. Once the ice melts, present-day climatic conditions will not allow its re-creation. Greenland's coastal ice often melts with a boost from the sea, warm water upwelling, flowing from below. Scientists have been debating the amount of additional warming that could cause Greenland's ice cap to cross a "tipping point," beyond which continued melting will be inevitable. During the winters between 2003 and 2007, Greenland lost two to three times as much ice in summer melt as it regained during winter snows.

Greenland's ice loss is accelerating irregularly year by year as well. During the 2007 melting season, with temperatures 4° to 6° Celsius higher than the previous thirty years' average, 450 billion metric tons of ice vanished, 30 percent more than the previous year and 4 percent more than the previous record, in 2005. During years of record melting, such as 2005 and 2007, high-pressure systems over Greenland keep storms away, clearing skies, allowing the Sun to shine for extended hours. Greenland's ice-mass loss between 2004 and 2006 was two and a half times the loss between 2002 and 2004.

While increases in the rate of ice loss to date have been greatest in southern Greenland, melting has been spreading northward, especially along the coastline. By the summer of 2007, the ice cap was studded by more than one thousand shallow meltwater lakes, some as wide as 5 kilometers. Tens of millions of cubic meters of water swirl from these lakes to the base of the ice sheet within a matter of days, opening huge waterfalls where none had previously existed.

• Context

Melting of the Greenland ice sheet's western reaches increased by about 30 percent from 1979 to 2006. Ice is melting most rapidly at the edges of the ice sheet. Although Greenland's ice sheet has been thickening at higher elevations due to increases in snowfall (warmer air holds more moisture, thus more snow), the gain is more than offset by an accelerating mass loss, primarily from rapidly thinning and accelerating outlet glaciers.

Scientists using pollen records from marine sediment off southwest Greenland have deduced that much of the Greenland ice sheet has melted relatively quickly during sharp natural warming in Earth's climate, some warming as recent as 400,000 years ago, when carbon dioxide levels were lower than they are today. During these spells, boreal coniferous forest covered much of the island. These spells of abrupt warming (abrupt, that is, in geologic time) reduced the ice sheet to about one-quarter of its present size and by themselves have raised world sea levels 4 to 6 meters.

Greenpeace

- **Categories:** Organizations and agencies; environmentalism, conservation, and ecosystems
- **Date:** Established 1971
- **Web address:** http://www.greenpeace.org

• Mission

An independent international activist and research organization, Greenpeace is funded almost entirely by contributions from its members. It works to produce and distribute educational and advocacy materials, support grassroots activism, encourage pressure on legislatures and other national and international bodies, and conduct original research on global warming, clean energy, and other issues.

Greenpeace's first action in 1971 was to protest U.S. nuclear testing off the Alaskan coast at the island of Amchitka, attempting to stop a test by steering a fishing boat named *Greenpeace I* into the path of military vessels. In 1974, the organization launched its first environmental effort with the Save the Whales campaign, capturing the attention and imagination of people worldwide. These first activities illustrated what would become Greenpeace trademarks: well-publicized actions of nonviolent resistance based on solid science, attracting widespread public attention to pacifist and environmental causes.

As of 2008, Greenpeace had expanded to become an international organization with a presence in forty-two countries and a wide-ranging, six-part mission. Its Web site identifies climate change as the single most serious global threat, and it lists working to support new forms of energy as the first action in the mission statement. The other goals of the organization include defending oceans and forests, reducing the use of hazardous chemicals by finding alternatives, encouraging more responsible agriculture, and the original goal of stopping nuclear proliferation and working for peaceful disarmament.

To combat global warming, Greenpeace takes a multipronged approach. Its Project Hot Seat campaign targets individual members of the U.S. Congress, encouraging supporters to pressure legislators to support global warming bills. Greenpeace also conducts and publishes research projects, engages in legal action against large emitters of greenhouse gases (GHGs), and campaigns actively to sway opinions of participants in United Nations climate conferences. Its Web site and publications attempt to reach a broad audience with information about global warming, refutation of arguments made by skeptics, and opportunities for activism.

• Significance for Climate Change

Greenpeace has an international headquarters in Amsterdam, as well as regional offices in more than thirty countries. It has more than 250,000 contributing members in the United States and 2.5 million worldwide. With a small paid staff and thousands of volunteers, Greenpeace works to increase awareness of global warming among the general population, and it targets particular experts and officials at opportune moments, as it did when it lobbied participants in the United Nations Climate Conference in Bali in 2007.

Greenpeace publishes research reports with titles such as *False Hope: Why Carbon Capture and Storage Won't Save the Planet* (2008) and *Impacts of Climate Change on Glaciers Around the World* (2004), legislative and press briefings including *Kyoto and the Bali Mandate: What the World Needs to Do to Combat Climate Change* (2007), and a 2004 activists' guide for students interested in organizing to help their college campuses switch to clean energy, as well as brochures, videos, and blogs. Two of its most significant climate change campaigns are the research project ExxonSecrets, which targets scientists and lobbyists employed by the Exxon Corporation to downplay the importance of global warming, and Energy [R]evolution, whose name is a combination of the words "revolution" and "evolution," suggesting the need for a massive overhaul of the way the world produces and consumes energy.

Through the project Greenpeace Solutions, the organization collaborates with business, technology, financial, and government organizations to help individual consumers make good purchasing decisions. The group developed and marketed the GreenFreeze refrigerator, which does not use dangerous hydrofluorocarbons (HFCs), a GHG. Though the product is not widely known in North America, more than 150 million units have sold in Europe and Asia. Greenpeace has also cooperated with European and United Nations groups to develop the SolarChill battery-free solar refrigerator, and it has worked in the United States to develop and promote wind power.

The Greenpeace ship Rainbow Warrior *attempts to block a coal ship at the port of Newcastle, Australia, the largest coal port in the world, in July, 2005.* (AP/Wide World Photos)

In August, 2002, Greenpeace filed suit, along with the environmental organization Friends of the Earth and the city of Boulder, Colorado, against the U.S. Export Import Bank and the U.S. Overseas Private Investment Corporation, accusing them of helping to fund dangerous fossil fuel projects with taxpayer money. The suit claims that these government agencies should have studied the potential climate change effects of these projects before granting funding.

Ground ice

- **Category:** Cryology and glaciology

• Definition

Ground ice is found in cavities, voids, pores, and other openings in frozen or freezing ground. It is a feature of a permafrost region, but the two terms are not interchangeable. A permafrost region is defined as an area where the soil and rocks making up the land remain below the freezing point for two or more consecutive years and can include areas with little or no water content. Permafrost regions account for nearly one-quarter of the landmass of the Northern Hemisphere, and some of these areas have been frozen since the Pleistocene ice age. Ground ice differs from glacier ice as well. Glaciers are created when fallen snow compresses into thick ice masses over long periods of time, and they are capable of riverlike movement, albeit at a pace so slow as to be imperceptible to the human eye.

Ground ice is formed once the temperature drops below 0° Celsius, when most of the moisture in the soil freezes. There are two different types of ground ice: structure-forming ice and pure ice. Structure-forming ice, which holds sediment together, comes in multiple varieties, including ice crystals, intrusive ice, reticulate vein ice, segregated ice, and icy coatings on soil particles. Pure, or massive, ice exists primarily toward the surface and is found as ice wedges, massive icy beds, and pingo cores. Massive ice beds are those with a minimum ice-to-soil ratio of 2.5 to 1.

Ancient ground ice, known as fossil ice, is a valuable source of historical information for geologists, paleontologists, and climatologists. Fossil ice preserves organic material and provides a measurable history of sediment and air quality covering hundreds of thousands of years. Cores drilled from fossil ice are studied to learn about the climates of the distant past.

In 2002, the National Aeronautics and Space Administration reported that the Odyssey orbiter had identified ground ice on Mars, a find that was confirmed by the Phoenix lander in June, 2008. The extreme cold and thin atmosphere on Mars would cause surface water to vaporize as dry ice does on Earth, but ground ice buried under the surface remains frozen and should prove invaluable to studies of the planet's history.

• Significance for Climate Change

Ground ice and permafrost play crucial roles in the industrial development of a region's energy and mining industries, as well as in the infrastructure needed to support such enterprises. It is possible to build in the presence of ground ice in its structure-forming state, so long as its properties are taken into consideration.

The presence of ground ice is closely linked to a region's climate, especially to the temperature at ground level. Its impact varies based on a variety of factors, including drainage, snow cover, soil composition, and vegetation. Ground ice affects both topography and vegetation, as well as a region's response to changes in climate and population.

In regions where the temperature remains close to freezing, a change of only a few degrees can be enough to cause ground ice to start melting. Changes can occur naturally, with normal temperature fluctuations, or as a result of ground clearing through construction or forest fire. When structure-forming ground ice melts, the surrounding terrain is significantly weakened, creating slope instabilities and thaw settlement.

Scientists predict that as much as 90 percent of the permafrost in the Northern Hemisphere could melt by the end of the twenty-first century, with most of the thaw taking place in the top 3 meters of terrain. Some regions in Alaska and Siberia have already experienced collapsed infrastructure and increased rock fall in the high elevations. The resulting meltwater would eventually reach the oceans, causing sea levels to rise around the world. Since the 1930's, Arctic water runoff has increased by 7 percent, and it is projected to reach a 28 percent increase by 2100.

Permafrost traps and holds approximately 30 percent of Earth's carbon, sequestering it from the atmosphere. Melting ground ice will release the trapped carbon into the atmosphere, contributing to the greenhouse effect, which in turn will cause even more ice to melt.

Coastlines in permafrost regions become more vulnerable to erosion as the ice retreats. The Alaskan island of Shishmaref, home to a native population whose ancestors have lived there for more than four thousand years, lost 7 meters of coastline annually between 2001 and 2006.

Groundwater

- **Category:** Water resources

- **Definition**

There are approximately 1.385 billion cubic kilometers of water on, above, and in the Earth. However, the vast majority of the Earth's water (around 97 percent) is found in its oceans. Groundwater, though constituting less than 2 percent of the world's water, accounts for more than 98 percent of its available freshwater resources. In the United States, more than half of the population depends on groundwater, while in semiarid to arid regions the percentage of people using groundwater is almost 100 percent.

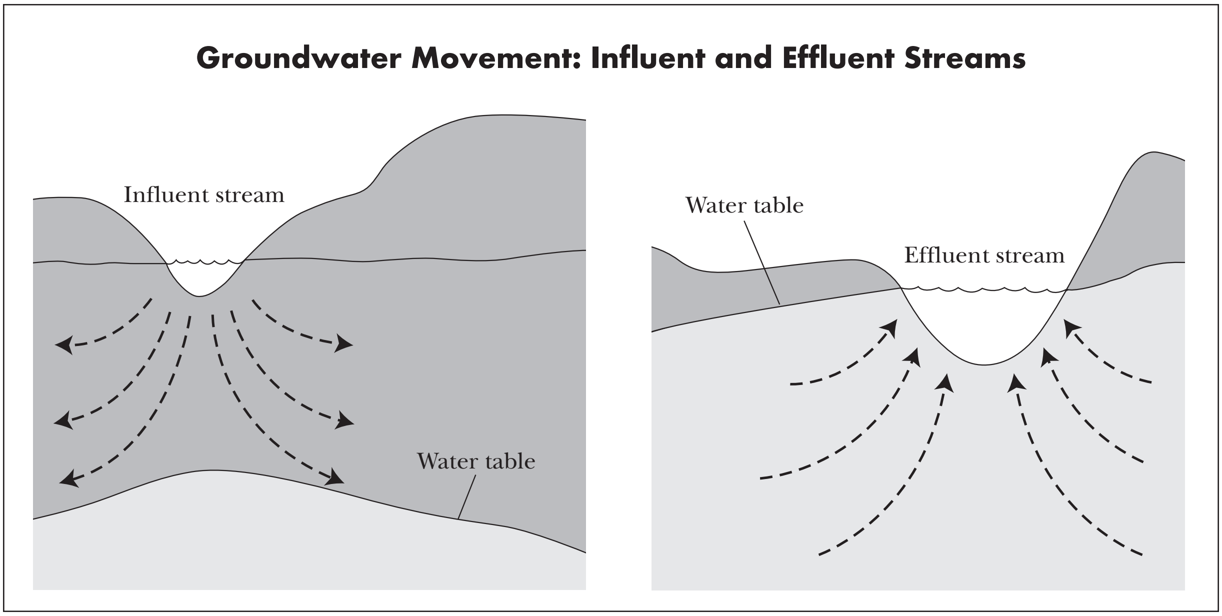
Groundwater is water found in pore spaces (pores) in soil and rocks. It differs from soil water in that groundwater is found below a water table—the demarcation separating saturated pores from unsaturated pores. Soil or rock that is saturated with water and is capable of supporting a well is called an aquifer. An aquifer can comprise one or multiple rock or sediment layers, ranging in size from a few meters to several hundred kilometers long, several meters thick, and meters to kilometers in width. An aquifer could be unconsolidated material, such as sand, or consolidated material, such as sandstone and other rocks. Limestone also makes good aquifers.

Aquifers may be divided into two main types. Open aquifers enjoy direct access to surface water. Closed aquifers sit underneath confining layers of semi- or nonpermeable material, which prevent such access. Water recharges aquifers by infiltration or seepage through permeable materials, and the recharge rate depends on the type of surface material, land cover, slope, and amount and intensity of precipitation melt.

- **Significance for Climate Change**

The effect of global warming on groundwater varies from place to place, with differing effects on water quality and quantity. In semiarid to arid regions, the higher rate of evaporation increases the concentration of dissolved salts in the groundwater, as is the case in Lake Chad, in Africa, where the surface water in some closed areas is becoming more saline. This saline water may recharge the African groundwater system, making the water saline.

With global warming, snow and ice caps will melt, resulting in rapid sea-level rise. This rise may force saline waters into aquifers, reducing the water's suitability for human and ecological use. Already, such seawater intrusion has occurred along some coastal aquifers, including one in El Paso, Texas.



Two examples of groundwater movement: Influent streams, found in dry climates, cause an upward bulge in the water table as water from the stream migrates downward. Effluent streams, found in wet climates, are produced by a high water table that migrates water into channels in the ground's surface.

Global temperature rise will lead to an increase in precipitation in the Northern Hemisphere. As snow and glaciers melt, the groundwater table will rise in most places. Sinkhole numbers may increase in limestone terrains with higher rates of solution weathering resulting from acid rain. These sinkholes could become conduits through which contaminants from the land surface could reach the groundwater.

Groundwater resident time (the length of time water stays in an aquifer) varies from a few days to several thousand years. Generally, the shorter the resident time, the greater the infiltration rate or the shallower the aquifer. In areas such as Libya, where resident time can stretch to hundreds or thousands of years, drought-induced demands for groundwater can cause faster depletion of that water. In areas where the land surface is highly permeable and where rainfall or snowmelt is heavy, the resident time may be low; such areas may experience a dramatic rise in groundwater level. Assuming the anthropogenic effect upon groundwater is minimized or maintained at its current rate, a reduction in rainfall would lead to the lowering of water tables. Such lower water tables could cause ground compaction, loss of permeability of the land surface, and an increased runoff that could lead to flooding. Groundwater withdrawal could also lead to ground subsidence, as has occurred in Texas and California. Heavy cracks, rills, or gullies may develop on the surface, as in Lake Chad, where the soil is clayey.

Global warming is likely to increase flood and drought conditions in different parts of the world. This in turn would affect the rate of evaporation, lowering water levels in rivers and lakes during the summer months. Some of these water bodies could become groundwater recharging zones. Near-surface water tables will lose increasing amounts of water to evaporation as surface temperatures increase. In addition, surface water infiltration will lead to a reduction of groundwater flows to lakes.

Group of 77 and China

- **Categories:** Organizations and agencies; nations and peoples
- **Date:** Established June 15, 1964
- **Web address:** http://www.G7.org

• Mission

In the early 1960's, at the height of the Cold War, the agenda at the United Nations reflected a world divided between East and West. As part of the United Nations mission to offer a forum for the representation of the global community, efforts began as early as 1962 to organize the developing countries of the nonaligned Third World into a coalition within the United Nations. The original protocol for establishing the network of less influential nations was to address questions of trade. The interests of the United States and its allies and the Soviet Union and its satellites threatened smaller countries, which demanded relaxed trade barriers and stabilized commodity prices. "Solidarity" was seen as the only way to promote the economic interests of this diverse international community of nations.

The coalition was officially chartered with the Joint Declaration of the Developing Countries in October, 1963, and first convened on June 15, 1964, at the close of the first session of the United Nations Conference on Trade and Development in Geneva. Originally, the charter included seventy-seven nations that represented six continents. The group endorsed the central vitality of the United Nations as the forum most appropriate for presenting—and addressing—trade problems. Given the wide range of cultural and religious elements among the group's membership, the Group of 77 became a paradigm for the mission of the United Nations itself: forging community from diversity.

The first meeting of the Group of 77 was held in Algiers in September, 1967. That assembly adopted a superstructure for the organization, a protocol for annual meetings to be held in conjunction with the opening of the General Assembly in New York. Currently member nations number 130, although the name of the organization was retained for its historical importance. The Republic of China has been recognized as a conditional invitee since 1981. In 1971, a separate chapter-entity, the Group of 24, was established to work specifically on international monetary issues.

• Significance for Climate Change

After more than three decades of monitoring the economic development, trade growth, health care, and technological development of developing countries, the Group of 77 in the mid-1990's shifted its agenda to consider the ramifications of the growing alarming data that projected dire consequences for global climate patterns should the emission of greenhouse gases (GHGs) fail to be significantly curbed. Global warming accelerated by the burning of oil, gas, and coal—the primary energy resource of the powerful dominant world economies—created a frustrating problem for those less industrial countries. Many of these countries were largely agricultural and most lacked the developed industrial grid that produced GHGs; hence, these countries were not part of the GHG emission problem. Yet, as climatologists began to gather data, it was increasingly clear that impoverished countries would bear the initial brunt of any catastrophic change in the Earth's climate patterns.

The ambitious and controversial 1997 Kyoto Protocol called for thirty-eight developed countries to reduce fossil fuel emissions by an average of 5.2 percent by 2012. Since that agreement, the Group of 77 has become aggressive in its efforts to represent the impact of global warming on developing countries. Each successive chair of the powerful caucus has endeavored to stress that the economies of developing countries are most vulnerable to the earliest effects of global warming. The Group of 77, in a series of communiqués issued through its agencies, has argued that the strategy proposed by the Kyoto Protocol to help smaller nations—transferring to these nations cutting-edge technology as a way to minimize the production of GHGs from their obsolete facilities—would not sufficiently address the magnitude of the fast-approaching problems.

The Group of 77 pointed out the need for an international water management strategy to handle diminishing water supplies; the need to chart the catastrophic impact of irregular weather patterns (most notably the increase in droughts, heat waves, and cyclones); the need to assess the impact of dropping of sea levels on trade and navigation routes and the economies that rely on them; the need for strategies to handle the sharp increase in food riots in areas stricken by droughts; and the impact on previously stable governments as countries struggle to address these concerns. Given the reluctance of entrenched dominant world economies to reduce fossil fuel emissions, the Group of 77 aggressively pursued its role as agitator, arguing that the crisis of global warming will demand the cooperation of developing nations as the only way to make their interests part of the international dialogue on addressing the crisis.

Gulf Stream

• **Category:** Oceanography

The Gulf Stream moves huge amounts of water, salt, and heat around the Atlantic Ocean. Many scientists have argued that the position of the Gulf Stream has shifted at times in the geologic past, causing significant changes in the climate of Greenland and northern Europe.

• Key concepts

Coriolis effect: the deflection of moving objects caused by Earth's rotation

geostrophic current: a current driven by horizontal gradients in pressure that are balanced by the Coriolis effect

North Atlantic drift: a current that diverges from the Gulf Stream, moving warm water northward to areas where it will cool and sink

subtropical gyre: a gigantic lens of warm water, usually occupying a substantial portion of an ocean basin, that rotates because of geostrophic currents

thermohaline circulation: circulation driven by differences in density

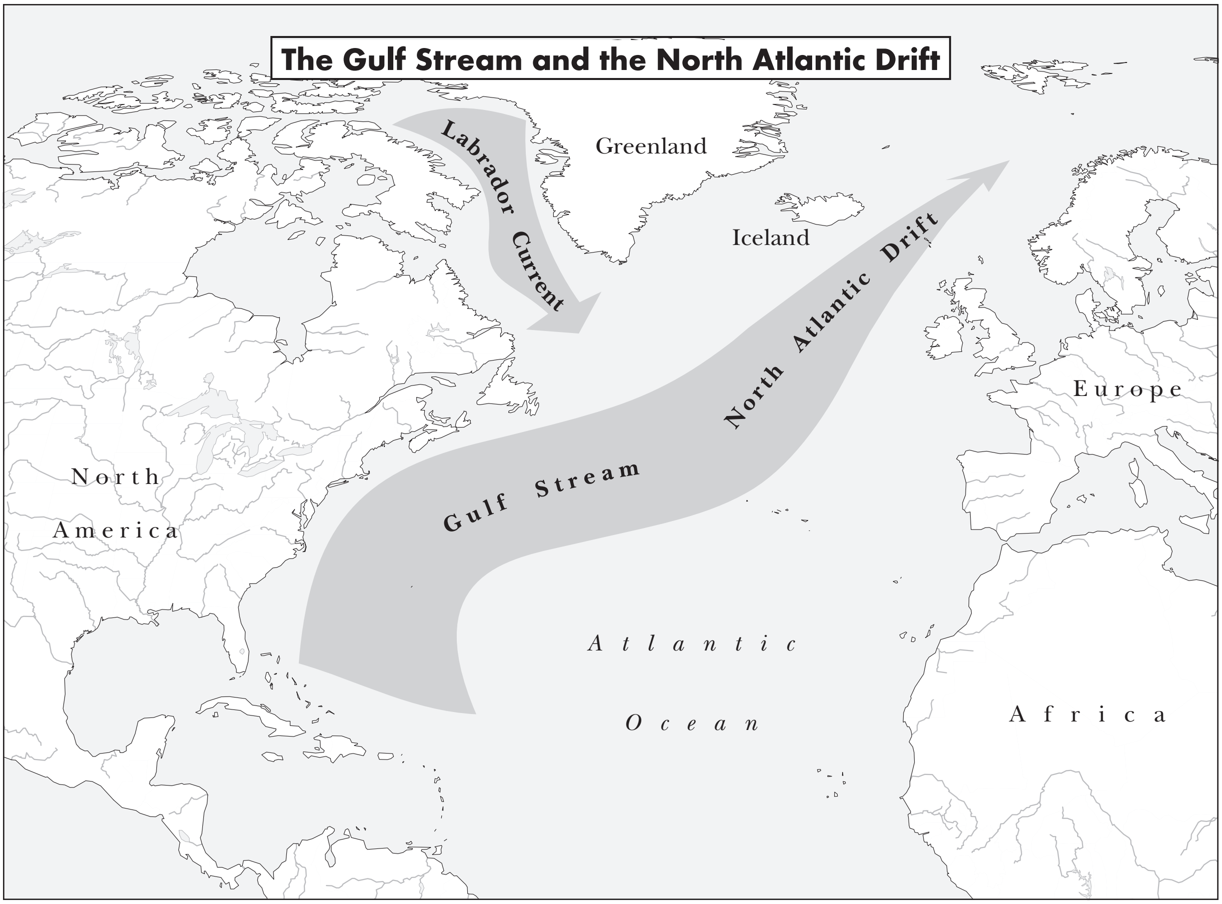
westerlies: the prevailing winds in the midlatitudes, resulting from a combination of vertical circulation patterns in the atmosphere and the rotation of the Earth

• Background

The Gulf Stream has a peak flow of more than a hundred times that of all the rivers and streams on Earth, combined. Much of this is warm water from the Gulf of Mexico or the Caribbean, being transported to the North Atlantic, transferring a great amount of heat. A strong belief has developed that this ocean current is responsible for the mild climate of Europe. Recent data and global climate models indicate, however, that it is only one of several factors, as the heat transported by winds is several times greater.

• Geostrophic Flow and the North Atlantic Gyre

The Sun warms the surface waters of the oceans, expanding them and reducing their density. The prevailing wind patterns in the subtropics (near 20° latitude) pile up these surface waters into hills, which are actually lens-shaped water masses floating on denser, cooler water, and bounded in part by continents. These hills have "peaks" no more than two meters higher than their edges, thousands of kilometers away. As the water at the surface tries to flow down this slope, the Coriolis effect, which is a consequence of the Earth's rotation, causes it to be deflected. In the Northern Hemisphere this deflection is to the right, so the circulation actually follows the hill contours, forming a rotating gyre. In the North Atlantic and North Pacific, subtropical gyres rotate in a clockwise sense. Constraints of flow on a rotating planet require that gyres are asymmetric, with a very steep slope on the western side. The rate at which these geostrophic currents flow is proportional to the slope. The Gulf Stream is a result of this steep slope, produced by a combi-



nation of solar heating, basin geometry, prevailing wind directions, and the rotation of the Earth.

The magnitude of this flow is prodigious. Peak flows are about 150×10^6 cubic meters per second. Put another way, a mass of ocean water, equivalent to the mass of the entire human population, flows by in less than four seconds. In a year the Gulf Stream moves 4.71 million cubic kilometers of water, which is huge compared to the annual runoff from all the continents (40,000 cubic kilometers) or even the total water moving between the surface of the Earth and the atmosphere (489,000 cubic kilometers).

- **Heat Transport**

Along with all the water, the Gulf Stream moves a great deal of heat to the north. At the northern end of its range (near 50° north latitude), the North Atlantic Drift, with a flow of 14×10^6 cubic meters per second, diverges from it, moving this water farther north, where it cools and sinks. If it loses 20° Celsius in the process, or 20 calories per gram, about 1×10^{15} watts are released. This is fifty times the total human energy use of 0.018×10^{15} watts, and about half of the total poleward ocean heat transport on the planet. However, the heat transported by the atmosphere is about four times greater.

The cause of this disparity lies in the heat of vaporization of water. Every gram that evaporates moves at least 540 calories of heat from the ocean to the atmosphere. Of the 413,000 cubic kilometers of water evaporated from the sea every year, perhaps 56,000 cubic kilometers, evaporate near the equator in the Atlantic and precipitate farther north. That would release 4×10^{15} watts.

The Gulf Stream may not be directly responsible for the mild climate of Europe, but it probably is responsible for the warm temperatures of the North Atlantic. If these temperatures fall, the ocean surface may become covered with ice, the wind will not be warmed, and Europe will surely chill. Furthermore, the strength of the North Atlantic Oscillation (NAO) may well depend on these warm temperatures, and hence on the Gulf Stream.

• Context

Intuitively, it would seem that a current that brings about 1×10^{15} watts of heat into the North Atlantic should be a dominant player in the climate of Europe. Since its discovery, many people have thought so and have written about it. Recent studies indicate, however, that the heat brought by the Gulf Stream is only a tenth of the heat transported, it is responsible for only a few degrees of warming, and it does nothing to explain why Europe is 15°-20° Celsius warmer, in winter, than places at similar latitudes on the East Coast of North America. Most of the heat, and all of the heat producing the contrast between Europe and North America, comes from atmospheric transport and the heating of the surface waters during the summer. Because the myth is so entrenched in the collective understanding of climate science, changing the way people think about it has proven to be extremely difficult. The strength of the NAO may be more important to Earth's climate than the strength of the Gulf Stream; however, the Gulf Stream may control the NAO.

Gyres

• Category: Oceanography

• Definition

The oceans' gyres are basin-scale circulation patterns in which the net flow of water occurs in a circular pattern around the basin. Each gyre is generally made up of four distinct currents that are driven by wind stresses, and its circulation direction is governed by the Coriolis effect. The major, subtropical gyres in the Atlantic and Pacific Oceans are located between the equator and approximately 45° north latitude, while the smaller, subpolar gyres lie north of that latitude. The Antarctic Circumpolar Current is a gyre that flows continuously around Antarctica, because there are no landmasses to impede it.

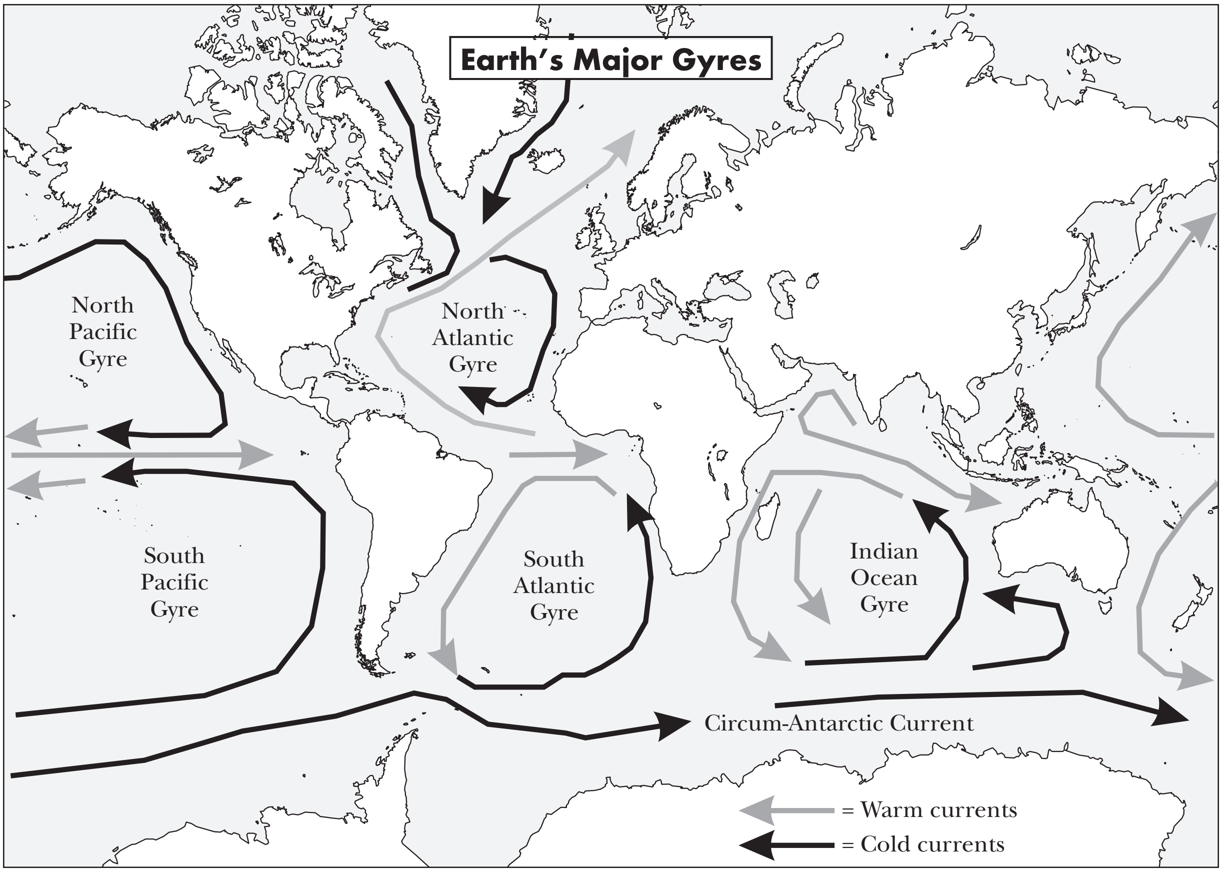
Individual currents that make up a gyre have different characteristics. Because of the Coriolis effect and resulting differences in sea surface elevation, the western boundary currents (currents that flow on the western side of the ocean basins and flow northward from the equator) are narrow, are relatively deep (up to 1,200 meters), and have velocities of up to 178 kilometers per day. Examples of western boundary currents include the Gulf Stream in the Atlantic Ocean and the Kuroshio Current in the Pacific Ocean.

Eastern boundary currents have widths of up to almost 1,000 kilometers but are only 500 meters deep. Examples of eastern boundary currents include the California Current in the Pacific Ocean and the Canary Current in the Atlantic Ocean. Offshore Ekman transport associated with the eastern boundary currents leads to upwelling and high levels of productivity in these surface waters. Circulation of the gyres is completed by transverse currents that flow east and west across the ocean basins, connecting the western and eastern boundary currents.

The subtropical gyres are associated with persistent high-pressure regions in the atmosphere, which leads to a net motion of surface water to the center of the gyre—a process known as convergence. These regions of high pressure are associated with low annual rainfall totals, so the salinity of water in the center of the gyres is somewhat elevated. Elevated salinity and convergence lead to downwelling, so the central gyres are regions of low productivity.

• Significance for Climate Change

The gyres transfer large amounts of heat from the equator to the poles. For example, the Gulf Stream carries heat north from the Caribbean Ocean, trav-



els along the East Coast of the United States, and then curves eastward toward Europe. The heat released from the Gulf Stream may lead to warmer average temperatures in Europe than those found at similar latitudes in North America. It has been hypothesized that global warming will lead to an increased influx of freshwater to the Arctic Ocean, which could block the northward flow of the warm, salty water of the Gulf Stream. In turn, this could prevent heat transport from the equator and could lead to cooling of the Northern Hemisphere.

The strength of the gyral currents can vary on decadal timescales, such as is observed in the Atlantic Multidecadal Oscillation (AMO), which manifests as cycles in average sea surface temperatures (SSTs), as lesser or greater amounts of warm water are transported from equatorial regions. The intensity of hurricanes is strongly dependent on SST, with stronger, more frequent hurricanes occurring when SSTs are higher. Thus, if global temperatures increase, the amplitude of the AMO will increase, leading to the circulation of warmer water and increased hurricane intensity.

Decadal variations in gyral flow can also affect the extent of coastal upwelling, salinity, and nutrient concentrations. Scientists from the Georgia Institute of Technology have discovered the existence of the North Pacific Gyre Oscillation. Variations in the mode of the oscillation are thought to cause historical variations in fish populations that are critical to Pacific fisheries. While such oscillations are part of the natural climate cycle, evidence indicates that the amplitude of the oscillations may increase with global warming.

Water in the center of the gyres is isolated from the rest of the world's oceans. An important consequence of this isolation is the low levels of phytoplankton productivity of the water—a situation described as "oligotrophic." The major source of nutrients to support productivity in the central gyres is upwelling of deep waters. However, downwelling, not upwelling, occurs in the central gyres, making these waters the equivalent of large, open-ocean deserts. As global temperatures have increased, the size of these ocean deserts has increased. Scientists from the National Oceanic and Atmospheric Administration and the University of Hawaii have examined a nine-year series of remotely sensed ocean color data from the SeaWiFS satellite and concluded that these open-ocean deserts have expanded by up to 15 percent. The expansion of the oligotrophic regions is consistent with computer models of oceanic vertical stratification in the gyres, but the rate of expansion exceeds all model predictions.

Hadley circulation

• **Category:** Meteorology and atmospheric sciences

• **Definition**

Named for eighteenth century meteorologist George Hadley, who explained how it worked, the Hadley circulation is a loop of air that starts near the equator. The hot air in the equator region rises to the troposphere level and is carried toward the poles. At about 30° latitude, the air drops back to the surface, creating a high-pressure area. The air is pulled back toward the equator, completing the loop and generating the trade winds. Because the Earth is spinning, the air traveling back to the equator goes toward the southwest in the Northern Hemisphere and is called the Northeast Trades. In the Southern Hemisphere, the air movement generates the Southeast Trades. The low-pressure area where the Northeast Trades meet the Southeast Trades and where the hot air rises is called the Inter-Tropical Convergence Zone (ITCZ). The ITCZ does shift with the seasons.

The Hadley circulation is caused by solar heating. The intensity of the Hadley circulation is related to the sea surface temperature. The hot air will carry moisture aloft, but as the air rises, it cools and is able to contain less moisture, causing the large amount of rainfall in the equatorial region. Still, it is moist hot air that travels toward the poles and drier cool air that blows back toward the equator.

The Hadley circulation is one of the major regulators of the Earth's energy budget. It spreads heat collected at the equator to the northern and southern subtropical areas. It also carries heat into the troposphere, where it can radiate into space. Hadley's ascending limb controls the rainfall in the tropical areas, where large amounts of rain occur. The descending limb controls the dryness of the subtropical area. Although the Hadley circulation covers only part of the Earth, it covers the area where a large percentage of the people of the world live.

• **Significance for Climate Change**

A difference in the patterns of the sea surface temperature would force a change in precipitation and cause a change in the Hadley circulation. A change in that system would cause a change in the flow of heat, momentum, and humidity along the meridians. The Earth's overall radiative balance, along with the monsoon systems and the ocean circulation, are also affected by a change in Hadley circulation. Different climate models diverge when they project the effect of an increase in greenhouse gases (GHGs) on the Hadley circulation. Some models indicate an increase of the intensity of the Hadley circulation, causing a more arid subtropical region to develop as the rising GHG concentration causes an increase in sea surface temperature. Other models indicate a weakening of the Hadley circulation.

Since 1950, there has been a more intense Hadley circulation, with a consequential increase in rainfall in the equatorial oceanic region and a drier tropical and subtropical landmass. This increase has accompanied a stronger westerly stratospheric flow and an increase in cyclones in the middle latitudes. The driving force behind these changes has been identified as the warming of the Indo-West Pacific tropical waters. The increased sea surface temperature difference between the winter and summer hemisphere tropics causes a stronger Hadley circulation.

Models indicate that the solar forcing of the increased Hadley circulation is more intense with GHGs than without. It is not clear from the models proposed whether the more intense Hadley circulation is due to a natural fluctuation, is anthropogenic, or is the combined result of natural and human factors. Solar forcing models indicate more evaporation and thus more moisture carried aloft. This causes less cloud cover and more solar heating. Thus, solar forcing seems to represent a positive feedback loop. The more solar heating, the less cloud cover and more solar heating.

Models of past data indicate that the ITCZ may have shifted over time by more than just the annual summer-to-winter position shift. Another shift would cause different areas of the Earth to be dry or to be rain-soaked. The extent of the Hadley circulation is influenced by several different factors according to models. One factor that was shown not to be related is the mean global temperature. Just increasing the Earth's temperature will not change the area covered by the Hadley circulation. The

Hadley circulation can be likened to El Niño-Southern Oscillation events. Since 1976, the increase in number and strength of El Niño events has caused an increase in the strength of the winter Hadley circulation.

Halocarbons

• **Category:** Chemistry and geochemistry

• Definition

The halocarbons are a group of partially halogenated organic compounds, in which carbon atoms link with halogen atoms by a covalent bond. (The halogen atoms include bromine, chlorine, fluorine, and iodine.) The most common type of halocarbon contains chlorine and belongs to the subclass of chlorocarbons, which includes substances such as carbon tetrachloride and tetrachloroethylene. The other common subclass of halocarbon, the fluorocarbons, contains fluorine and includes polytetrafluoroethylene (Teflon) and perfluorocarbons (PFCs). Some of the Freons, though not all, are halocarbons. Halocarbons are produced and valued because of their nonflammability, low chemical reactivity, and low toxicity.

The halocarbons include several compounds that affect the environment, compounds such as chlorofluorocarbons (CFCs), hydrochlorofluorocarbons (HCFCs), hydrofluorocarbons (HFCs), halons, methyl chloride, and methyl bromide. Though it is possible for halocarbons to form naturally, from volcanic activity or by the interaction of halogen and plant matter, most halocarbons are produced by humans for industrial and chemical use and include substances used as refrigerants and fire extinguishants.

• Significance for Climate Change

Many halocarbon compounds have a high global warming potential (GWP). Of these compounds, three (CFC-11, CFC-12, and CFC-113, all created by human activity) are the worst offenders. These gases are not reactive, so they are able to remain in the stratosphere for hundreds of years.

How Halocarbons Affect the Earth's Heat Retention. As light from the Sun enters the atmosphere, some of that light is scattered by molecules in the air or is reflected from clouds back into space. Some of the light that reaches Earth's surface is also reflected back into space, such as light that hits snow or ice. However, much of the light that reaches Earth is absorbed and retained as heat.

The Earth's surface warms and emits infrared photons, which make several passes between the Earth and the atmosphere, warming the atmosphere and the Earth as they go back and forth. Eventually, these infrared photons return to space.

The greenhouse gases (GHGs), which include many halocarbons, are able to absorb infrared photons, transferring their energy from the photons to gas molecules and thereby trapping thermal energy that would otherwise be released into space. Eventually, this absorption of energy causes a net change in the Earth's energy balance, increasing the overall amount of thermal energy held within the system. Different GHGs have different GWPs and lifetimes, measurements of the amount they contribute to global warming and the duration of that contribution, respectively. Both the GWP and the lifetime of halocarbons are unusually high. They may remain in the atmosphere for up to four hundred years, for example, continuing to affect the global climate long after their initial release.

How Halocarbons Deplete the Ozone Layer. Halocarbons containing chlorine and bromine also deplete the ozone layer. Until the 1970's, CFCs, perhaps the best known of the halocarbons, were used as propellants, solvents, and cleaners. Realizing that these compounds were depleting the ozone layer, many nations agreed to control halocarbon emissions when they signed the Montreal Protocol.

Ozone is a form of oxygen; it is formed of three atoms of oxygen bound together. Ozone in the stratosphere blocks harmful solar radiation. Halocarbons help speed the natural destruction of ozone. For example, CFCs are able to break down ozone when they combine with it in high-frequency ultraviolet (UV) light. During this breakdown, ozone molecules are destroyed, but chlorine reforms and is able to take part in the breakdown again. In this way, just one chlorine atom in the stratosphere is thought to be able to destroy about 100,000 ozone molecules.

Ozone depletion can have serious effects. The less ozone is available to shield the Earth, the more UV-B rays are able to penetrate the atmosphere and reach the planet's surface, where they cause skin cancer and cataracts in humans. Moreover, the disruption of the normal wavelengths of light reaching Earth's surface affects plants and their growth rates. It is also possible that the change in atmospheric radiation affects global wind patterns and therefore climate.

Halocarbons do not disintegrate easily and may become corrosive agents when burned, which makes them difficult to dispose of safely. Halocarbons are also implicated in liver disease, eye cataracts, and skin cancer, and they may affect the human immune system.

Halons

• **Category:** Chemistry and geochemistry

• **Definition**

Halons are gaseous compounds of carbon, bromine, and another halogen (such as hydrogen, chlorine, or fluorine). These gases, also known as bromofluorocarbons, include the chlorofluorocarbon (CFC) family. They are classified by the U.S. Environmental Protection Agency as Group II of the Class I ozone-depleting substances.

Halons were first used during World War II as fire-extinguishing agents. They are particularly useful in extinguishing electrical fires, because they are covalently bonded and thus do not react with electrical equipment. They continued to be used through 1994, when they were banned by the Montreal Protocol as ozone-depleting substances.

• **Significance for Climate Change**

Halons are members of the class of halogenated hydrocarbons, which have been shown to deplete the ozone layer. By some estimates, halons are three to ten times more destructive of the ozone layer than are other substances in this family, including CFCs, because they contain bromine. The bromine radicals in halons react with ozone particles and remove them from the stratosphere. They sometimes react with atmospheric chlorine as well, magnifying their effects on ozone. The bromine-containing halons are much more destructive of atmospheric ozone than are other compounds, such as those containing chlorine, because bromine compounds are much more likely to disassociate in ultraviolet light, so many more ozone molecules are destroyed before the bromine molecules diffuse.

Halon use worldwide has historically been less than CFC use, so halons are not as widely known as ozone-destruction agents. However, halons are more destructive than some other ozone-depleting compounds, because their concentration in the atmosphere is still rising as a result of their long lifetimes.

Less environmentally destructive fire-extinguishing agents have been found to replace halons. These include halocarbon-based agents that absorb heat and inert gas agents that deplete oxygen, smothering fires. Both of these agents are less threatening to the ozone layer than are halons.

Health impacts of global warming

• **Category:** Diseases and health effects

Ambient temperature in general, and systematic temperature changes in particular, have both direct and indirect impacts on human health. Direct effects include increases or decreases in heatstroke, hypothermia, and metabolic and physiological disorders. Indirect effects include increases or decreases in drought, famine, severe weather events, and disease.

• Key concepts

cardiac diseases: heart diseases, including those of relevant blood vessels (cardiovascular) and those caused by decreased blood supply (ischemic)

cerebrovascular disease: illness caused by abnormality in blood vessels supplying the brain

hemoconcentration: increased concentration or thickening of the blood resulting from dehydration or cooling of the body

mortality and morbidity: statistics on death and illness in population groups

pulmonary disease: illness of the lungs or affecting the breathing process

• Background

The threat of possible severe climate change, including predictions of global warming from politicians, media leaders, and scientists, has aroused worldwide concern about the potential effects of such change on human health. The United Nations' Intergovernmental Panel on Climate Change (IPCC) reported in 2007 that multiple computer-model predictions were consistent with significant climate warming occurring by 2050 and potentially disastrous warming occurring by 2100. These predictions depended on various scenarios of increasing greenhouse gases (GHGs), especially carbon dioxide (CO_2), in the atmosphere and were based on the anthropogenic hypothesis, which holds that the most important variable in climate predictions is the human contribution of atmospheric CO_2 from burning fossil fuels. Less significant contributing factors include methane production by farm animals.

There is significant scientific dissent on the causation of climate change, since human historical records show temperature variation profoundly affecting agriculture and worldwide human activity for centuries before the Industrial Revolution. Fur-

Two-year-old Nicholas Pollock, who suffers from allergies and asthma, rides past a sign for the Learn Green, Live Green conference being organized in Akron, Ohio, by his mother. (Ed Suba Jr./MCT/Landov) thermore, ice cores and other paleontological records show violent variations of temperature, CO_2, and methane for hundreds of thousands of years before human civilization.

The IPCC computer models predict increases in average global surface temperatures of 1.0 to 1.9° Celsius by 2050. These models calculate temperature rises of 2.0 to 4.5° Celsius by 2100, depending on whether CO_2 emissions stabilize downward at 5 gigatons per year or increase to as much as 28 gigatons per year by the end of the century.

Prior temperature records show that humans have been exposed to temperature shifts of similar magnitudes. The cooling that occurred from 1940 to 1970 was estimated at about 0.2° Celsius, and the warming from 1970 to 1998 is estimated at 0.5° to 0.7° Celsius. The average surface temperature in the decade following the 1998 El Niño did not increase significantly, and physicists who study solar effects on climate have predicted possible cooling because of the decrease in solar activity (such as sunspots).

S. Fred Singer and Dennis Avery have compiled extensive reports on prior temperature fluctuations, with examples of past climate cycles showing increased temperatures of more than 1° Celsius during the Medieval Warm Period and decreases of 0.3° Celsius during the Little Ice Age. South African data from stalagmite temperature proxies indicate temperature increases of up to 4° Celsius in the Medieval Warm Period.

• Urban Heat Island Effects

As Earth's population continues to migrate from rural areas to more densely concentrated suburbs and cities, more people become exposed to urban heat islands. Cities are warmer than surrounding countryside, because traditional roofs and paving surfaces absorb more solar heat than do dirt and vegetation, and significant heat is generated by industry, power plants, residential heating, and air conditioning. Large cities have shown average temperature increases of as much as 3° Celsius (Tokyo, 1876-2004) to 4° Celsius (New York City, 1822-2000). These data are relevant, because potential health effects may be evaluated by comparing the effects of these localized temperature changes to projected future temperature changes.

Global Deaths Due to Climate-Related Disasters, 1900-1999

Decade	*Deaths (thousands)*	*Death Rate (per million people)*
1900's	128	79
1910's	25	14
1920's	485	242
1930's	446	209
1940's	180	76
1950's	211	71
1960's	167	49
1970's	74	19
1980's	66	14
1990's	32	6

Data from: Indur M. Goklany, *The Improving State of the World.* Washington, D.C.: Cato Institute, 2007.

• Historical Context

Scientists have been speculating about the health effects of climate change since the concept of global warming became widespread. In 1992 and 1995, IPCC members expressed concern that increases in the number and severity of heat waves could cause a rise in deaths. The 1992 report found that temperature increases were more prevalent in the winter and at night, diminishing the health effects of extreme cold weather; summer temperature increases have fallen, which diminishes deaths from heat waves. This could explain the IPCC's 1995 statement that global warming could result in fewer cold-related deaths.

In 1995, Thomas Gale Moore published the first of his pioneering efforts, "Why Global Warming Would Be Good for You," followed in 1998 by "Health and Amenity Effects of Global Warming." He estimated that a temperature increase of 2.5° Celsius in the United States would cause a decrease of forty thousand deaths per year from respiratory and circulatory disease, based on U.S. mortality statistics as a function of monthly climate change.

In 1997, the Eurowinter Group published "Cold Exposure and Winter Mortality from Ischaemic Heart Disease, Cerebrovascular Diseases, Respiratory Diseases, and All Causes in Warm and Cold Regions of Europe." This was a landmark study that elucidated the mechanisms of serious illness from cold, which are dominated by hemoconcentration, which increases blood viscosity ("sludging"). Hemoconcentration can cause death from blockage of vessels serving the heart and brain tissue, and it accounts for half of all excess cold-related mortality.

The 1997 Eurowinter Group study was followed by "Heart Related Mortality in Warm and Cold Regions of Europe: Observational Study," which was published in the *British Medical Journal* in 2000. These two studies provided data on mortality rates as a function of mean daily temperature in Athens, Greece; London, England; and Helsinki, Finland, providing the most comprehensive collection of evidence that mortality decreases as temperature increases, over most of the current climate range in Europe.

In 2005, Robert E. Davis furnished a survey on climate change and human health, published in *Shattered Consensus: The True State of Global Warming*. He predicted that human adaptation "will be key in determining the ultimate impacts of climate change." He demonstrated that some adaptations are already taking place that effectively mitigate negative impacts of global warming. His data, for example, show that excess mortality due to heat waves in many U.S. cities dropped to essentially zero in the three decades following 1964. This decline in heat mortality was especially evident in Southern cities, where high heat and humidity are common, but also spread northward. This happy trend could be attributed to air conditioning, better health care, architectural changes, and public health measures such as shelters. The salutary result, however, is prevention of major death events that were previously associated with heat waves and diminution of negative effects of climate warming.

In 2006, A. J. McMichael and his colleagues published "Climate Change and Human Health: Present and Future Risks." This was an attempt at a comprehensive evaluation of the direct and indirect health risks associated with warming, including infections and vector-borne diseases such as malaria. The evaluation assumes that the maximum daily mortality in higher-temperature periods will be equal to or greater than the maximum mortality in colder periods, resulting in heat-related deaths increasing far more than the lives saved by warming of the cold periods. This hypothesis does not stand up to previous data from the United States that showed that mortality in winter due to cardiac, vascular, and respiratory disease is seven times greater than summer. This ratio is about 9 to 10 in Europe.

The most comprehensive data on daily mortality, from all causes, as a function of the day of the year, show a clear relationship, with maximum mortality in January and minimum mortality in the warmest months of July and August. These data strongly indicate that warming of average daily temperatures would cause a decrease in mortality in winter far greater than the slight increase of mortality from summer heat.

• Current Findings

In early 2008, the British Department of Health released "Health Effects of Climate Change in the U.K., 2008," an update of previous reports from 2001-2002 edited by Sari Kovats. It used IPCC models that predicted an increase of mean annual temperatures in the United Kingdom between 2.5 and 3° Celsius by 2100. They found that there was no increase in heat-related deaths from 1971-2002, despite warming in summers, suggesting that the British population is adapting to warmer conditions. Cold-related mortality fell by more than one-third in all regions. The overall trend in mortality for the warming (from 1971-2002) was beneficial. The report states, in summary, that "winter deaths will continue to decline as the climate warms."

• Quantitative Estimates of Benefit

The data from the Eurowinter Group on mortality versus temperature can be used to estimate mortality benefits from climate warming. The authors actually drew "straight-line" fits to the slope of the data. The slopes for Athens, Helsinki, and London vary between 1 and 2 percent decreased mortality per degree Celsius increased temperature. This would lead to an estimated decrease of twenty-five to fifty thousand deaths per year in the United States for a 1° Celsius temperature rise. This can be compared to thirty thousand deaths per year from breast cancer, thirty thousand for prostate cancer, and about forty thousand from motor-vehicle accidents.

Bjørn Lomborg, a distinguished Danish environmental economist, has estimated 1.7 million fewer deaths in the world per year from moderate warming, or 17 million by year 2100. (He also notes that deaths from cold are nine times greater than deaths from warmth.) Note that the converse is also true; that is, cooling would cause similar increases in death rates. Heat deaths often represent "displacement"; that is, weakened people die a few days or weeks before prior expectation. Deaths due to cold, on the other hand, usually result in months to years of life lost. Thus, the benefits in life expectancy from warming in cold periods may be much more than nine times greater than lifespan lost in warm periods.

• More Severe Climate Change

The slopes of the data on mortality versus temperature are fairly linear over temperature variations of more than 20° Celsius. Thus, the benefit of warming (and the risk of cooling) should be fairly proportional to the temperature change, for climate shifts of more than 2-4° Celsius. Increasingly urbanized populations have already been exposed, and presumably adapted, to warming of 2-4° Celsius, because of the urban heat island effect. A major drop in climatic temperatures could be more devastating, especially in rural and less developed societies.

• The Developing World

Unfortunately, there is a dearth of data on mortality versus temperature in the developing world, especially by comparison to Europe and the United States. Lower standards of living and health care could decrease technological response to climate change, but less developed societies have already evolved adaptation techniques and behaviors that promote survival under potentially adverse conditions such as daily and seasonal climate changes.

The most prominent variable affecting health and survival of less advanced societies is the amount and variety of food available. Food crop production is enhanced by increased CO_2 in the atmosphere, which promotes photosynthesis. Increased CO_2 also allows plants to flourish with less water, giving them greater resistance to drought. It is estimated that the current increase in CO_2 has already caused increased food production by about 10 percent, independent of other factors. If CO_2 continues to increase as expected, significant improvements in nutrition may benefit populations in developing nations, no matter how the climate changes.

There are data on global death rates on climate-related disasters, however. Goklany has shown that death rates fell between 1930 and 2004. It is not possible to separate the decreasing mortality from storms, floods, drought, and so on from deaths due to heat and cold, but the overall trend is extremely beneficial and is taking place during a period of multiple climate changes and increasing GHG emissions.

• Context

The direct effects of possible climate warming on mortality are likely to be beneficial and of substantial magnitude by comparison to mortality from disease and accidents. The impact on human life expectancy may be proportionally more significant because of the different characteristics of death due to cold versus heat.

Quality of life and health may also improve. Large populations have migrated from the northern to the southern United States, experiencing an increase in average temperature of more than 5° Celsius, resulting in improved health and life expectancy. There are similar effects beginning in Europe.

It is reasonable to expect better health and better health statistics in the industrialized world, with moderate climate warming. Better nutrition and human adaptation can be expected in the developing world. The consequences of widespread climatic cooling are likely to be much more threatening.

Heartland Institute

- **Category:** Organizations and agencies
- **Date:** Established 1984
- **Web address:** http://www.globalwarmingheartland.org

• Mission

An American, libertarian, free-market-oriented, tax-exempt 501(c)(3) nonprofit organization, the Heartland Institute researches and develops free market solutions to social and economic problems, including environmental problems. The institute was established in 1984 and is based in Chicago, Illinois. Its activities are directed by a fifteen-member board of directors that meets quarterly. As of 2008, thirty full-time staff, including editors and senior fellows, oversee the organization's day-to-day activities. The think tank focuses on issues such as government spending, taxation, education, health care, free market environmentalism, and global warming.

• Significance for Climate Change

The Heartland Institute asserts that there are no reliable data supporting the notion that global warming mechanisms or trends have ever taken place or are taking place presently. Furthermore, it claims that a moderate degree of global warming is beneficial to the environment and humans worldwide. The institute has partnered with other global warming skeptic organizations such as the Cooler Heads Coalition, which has itself been widely criticized for its work against penalizing big carbon dioxide (CO_2) emitters.

At the Heartland Institute's March, 2008, conference, global warming skeptics from around the world were brought together in New York. At the meeting, participants collectively criticized the Intergovernmental Panel on Climate Change, as well as proponents of any scientific studies that reported positive correlation between human activities and global warming. The organization's numerous publications and conferences have all shared a similar theme and tone.

The Heartland Institute received extensive scrutiny of its publication procedures in April, 2008, after environmental journalist Richard Littlemore revealed that it engaged in questionable practices. In compiling a list of "Five Hundred Scientists with Documented Doubts of Man-Made Global Warming Scares," the organization included over forty-five scientists as coauthors on various articles with which they had no affiliation, that they did not agree to coauthor, or that made claims with which they disagreed. Following this scandal, when scientists came forward to demand removal of their names from the list, the Heartland Institute claimed that they had no legal or ethical grounds to remove or amend the original list of names.

The institute has also been criticized for its policies on appointing and recruiting members of its board of directors. In the past, executives from such corporations such as ExxonMobil, an oil company, and Philip Morris, a tobacco company, have served on the Heartland Institute's steering committee.

Heat capacity

- **Category:** Physics and geophysics

- **Definition**

The total heat capacity of an object is the amount of energy needed to raise its temperature one degree Celsius. Heat capacity is usually measured in joules per Celsius degree. Thus, if an object has a heat capacity of 500 joules per Celsius degree, adding 500 joules of thermal energy will increase its temperature by 1° Celsius. Adding 1,500 joules will increase its temperature by 3° Celsius, and so forth. Removing the same amount of thermal energy will decrease the object's temperature by the same amount.

An object's heat capacity is related to both its composition and its mass. Scientists divide heat capacity by mass to determine an object's specific heat capacity, or specific heat, which is a property of composition alone. Heat capacity and specific heat are thus closely related, but heat capacity is a property of a particular object, while specific heat is a more general property of a type of material.

Particularly for gases or liquids, the heat capacity and specific heat can differ under different conditions, such as pressure or volume. Hence, specific heat capacity tables often list specific heats at constant pressure and at constant volume.

- **Significance for Climate Change**

Using various climate change computer models, climate researchers try to predict changes in global surface temperature. One of the many input parameters for these calculations is the change in the energy content of Earth's climate system. Energy sources can include incoming solar radiation, energy trapped by greenhouse gases, waste energy from machines or industrial processes, and so forth. After scientists determine the net energy change in Earth's climate system, they need to calculate the total heat capacity of the climate system, including Earth's atmosphere, oceans, and surface.

Using the calculated change in thermal energy contained in Earth's climate system and its total heat capacity, scientists can calculate the net change in Earth's temperature. The idea is relatively simple, but it is very difficult to calculate both the total thermal energy and the heat capacity for Earth's climate system. Therefore, it is difficult to make accurate predictions about changes in Earth's average temperature.

These complexities make global warming models very uncertain. Different global warming models will make different predictions as a result of these uncertainties.

Paul A. Heckert

Heat content

- **Category:** Physics and geophysics

- **Definition**

Touch a fluorescent light bulb. It may feel pleasantly warm, but it will not feel extremely hot. However, the gas inside a working fluorescent bulb is usually at a temperature of more than 10,000° Kelvin. For comparison, the Sun's surface temperature is 5,800° Kelvin. If the gas inside a fluorescent light bulb is at such a high temperature, why is the surface of the bulb relatively cool?

The key is heat content. The gas inside the bulb is at a high temperature, but, because the gas is so thin and there are relatively few gas atoms inside the bulb, relatively little total heat energy is contained within the gas. Heat content is the total thermal energy an object contains. The gas inside the bulb has a high temperature but a low heat content, so there is not enough thermal energy to burn one's hand.

A key related concept is heat capacity, which is the amount of heat energy needed to raise the temperature of an object. The gas in a fluorescent bulb has a low heat capacity, so the total amount of thermal energy needed to raise its temperature is small. Thus, it required relatively little heat energy to raise the temperature of the gas, which also contributes to explaining why the system contains relatively little energy.

- **Significance for Climate Change**

The total heat content of Earth's climate system, including its atmosphere, oceans, and surface, can change through a variety of processes. For example, the amount of direct solar radiation striking Earth's surface can change, either by the Sun's energy output changing or by the atmosphere's transparency changing. Changes in the concentration of greenhouse gases in Earth's atmosphere change the amount of thermal energy trapped within the atmosphere rather than radiated back into space. Industrial processes and waste heat from all types of engines pump thermal energy into Earth's climate system. These and many other processes change the total heat content of the planetary climate system.

As this total heat content changes, Earth's average temperature changes. Predictions of changes in Earth's temperature depend upon knowledge of the planet's current total heat content, as well as of all processes affecting Earth's climate system. Such comprehensive knowledge is elusive, so predicting future temperature changes is extremely difficult, and vastly divergent predictions are common.

Paul A. Heckert

Heat vs. temperature

- **Category:** Physics and geophysics

- **Definition**

The concepts of heat and temperature are closely related, so these quantities are often confused, and the terms are sometimes used interchangeably (but incorrectly) by laypersons. Temperature is a measurement of the average kinetic energy—that is, physical motion—of the atoms in a substance. The kinetic energy of an object is calculated according to the following formula:

$$E_K = \frac{1}{2}MV^2$$

where E_K is kinetic energy, M is mass, and V is velocity. The kinetic energy of atoms is generally due to a combination of their directional velocity and vibrational motion. This energy may be measured by a thermometer.

The two most common temperature scales in use are the Fahrenheit and Celsius (formerly centigrade) scales. In the Fahrenheit scale, the freezing point of water is defined as 32° and the boiling point is defined as 212°. In the Celsius scale, the freezing point of water is defined as 0° and the boiling point is defined as 100°. In science and engineering, the Rankine and Kelvin temperature scales are used. These are called absolute temperature scales, because their zero reference level is absolute zero, the lowest temperature that can theoretically exist. At absolute zero, the total kinetic energy of all the atoms in a substance is zero.

Heat is the form of energy transferred across the boundary of an object as a result of a temperature difference across that boundary. Consider what happens across a pane of window glass on a cold winter day. The air inside the heated house is warmer than the air outside. This temperature difference across the window pane causes an energy flow through the glass from the warm air inside to the cold air outside: The outer air next to the glass is warmed, while the air inside the house cools, requiring a heating system to maintain a constant, comfortable temperature. There are three types of heat transfer: conduction, convection, and radiation. All result from a temperature difference between an object and its surroundings.

Conduction is the primary mechanism of heat transfer in solids. It occurs because of molecular activity in the solid. Convection is the primary mechanism of heat transfer through fluids and results from bulk mixing between fluid layers. Radiation, the third type of heat transfer, is the only mechanism that can transfer heat through a vacuum. When the Sun heats the Earth, there is no solid between them through which heat can be conducted, nor is there is any fluid through which heat can be convected. The temperature difference between the Sun and the Earth still causes heat transfer to the Earth by means of electromagnetic waves. Electromagnetic waves can also transfer energy in the form of light, X rays, or radio waves.

Heat is measured as a function of the temperature change of a substance when heat transfer occurs. The commonly used units for heat are the calorie, the joule, and the British Thermal Unit (BTU). A calorie is the amount of heat required to raise the temperature of one gram of water by one degree Celsius. A BTU is the amount of heat required to raise the temperature of one pound of water by one degree Fahrenheit. One joule is equal to 0.239 calorie.

• Significance for Climate Change

Heat transfer to the Earth's oceans and atmosphere is the first step in, and at the very heart of, climate change. Most of the industrial or mechanical processes in which humans engage release heat as a waste by-product. For example, all fossil fuel and nuclear power plants generate waste heat as a by-product of producing power. A typical power plant may have an efficiency of between 35 percent and 50 percent, meaning that this percentage of the stored energy in a fuel is converted to useful energy, while the remaining energy is discharged to the atmosphere or some body of water as waste heat. This heat transfer to the environment causes a temperature increase of the environment. This temperature increase is a contributor to global warming. Even a degree or two increase in the average temperature of the oceans or the atmosphere can cause profound effects upon Earth's biosphere. All combustion engines also dissipate waste heat to the environment, as do heating and cooking appliances. Only power produced by wind, water, or geothermal energy does not directly contribute to global warming, although these types of power production can have other effects.

Heritage Foundation

- **Category:** Organizations and agencies
- **Date:** Established 1973
- **Web address:** http://www.heritage.org

• Mission

The Heritage Foundation is a conservative public policy research organization, or think tank, based in Washington, D.C. It is widely supported, with more than 390,000 individual, foundation, and corporate donors, and it promotes conservative ideas and principles as solutions to current problems. The foundation maintains a database of policy experts, including those with expertise in global warming issues, and publishes summary statements and analyses of proposed climate change legislation. Its stated mission is to "formulate and promote conservative public policies based on the principles of free enterprise, limited government, individual freedom, traditional values, and a strong national defense."

Using an executive summary format more likely to be read by government officials than are other formats, the Heritage Foundation distills complicated topics into shorter policy papers. Historically, the foundation has had considerable political influence; it became prominent during the conservative era of Ronald Reagan's presidency. Reagan's policies were influenced by a foundation-published book, *Mandate for Leadership* (1981), that provided policy, budget, and administrative action recommendations and advocated limited government. The foundation continues to play a significant role in public policy and is considered one of the most influential research organizations in the United States.

• Significance for Climate Change

The Heritage Foundation researches a broad range of policy issues, including issues related to the environment and global warming. It maintains a searchable online database of policy experts at www.policyexperts.org that includes several renowned climate change skeptics. The foundation's policy statements and legislative analysis related to climate change have included documents on greenhouse gas emission and other issues related to global warming. Most statements published by the foundation argue against mainstream views of the severity and extent of global warming and downplay its potential impacts.

Policy statements issued by the Heritage Foundation suggest that proposed legislation directed toward mitigating global warming may be prohibitively expensive. The foundation concluded that the proposed Climate Security Bill of 2007 would have resulted in substantial costs for little gain. The foundation maintains that global warming is neither unprecedented nor a cause for major concern. A statement published on its Web site reads, "Global warming is a concern, not a crisis. Both the seriousness and imminence of the threat are overstated." The foundation's viewpoint is that anthropogenic emissions contribute little to greenhouse gases and that climate variability has been present throughout the ages, with current temperatures within the range of natural variability rather than evidence of anthropogenic warming.

Heterotrophic respiration

• **Categories:** Animals; plants and vegetation

• Definition

Heterotrophic respiration is a set of metabolic processes through which organisms produce carbon dioxide (CO_2) and release energy from organic compounds that they have ingested or otherwise incorporated from outside themselves. It may be differentiated from autotrophic respiration, in which energy-bearing compounds are produced by the organism through processes such as photosynthesis. Heterotrophic organisms include animals, fungi, and many types of bacteria.

• Significance for Climate Change

CO_2 is a greenhouse gas (GHG), meaning that its increased atmospheric concentration may trap more heat on Earth and raise global temperatures. The amount of carbon in the top meter of Earth's soil has been estimated to be twice that present as CO_2 in the planet's atmosphere. Consequently, increased decomposition of organic matter in the soil—a type of heterotrophic respiration—could make a substantial contribution to global atmospheric CO_2 and thus to global warming.

As a result of these relationships, factors that increase heterotrophic respiration could affect global climate. Certain types of land use are reported to affect heterotrophic respiration in soil. For example, deforestation increases CO_2 release from soil. In addition, CO_2 released into the atmosphere from other sources, such as fossil fuel, can increase global temperatures, which in turn increases the rate of soil heterotrophic respiration, releasing more CO_2. The effect of temperature on heterotrophic respiration may be more pronounced in temperate climates than in tropical ones, in which the effect of temperature may already be at or near maximal.

The soil organisms involved in heterotrophic respiration include macro fauna, such as earthworms, insects, and burrowing mammals; micro and meso fauna, such as protozoa and nematodes; and microscopic fauna, such as bacteria and fungi. The major soil heterotrophs are bacteria, in terms of numbers, and fungi, in terms of mass. Cellulose is a major molecule that is transformed into CO_2 by the process, and fungi, termites, and bacteria are the main types of organisms that produce enzymes that break down cellulose into simpler compounds.

High global warming potential

• Category: Meteorology and atmospheric sciences

• Definition

High global warming potential (HGWP) is a term assigned to industrially produced gases that have extremely high global warming potentials (GWPs). There are three major groups of HGWP gases: perfluorocarbons (PFCs), hydrofluorocarbons (HFCs), and sulfur hexafluoride (SF_6). Emissions of a given mass of one of these gases contribute significantly more to the greenhouse effect than does an equivalent mass of carbon dioxide (CO_2) or other, more common gases.

• Significance for Climate Change

Measurement of GWP was developed as a tool to quantify and compare the efficiency of different gases to trap heat in the atmosphere. GWP depends on both the potency of the substance as a greenhouse gas (GHG) and its atmospheric lifetime and is measured relative to the equivalent mass of CO_2 and described for a set time period. HGWP gases operate in a manner similar to all other GHGs, by absorbing and emitting radiation within the thermal infrared range. However, HGWP gases are hundreds to thousands of times more potent than is CO_2 with respect to their atmospheric heat-trapping properties over a set time period. For example, the most potent GHG, SF_6, has an atmospheric lifetime of thirty-two hundred years and a GWP of 16,300 over twenty years, 22,800 over one hundred years, and 32,600 over five hundred years (relative to CO_2, which is defined to have a GWP of 1 over all time periods).

There are few natural sources of HGWP emissions. The majority of anthropogenic emissions result from the decision to use HGWP chemicals in-

stead of ozone-depleting substances for equivalent functions. Preventing ozone depletion is a higher priority than preventing increases in the greenhouse effect, as outlined in authoritative publications such as the Kyoto Protocol and the Montreal Protocol. HGWP gases are also emitted during industrial processes, such as aluminum and magnesium production, and from commercial products such as automobile air conditioning.

In the early twenty-first century, nitrogen trifluoride (NF_3) began receiving increased attention due to its initial marketing as a green alternative in the technological manufacturing sector. Subsequent data indicated that it is seventeen thousand times more potent as a GHG than is CO_2, but by the time this was known, NF_3 was used to produce a wide range of household products, including computer chips, flat-screen televisions, and thin-film solar photovoltaic cells. HGWP emissions are relatively low in developed countries, accounting for less than 2 percent of total emissions in the United States in 2001, for example. They are so potent, however, that even small amounts can have significant effects, especially given that very few sinks exist for these gases. There is therefore a global movement to reduce HGWP emissions by improving industrial processes.

High Park Group

- **Category:** Organizations and agencies
- **Date:** Registered January 22, 2003
- **Web address:** http://www.highpark group.com

- **Mission**

The High Park Group (HPG) is a public affairs and policy consulting group in Toronto and Ottawa that represents many energy industry clients. The firm appears to support skepticism of anthropogenic climate change.

The group claims to work in a wide range of areas, but its primary areas are energy, environment, and ethics. Among its services are policy and strategic consulting, direct lobbying, media relations, and issues management. In 2009 the president was Timothy M. Egan. One of the directors was Kathleen McGinnis. The director of regulatory affairs was Julio Legos. The Ottawa director until September, 2006, was Tom Harris. The High Park Group is registered as lobbying for several energy clients, including Areva Canada Inc., the world's largest nuclear power company; ARISE Technologies Corporation, a solar technology company; the Canadian Electricity Association; and the Canadian Gas Association. Harris was a lobbyist for the Canadian Electricity Association and Canadian Gas Association. McGinnis was registered to represent the Canadian Electricity Association to lobby government agencies regarding activities of the National Energy Board related to electric transmission. Egan was senior adviser to the Canadian Electricity Association and monitored U.S. policy as it related to the electricity industry of Canada.

In September, 2006, Harris became head of the Natural Resources Stewardship Project (NRSP), a group that describes itself as "promot[ing] responsible environmental stewardship." Two of the three directors of the board of the Natural Resources Stewardship Project are Egan and Legos of the High Park Group. NRSP promotes global warming skepticism. Tom Harris wrote in the June 7, 2006, *National Post* that "the hypothesis that human release of CO_2 is a major contributor to global warming is just that—an unproven hypothesis, against which evidence is increasingly mounting." Critics have claimed that the Natural Resources Stewardship Project allows the High Park Group to lobby against climate change regulations on behalf of its energy clients without the clients being identified.

Although not trained in climatology, Harris has bachelor's and master's degrees in mechanical engineering. Even before the formation of High Park Group, he made statements such as

> I think most investors would sensibly conclude that until the science is more mature, pressuring companies to do something, or not to do something, about GHG emissions is a costly gamble and that they should wait until the verdict is in before deciding what to do (if anything).

In a March 8-14, 2001, *European Voice* article coauthored with geologist Tim Patterson, Harris asked, "Is the UN guilty of exaggerating fears over climate change?" In November, 2002, Harris was one of the organizers of an event in Ottawa at which climate change skeptics were "to reveal the science and technology flaws of the Kyoto Accord."

In the June 8, 2006, *Vancouver Sun*, Harris wrote an editorial titled "Environmental Heresy." The subtitle read: "Failing to question the scientific assumptions underlying Kyoto isn't fair to citizens concerned about climate change." After his associations with the High Park Group and the Natural Resources Stewardship Project, he became executive director of the International Climate Science Coalition (ICSC), in March, 2008. This coalition describes itself as an association of scientists, economists, and energy and policy experts working to promote better understanding of climate change science and policy. Patterson is chairman.

• Significance for Climate Change

Some skepticism is good when considering conclusions made from scientific data, especially when different scientists reach conclusions that do not agree. Skepticism can also be used to confuse people. Critics of HPG, NRSP, and ICSC claim that they lobby against regulation to protect their clients' profits. They emphasize that the registered lobbyist HPG directs the flow of skepticism from NRSP and ICSC, so that government decision makers will be so confused as to make no changes or the wrong change. If the wrong decision is made, then the world and its climate could be drastically changed.

Hockey stick graph

• **Categories:** Meteorology and atmospheric sciences; climatic events and epochs

The hockey stick graph, named for its shape, represents a thousand-year period of essentially stable average temperatures in the Northern Hemisphere, followed by an upward spike around 1900. The graph, which suggests the impact of industrial activity on global warming, has been cited to support arguments that global warming has anthropogenic causes, but its accuracy has been questioned; it has thus been both prominent and controversial.

• Key concepts

Medieval Warm Period: a period of warmer-than-average temperatures between the tenth and fourteenth centuries

multiproxy reconstruction: a method of estimating prehistoric climate conditions using a combination of proxy indicators
paleoclimatology: the study of prehistoric climate conditions
proxy indicators: tree rings, fossils, and other artifacts that provide indirect evidence of past temperatures

• Background

The "hockey stick" is a nickname given to a dramatic graph of historic average temperatures in the Northern Hemisphere. The graph became a prominent—and controversial—symbol in the debate over whether or not recent global average temperatures are historically abnormal and thus more likely to have been caused by human activities. The graph gets its nickname from its shape, which represents a flat, thousand-year period of stability (the stick) followed by a sudden upward spike (the blade). The nickname is generally attributed to Jerry Mahlman, head of the Geophysical Fluid Dynamics Laboratory, part of the National Oceanographic and Atmospheric Administration.

The hockey stick graph was first published in *Nature* magazine in 1998 by a research team of Michael E. Mann, Raymond S. Bradley, and Malcolm K. Hughes and was featured prominently in the 2001 Second Assessment Report of the United Nations Intergovernmental Panel on Climate Change (IPCC). Mann and Bradley were researchers with the University of Massachusetts, while Hughes was a specialist in dendrochronology (tree-ring dating), working at the University of Arizona in Tucson. The scientists engaged in a type of historical temperature reconstruction generally referred to as "multiproxy" reconstruction. That is, they combined a broad set of measured temperatures with estimates based on several proxy temperature indicators, such as tree-ring growth, fossilized leaf stomata, boreholes, lake sediments, and tree pollen.

The graph published in *Nature* was a radical departure from previous temperature reconstructions, which had depicted a period of significant warmth (equal to or greater than current temperatures) during the Medieval Warm Period, which lasted from the tenth to the fourteenth century. Controversy over the hockey stick graph arose when two Canadian researchers—Steven McIntyre, a policy analyst with a background in mathematics and mineral exploration, and Ross McKitrick, an economist at the University of Guelph—sought to examine the underlying data and programming used by Mann and his colleagues in creating the graph.

• The Criticism

McIntyre and McKitrick examined the data and attempted to reproduce the hockey stick model using the same methodology Mann's team had employed. They then published an article in the European journal *Energy and Environment* asserting that the earlier team's data set contained significant errors, omissions, and duplicated data. They also claimed that the computer program used to analyze the data gave undue importance to a single proxy series of dubious value. In later analyses, published outside of the scientific literature, McIntyre and McKitrick asserted that the analytical program had a built-in bias that would produce a hockey-stick shape even if it was analyzing completely random data. A continuing bone of contention was the resistance that Mann's group demonstrated to sharing its data or providing sufficient information about its computer program to facilitate others' efforts to reproduce the hockey stick.

• Mann's Response

The claims made by McIntyre and McKitrick have been sharply rejected by Mann, Bradley, Hughes, and other members of the academic paleoclimatology community. In addition to questioning McIntyre and McKitrick's ability to understand the development of multiproxy temperature reconstructions, Mann and other paleoclimatologists argue that what McIntyre and McKitrick found were only trivial data errors that did not alter the fundamental shape of the graph. Claims regarding bias in the analytical program have also been disputed and attributed to improper mathematical analysis techniques, as well as to failures properly to use the program.

• Third-Party Referees

The controversy over the hockey stick graph led several high-level review panels to be convened. One such panel was created by the National Academy of Sciences' National Research Council at the request of U.S. representative Sherwood Bohlert, chair of the House Committee on Science. It was led by climate modeler Gerald North. Another committee, assembled at the request of two other Republican members of the House, was directed by statistician Edward Wegman, head of the National Academy of Sciences' Committee on Applied and Theoretical Statistics. Both of these committees upheld many of the findings of McIntyre and McKitrick, although the North panel was slightly less critical of the hockey stick model than was the Wegman panel.

• Context

Despite the findings of the two review panels, the hockey stick controversy continued to rage with considerable rancor. It was conducted primarily via claims and counterclaims about various elements of the debate on blogs such as that of Steven McIntyre (www.climateaudit.org) and Real Climate, a collective blog operated by a group of climate researchers (www.realclimate.org). Areas of contention involved assumptions regarding the accuracy and global representativeness of individual proxy data sets.

The hockey stick controversy affected public opinion and the methodology of climate reconstruction, as well as the representation of such reconstructions in scientific publications. It became a rallying point for climate change skeptics, especially those doubting that greenhouse gas emissions and other anthropogenic factors play a role in global warming. These skeptics saw the controversy as evidence that climate researchers were intentionally exaggerating recent warming by erasing warmth from prior centuries. They produced a huge number of publications proclaiming the "breaking" of the hockey stick and, with it, the refutation of the idea that recent temperatures are historically abnormal.

Many believe that the controversy over the hockey stick also led to changes in the way that the IPCC chose to represent historical temperature reconstructions in its Fourth Assessment Report on the science of climate change. Rather than relying on a single historical climate reconstruction, the report presented the results of an ensemble of reconstructions. Some of these reconstructions included the Medieval Warm Period; others did not.

Holocene climate

- **Category:** Climatic events and epochs

Understanding climatic fluctuations since the last ice age provides a context for evaluating the extent to which the present global warming trend is an anthropogenic phenomenon. Correlation of archaeological and historical records allows projections of the impact of global warming on human society.

Key concepts

positive feedback loops: self-accelerating processes, such as increased snow cover increasing planetary albedo and promoting additional cooling, leading to more snow cover

proxies: preserved, measurable parameters that correlate with climate and serve as evidence of past climatic conditions

thermohaline circulation: the rising and sinking of water caused by differences in water density due to differences in temperature and salinity

Background

Climatic changes since the end of the last ice age form the backdrop for much of human prehistory and are viewed by some as a driving force in the rise and fall of civilizations. The retreat of continental glaciers began in earnest 13 million years ago, with a gradual warming trend that reached its peak around 6,000 years ago during a period known as the Hypsithermal or Holocene climatic optimum. Proxy records, supplemented by historical data in more recent times, suggest six periods of abrupt cooling in the Holocene, 9,000-8,000, 6,000-5,000, 4,200-3,800, 3,500-2,500, 1,200-1,000, and 650-150 years before the present. Within warm periods and cold periods, there is considerable fluctuation on scales ranging from decades to centuries. Temperature variations as measured by a variety of proxies are more dramatic near the poles, while variations in rainfall associated with temperature-induced fluctuations in oceanic currents predominate in the tropics. Overall, climatic variability in the Holocene is considerably less than it was in the Pleistocene, and what fluctuations have occurred in the Holocene have decreased over the course of the period.

Climatologists are continually modifying the prevailing picture of climate change in the Holocene as more high-resolution studies become available from areas other than Europe and eastern North America. Climatic shifts typically appear earlier in the Southern Hemisphere than in the Northern Hemisphere. Signs of the 8.2ka event, a period of dramatic European cooling due to disruption of currents in the Atlantic Ocean, are much less evident in western North America and are absent in New Zealand.

Measuring Holocene Climate

Systematic instrumental records of weather in parts of Europe and North America exist for the last 150 years. Agricultural records, historic narratives, and even legendary sources chronicle catastrophic events throughout human history.

Until recently, much of the available information about climate in prehistoric times came from archaeological investigations. The study of artifacts and settlement patterns reveals a great deal about the climate in which ancient people lived. For example, prolonged drought in the American Southwest, corresponding to the culturally benign Medieval Warm Period in Europe, is evident in shifting patterns of cultivation, declining population, skeletal deformities due to malnutrition, compressed tree rings in construction timbers, and eventual abandonment of cliff dwellings.

Vegetation is a good climatic indicator. Leaves, woody material, and particularly pollen occur in abundance in bogs, lake sediments, and areas of human settlement. Pollen analysis is a powerful tool, because pollen is extraordinarily decay-resistant. Many pollen grains can be identified to genus, and relative abundance provides a fairly complete picture of a region's flora. Wind-pollinated plants with narrow ecological niches are particularly useful. In Europe, the arctic-alpine herb *Dryas octopetala* indicates arctic-alpine conditions, spruce (*Picea*) indicates a cold, humid climate, and oak (*Quercus*) provides evidence of a drier, warm climate. Pollen of *Plantago*, a weed in grain fields, suggests cultivation. In marine sediments, relative abundance of planktonic types serves as a proxy for water temperature.

Various geological formations permit high-resolution analysis of local climate. Moraines and scouring document the advance and retreat of glaciers. Varves, which are layers of sediment in lakebeds, provide a record of stream flow into lakes. When precipitation is high, increased runoff and sediment load create thick varves and rapid deposition of alluvial fans at the mouths of rivers. Terraces along lake and ocean shores document rises and falls in water level. In some areas, the land may also be rising or subsiding relative to sea level.

Ice cores taken from glaciers in Greenland and Antarctica provide evidence of climate over the last 400,000 years, including rates of precipitation, amounts of atmospheric dust, and concentrations of carbon dioxide (CO_2) in trapped air. Analysis of the ratios of carbon and oxygen isotopes in carbonates and of oxygen isotopes in ice also provides clues to climate, since both biotic and abiotic processes use isotopes selectively. Isotope ratios can also be used as proxies for sunspot activity, a suspected factor in warming and cooling trends.

• Climatic Change in Human Prehistory

The tenure of modern humans on Earth encompasses the last Pleistocene glaciation and the ten thousand years of the Holocene, during which the Earth's climate has fluctuated, with a temperature maximum roughly six thousand years ago. There are many studies correlating prehistoric cultural changes with climatic changes. For agricultural societies, the droughts associated with colder periods are more devastating than are lower temperatures themselves. The Holocene historical and geologic records contain no compelling evidence of rapid rises in temperature such as the Earth is currently experiencing: Global warming in geologic time appears to be a gradual process to which life adapts. Cooling, on the other hand, can be extremely rapid and catastrophic.

Gradual warming can also produce catastrophic results, when rising waters overwhelm a natural dam, unleashing a flood of biblical proportions. Indeed, a controversial theory postulates that the biblical flood was just such an event, and that the fertile agricultural land surrounding the Black Sea was suddenly inundated when rising waters in the Mediterranean breached the Bosporus roughly seven thousand years ago. Similar floods occurred in the lower reaches of the Tigris and Euphrates rivers and the northern Red Sea at about the same time.

In North America, rapid draining of Glacial Lake Agassiz through the St. Lawrence River caused local devastation, as well as disrupting oceanic currents. The Missoula floods in the Columbia River basin resulted from periodic breaching and reforming of an ice dam at the glacial margin. The widespread occurrence of devastating warming-induced floods in prehistoric times holds a lesson for the present. If there is a dam protecting a city from rising waters, whether it is natural or artificial,

Holocene Climate Time Line

Years Before Present	*Climate Trend*
9,000 to 8,000	Cooling
8,000 to 6,000	Warming
6,000 to 5,000	Cooling
5,000 to 4,200	Warming
4,200 to 3,800	Cooling
3,800 to 3,500	Warming
3,500 to 2,500	Cooling
2,500 to 1,200	Warming
1,200 to 1,000	Cooling
1,000 to 650	Warming
650 to 150	Cooling
150 to present	Warming

every incremental temperature rise increases the likelihood of disaster.

The causes of cooling episodes are various. They include changes in solar radiation levels, volcanic aerosol concentration, greenhouse gas (GHG) concentration, the hydrologic cycle, sea level, sea ice extent, and forest cover. The six defined periods of cooling in the Holocene most probably all derive from several such factors acting in concert.

The rapid cooling that occurred between nine thousand and eight thousand years ago took place during a decline in insolation and a high level of volcanic SO_2 production. A massive infusion of glacial meltwater into the North Atlantic disrupted thermohaline circulation. A weakening Afro-Asian monsoon contributed to tropical aridity. Atmospheric methane concentrations declined because of the drought; this depletion of GHGs created a feedback loop prolonging cooling conditions.

Proxy records based on isotope ratios suggest a decline in solar radiation during the four subsequent cooling periods. The cooling corresponds to lows in solar radiation that correspond to variation in the Earth's orbit. In the case of the 8.2ka event and the onset of the Little Ice Age, there is also evidence of increased volcanic activity. Massive volcanic eruptions cause global cooling by ejecting fine ash and sulfates into the atmosphere. However, in the absence of reinforcement from orbital forcing, this effect dissipates in about three years.

• Cultural Effects of Holocene Climate Change

As several analysts have pointed out, climate has helped shape civilization, but not by being benign. Human technological and social advances appear in the archaeological and historical record as responses to climate change that rendered older ways of life maladaptive. The general pattern appears to involve a buildup of population and associated infrastructure during periods characterized by warm temperatures, adequate rainfall, and low variability, such as the Hypsithermal or the Medieval Warm Period. This is followed by a population crash due to famine, war, and pestilence when the climate changes, and a period of rapid technological and social innovation as the population adapts to the new conditions.

In the Middle East, the 8.2ka event, which occurred at a time when agriculture had not yet entirely supplanted the hunter-gatherer economy, spurred the transition to a permanently settled mode of life, more intensive methods of cultivation, and the rise of towns. The 6ka cooling period corresponds to the beginnings of civilization in the Middle East, China, and Southeast Asia. The need to coordinate a large population base over a wide area to manage irrigation during a prolonged drought has been postulated as a key factor in the rise of city-states in Mesopotamia.

During the Hypsithermal, large portions of the Sahara Desert were savanna dotted with seasonal lakes, supporting abundant game and hunters who left rock art and artifacts in areas that are completely barren today. The present aridity of the Sahara and much of the Middle East was well established in classical times (twenty-five hundred to fifteen hundred years ago) and has persisted through warm periods of increased rainfall, in part as a result of human activities such as overgrazing. Global warming could increase rainfall in regions such as the Sahel. Although this would ultimately be beneficial, immediate effects would include flash flooding, erosion, and the proliferation of invasive species.

The cultural pattern is less clear-cut in the humid tropics, but studies of the rise and fall of lowland Mayan civilization in Central America suggest that, contrary to expectation, the peak of this civilization corresponded to the cooling period that occurred twelve hundred to one thousand years ago. Its subsequent decline came during the Medieval Warm Period. In the tropics, cold conditions at the poles cause a weakening of monsoons. Seasonally dry conditions advance toward the equator. Climates with strongly marked wet and dry seasons are more favorable to intensive, highly productive agriculture than is a permanently wet tropical rain forest.

Modern Western civilization is the product of the Little Ice Age. (The term "Little Ice Age" is used differently by different writers. Many use it to refer to the climate cooling from about 1300 to 1850, while others use it for the latter half of that interval, when cooling was greatest, beginning around 1550 or 1600.) The abrupt drop in temperatures that occurred in 1315 produced first a famine, then war, and finally a pestilence that wiped out one-third of Europe's population. Without a famine-weakened population and the disruptions of war, the bubonic plague might well have remained localized, as it did in North Africa in the eighteenth century. Temperatures remained low during the recovery period. Thus, a return to the population levels and living standards of the thirteenth century required first technological innovation and later exploitation of warmer areas through colonialism. For reasons not clearly understood, the Little Ice Age did not produce increased drought in the tropics.

• Context

Probably the most important global warming lesson to be learned from the Holocene record is that of the disruption of North Atlantic currents and resulting deep freeze in Europe eighty-two hundred years ago. Very rapid melting of the Greenland ice cap and release of freshwater into the Atlantic could well produce a similar effect. Short-lived episodes of warming and cooling are documented in the climate proxy record. On a local level, such episodes undoubtedly produced dramatic effects, but they left no lasting impression on the world's flora and fauna, nor on human culture as a whole. In today's overpopulated and environmentally degraded world, the consequences of a temporary drop in global temperatures due to either massive volcanism or a disruption of thermohaline circulation in any of the Earth's oceans present a much grimmer prospect than they did at any other time in history. Both scenarios have sufficiently high probability to attract the attention of Pentagon analysts.

Hubbert's peak

• **Categories:** Fossil fuels; energy

Geophysicist Hubbert's prediction that American oil production would peak in 1972 proved accurate and presaged the rise of energy independence and security as crucial national and international issues.

• Key concepts

fossil fuels: fuels, including coal, oil, and natural gas, produced by chemical alteration of organic matter under pressure

greenhouse gases (GHGs): atmospheric trace gases that trap heat, preventing it from escaping into space

nonrenewable resource: a resource that, once consumed, cannot be renewed

reserves: the estimated amount of a nonrenewable resource remaining to be consumed

• Background

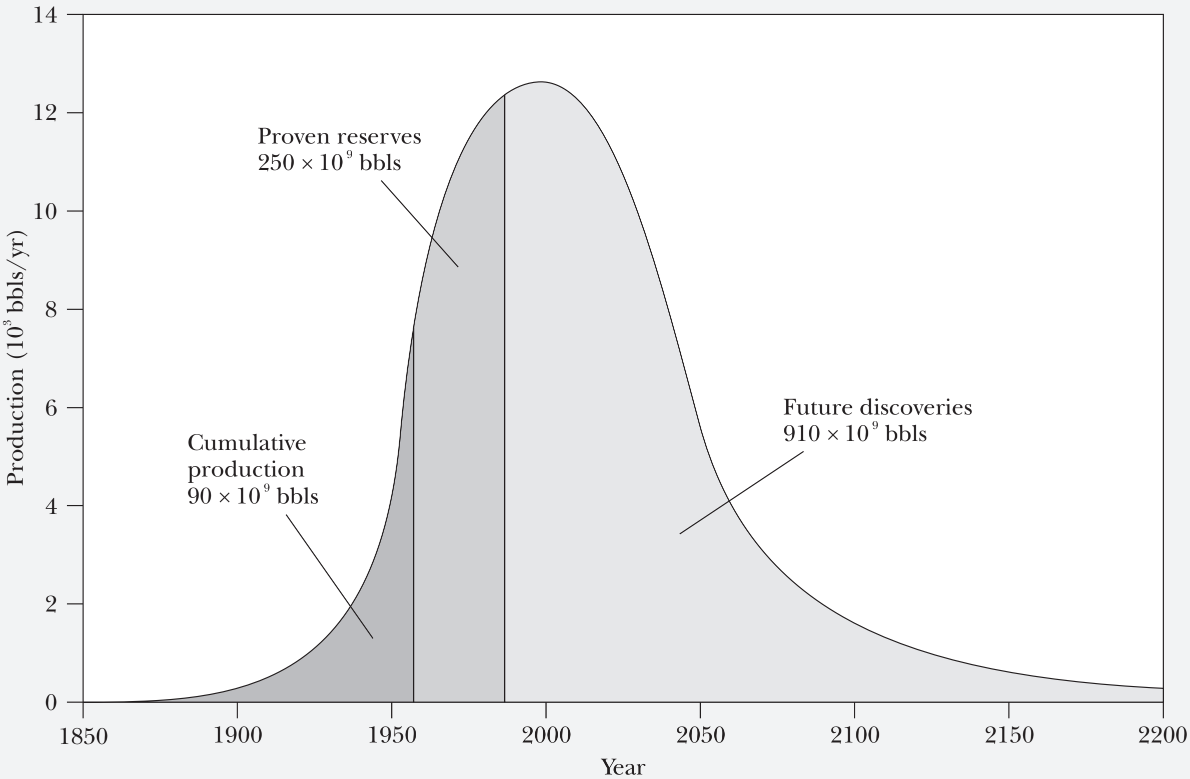
In 1956, Shell Oil Company geophysicist M. King Hubbert predicted that U.S. oil production in the lower forty-eight states would peak in 1972; it peaked in 1970. Other scholars have extended Hubbert's work to predict that world oil production would peak sometime between 2005 and 2011. Although there are critics of Hubbert's approach, most geologists and geophysicists agree with the basic premises of his work. World demand would exceed production capacity about the time of peak production, driving up the cost of oil. Burning oil is a major producer of carbon dioxide (CO_2), a greenhouse gas (GHG). The impending oil shortage and resulting increases in the price of oil may help spur people to turn to alternative energy sources, many of which do not produce CO_2.

• Hubbert's Predictions

Basing his analysis on proven oil reserves in the United States and on an analysis of production patterns in the anthracite coal industry, Hubbert produced a bell curve that showed the growth, peak, and eventual decline in American oil production. He described what has come to be called Hubbert's peak, the one-hundred-year period in which oil was the driving force of the economy. Hubbert tied his analysis to patterns of production for other fossil

Hubbert's Peak

Reproduced below is a graph of M. King Hubbert's original 1956 prediction of global oil production over two and one-half centuries.



bbls = billions of barrels.

fuels, most notably anthracite coal in the eastern U.S. Because fossil fuels are a nonrenewable resource, they cannot be re-created once used. The model that Hubbert produced contained two scenarios, one predicting that U.S. oil production would peak in 1965, and a more optimistic one indicating 1972. Actual U.S. oil production peaked in 1970, giving additional weight to Hubbert's approach.

Hubbert's bell curve indicated that there would continue to be significant American oil production after the early 1970's, as has occurred. However, as easily accessible reserves are consumed, oil producers are forced to turn to increasingly expensive means to produce oil. This has meant drilling in unlikely places, often at great expense and to no avail; expensive recovery processes that try to obtain what oil remains in an underground reservoir; and increased emphasis on offshore drilling, in some cases through 3,000 meters of water and then 6,000 meters below the ocean floor.

Several scholars, such as Kenneth Deffeyes, have extended Hubbert's approach and predicted the peak for world oil production would occur some time during the first decade of the twenty-first century. Because the United States has come to rely on foreign oil, a decline in world oil production will have a significant impact on the American economy as well as climatic conditions. This second peak production point will lead to increasingly expensive means of trying to obtain oil.

• A Question of Reserves

Hubbert's analysis was based on his knowledge of proven oil reserves taken from several sources. Oil is generally found in particular types of geologic formations between 2,300 and 4,600 meters beneath the surface of the Earth. These oil-bearing formations are found in both the land and beneath the ocean. In the past oil companies and government bodies have often overstated oil reserves for political and economic reasons. This situation may be changing, as Shell Oil sharply decreased its reserve predictions early in the twenty-first century. Although further exploration has led to higher estimates for reserves, by the early twenty-first century only the South China Sea region had not been fully explored, and most geologists do not expect any oil fields approaching the magnitude of the Saudi Arabian fields to be found there.

Economists often raise the principle of substitutability in dealing with oil reserve predictions. They indicate that as it becomes more expensive to drill for oil in one area, oil companies will drill elsewhere distorting reserve predictions as oil still remains in the ground in the old fields. This was true for a time, but now oil companies are using new technologies to extract oil from old fields in places such as east Texas and Mexico. The criticism of Hubbert that he ignored substitutability may have been somewhat true at one point, but it is less true at present.

Oil is a finite resource, and as oil fields are depleted oil companies turn to more expensive means of production. For example, in 2008 some oil companies were paying more than $600,000 a day to lease drill ships for offshore drilling. In addition, some oil reserves are now found in politically unstable locations, such as off the east coast of Africa, a condition likely to drive up the costs of obtaining oil. Oil is also found in tar sands in Canada, but extraction is expensive and causes several environmental problems. Moreover, oil is used for more than energy. It is also the feedstock for the chemical industry for such products as plastics.

• Context

Burning fossil fuels such as oil is a major source of GHGs such as CO_2. It is estimated that CO_2 generated by burning fossil fuels represents 57 percent of the GHGs emitted into the atmosphere. Although oil- and gasoline-burning comprise only parts of this figure (coal-burning is also a major source of CO_2), decreasing the burning of oil will help to reduce this source of CO_2 emissions. Oil consumption is so ingrained in industrial society in the use of oil for industrial and home energy and for transportation that simply turning to another source is not likely in the short run without the impetus of a steep price increase. With the exception of coal most other, cleaner energy sources have been more expensive than fossil fuels, so there has been little economic incentive to adopt them.

It is likely that the assumptions concerning world oil production derived from Hubbert's model are correct and the production of oil will become increasingly expensive in the next few years. The increasing cost of oil predicted by Hubbert's model may help to lower consumption of oil. Confronted by sharp increases in the prices of gasoline and fuel oil in 2008, more industries and consumers were searching for alternative fuels, fuels that often produced a smaller carbon footprint than oil.

Human behavior change

• **Category:** Popular culture and society

Climate change will affect human welfare, and changing behavior may mitigate the threat. Technologies exist to facilitate the development of proactive behavior and problem solving, as well as the reduction of human contributions to global warming.

• Key concepts

adaptation: the process through which entities adjust in response to external circumstances

altruism: behavior intended to benefit others rather than the self

behavioral economics: the study of the combined economic and psychological principles affecting human behavior and decision making

environmental psychology: the study of the interaction between behavior and the environment among individuals, groups, organizations, and systems

negative reinforcement: deployment of stimuli to decrease a given behavior

positive reinforcement: deployment of stimuli to increase a given behavior

punishment: a type of negative reinforcement incorporating a moral component

systems theory: approaches to understanding interdependent behavior within and among groups or systems

• Background

Humans regularly adapt their behavior to daily and seasonal weather changes with ease. With global climate change, however, the adaptation demands facing humans are expected to be extraordinary. There is scientific consensus that human activities will need to adapt substantially to meet the anticipated changes of the near future and beyond. Such changes will demand local and regional adaptations in daily individual and community functioning, as well as sustained behavior changes by individuals, organizations, and systems to reduce or cease activities affecting the climate deleteriously in a more global and persisting way. Behavioral economics and environmental psychology provide tools for making such change occur.

• Preparing for Climate Change Through Behavior Change

Global climate change will demand different preparation activities from different people. This variation is partly a function of the varied effects of climate change experienced by different regions of

Vivian deZwager shows off the newly planted green roof on her garage. Such roofs help reduce carbon dioxide, as well as heating and cooling costs. Treating the planting as an artistic project may help motivate others to follow suit. (Janet Jensen/MCT/Landov)

the globe. Some regions may become hotter or cooler, drier or wetter, or may have more or less seasonal variation in weather than previously known. Necessary individual, organizational, and systems-level preparations vary by location. Relevant factors include latitude, longitude, elevation above sea level, and the time span considered.

People may adapt by adjusting where and how they live, making home improvements to meet new climate challenges, and developing personal climate disaster plans. Assessment and acquisition of skills needed in the event of a climate-related crisis also will be necessary. Community organizations may seek to protect whole communities and neighborhoods. Organizations such as businesses and governments may adapt by changing locations for headquarters, road systems, and other construction, as well as arrangements for food, medical, and other natural resource distribution. They also may prepare on the systems level by engaging with other governments to coordinate responses to challenges should they arrive, such as dispersing aid and assistance and ensuring vital communications.

• Lessening the Impact of Climate Change Through Behavior Change

Individuals, organizations, and governments must consider what they can do to lessen the continued development and ultimate impact of global climate change using available knowledge and technologies. For individuals, education about carbon footprints, water-use habits, use of natural space, and resource use related to climate change will be a first step. After understanding their personal behavior, people may need to alter their lifestyles, travel patterns, and consumption of goods to lessen their carbon footprints and other environmental impacts. Such proactive and altruistic behavior will lessen the overall burden on those expected to be most affected by climate changes and will perhaps lessen the overall damage that may occur.

Individuals also may consider changing how they influence other individuals and the relevant organizations and systems in which they interact. They may examine their work and governmental behavior and policies affecting climate. They may advocate for change to initiate and reinforce larger systems adjustments, as well as smaller change in local communities, such as within a family or among friends and neighbors. Climate change is not affected only by individuals, however; organizational and systems behavior matters too.

Governments and businesses are the largest global consumers of energy, having much greater carbon footprints and environmental impacts than individuals. Therefore, attempts to lessen the overall impact of climate change must incorporate organizational and systems-level adjustment. For families, this may mean assessing the overall impact of living far away from schools and workplaces. Businesses and government could similarly assess their employees' air travel and consider ways to minimize or replace such travel. At a systems level, efforts such as the Montreal Protocol and Kyoto

Protocol may need to be updated and expanded, encouraging greater coordinated efforts across larger systems of human behavior.

- **Climate Change, Behavioral Economics, and Managing Human Behavior**

Individuals, organizations, and systems do not enact behavior merely based on morals, principles, or theories. Incentives, such as positive and negative reinforcement, as well as costs, such as punishments, pay a role. In effect, human behavior is subject to behavioral economics—a valuable tool for changing human behavior. Examination of key behaviors needing change among individuals, organizations, and systems, coupled with identification of key incentives and costs, can be used to encourage change. Rebates, taxes, credits, budgets, fines, barter, and allowances for different climate-related behaviors are examples of how behavioral economics may be applied for both businesses and individuals. Similarly, organizations such as governments can be subject to incentives, such as basing the right to import or export goods on climate-related practices within a particular country. At the systems level, governments can develop agreements with one another that suit the goals of preparing for climate change and enacting behavior to lessen its impact.

- **Context**

Scientific advances allow humans to predict, shape, and respond to future change by adapting both individual and collective behavior. The ability of humans to communicate globally, cooperatively, and quickly has increased dramatically as a function of modern communications technologies. These technologies facilitate the communication of complex environmental and behavioral information, along with insights into the dynamics of human behavioral economics, market forces, and the connectedness of people across the globe. Such abilities may be combined with psychological technology to affect and shape human behavior at the individual, organizational, and systems levels, and thoughtful and sustained leadership can provide solutions to the pressing climate problems ahead.

Human migration

- **Category:** Ethics, human rights, and social justice

- **Definition**

Most literature uses the term "environmental refugees" or "climate refugees" to conceptualize the complex relationships between human migration and climate change. In the 1970's, Lester Brown of the Worldwatch Institute defined environmental refugees as people forced to leave their traditional habitats, temporarily or permanently, because of marked environmental disruptions.

- **Significance for Climate Change**

Migration caused by environmental degradation is not a new phenomenon. People throughout history have migrated in order to seek new opportunities and resources for survival. What makes climate-change-related displacement different is the scale of the problem and the size of the population affected by them. Both the Intergovernmental Panel on Climate Change (IPCC) and the United Nations Environment Programme warn that human mass migration caused by climate change can turn into humanitarian crises and a global security threat, because the change of settlement may cause conflict over resources within nations or in host communities.

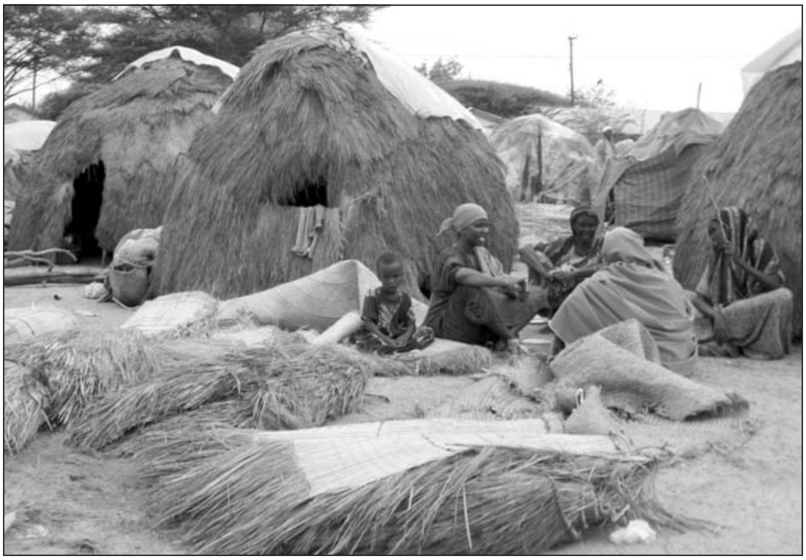
The Office of the United Nations High Commissioner for Refugees estimates that 24 million people around the world will be displaced because of floods, famines, and other environmental factors by 2050. The *Stein Review* and Friends of the Earth both predict that by that year 200 million people will become climate change migrants worldwide, including one million from small island states affected by shoreline erosion, coastal flooding, and severe drought resulting from rising sea levels, deforestation, dry-land degradation, and natural disasters. Christian Aid makes the most extreme prediction: One billion people will be forcibly displaced by 2050.

The impact of global warming is twofold: First, climate change increases the variability of extreme weather events associated with the changes in surface temperature and precipitation. This results in floods, droughts, and a high incidence of diseases that affect both human and animal health. Second, rising sea levels mean loss of farmland, accelerating shoreline erosion, and disruption of agricultural production. For example, in Egypt, the anticipated rise in sea level could cause 12 to 15 percent loss of arable land by 2050, and consequently 14 million people would be forced to disperse. In Bangladesh, a 1 meter increase in sea level would inundate half of Bangladeshi rice land, forcing the relocation of 40 million people.

Studies show that climate-change-related displacement has a negative impact on the well-being of migrants. The process may cause severe long-term stress and psychological effects. Prolonged uprooting may result in culture and identity loss. Displaced people become landless, homeless, and unemployed, and they are restricted from getting access to common property resources in new areas. The weakening of community ties will reduce their social networks and further reinforce social marginalization.

The IPCC warns that climate-related migration may increase the risk of group-identity conflict and political instability within states. Reduced water availability, for example, may induce conflict between different water users, such as pastoralists and farmers. People may resort to violence to gain dominant control over limited natural resources. The grievance could increase recruitment opportunities for rebel movements and lead to civil war. Environmental scarcity could also bring about conflict across borders. Water scarcity can cause transboundary disputes.

Migration would also bring problems to host communities or nations, especially if they are not well prepared for the influx of migrants. The rising numbers of migrants will exert pressure on resources and social services. The migrants them-



An encampment of Somalian refugees who have been displaced from their homes by flooding. (Daud Yussuf/Reuters/Landov) selves will compete for jobs, and that competition may increase social tensions and intergroup clashes. In order to curb the influx of migrants, host societies may change their immigration laws and restrict asylum. International law does not require states to provide asylum to those displaced by environmental degradation.

The literature suggests that the impact of climate change on human migration is complex. The causes of migration are multiple, and many problems created by climate change build on existing development problems, such as socioeconomic vulnerability, political suppression, and institutional weakening. The consequences of climate-change-induced migration also depend on the rate of recovery, adaptive capability, preparedness for disasters, and effectiveness of conflict resolution mechanisms. Questions as to whether the deterioration of environmental conditions by climate change is sudden or gradual, whether the displacement is temporary or permanent, and whether migrants are victims or strategists who choose to migrate because of foreseeable opportunities in a new environment need to be carefully examined.

To address these problems, disaster preparedness must be improved; this includes building better adverse-weather advance-warning systems for vulnerable areas. Effective conflict resolution mechanisms can be developed to settle disputes. Governments can increase community resilience by reducing soil erosion and deforestation and enhancing awareness about sustainable use of resources. Better coordinated assistance is needed to reconstruct the livelihoods of the displaced. Land-based resettlement, rehousing, social inclusion, improved health care, and building community assets and services are a few strategies to reduce the impact of migration.

Humidity

• Category: Meteorology and atmospheric sciences

• Definition

Humidity is the amount of water present in the atmosphere in the form of vapor. As a gas, water vapor contributes to the local atmospheric pressure in accordance with Dalton's law of partial pressures: In any mixture of gases, the partial pressure of any one component is equal to the total pressure of the mixture multiplied by the fraction of the gas present in the mixture. For example, molecular oxygen constitutes 20 percent of the atmosphere, so the partial atmospheric pressure of oxygen is 20 percent of Earth's total atmospheric pressure. The total pressure is about 1.03 kilograms per square centimeter, so the partial atmospheric pressure of oxygen is about .20 kilograms per square centimeter.

Water normally exists in liquid and solid as well as vaporous form. Its vapor pressure is the pressure at which pure water vapor coexists in equilibrium with either the liquid or the solid state. At equilibrium, the liquid would not evaporate, the solid would not sublimate, and the vapor would not condense. By contrast, if the local partial pressure of water vapor is greater than its vapor pressure, the vapor condenses; if the local partial pressure is less than the vapor pressure, then the liquid evaporates and the solid sublimates. Vapor pressure is not a constant but rather is a function of temperature.

If the local partial pressure of water is exactly equal to its vapor pressure, the air is said to be saturated. This state is defined as 100 percent humidity, and the corresponding temperature is water's dew point. If the vapor pressure of water is equal to the total local atmospheric pressure, the water will evaporate without limit, and the corresponding temperature is water's boiling point. Relative humidity is the ratio, expressed as a percentage, of the local partial pressure of water vapor to the vapor pressure associated with the local temperature.

Humidity can exceed 100 percent, a condition known as supersaturation. In supersaturation, water vapor's partial pressure exceeds the theoretical vapor pressure at that temperature. Condensation cannot take place, however, unless condensation nuclei are present. Water droplets exceeding a certain critical size act as such nuclei, absorbing water vapor and growing; water droplets below the critical size evaporate. If no droplets larger than the critical size exist and no other condensation nuclei are present, then the supersaturated vapor is stable. Fine, dry particles, such as dust or pollutants, also act as condensation nuclei in supersaturated air.

Evaporation is an endothermic process, or one that requires an input of energy in order to occur. The change of phase from liquid to gas takes place at constant temperature. The energy consumed by the process is stored in the water vapor in the form of latent heat of vaporization. When the vapor condenses, all of the latent heat is released, which means that condensation is exothermic. Water has a latent heat of vaporization of 2,256,000 joules per kilogram, an unusually high value for such a simple compound.

• Significance for Climate Change

Water vapor is the most abundant greenhouse gas (GHG) in Earth's atmosphere, exceeding the amount of CO_2 by a factor of one thousand. It is transparent to visible radiation but opaque to infrared radiation of 5.25 to 7.5 micrometers in wavelength, which is a lower frequency range than that of visible light. Incoming solar radiation peaks in the visible spectrum. Energy re-emitted by the Earth peaks in the infrared portion of the spectrum. Thus, incoming energy is better able to penetrate water vapor than is outgoing energy.

In order for the Earth to maintain thermal equilibrium, radiating as much energy back to space as it receives from the Sun, the global average temperature must rise higher than it would if there were no humidity in the atmosphere. The balance of the amounts of radiation received from the Sun and emitted back into space is called the radiation budget.

No simple statements about the effect of total atmospheric water vapor on climate change are possible, because the atmosphere is a nonequilibrium system. Water vapor resides in the air for fairly short periods before precipitating out as rain, snow, or dew. As a result, the amount of water vapor in the atmosphere itself responds quickly to changes in climate. Water vapor in turn affects Earth's radiation budget and, through it, surface temperatures, closing the loop and generating feedback. Layers of air near the planet's surface are warm enough and close enough to the oceans to stay relatively saturated. Their effect on the radiation budget is small, because they are nearly as warm as the surface itself. Upper layers of the atmosphere are cooler and moistened only by the water vapor that convects or diffuses upward from the layers below. Small quantities of water in these upper layers can have a disproportionate effect on the radiation budget, trapping enough infrared energy to significantly warm the climate.

This feedback is complicated, however, by the presence of water in the air as suspended droplets in the form of clouds and fog. These droplets scatter visible radiation in all directions, preventing an appreciable fraction of the incident solar energy from reaching the ground and contributing to Earth's albedo (the fraction of incident solar energy reflected back into space). Ice and snow have the same effect. Increases in albedo have a cooling effect and act to moderate any global average temperature increases.

Hybrid automobiles

• Categories: Economics, industries, and products; energy

Hybrid automobiles derive their energy from two or more sources, such as gasoline and electricity. They are low- or zero-emission vehicles and greatly reduce or eliminate the toxic carbon emissions that are by-products of gasoline-powered internal combustion engines.

• Key concepts

aerodynamic: designed to minimize drag from the air

compressed air: air that is forced into a small space under high pressure

fossil fuels: fuels derived from decayed plants and animals under geologic pressure over millions of years

hydrogen automobiles: vehicles that use electricity generated from combining hydrogen and oxygen to produce water

lithium-ion batteries: long-lasting, lightweight batteries made from lithium

prototype: a trial model of a product a manufacturer is considering mass-producing

regenerative braking: process that uses the friction caused by applying a car's brakes to produce energy to help power the vehicle

zero-emission automobiles: motor vehicles that do not produce toxic pollutants

• Background

Hybrid vehicles combine electric motors and internal combustion engines in such a way that their drive shafts can be powered by the gasoline engine, by the lithium-ion batteries of their electrical engines, or by a combination of the two. Although such vehicles existed as experimental prototypes as early as the late nineteenth century, they did not become commercially viable until the last quarter of the twentieth century, when fuel shortages, problems with air pollution, and concern over global warming converged to make fuel-efficient, nonpolluting vehicles attractive to the public.

The Japanese automobile company Toyota launched the first mass-produced hybrid, the Prius, in 1997. Although this vehicle was not expected to attract many buyers, its initial American reception after it was introduced to the U.S. market in 2000 was enthusiastic. Toyota increased production and moved toward the manufacture of an aerodynamic Prius the size of Toyota's Corolla that would travel more than 21 kilometers on a liter of gasoline. Soon, Honda was producing comparable hybrids.

People who wanted to buy a Prius often had to wait four to six months to have their orders filled. Prius sales in the United States doubled between 2003 and 2004, and they doubled again in 2005. By 2007, some 250,000 hybrids were sold in the United States.

• Hybrid Technology

Hybrids generate much of their own power and are essentially low- or zero-emission vehicles. Although their internal combustion engines can provide power in ways comparable to those of more conventional vehicles, these vehicles derive much of their power from a lithium-ion battery pack that is continuously charged and recharged while the vehicle is operated by its gasoline-powered engine and by the friction caused in normal braking. This regenerative process permits hybrids to deliver higher mileage in stop-start, urban driving than in long-distance, highway driving.

The key to producing hybrid vehicles that will deliver over 40 kilometers to a liter of gasoline is the development of increasingly light, rechargeable lithium-ion batteries. Toyota and other manufacturers have already developed lithium-ion batteries that do not encroach upon the vehicle's interior space, as earlier versions of such batteries did.

Some hybrid automobiles are capable of recharging their batteries by plugging into charging stations such as this one in Berkeley Square, London. (Getty Images)

• Other Kinds of Hybrids

A number of automobile manufacturers have produced electric cars, "plug-in" vehicles that usually have ancillary gasoline-powered engines. Most of these vehicles must be plugged in for periods of from four to six hours for recharging. Most of them have a limited range, generally at best about 160 kilometers, and some are incapable of operating at interstate speeds. Despite these limitations, many such vehicles are in service with the United States Postal Service and other groups. They are practical if they are required to be in service for eight or ten hours a day, after which they can be plugged in to have their batteries recharged before the next work day.

Hydrogen vehicles have also been developed. These carry hydrogen in their fuel tanks, where it combines with oxygen taken in from the air and produces electricity to power the vehicle. The by-product of this technology is water vapor, which results in zero emissions.

The Tata Motor Company of India has developed automobiles that will retail for under five thousand dollars and are directed toward buyers in India and China. It is doubtful that the initial Tata vehicles could meet U.S. safety standards. One of the most exciting Tata hybrids is being produced for developing nations. These vehicles, equipped with auxiliary gasoline engines, operate on compressed air using a technology developed by Guy Nègre, a French engineer. They are extremely economical to operate.

• Context

The rapid development of hybrid vehicles has been stimulated by a number of compelling forces, not the least of which is the problem of the worldwide pollution being caused by the burning of fossil fuels. The toxic residues that the burning of such fuels produces are poisoning the environments of every nation in the world.

Even if one ignores the threat posed by burning fossil fuels, society worldwide is exhausting the supplies of such fuels. In a world dependent for its transportation upon vehicles powered by various sources of energy, it is crucial that these sources must be both nonpolluting and renewable. It is unrealistic to assume that the contemporary world will drastically reduce its consumption of energy in the foreseeable future. Thus, the development of technologies that will make optimal use of renewable energy is perhaps society's greatest hope for the future.

Hydroelectricity

• Category: Energy

Because hydroelectricity uses falling water rather than fossil fuels for its production, it does not contribute GHGs to the atmosphere. It is both a clean and a renewable energy source.

• Key concepts

fossil fuels: fuels, such as coal, gas, or oil, created during early geologic eras

generator: a mechanical device whose rotational movement around magnets produces an electrical current

head: the fall of the water at a site selected for production of hydroelectricity

reservoir: a gathering place for water held in reserve for later hydroelectric production

turbine: an enclosed vessel containing rotating parts turned by the passage of a fluid, such as water or air

• Background

Hydroelectricity is a twentieth century phenomenon. Although the use of moving water for the production of mechanical energy is ancient (water wheels go back to ancient times), the use of falling water to create electricity awaited knowledge about using electricity as a motive power. Although Michael Faraday invented a dynamo that produced an electric current in 1831, the concept of using an electric current to move energy from one place to another awaited the appearance of Thomas Alva Edison and the electric light in the 1870's. Critical for hydroelectricity were the understanding that electricity could be produced by other kinds of mechanical energy, the development of machines that could use mechanical energy to induce an electric current (generators), and knowledge of the transmission systems that made it possible to move electricity across significant distances.

• Early History of Hydroelectricity

The invention of the turbine allowed water run through a containing vessel to produce mechanical energy that could, in turn, generate an electrical current. The turbine designed by James Francis was the earliest to appear, but modifications made by Lester Allan Pelton and later Viktor Kaplan adapted the turbine to use in situations involving falls of significant distance. Generally, hydraulic installations are classified into either low-head facilities, where the drop is on the order of 15 meters, and high-head facilities, with a drop of more than 60 meters. The height of the head determines whether a vertical- or horizontal-impulse turbine is used. The determining factor is the continuous volume of water passing through the turbine.

Initially, use was made of sites that both were close to manufacturing facilities and involved large volumes of water falling substantial distances. The most notable example was Niagara Falls. Sites with this combination of features are relatively rare, however. Most suitable sites tend to be located at the base of chains of mountains, where they can make use of the water generated by large amounts of melting snow. The drawback to such sites is that the amount of water they generate is seasonally variable. The very high capital costs of constructing such installations make it essential that they be sited where the flow of water is steady, allowing them to operate year-round. Thus, in the twentieth century, operators of hydroelectric facilities began to build holding ponds or reservoirs. These structures allowed them to collect water when its flow was great and store it for later use during drier seasons.

- **Major Facilities**

The common preference, especially among governments, for economies of scale has led to the development of a number of very large hydroelectric facilities, of which the largest, in China, is the Three Gorges Dam in Hubei province. Governmental priorities also entailed building a large reservoir to ensure that there would always be sufficient water to operate the facility's generators. This construction in turn flooded some 100,000 of China's towns and villages, forced one million peo-

The Sayano-Shushenskaya hydroelectric power station in Khakassia, Siberia, Russia. (Sergei Karpukhin/Reuters/Landov) ple to move, and submerged about 400 square kilometers of farmland.

Other large facilities include the Itaipu, serving both Paraguay and Brazil; the Yacyreta, serving Argentina and Brazil; the Krasnoyarsk, the Bratsk, the Ust-Ilim, and the Volgograd in Russia; the Minamiaiki in Japan; and the Chief Joseph in the United States. The United States also has a number of facilities built during the 1920's and 1930's, notably the Hoover Dam, the Glen Canyon Dam, the Grand Coulee, and the Bonneville facility. Although many of these were built in sparsely inhabited areas, they have had an effect on the human populations in their area, though perhaps none so much as the Three Gorges Dam in China.

• Environmental Effects of Hydroelectricity

Although the construction of large hydroelectric projects has had some benefit for the population served by the electricity they produce, the heavy use of hydroelectricity in some parts of the world has also had some negative effects. Among the advantages are the production of low-cost electricity without burning fossil fuels (although many hydroelectric plants have back-up fossil fuel generators so as to keep the generation steady); the creation of dams that can also be used for flood control, controlling water supply in urban areas with large populations; and the creation of artificial lakes that can provide many recreational opportunities.

The disadvantages include high construction costs, conflicting demands for flood control and hydroelectric generating capacity, the withdrawal of substantial amounts of land from agricultural use (as in China), degradation of fish habitat, and the elimination of trees on the flooded land. In several cases, aboriginal communities have lost the land that they traditionally used for their sustenance.

• Context

The steadily growing need of human populations for electricity has created a continuing demand for large facilities that appear to place little burden on the environment. By producing electricity without burning fossil fuels and at low cost, hydroelectric plants are seductive, especially to the politicians who make public policy. Although the best sites have already been taken, there are still a number of lesser locations that may yet be claimed. For many countries in the developing world, hydroelectricity has a large attraction, especially if those countries lack local sources of fossil fuels.

Hydrofluorocarbons

• **Category:** Chemistry and geochemistry

• **Definition**

Hydrofluorocarbons (HFCs) are a family of organic chemical compounds composed entirely of hydrogen, fluorine, and carbon. They are generally colorless, odorless, and chemically unreactive gases at room temperature. HFCs fall under the broader classification of haloalkanes. While HFCs do not harm the ozone layer, they contribute to global warming as greenhouse gases (GHGs) and are considered one of the major groups of high global warming potential (HGWP) gases.

• **Significance for Climate Change**

Many of the HFCs were developed for use in industrial, commercial, and consumer products as alternatives to ozone-depleting substances such as chlorofluorocarbons (CFCs) and hydrochlorofluorocarbons (HCFCs). Common HFCs, in order of atmospheric abundance, include HFC-23 (fluoroform), HFC 134a (1,1,1,2-Tetrafluoroethane, tetrafluoroethane, R-134a, Genetron 134a, or Suva 134a), and HFC-152a (1,1-Difluoroethane, difluoroethane, or R-152a). HFC-23 is used in a wide range of industrial processes and is a by-product of Teflon(TM) production. HFC-134a is primarily used as a refrigerant for domestic refrigeration and automobile air conditioners. HFC-152a is commonly used in refrigeration, electronic cleaning products, and automobile applications as an alternative to HFC-134a.

The global warming potentials (GWPs) of HFCs range from 140 (for HFC-152a) to 11,700 (for HFC-23). These GWPs are significantly lower than those of the gases the HFCs are designed to replace. The atmospheric lifetimes of the same two HFCs are just over 1 year and 260 years, respectively. HFCs are one of two groups of haloalkanes targeted in the Kyoto Protocol. HFC emissions are projected to increase in the coming years, as industry continues to strive to decrease CFC and HCFC production.

HFCs are preferred over CFCs and HCFCs, because HFCs lack chlorine. When CFCs are emitted into the atmosphere, chlorine (Cl) atoms contained in those CFCs become disassociated through interaction with ultraviolet light. The resulting free Cl atoms decompose ozone into oxygen, and regenerated Cl atoms go on to degrade more ozone molecules. This reaction continues for the atmospheric lifetime of the Cl atom, which ranges from one to two years. On average, a single Cl atom destroys 100,000 ozone molecules. Thus, the lack of Cl in HFCs makes them a desirable alternative.

Some studies indicate that excessive exposure to HFCs may affect the brain and heart. However, this has only been established for concentrations higher than those found in the atmosphere.

Hydrogen power

• **Category:** Energy

• **Definition**

Molecular hydrogen (H_2) is an ideal fuel to be used for transportation, since the energy content of hydrogen is three times greater than that of gasoline and four times greater than that of ethanol. Hydrogen power powered rockets launched by the National Aeronautics and Space Administration (NASA) for many years. Today, a growing number of automobile manufactures around the world are making hydrogen-powered vehicles. Because of depleting supplies and growing demand for oil, H_2 may become an alternative to gasoline.

The idea of hydrogen as the fuel of the future was expressed long ago by Jules Verne in his novel *L'Île mystérieuse* (1874-1875; *The Mysterious Island*, 1875). However, compared to oil, H_2 is not abundant on Earth. Its atmospheric concentration is only 0.00001 percent, and there is even less of it in the oceans. Though many microorganisms pro-

A hydrogen-powered car sits in front of a fueling station at New York's JFK International Airport on the station's first day of operation, July 14, 2009. (Shannon Stapleton/Reuters/Landov)

duce H_2 during fermentation, it is such a good source of energy that it is used almost immediately by other microbes. Thus, in order for humans to use hydrogen as fuel, it must be generated using other energy sources.

While molecular hydrogen is rare, the chemical element hydrogen is the most basic and plentiful element in the universe. It also forms a part of the most abundant chemical compound on Earth, water. Therefore, the challenge posed is to find a cost-effective and environmentally friendly way to generate H_2 from water or other chemical compounds. At present, H_2 is obtained mainly from natural gas (methane and propane) via steam reforming. Although this approach is practically attractive, it is not sustainable. Molecular hydrogen can be also produced by electrolysis. In this process, electric energy is employed to split water into H_2 and O_2. The requisite electricity can be obtained using clean, sustainable energy technologies such as wind and solar power. However, the process is not efficient, requiring significant expenditure of energy and purified water.

There are other technological and economic obstacles to hydrogen power. These obstacles include safety issues, as well as the lack of effective solutions for storage and distribution of H_2. Hydrogen has gained an unwarranted reputation as a highly dangerous substance among the general public. Like all fuels, H_2 may produce an explosion, but it has been used for years in industry and earned an excellent safety record when handled properly.

Hydrogen is the lightest chemical, so it has a much lower energy density by volume than do other fuels. As a gas, it requires three thousand times more space for storage than does gasoline. Thus, hydrogen storage, especially in cars, represents a challenge for scientists and engineers. For storage, H_2 is pressurized in cylinders or liquefied in cryotanks at −253° Celsius. Both processes require a significant expenditure of energy and generate large quantities of waste carbon dioxide (CO_2). In most contemporary hydrogen-powered vehicles, H_2 is stored as compressed gas. Because compressed gas cannot be delivered in the same fashion as liquid fuel, gasoline stations and pumps cannot simply be converted into hydrogen stations. Thus, the distribution system for the new fuel would have to be constructed from scatch, requiring considerable monetary investment.

- **Significance for Climate Change**

Fossil fuels generate CO_2, contributing to the greenhouse effect. Switching from fossil fuels to H_2 would eliminate that source of greenhouse gas (GHG) emissions, provided that the new fuel could be produced without carbon-emitting technologies. Burning H_2 for an energy source produces only water as a by-product, and H_2 is also a renewable fuel, since it can be made from water again. Unfortunately, current methods of H_2 production from natural gas also generate CO_2. The ultimate goal is to generate H_2 without emitting GHGs into the atmosphere, perhaps by using wind or solar power.

One promising green method of H_2 production is a biological approach: A great number of microorganisms produce H_2 from inorganic materials, such as water, or from organic materials, such as sugar, in reactions catalyzed by the enzymes hydrogenase and nitrogenase. Hydrogen produced by microorganisms is called biohydrogen. The most attractive biohydrogen for industrial applications is that produced by photosynthetic microbes. These microorganisms, such as microscopic algae, cyanobacteria, and photosynthetic bacteria, use sunlight as an energy source and water to generate hydrogen. Hydrogen production by photosynthetic microbes holds the promise of generating a renewable hydrogen fuel using the plentiful resources of solar light and water.

It is possible to use hydrogen to fuel internal combustion engines. Doing so produces at least one GHG, nitrogen oxide, because the burning of hydrogen requires air, which is almost 80 percent nitrogen (N_2). To use hydrogen power in climate-friendly ways, it will be necessary to replace the internal combustion engine with fuel cells, which would produce electricity to power vehicles without motors. Fuel cells are like batteries: They generate electricity via chemical reactions between H_2 and O_2. Fuel cells emit water and heat, not CO_2 or other GHGs. In addition, fuel cells are 2.5 to 3 times more efficient in converting H_2 energy than are internal combustion engines. Hydrogen fuel-cell cars could even provide power for homes and offices if necessary.

For hydrogen power to become a reality, tremendous research and investment efforts are necessary. The fate of hydrogen power technology will also depend on consumers' willingness to spend money on climate-friendly technologies.

Hydrologic cycle

- **Category:** Environmentalism, conservation, and ecosystems

- **Definition**

The hydrologic cycle comprises the movement of water on Earth: It evaporates from the oceans, precipitates back to the surface, flows in the form of runoff to bodies of water, and infiltrates and is stored underground. A warming climate affects this cycle and therefore all life on the planet.

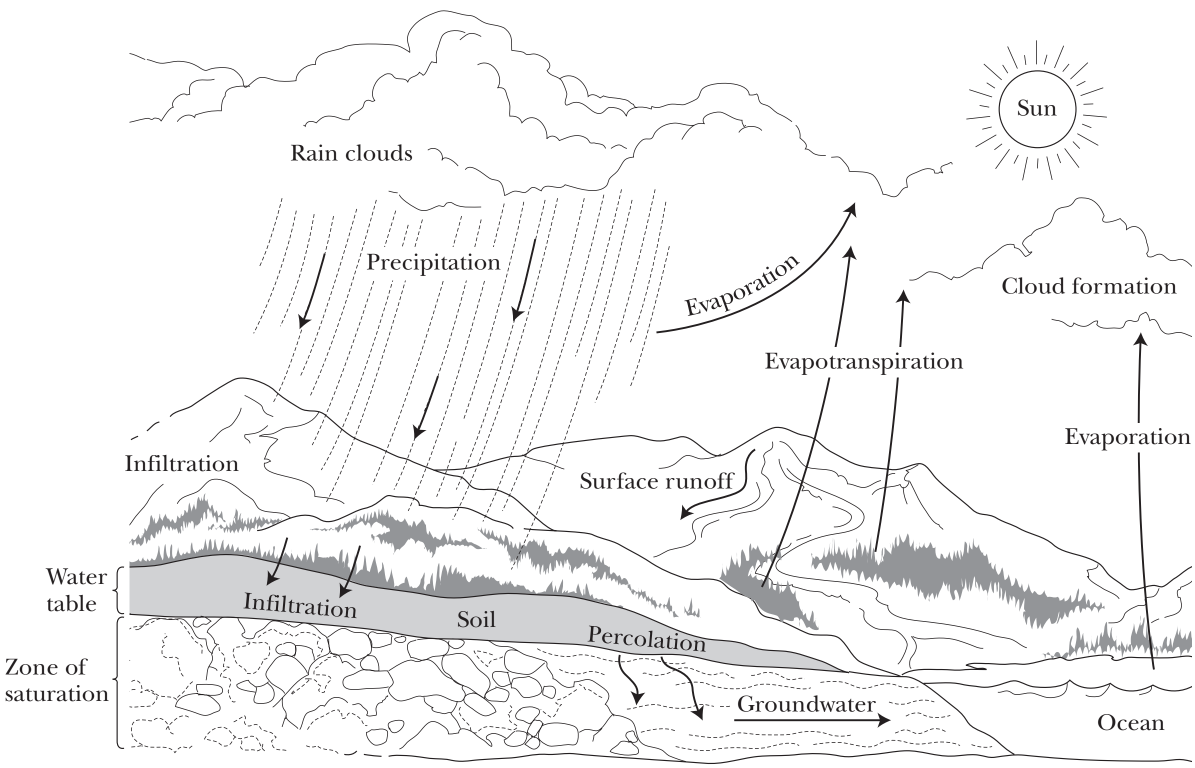
Steady warming increases the atmosphere's moisture-holding capacity, altering the hydrologic cycle and the characteristics of precipitation, most notably intensity. Changes in the global rate and distribution of precipitation may have a greater direct effect on human well-being and ecosystem dynamics than do changes in temperature. While temperature increases in a linear fashion, scientific research indicates that the hydrologic cycle may change exponentially, according to David Easterling of the U.S. National Climatic Data Center.

Atmospheric moisture increases rapidly as temperatures rise; over the United States and Europe, atmospheric moisture increased by 10 to 20 percent from 1980 to 2000. Studies of tree rings have provided a reconstruction of precipitation variability in the high mountains of northern Pakistan going back one thousand years that indicates a large-scale intensification of the hydrologic cycle coincided with the onset of industrialization and global warming. The unprecedented amplitude of this change strongly suggests a human role. This study suggests that an unprecedented intensification of the hydrologic cycle in western Central Asia occurred during the twentieth century.

• Significance for Climate Change

Theory as well as an increasing number of daily weather reports strongly indicates that changes in precipitation patterns may vary widely across time and space. Such changes will be highly uneven, episodic, and sometimes damaging. Both droughts and deluges are likely to become more severe. They may even alternate in some regions. By 2007, the hydrologic cycle seemed to be changing more rapidly than temperatures. With sustained warming, usually wet places often seemed to be receiving more rain than before; dry places often were experiencing less rain and becoming subject to more persistent droughts. Some drought-stricken regions occasionally were doused with brief deluges that washed away cracking earth.

The Hydrologic Cycle



In many places, the daily weather increasingly was becoming a question of drought or deluge. Paradoxically, the intensification of the hydrologic cycle due to a warming climate may provoke both drought and deluge—sometimes alternately in the same location. The behavior of this cycle also figures into a lively debate regarding whether a generally warming climate may cause hurricanes to intensify, as well as the impact of climate change on the worldwide spread of deserts, which may contribute to the number of "environmental refugees," and on disaster relief generally.

By 2000, the hydrologic cycle seemed to be changing more quickly than temperatures. In 2005, for example, India's annual monsoon brought a 94-centimeter rainfall in 24 hours to Mumbai (Bombay). India is accustomed to a drought-and-deluge cycle because of its annual monsoon, but the rains have become more intense, as well as more variable. Excessive rain has deluged parts of Europe and Asia, swamping cities and villages and killing many people, while drought and heat have scorched other areas. Unprecedented precipitation events have occurred recently in the Arctic, where temperatures have risen rapidly. Winter rains with thunder and lightning have been experienced on Southern Baffin Island, the Alaskan North Slope, and southwestern Greenland. Climate-change skeptics argued that weather is always variable, but other observers noted that extremes seemed to be more frequent than before.

Violent weather has been hitting unusual areas with increasing frequency. Major tornadoes, for example, have been sighted in Michigan and Japan. At least nine people were killed, at least twenty injured, and others trapped under rubble when a tornado hit northern Japan on November 6, 2006, in a location where such storms had been all but unknown. The tornado demolished two prefabricated buildings at a construction site, about eight private houses, and a factory, according to an official at the fire department in Engaru, on the northeastern part of Japan's northern island of Hokkaido. Fire engines and ambulances were at the site, where crushed cars could be seen along with lumber and other scattered debris. Several houses were reduced to rubble.

Hydrosphere

- **Categories:** Water resources; oceanography; cryology and glaciology

The hydrosphere, the collective designation of all water on Earth, significantly affects Earth's greenhouse effect and global temperatures generally. Atmospheric water vapor is the major GHG, and the oceans are major storage sites for water, heat, and CO_2.

- **Key concepts**

cryosphere: water on the Earth's surface in solid form, especially as snow, glaciers, ice caps, and ice sheets

evaporation: the transformation of liquid water into water vapor
hydrologic cycle: water's movement among the spheres of the climate system
thermal expansion: the increase in water volume as its temperature increases and density decreases
water vapor: water in the gaseous state

• Background

The range of Earth's surface temperatures and atmospheric pressures permits water to occur naturally as a solid, liquid, and vapor. Water is present in all Earth's climate subsystems. In broadest terms, the hydrosphere includes liquid water at the Earth's surface, water in the atmosphere in all its forms, and water in the cryosphere stored as ice. It extends several kilometers below Earth's surface and reaches 12 kilometers into the atmosphere.

• Distribution of Water

The hydrosphere contains an estimated 1.36 billion cubic kilometers of water, and liquid water covers about 71 percent of the Earth's surface. Most of the world's water is contained in the oceans as salt water; only 2.5 percent is freshwater. Ice sheets and glaciers concentrated on about 10 percent of the Earth's land area, mainly in Antarctica and Greenland, constitute less than 2 percent of all water, but they account for 69 percent of freshwater. Groundwater and soil water constitute the subsurface water storage, which is important as a water supply for humans in arid regions and as a moisture source for plants. Groundwater and soil water together account for 0.5 percent of all water, but 30 percent of freshwater. Rivers, lakes, and streams contain 0.02 percent of all water and 0.3 percent of freshwater. Water vapor and cloud droplets in the atmosphere account for 0.0001 percent of all water and 0.04 percent of freshwater, but water vapor and cloud droplets contribute between 66 and 85 percent of the greenhouse effect, which traps heat in the atmosphere, preventing it from escaping into space.

• Formation of the Hydrosphere

The hydrosphere's formation required a series of steps occurring over millions of years to reach the sequence of energy and moisture transfers currently linking the hydrosphere and Earth's climate. Water from outgassing by volcanic eruptions and possibly from incoming comets collected in the early atmosphere as water vapor along with other gases. Eventual cooling of the Earth's surface and the atmosphere caused the water vapor to condense into droplets and fall as rain to the Earth's surface. The rain collected in topographic depressions in the Earth's crust and formed rivers, lakes, and oceans. Some water drained vertically through the rocks and collected in large underground reservoirs, and some water was held by the soil that developed as rocks disintegrated.

The Earth's original hydrosphere probably was freshwater exclusively, with the hydrologic cycle as the centerpiece. Water cycling was sustained by evaporation mainly from the oceans that returned water vapor to the atmosphere to fall as rain. Dissolved gases fell with the rain from the early atmosphere, and the oceans absorbed large amounts of atmospheric carbon dioxide (CO_2). The transition to today's salt-dominated oceans spanned hundreds of millions of years and involved crustal differentiation, life processes, and a series of mineral equilibriums. Rain on the land dissolved minerals from rocks; rivers and streams carried the minerals to the oceans; chlorine leached from the oceanic crust accumulated in seawater; and dissolved carbonates were gradually removed. During periods of global cooling, snow accumulated on the continents, forming glaciers and ice sheets, and sea levels were lowered.

• Effects of a Warmer Climate

Evidence of warmer temperatures exists in all the hydrosphere's components, but it is most apparent in the oceans. Oceans store more than 90 percent of the heat in the Earth's climate system, and they buffer the effects of climate change. Sea surface temperatures since 1860 show essentially the same trends as land temperatures, and ocean temperature changes contribute about one-half Earth's net temperature gain. Ocean circulation transfers energy from warm tropical regions toward the poles and brings colder water back to the tropics. Ocean circulation is accomplished by powerful, wind-driven surface currents coupled with deep-ocean currents responding to density differences produced by temperature and salinity variations. British oceanographers have reported that circulation in a section of the Atlantic Ocean has slowed 30 percent in the past five decades, which raises concern that the global transfer of energy by the oceans may be weakening.

Warmer oceans produce thermal expansion, which is a major contributor to rising sea levels of 15-20 centimeters over the last century. Observed twentieth century melting of glaciers and ice sheets contributed to sea-level rise, but the volume of melting accounts for about 20 percent of the observed increase. An observed 10 percent per decade decrease in Arctic sea ice probably contributes more to radiation balance changes and warming the air and water than to sea-level rise.

Oceans are the source for 85 percent of the water vapor transferred into the atmosphere, and warmer temperatures increase evaporation. Increased atmospheric water vapor supports greater precipitation, an intensification of the greenhouse effect, increased cloud cover, and increased global albedo. Changes in the timing, amount, and location of precipitation and runoff are occurring as global temperatures increase, and these changes alter water availability and quality and the duration and intensity of floods and drought.

CO_2 in the oceans increases as atmospheric CO_2 increases, but warm oceans are a less efficient absorber of CO_2. About half of the known CO_2 produced by fossil fuel consumption over the past fifty years has been absorbed by the oceans.

• Context

Water is essential for humans and for natural ecosystems, but the relatively small proportion of Earth's total water represented by freshwater is unevenly distributed globally. Approximately one-third of the world's population lives in regions where the freshwater supply is less than the recommended per capita minimum, and 70 percent of all freshwater withdrawals are used for crop irrigation. The freshwater resource relies on precipitation delivered by the hydrologic cycle. Precipitation is sustained through the conversion of ocean water into freshwater by a complex system responding to global-scale climatic influences. Hydrological processes, related energy exchanges, and interactions of these exchanges with clouds and the radiation balance are highly variable at the regional scale where the global warming impact on the freshwater resource is greatest. Quantifying regional temperature and precipitation patterns and the effects of altered evaporation, transpiration, soil moisture storage, and runoff on the freshwater supply is a great challenge facing scientists as they strive to understand global warming at the regional scale.

Ice cores

• **Category:** Cryology and glaciology

Ice cores contain evidence of an orderly sequence of changes that occurred in the Earth's atmosphere, including changes in temperature and trace gases. They therefore provide a history of the Earth's climates.

• Key concepts

Dome C: the Antarctic Plateau location of the Concordia Research Station
glacial ice: ice created by the compression of snow into glaciers
paleoclimatology: the study of past climates
Vostok: a Russian Antarctic research station built in 1957 during the First Geophysical Year

• Background

An ice core is a cylinder of ice measuring 10 centimeters in diameter and obtained by drilling vertically into a glacier. Glacial ice is produced by the natural, gradual transformation of snow into ice. Snow is made of fragile ice crystals surrounded by air. In the process that transforms snow into ice, this air is trapped in tiny bubbles that are identical in composition to the atmosphere that produced the snowfall. As snow falls year after year and is compacted into ice, each layer can be identified visually or electronically. In this way, glaciers preserve a record of atmospheric changes that have occurred over time, and ice cores can be drilled to retrieve that record.

• Variation in the Atmosphere's Composition

Because they contain a chronologically ordered record of atmospheric composition, ice cores can be used to reconstruct the history of both natural and anthropogenic pollution. The chemical composition of Earth's atmosphere varies over time. It reacts to volcanic eruptions, for instance, which add carbon monoxide, carbon dioxide (CO_2), and sulfur dioxide to its normal content of nitrogen, oxygen, argon, CO_2, and methane. Thus, changes in the chemical composition of the air trapped in ice cores make it possible to date past volcanic eruptions.

In the same way, some human activities can be identified and dated. Analysis of ice cores from the Alps and Greenland has identified the pollution resulting from the smelting of lead ore by the Romans more than two thousand years ago. More recently, traces of chemicals linked to nuclear explosions or to the Chernobyl nuclear reactor meltdown have been detected in glacial ice. Today, at a time when issues of climate change and pollution are uppermost in the minds of many, glaciologists have sought to retrieve the longest possible ice cores in order to produce a substantial historical record to contextualize current atmospheric trends.

• The Longest Ice Cores

The first giant ice core was drilled in Vostok, the Russian base in Antarctica. The region of Antarctica in which Vostok is located is extremely cold and dry. The advantage of low precipitation in glaciology is that, because each year produces less ice, a large number of years is recorded relative to core length. The disadvantage of such low precipitation is that, because each annual layer of ice is extremely thin, it can be very difficult to produce an accurate count. When all analyses were complete, Vostok glaciologists concluded that the 3,623-meter core drilled in 1996 represented the last 420,000 years of the Earth's history.

The normal analysis of an ice core consists of analyzing the content of the ice for the presence of deuterium (an isotope of hydrogen) and the presence of oxygen 18 (O^{18}; an isotope of oxygen), because both are reliable indicators of the Earth's temperature at the time of the snowfall. The temperature records obtained thanks to the Vostok ice core compare well with cores obtained in the center of Greenland. Since the Greenland ice sheet is smaller and thinner (1,600 meters deep on average) than the Antarctic ice sheet (2,400 meters deep on average), the paleoclimatic record derivable from Greenland ice cores is shorter. However, that record is consistent with the Vostok ice core record. Greenland also receives more precipitation than does Vostok, resulting in thicker annual layers of ice; a layer as old as 100,000 years can still be as much as 1 centimeter thick. Greenland ice cores therefore are outstanding at establishing a chronol-

Cryologist Hideaki Motoyama displays a million-year-old ice core drilled from 3 kilometers underneath Antarctica. (AP/Wide World Photos)

ogy for the last glacial period for which the estimated error does not exceed 2 percent for the first forty thousand years.

In an effort to increase the length of the paleoclimatic record, scientists from Europe have drilled in two other regions of the East Antarctic Ice Sheet under the European Project for Ice Coring in Antarctic (EPICA). A site on Dome C located at 75°06′ south latitude and longitude 123°21′ east was selected. There, where the ice sheet is thicker while both the ice and the air remain extremely cold, a permanent research base, Concordia, was built by France and Italy (partly financed by the European Union). Dome C is ideal for the thickness of its ice and its low precipitation; it initially provided a 3,140-meter ice core, revealing 740,000 years of climatic history. Since then, even deeper ice has been retrieved, extending knowledge of climatic history to over 800,000 years.

- **Testing Theories of Climate Change**

In order to analyze the ice core samples that have been retrieved, scientists crush the ice in a vacuum, releasing the air trapped within the sample without allowing it to mix with the modern atmosphere. They can then analyze these air samples, compute the proportion of greenhouse gases (GHGs) such as CO_2 and methane in the air, and compare their proportions to the temperature record derived from the deuterium and O^{18} analyses. The goal is to see if an increase of GHGs in ice always leads to an increase in the Earth's temperature or, conversely, if an increase in the Earth's temperature releases CO_2 and methane into the atmosphere.

- **Context**

Scientists continue to search for deeper deposits of ice from which even longer historical sequences can be identified. The Dome C site holds the promise of ice cores that will extend the scientific record to more than one million years into the past. Meanwhile, research also continues on ways to recover more, and more precise, information from ice cores. Analysis of core samples containing volcanic dust taken at Dome C, for instance, has demonstrated that the magnetic polarity of the Earth reversed about 780,000 years ago. As ice cores get longer and scientists find ways to learn more from them, the historical record will become more detailed over longer periods of time.

Ice-out studies

• **Categories:** Arctic and Antarctic; cryology and glaciology

• Definition

Across the northern United States, a popular tradition for many decades has been guessing the date of ice breakup ("ice-out") on local lakes. Not only is it a local news story and harbinger of spring, but ice-out has numerous practical ramifications as well. It marks the end of winter activities on the lake, such as ice fishing and travel across the ice, and the beginning of summer activities, such as open-water fishing.

In earlier days, ice-out was important for commercial activities such as log drives and steamship navigation. As a result, for many lakes ice-out data are available since the middle of the nineteenth century. Moosehead Lake, the largest lake in Maine, has continuous data since 1848; Sebago Lake in southern Maine has sporadic data since 1807. Areas outside New England also maintain ice-out statistics. Minnesota has at least four lakes with more than 100 years of data, and the longest record is 139 years. Lakes Mendota and Monona, which flank the city of Madison, Wisconsin, have records extending back more than 150 years.

Ice-out dates are quite variable from year to year and depend on air temperature, the flux of meltwater into the lake, and the discharge of the outlet stream. For example, the earliest and latest ice-out dates for Moosehead Lake differ by forty-five days. Nevertheless, scientists from the U.S. Geological Survey analyzed ice-out dates for New England lakes and found that the average date of ice-out was nine days earlier in 2000 than it was in 1850. Generally, ice-out data are tabulated in terms of day of the year (the Julian date) rather than the calendar date. For example, February 20 is Julian day 51. The data indicate generally steady ice-out dates until 1900, decreasing (earlier) dates until roughly 1950, a slight increase in ice-out dates until about 1970, and decreasing dates thereafter. Despite the wide variability from year to year, the overall pattern is consistent across numerous lakes.

• Significance for Climate Change

There are many complexities in the use of ice-out data, largely due to variations in what defined "ice-out." Sometimes a marker placed on the ice has been used to signal ice breakup. In some places the marker was even a junked car (an environmentally dubious practice). In other places the criterion has been the ability to cross the lake by boat without being blocked by ice. Still other places have used visual estimates of ice cover. Such estimates can be quite subjective. It may take several days for ice to clear out, and ice may persist in restricted coves long after most of a lake is ice-free.

Unfortunately, it is not always clear what criterion was used for many early records. Also, ice-out data are extremely "noisy"—that is, the range in the data is much larger than the long-term change in average date. For example, for Maine's Moosehead Lake, the best-fit trend line for the ice-out data shows a nine-day decrease in ice-out day between 1849 and 2005, but the variation between earliest and latest ice-out is forty-five days. Even from year to year, the variations can be quite large: In 2001 ice-out occurred on day 124, dropping to day 110 in 2002 and increasing to day 127 in 2003.

Ice-out data for any individual lake are usually so variable that there is a significant possibility that the data, just by chance, happen to show a decrease over time. For example, if one flips a coin and keeps score of the difference between heads and tails, even though the flips are completely random there may be long runs where the difference increases or decreases steadily. However, when data from many lakes, especially those separated by large distances, show the same pattern, the statistical significance of the data becomes far greater.

Taking all these considerations into account, ice-out data for lakes across the northern United States show a broad trend of earlier ice breakup. Climate change skeptics have not paid much attention to ice-out data. Their most common approach has been to use anecdotal data—that is, point to unusually late ice-out on some particular lake, rather than examine long-term trends.

Ice shelves

• **Category:** Cryology and glaciology

The debate over global warming has prompted a renewed interest in the study of ice shelves, particularly after the collapse of the Larsen A and Larsen B shelves in 1995 and 2002, respectively. These collapses have been seen not only as products of global warming but also as part of a process by which the movement of Antarctic ice toward the ocean has been accelerated.

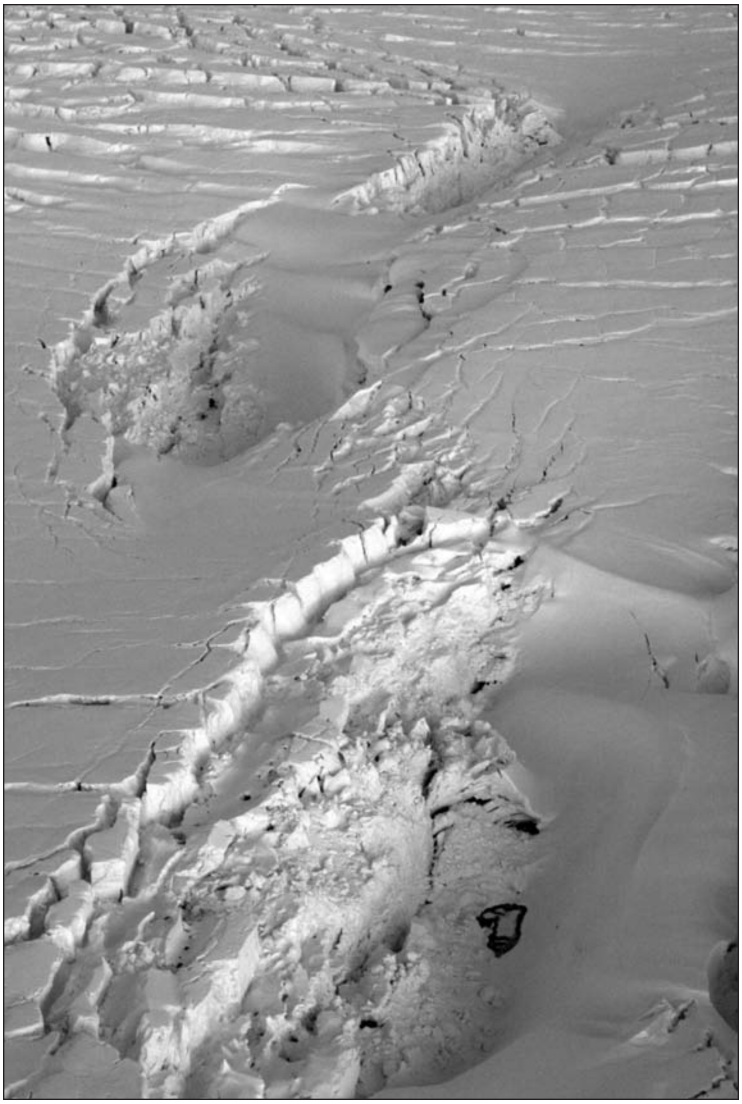
• Key concepts

glacier: a mass of ice that flows downhill, usually within the confines of a former stream valley

ice sheets: masses of ice covering large areas of land
ice shelf: a platform of freshwater ice floating over the ocean
West Antarctic ice sheet: the smallest ice sheet in Antarctica, located west of the Transantarctic Mountains

• Background

Ice shelves are the seaward extensions of continental ice sheets. They are found extending from 50 percent of the coast of Antarctica and account for 11 percent of the mass of ice of the Antarctic Ice Sheets. The two largest ice shelves—Ross (472,960 square kilometers) and Ronne-Filchner (422,420 square kilometers)—together represent 67 percent of the total area of Antarctic ice shelves. Ice shelves are typically thinner at their seaward edge; the largest shelves reach a depth of 1,300 meters near the grounding line (the location where the ice begins to float), but thin to 200 meters at the leading edge.



A gigantic iceberg separates from the ice shelf on the Knox Coast of Australia's Antarctic territory in January, 2008. (Reuters/Landov)

• Formation of Ice Shelves

Ice shelves gain mass in three different ways. The primary source is the ice sheet that moves off the land surface onto the water, but accumulated snow on their upper surface and the freezing of seawater to the lower one also contribute. On the other hand, ice shelves lose mass in five ways: by calving of icebergs, by the melting of ice in contact with the sea, by snow blowing off the edge of ice shelves, by enhanced sublimation of ice under the very strong Antarctic winds, and by superficial melting. Since surface melting in Antarctica is negligible, and since wind ablation is limited in general, nearly all mass loss is the result of either iceberg calving at the seaward margin or bottom melting of ice in contact with the sea.

• Ice Shelves of the West Antarctic Peninsula

With the widespread availability of video clips on the Internet, many people have observed the breaking of very large tabular icebergs off the Antarctic Peninsula. The calving of icebergs is a natural phenomenon that occurs regularly under normal climatic conditions. This calving should not be interpreted as a sure sign of global warming. In the extreme north of the Antarctic Peninsula, ice shelves are called Larsen A, B, C, and D, named in sequence from north to south. The

Larsen A ice shelf began to retreat at a very rapid pace in January, 1995. The breakup of Larsen A was irrefutably a response to the rise in ocean temperature. South of Larsen A, Larsen B calved large tabular icebergs beginning in 1995, prior to a larger disintegration that occurred in the first three months of 2002. More recently, in 2008, the Wilkins Ice Shelf that had broken up in 1998 partially disintegrated. The culprit seemed to be the presence of warm ocean waters melting ice shelves from beneath and destabilizing the ice shelf at the grounding line.

• Ice Shelves as Buttresses

Because ice shelves may be very thick, they are often anchored on the continental shelf, where they begin to float. The grounding of these ice shelves allows them to slow down the outward movement of ice sheets by acting as a buttress if they are thick enough. This effect is lost if the ice shelf disintegrates. In the case of the Larsen B Ice Shelf, its disintegration in 2002 led to an acceleration of the outward flow of ice from the glacier that feeds it.

• Context

Although there is no doubt that ice shelves in the West Antarctic Peninsula have decreased in size over the last three decades, their complete melting would not raise sea level by more than a few millimeters. Their destruction could, however, contribute significantly to rising sea level if the glaciers feeding these ice shelves were to speed up once the ice shelf stops being grounded. A 2004 study by researchers from the National Snow and Ice Data Center and NASA described accelerations of such glaciers reaching four to six times their normal speed.

Interestingly, the ice shelves of the southern part of the West Antarctic ice sheet and those of the East Antarctic ice sheet do not seem to be affected by global climate change. Their temperature remains below freezing, probably because they are surrounded by abundant sea ice that acts as a buffer, protecting them from the advection of warmer water.

Inconvenient Truth, An

- **Category:** Popular culture and society
- **Dates:** Book published and film released 2006
- **Author:** Al Gore (1948-)
- **Director:** Davis Guggenheim (1963-)

An Inconvenient Truth *emphasizes the need to stop global warming in order to prevent the destruction of Earth's natural resources and the accompanying loss of biodiversity. A centerpiece of Al Gore's work on climate change, it was the primary factor behind Gore's receipt of the 2007 Nobel Peace Prize.*

• Key concepts

carbon dioxide (CO_2): a greenhouse gas produced by burning fossil fuels

climate change: a lasting, significant change in the average weather of a given area

fossil fuels: hydrocarbon deposits, such as petroleum or coal, that have been derived from the remains of ancient plants and animals and are useful sources of energy

global warming: a significant increase in the mean temperature of the Earth's air and water over time

greenhouse effect: the ability of certain gases in the atmosphere to trap heat emitted from the surface of the Earth, resulting in the insulation and warming of the planet

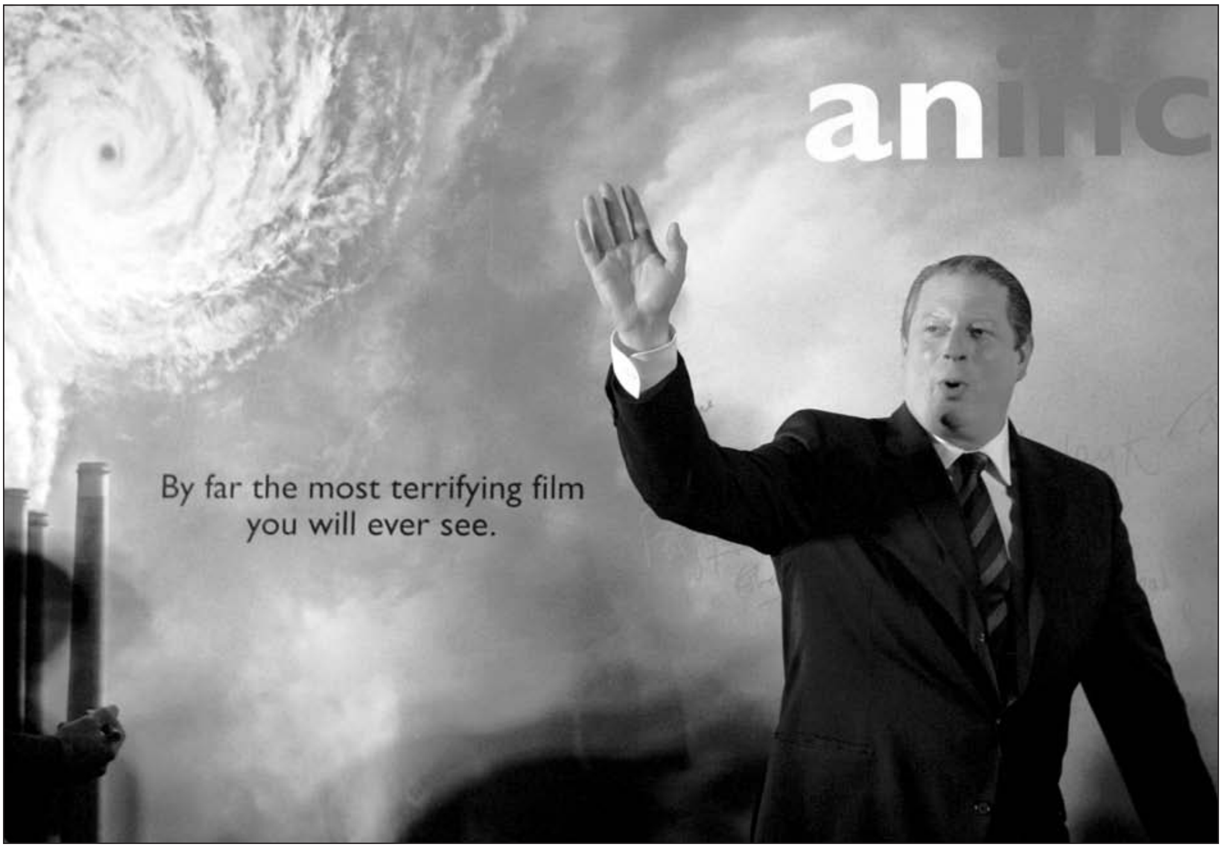
greenhouse gases (GHGs): gases present in the Earth's atmosphere that reduce the loss of heat into space, thereby contributing to global warming through the greenhouse effect

• Background

Throughout his time as vice president of the United States, and for many years before, Al Gore advocated for changes in environmental policies, especially as they related to the climate, most notably global warming. Over the years, he had prepared and worked to perfect a slide show dealing with the problem of global warming. This slide show, which he presented many times, became the basis for the movie *An Inconvenient Truth.*

• The Film

The one-hundred-minute documentary film made its debut on May 24, 2006, in New York and Los Angeles. Directed by Davis Guggenheim, the movie features Gore. In the slide show within the movie, Gore presents scientific evidence of Earth's changing climate and looks at the economic and political impact of global warming on the planet. Gore goes on to discuss likely consequences of global warming if society does not find a way to reduce the production of greenhouse gases (GHGs). Throughout the film, Gore makes an impassioned plea to society to take the steps necessary to halt global warming in



Al Gore arrives at the Hong Kong premiere of An Inconvenient Truth. (Paul Yeung/Reuters/Landov) order to stop a worldwide crisis. The film garnered the 2007 Academy Award for Best Documentary.

• The Book

Titled *An Inconvenient Truth: The Planetary Emergency of Global Warming and What We Can Do About It*, Gore's book was published by Rodale Press in conjunction with the release of the movie. The 328-page book highlights most of the scientific evidence concerning GHGs and global warming, and it issues the same plea for major environmental changes to avoid global crisis. In 2007, Gore and Rodale Press in conjunction with Viking Press published a version of the book aimed at adolescents and young adults, *An Inconvenient Truth: The Crisis of Global Warming*. Gore believed that the younger generation would have to be involved in bringing about the technological and policy changes necessary to halt devastating climate change.

• Origins of Gore's Interest in Climate Change

Gore's interest in global warming began when, as a student at Harvard University, he took a course dealing with climate change and the greenhouse effect. When he became a congressman, he introduced the first congressional hearings on global warming. When congressional response was slow, Gore responded by writing his first book dealing with environmental issues, *Earth in Balance* (1992), published the year he was elected vice president. As vice president, Gore encouraged passage of a tax designed to decrease the use of fossil fuels, which would thereby decrease carbon dioxide (CO_2) buildup and global warming. In 1997, he was also instrumental in the development of the Kyoto Protocol, an international treaty aimed at decreasing the emission of GHGs.

When he ran for president in 2000, Gore made saving the environment one of his platform issues, as he hoped to convince the Senate to ratify the Kyoto treaty. After losing the presidential election in 2000, Gore began to focus his attention fully on environmental concerns, revising his slide show and lecturing on global warming around the world. This slide show evolved into the basis for *An Inconvenient Truth*. For his work focused on the prevention of global warming, Al Gore was nominated for and received the Nobel Peace Prize in October of 2007.

• Context

According to the Nobel Prize committee, Al Gore is probably the one man who has done the most to create an understanding of global warming and its potential planetary impact. By promoting this understanding and advocating for the changes that need to be made to avoid further climate change, Gore is leading the march against planetary destruction. This battle against global warming is one Gore believes must be won if society is to continue.

When people are exposed to *An Inconvenient Truth* (either the movie or book), they are made aware of the problems of climate change and are urged to focus on means that can be used to prevent the greenhouse effect and global warming. Since the first showing of the movie, Gore has run hundreds of training sessions, in which he has taught thousands of people to be ambassadors to the planet for *An Inconvenient Truth*. These ambassadors, known as climate project presenters, have traveled the planet, giving abridged versions of Gore's slide show and answering any questions that arise from the audience. Thanks to Gore and those that have been trained by him, many more people are aware of the problems of global warming and are taking steps to prevent it.

India

- **Category:** Nations and peoples
- **Key facts**

Population: 1,148,000,000 (2008)
Area: 3,287,590 square kilometers
Gross domestic product (GDP): $3.267 trillion (purchasing power parity, 2008 estimate)
Greenhouse gas (GHG) emissions in millions of metric tons of carbon dioxide equivalent (CO_2e): 1,000-1,300 in 2001
Kyoto Protocol status: Ratified August, 2002

• History and Political Context

Great Britain's colonial occupation of India destroyed and replaced the region's traditional, cottage-based textile, metal, and crafts industries with plantations and infrastructure to export raw materials and mined ores through a few ports to the factories of the British Empire. By the early 1900's, India had a desperately poor subsistence economy that was dependent on the monsoons and experienced frequent famines when crops failed. The world wars necessitated steel plants to be located in India to build railways and armaments to supply the war effort, and a few entrepreneurs such as the Tatas and Birlas won access to the capital needed to create heavy industry.

Upon independence in 1947, India boosted irrigation, agriculture, education, public transport, and heavy industry through a series of central five-year plans. Capital and technology came from the United Kingdom, United States, West Germany, and the Soviet Union. Public-sector plants produced steel, cement, fertilizers, chemicals, aluminum, titanium, railway equipment, heavy electricals and electronics, aircraft, ships, and refined oil. Democratic governments tried to invest scarce resources in education and to improve the desperately poor standard of living of the entire population, with the result that a socialist economy with top-tier tax rates as high as 90 percent and many restrictions on private enterprise evolved and stagnated. Free primary schooling was instituted in many states, and central institutes imparted essentially free, world-class scientific and technical education to students selected on merit.

The investments in education and broad-based opportunity paid off. By 1980, Indian agriculture had outpaced population growth and turned the famine nation into a net exporter of food. Even as the rupee plunged in the 1980's as a result of rising energy costs and the inability of government enterprises to compete in the world market, remittances from skilled expatriates in the Middle East oil economies and the West boosted the foreign exchange reserves and the demand for good housing and consumer goods. In 1991, as the nation was facing a debt crisis, the Indian economy was opened to free enterprise and began to advance rapidly.

Globe-trotting Indian software engineers and entrepreneurs led competitive knowledge-based and global service industries and drove explosive growth in information technology, communications, consumer goods, manufacturing, and construction. Investment in space research spawned a thriving remote sensing, educational, communications, and weather satellite system leap-frogging the terrestrial communications grid to the villages. Today there is growing industry and export in chemicals, food processing, steel, transportation equipment, cement, mining, petroleum, machinery, and software. Automobile manufacturing is expanding for the domestic and export markets. Indian-owned steel manufacturing is among the leaders in the world. Modernization is creeping into the hinterland, with rising land values, education, food prices, and expectations.

• Impact of Indian Policies on Climate Change

Energy shortage and Akshay Urja (inexhaustible energy). As of 2007, India had proven resources of 668 billion liters of oil and 1 trillion cubic meters of natural gas. National consumption was 98 billion liters of oil and 31 billion cubic meters of gas per year, mostly imports. Recoverable coal reserves were 92 billion metric tons, consumed at 434 million metric tons per year. Installed electric capacity in 2004 was 131 gigawatts, consumed at 588 billion kilowatt-hours per year. Total energy consumption was 16.3 quadrillion kilojoules. Coal accounted for 53 percent of energy consumption, oil accounted for 33 percent, natural gas 8 percent, and hydroelectricity 5 percent. Kerosene, a staple fuel for cooking and lighting of rural and lower-income homes, and diesel fuel for trucks were heavily subsidized. Over 56 percent of Indian homes and some 112,000 villages still lacked grid access to electric power.

India has a central ministry for renewable energy (RE). In 2008, the RE industry turnover was $500 million, with about $3 billion in investments. The government aimed to electrify eighteen thousand villages by 2012, with a 10 percent RE contribution. Micro-hydel plants of 2 to 25 megawatts exploit mountain streams and account for 2,500 megawatts, lighting many remote villages. By 2008, 3.94 million family-level biogas plants and over 2.15 million square meters of solar collectors had been installed, and 617,000 solar cookers were in use. Some 3,365 villages and 830 hamlets had been electrified using renewable off-grid sources. Renewable power installation totaled over 11 gigawatts. India had become fourth in the world in installed wind power capacity, with 7.8 gigawatts. Large solar thermal plants operate in Rajasthan. Wind farms of 500 kilowatt turbines, limited by Indian roads, were coming up in Tamil Nadu, Gujarat, and Karnataka and along the Western Ghat mountain range. Indian Railways cultivates the jatropha plant along its right-of-way to generate biodiesel.

Indian nuclear energy. Since 1955, India has developed a series of nuclear power plants. In 2007, nuclear power supplied 15.8 billion kilowatt-hours (2.5 percent of the total) from 3.7 gigawatt-hours of capacity. In 2008, with approval from the International Atomic Energy Agency (IAEA) and the Nuclear Supplier Group cartel, India signed civilian nuclear cooperation agreements with the United States, France, and Russia to embark on 40 gigawatt-hours of civilian nuclear power by 2030. This would form the core of clean baseload generation for advanced industry and critical services. The ultimate aim was a three-stage cycle to use vast indigenous reserves of thorium, before uranium was depleted.

CDM projects and GHG alleviation. The energy sector accounts for 61 percent of Indian greenhouse gas (GHG) emissions. As of 2008, India has 815 projects under the clean development mechanism (CDM), of which 536 deal with renewable energy. Other projects focus on sequestering carbon dioxide (CO_2) by creating green spaces in urban areas and replanting forests. Pollution-control laws in major cities such as New Delhi have converted

buses and taxis to compressed natural gas fuel. The competition to build a small, cheap automobile has excited public interest, opening the market for hybrid and electric cars suited to regenerating power from the frequent braking needed on Indian roads. Mandatory rainwater collection for most new construction is making a huge impact on urban water supply and helping alleviate the flood-drought cycle and soil erosion. Tube wells must be supplemented with replenishment tubes.

• India as a GHG Emitter

Home to more than 16 percent of the world's population, India accounts for only 4.9 percent of the world's GHG emissions. This places it in fifth place, behind the United States (22.2 percent), China and Taiwan (18.4 percent), the European Union (14.7 percent), and Russia (5.6 percent) and followed by Japan (4.6 percent) and Germany (3.1 percent). The average Indian's carbon footprint is 0.87 metric ton per year, compared to the average American's 18.1 metric tons, the average Australian's 25.5 metric tons, and the average Chinese's 2.5 metric tons. The Indian carbon footprint is growing rapidly and expected to reach the level of today's China by 2030.

Low carbon footprint but high air pollution. Southern and central India are in the tropical climate zone, and even in the northern plains winter home heating is rarely needed. Residential air conditioning is generally impractical because of power shortages in summer. Houses built to resist summer heat and monsoon rains have efficient throughflow ventilation. Windows are kept open.

Most Indians live in small villages. The cities are densely populated, with few zoning restrictions. Many people can walk or ride bicycles or scooters to work. Commuters use public transportation heavily. Long-distance travel is mostly by rail or bus. The Indian staple diet is organically grown, mostly in small farms, and consists of grain, vegetables, fish, and meat products marketed and consumed locally, minimizing energy use in processing, packaging, and transportation. Few homes have large appliances. Much Indian clothing is made from cotton, suited for the hot, humid climate, rather than from synthetic petroleum products. For these reasons, the personal and discretionary parts of the Indian carbon footprint are minimal.

The primary power resource in India is coal, powering much of Indian industry with thermal plants. With heavy industry near cities, GHG emissions and urban air pollution are severe. Much of the population uses open, wood-burning stoves or other biomass burners for cooking. Composting and outdoor burning generate GHGs, fumes, and particulates. Fleets of two- and three-wheelers powered by two-stroke engines and ancient diesel trucks that survive vehicle emission laws generate noxious fumes in gridlocked traffic on narrow, monsoon-damaged roads.

Scenarios for GHG emission growth. Moderate economic growth is likely to double GHG emissions by 2030. Assuming that the population reaches 1.3 billion, the Indian CO_2 footprint will reach 2.4 metric tons. Scenarios assuming sustainable technologies and clean coal burning reduce the growth rate of emissions by roughly 50 percent, leveling it off at a much lower footprint.

• Summary and Foresight

India has signed and ratified most of the United Nations treaties related to climate change, including the Kyoto Protocol, but understanding Indian progress requires a deeper perspective. This vast, densely populated nation has a common culture but a diverse population. The vibrant democracy holds regular, free elections and frequent, vociferous, and even violent protests. In every city, dozens of newspapers in English and Indian languages present diverse viewpoints, and hundreds if not thousands of political parties span the entire spectrum. The Internet has caught on rapidly. The transistor radio and newspaper are now supplemented by satellite television even in the villages, and Indians are connected to a worldwide diaspora through bicycle-delivered email, but also cell phones, text messaging, and voice-over-Internet.

In the 1980's, the Panchayati Raj law devolved many powers from the central government to elected village Panchayats (originally meaning an assembly of five or more wise people). Grassroots movements draw power partially from an ancient native respect for nature, partially from a fear of foreign enslavement, and partially from the class war ambitions of the communist parties. Skepticism about big corporations has evolved into critical examination of large-scale development and its effects on the environment. Intense and sophisticated opposition ostensibly based on concern for people displaced from fertile areas by dam reservoirs or large industrial plants has raised public awareness and interest in climate change and sustainable development issues all over India. This situation creates unique opportunities for game-changing developments.

Middle-class initiatives may revolutionize renewable power and sustainable development far beyond government targets, adapting advanced technology to Indian needs and preferences. Millions of Indian homes and businesses, forced by the abysmally unreliable power grid, already have grid-connected inverters, battery storage, voltage regulators, and auxiliary generators, and they are ready to incorporate renewable sources and perhaps a hydrogen economy. Highly efficient light emitting diodes are becoming popular for home lighting. Cell phones have rendered the landline telephone network obsolete, and beamed power may do the same to the power grid. Clean-burning liquefied petroleum gas (LPG) delivered in cylinders has become popular in Indian urban homes, but rising fossil fuel prices may replace these with biomass natural gas. Family-level solar thermal and biomass system installations are reaching critical mass numbers for explosive growth. With these, India has the potential rapidly to become a leader in sustainable development.

Industrial ecology

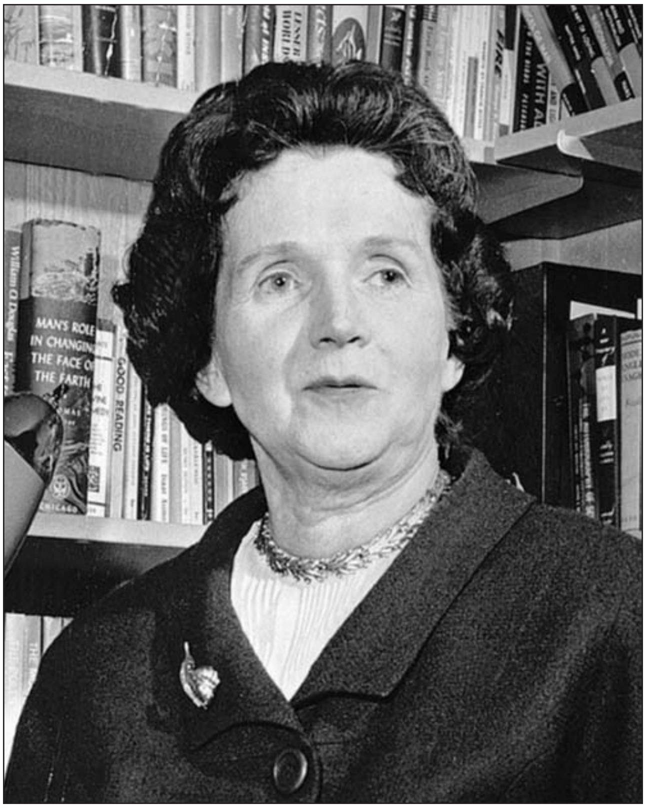
• **Categories:** Economics, industries, and products; environmentalism, conservation, and ecosystems

• Definition

Industrial ecology is the study of the flows of materials and energy in industrial and consumer activities and their impact on the environment. It includes the effects of economic, political, and social factors bearing on those flows and their environmental consequences. The discipline is an adaptation of the concept of a biological ecosystem, which has been at the core of environmental studies for many decades, applying the same analysis to the human-created world as had been applied to the biological world. It is also an adaptation of the idea of materials flow, which has been applied to geologic and industrial evaluations, applying the concept to industrial production and to the consumption of industrial products.

The roots of industrial ecology go back to the "tragedy of the commons," defined by Garrett Hardin in 1968 in an article of the same name. Hardin pointed out that while humans are very sensitive to the costs of generating income from producing goods that they personally own, they are largely insensitive to the costs of production that derive from assets owned in common. That same self-centered approach has been adapted to industrial production, particularly in the framework of a market-based economy (though the unraveling of the Soviet system in the late 1980's and the 1990's arguably showed that it also applied in systems of collective ownership).

The result of this self-centered approach has been that environmental assets have not enjoyed the kind of value recognition that has gone into private ownership. The reevaluation of those assets' value has been driven by those who maintain that failure to maintain and protect the environment has caused environmental assets to lose a great deal of value. This loss of value has been documented by individuals such as Rachel Carson, whose paradigm-changing work on the effects of DDT pointed out that environmental damage can harm humans



Rachel Carson, whose groundbreaking work on the effects of pesticides on humans transformed understandings of industrial ecology. (Library of Congress)

as well. Industrialists responding to such studies applied the methodology of systems analysis to industrial and ecological processes, producing "materials flow assessments." The techniques involved came to be called "life cycle assessment," or LCA.

In the 1990's, scientists began to observe what looked like systemic changes to the atmosphere and began looking for causes and defining the consequences through the absorption of carbon into the atmosphere. As a result, people began to realize that the human-created world might have a very important part to play in climate. The conclusions of the Intergovernmental Panel on Climate Change, that atmospheric changes were to a substantial extent caused by human activities, put a focus on evaluating those activities, especially those carried out by industry. Industrial ecology offered a method of analysis that, by tracing the flow of materials through the industrial system, could provide detailed information on the anthropogenic influences on global climate.

Because of the multiplicity of industries that convert various materials into saleable products, performing LCAs for the manufactured world involves several kinds of disciplinary expertise. Raw materials, very often taken from the ground, are subjected to a number of alterations to convert them into a form that humans need, so geologists play a significant part in the analysis, as they have specialized knowledge that reveals how the raw materials can be altered. Very often, chemical processes are employed in this alteration, and for this to be fully understood requires sophisticated knowledge of those processes. Moreover, in most cases, industrial production involves the application of forces generated by energy, for which an understanding of the physics of energy use is essential. Finally, most manufacturing processes create waste by-products. Indeed, life in the industrialized world in general generates enormous amounts of waste, and its disposition, without harming the environment or generating environmental changes that affect the climate, is a major political and social concern requiring knowledge of ecology and biogeochemistry to achieve.

• Significance for Climate Change

Since anthropogenic changes to the environment have been identified as major contributors to the changing climate, ways need to be found to minimize this impact. Full knowledge of the effects of the various parts of industrial production is essential to changing those effects. Industrial ecology, a specialized branch of environmental studies, has its own journal, the *Journal of Industrial Ecology*, edited at the Yale School of Environmental Studies. It draws on contributions from academics, members of the business community, and government officials. Through this journal and in other academic, private, and public forums, ideas and processes that can serve to modify industrial production and thereby reduce its negative impact on the climate are spread.

Industrial emission controls

- **Category:** Pollution and waste

Governmental regulations and technological innovations have helped reduce the amount of environmental pollutants and GHGs emitted into the environment as byproducts of industrial manufacturing.

- **Key concepts**

capture: to secure and contain harmful particles and chemicals
combustion: the burning of fuels to produce energy
emissions: gases and particulates released by industrial and other processes
filtration: separation or removal of contaminants from emissions
industrial: related to large-scale manufacturing or energy production
neutralization: elimination of harmful characteristics or properties to render contaminants benign
scrubbers: liquids that remove pollutants from emissions
sequestration: isolation of hazardous emissions to prevent them from polluting the atmosphere

- **Background**

Since the Industrial Revolution began in the mid-nineteenth century, factories using combustion to power machinery manufacturing products have released chemicals detrimental to the environment in their emissions. By the twentieth century, power plants generating energy through burning fuels such as coal and natural gas added to this pollution, and industrial greenhouse gases (GHGs) accelerated climate change. Motivated by economic, legislative, and environmental incentives, many industry operators sought ways to control industrial emissions. Engineers and scientists innovated and devised technology or methods to minimize, remove, convert, or store chemicals emitted during industrial combustion activities.

- **Industrial Emissions and Control Strategies**

Turbines, boilers, generators, engines, and furnaces powered by burning fuels release GHGs produced during combustion. Emissions frequently associated with industries include nitrogen oxides, sulfur dioxide, carbon dioxide (CO_2), and methane. The U.S. Environmental Protection Agency identified petrochemical, ammonia, aluminum, steel, iron, and cement manufacturers as emitters of large amounts of GHGs.

Political and social demands to reduce emissions resulted in many industry leaders evaluating how to alter production methods and technology in order to satisfy laws limiting emissions while not experiencing profit losses. Intergovernmental Panel on Climate Change (IPCC) reports discussed how to control industrial emissions, recommending industry managers seek control strategies and technology appropriate for manufacturing processes and fuels their factories utilized.

- **Carbon Capture and Storage**

Industries have successfully controlled emissions with carbon-capture-and-storage (CCS) methods by securing carbons released during combustion and then compressing and sequestering them in remote areas, usually underground, distant from the Earth's atmosphere. CCS is especially effective for minimizing CO_2 released in emissions from petroleum, iron, cement, and ammonia industrial processes and refineries.

Norwegian industries were early users of CCS because Norway's government began taxing carbon emissions in 1991. Norwegian engineers and scientists created CCS technology and procedures to store CO_2 in sandstone approximately 1,000 meters beneath the North Sea. Starting in 1996, the Norwegian industry StatoilHydro sequestered almost one million metric tons of carbon emissions annually.

Experts emphasized CCS technology is essential to achieve projected emission reductions by 2100. Researchers collaborated on CCS projects. Scientists experimented using chemicals to enhance CCS effectiveness and burning biomass to power equipment used to capture CO_2. In 2007, researchers demonstrated how algae capture carbon.

• Scrubbers

Scrubber technology cleans exhaust and emissions from industrial sources by removing particulates from acidic gases. A typical scrubbing procedure results in chemicals in emissions being altered, sometimes undergoing reactions to transform into other compounds, or lessening their strength.

Scrubbing equipment designs incorporate a tank and recirculation system cycling liquid scrubbers into the presence of emissions. The basic particulate scrubbing process involves the swift movement, from 45 to 120 meters per second, of emissions inside a tank constructed from fiberglass or metals that will not corrode. In this vessel, a liquid, often water, serving as the scrubber impacts the fast moving emissions and transforms into small drops that absorb particles in emissions.

Engineers designed scrubbers to meet specific industrial needs. Scientists identified chemical solutions, including chlorine dioxide, hydrogen peroxide, sodium chlorate, and sulfuric acid, effective as scrubbers to minimize sulfur oxides, nitrogen oxides, and heavy metals, such as mercury, in flue gas emissions.

• Filtration

Industrial emissions can be controlled by filtering contaminants produced during combustion. Filtration technology consists of an insulated metal chamber, usually made from stainless steel or an alloy, and mesh filters, mostly constructed with copper, silicon, or aluminum. Tanks store water before and after filtration. Sprayers and pipes transport water during filtration.

Water and temperatures control industrial emissions during filtration. Inside the chamber, sprayers coat water that has been cooled to 2° Celsius in an adjacent refrigerator tank on one or more mesh filters near the top of the chamber prior to hot emissions rising beneath the filter in the chamber. The dripping water hits the emissions, cooling them, and capturing particulates or liquefying such gases as sulfur dioxide and CO_2 when they reach the filter. The water containing particulates and gases is expelled into a dump tank.

• Neutralization and Absorption

Some industrial emissions are managed by neutralizing them. Researchers innovated methods to extract toxic chemicals prior to combustion. Engineers developed technology to impede nitrogen oxidization during combustion. In selective catalytic reduction (SCR), the reaction of ammonia with flue gases, aided by use of a catalyst such as tungsten oxide, breaks nitrogen oxides into nitrogen molecules and water. SCR effectively reduces emissions by 80 to 90 percent but is costly due to catalyst expenses.

Fluidized bed combustion (FBC) keeps nitrogen oxides from being produced because chamber temperatures are lowered to 750° to 950° Celsius by water tubes in the bed absorbing heat. FBC control methods used when burning coal achieve 80 to 90 percent reduction of sulfur oxides. Various flue gas desulfurization (FGD) methods utilize chemicals or minerals such as limestone that absorb emission contaminants, particularly sulfur dioxide.

• Context

of clean technology, particularly due to the expansion of industry because of economic incentives to produce more goods and energy to support expanding populations. Legislation such as the U.S. Clean Air Acts (1963-1990) outlined requirements for industries to control emissions. The Kyoto Protocol addressed industrial emissions control and suggested reductions. As global warming worsened into the twenty-first century, governments worldwide, such as the European Union, revised limits previously set for GHGs produced by industries.

Many industrial leaders recognized their environmental responsibilities and willingly limited emissions from factories and acquired updated equipment, trained operators, and enforced stricter procedures to minimize the impact of industrial emissions on climate change. Other industries, however, continued to release excessive GHGs because of apathy, ignorance, or inability to afford or attain access to emissions control technologies.

Industrial greenhouse emissions

• **Categories:** Pollution and waste; economics, industries, and products

Since the Industrial Revolution, increased amounts of anthropogenic industrial GHG emissions from factories and power plants have combined with emissions from other sources to raise the global temperature and change the climate. Modern technology has accelerated the global warming process with the production of new industrial GHGs.

• Key concepts

albedo: the fraction of incident light reflected from a body such as Earth

anthropogenic: derived from human sources or activities

biodiversity: the variety of organisms at a particular geographic location

biosecurity: measures required or taken to protect organisms from risk or danger

fossil fuels: fuels formed by the chemical alteration of plant and animal matter under geologic pressure over long periods, including coal, oil, and natural gas

greenhouse gases (GHGs): gaseous constituents of the atmosphere, both natural and anthropogenic, that contribute to the greenhouse effect

industrial: related to large-scale manufacturing or energy production

Intergovernmental Panel on Climate Change (IPCC): a scientific intergovernmental body set up by the World Meteorological Organization (WMO) and by the United Nations Environment Programme (UNEP)

ozone layer: a region of the upper atmosphere with high concentration of ozone (a gaseous form of oxygen) that protects the Earth by absorbing solar ultraviolet radiation

• Background

Industrial greenhouse gases (GHGs) are anthropogenic gaseous constituents of the atmosphere produced by human industrial processes that absorb and emit radiation at specific wavelengths within the spectrum of thermal infrared radiation, emitted by the Earth's surface, the atmosphere, and by clouds. This phenomenon causes the greenhouse effect, which contributes to global warming. The concentrations of carbon dioxide (CO_2) among such emissions are now more than one-third higher than they were before the Industrial Revolution. The Earth is artificially made even warmer by hydrofluorocarbons (HFCs) from industrial activities that trap extra heat from the sun, causing changes in weather patterns around the globe.

• The Sources and Levels of Industrial Greenhouse Emissions

CO_2, the most abundant GHG, is emitted from products and by-products of manufacturing sites, and from burning fossil fuels at large industrial facilities. Natural gas, coal, and oil are the three types of polluting power plants, and they produce 40 percent of CO_2 in the United States, coal being the biggest contributor. Brown coal produces more CO_2 than black coal. In the United States, industrial CO_2 emissions, resulting both directly from the combustion of fossil fuels and indirectly from the generation of electricity that is consumed by industry, accounted for 28 percent of CO_2 from fossil fuel combustion in 2006.

Industrial processes are among the six major sources of pollution in the United States and are responsible for over 60 percent of Canada's total emissions. In the United States, energy-related activities account for over three-quarters of anthropogenic GHG emissions, more than half of which comes from power plants and industrial processes. When emissions from electricity were distributed among various sectors, industry accounted for the largest share of U.S. GHG emissions (29 percent) in 2006. Overall, emission sources from industrial processes accounted for 4.5 percent of U.S. GHG emissions in 2006.

The six major industrial GHGs are CO_2, methane, nitrous oxide, hydrofluorocarbons, perfluorocarbons (PFCs), and sulfur hexafluoride (SF_6). The major industrial greenhouse gases are released from manufacturing and production processes related to iron ore pelletizing, lime, iron and steel, titanium, pulp and paper, aluminum and alumina, cement, petroleum refining, chemicals and fertilizers, electricity (produced with oil, coal, and gas), natural gas pipelines, potash, base metal smelters, silicon carbide, nitric acid, ammonia, urea, limestone and dolomite use (such as flux stone, flue gas desulfurization, and glass manufacturing), soda ash, ferroalloy, zinc, phosphoric acid, titanium dioxide production, lead, coal mining, wastewater treatment, stationary combustion, composting, manure management, semiconductors, magnesium, and adipic acid.

At present, electric power generation is the largest contributor to industrial GHG emissions. Industrial methane comes from petroleum systems and coal mining. Unintentional fugitive industrial methane emissions come from equipment leaks, natural gas distribution, and storage facilities. Nitrous oxide is generated during the production of nitric acid and adipic acid. The manufacture of liquid crystal display (LCD) screens releases nitrogen trifluoride. Reports in 2008 indicated a rise in airborne levels of nitrogen trifluoride from flat-panel screen technology (manufacture of LCD screens).

Industrial activities also produce several classes of greenhouse halogenated substances that contain fluorine, chlorine, or bromine, such as potent greenhouse HFCs, PFCs, and SF_6 gases. Sulfur hexafluoride is the most potent GHG the IPCC has evaluated. Chlorofluorocarbons, or CFCs, are wholly human-made, new to the atmosphere, and widely used in aerosols, foam manufacture, air conditioning, and refrigeration. Other industrial sources include HCFC-22 production, semiconductor manufacturing, aluminum production, and magnesium production and processing.

• Capacity of Industrial Emissions to Affect Climate Change

Industrial emissions form a significant percentage of anthropogenic sources of GHGs that are blanketing the Earth and increasing the average global air temperature near the Earth's surface. Industrial processes can chemically transform raw materials, which often release waste gases such as CO_2, CH_4, and N_2O, gases that can influence the atmospheric lifetimes of other gases. These emissions can affect atmospheric processes that alter the radiative balance of the Earth, such as cloud formation or albedo. The IPCC reported in 2007 that methane is twenty times as effective as CO_2 at trapping heat in the atmosphere, and its concentration in the atmosphere has increased by 148 percent over the last 250 years.

Nitrous oxide is over three hundred times more powerful than CO_2. Nitrogen trifluoride is thousands of times stronger at trapping atmospheric heat than CO_2. Human industrial activity has produced very potent GHGs such as hydrofluorocar-

Contribution of Anthropogenic GHG Emissions to Earth's Greenhouse Effect

Methane	22.9
Nitrous oxide	7.1
HGWP gases	0.4

Data from U.S. Environmental Protection Agency.

bons that trap more heat from the Sun than CO_2 and other GHGs, making the Earth artificially warmer. As a result, extreme weather events will become more frequent, more widespread, and more intense in the times ahead. In addition to having high global warming potentials, SF_6 and PFCs have extremely long atmospheric lifetimes, resulting in their irreversible accumulation in the atmosphere once emitted.

• How Industrial Greenhouse Emissions Affect Climate and Global Events

Industrial greenhouse emissions play a major role in the gaseous blanketing effects that create higher temperatures around the Earth. Chlorofluorocarbons emitted from factories destroy the protective ozone layer, causing more intense solar radiation to bombard the Earth. Increasing global temperature is expected to cause sea levels to rise, increase the intensity of extreme weather events, and create significant changes to the amount and pattern of precipitation, likely leading to an expanse of tropical areas, loss of biodiversity, and increased pace of desertification.

The effects of climate change have serious implications for the economy and environment of nations. Winters are becoming milder, and summers are becoming hotter. Snowpacks are shrinking, and unseasonably warm temperatures are leading to rapid spring melts, depleting the supply of summer water for agriculture and stream flows for wildlife. Storms and forest fires are becoming more severe while the risk of coastal flooding is increasing. These climatic changes will potentially affect native ecosystems, industries, infrastructure, health, biosecurity, and the economy.

Industrial smog emissions provoke responses of the atmosphere that cause health hazards, and affect agricultural as well as drinking water supplies. Other expected effects include modifications of trade routes, glacier retreat and disappearance, mass species extinctions, increases in the ranges of disease vectors, changes in quantity and quality of agricultural yields, and impacts on land use due to significant alterations in temperature and rainfall patterns. The health of livestock and other animals will be affected, as pests, pathogens, and diseases become modified or multiply. Land erosion and impoverishment will abound, with increase in soil infertility and proliferation of weeds. All these factors will have poverty impacts on people and jeopardize the global economy.

• Direct and Indirect Industrial Emission Impacts on the Atmosphere and Environment

Direct radiative effects of industrial GHGs occur when the gases themselves absorb radiation and warm the Earth. Strong industrial greenhouse emissions such as CFCs directly contribute significantly to the depletion of the protective ozone layer around the Earth.

The IPCC reported in 2007 that from the preindustrial era (ending about 1750) to 2005, concentrations of CO_2, CH_4, and N_2O have increased globally by 36, 148, and 18 percent, respectively. Their emissions from industrial sources directly pollute groundwater after rainfall has washed the pollutants into the soil. Toxins from the pollutants directly affect the health, growth, and reproduction of plants and animals.

Indirect atmospheric modification occurs when chemical transformations of the substances emitted from industrial processes produce other GHGs. Industries contain by-product or fugitive emissions of GHGs from industrial processes not directly related to energy activities. Industrial gases can also indirectly influence the atmospheric lifetimes of other gases. There are several gases that do not have a direct global warming effect but indirectly affect terrestrial and solar radiation absorption by causing some GHGs to persist longer in the atmosphere, and influencing the formation or destruction of other GHGs, including tropospheric and stratospheric ozone depletion. These gases include carbon monoxide (CO), oxides of nitrogen (NOx), and non-CH_4 volatile organic compounds (NMVOCs).

• Context

Today, Earth is hotter than it has been in two thousand years. The global temperature will rise higher, to destructive levels, than at any time in the past two million years if industrial emissions are not reduced. The IPCC predicts a further rise of 1.1° to 6.4 ° Celsius in the average global surface temperature. According to the *Science Daily* of September 17, 2008, the Earth will warm about 2.4° Celsius above preindustrial levels even under extremely conservative GHG emission conditions and under the assumption that efforts to clean up pollution continue to be successful. Although most studies focus on the period up to 2100, warming and sea-level rise are expected to continue for more than a thousand years even if GHG levels are stabilized. The delay in reaching equilibrium is due to the large heat capacity of the oceans.

As a result of the 1987 Montreal Protocol to curb CFCs, the IPCC reported in 2007 that the production of ozone-depleting substances (ODS) is being phased out, as CFCs and HCFCs are replaced by ODS substitutes such as HFCs and PFCs. Unfortunately, the substitutes, while being relatively harmless to the ozone layer, are equally potent GHGs, and at present their phase-out dates are not due for another 20 to 30 years.

Technological advancement and innovation are critical to achieving significant, long-term reductions in industrial GHG emissions. Investments in biofuels and alternative energy sources would promote clean electricity. Cement producers could use waste material from other industries in place of emission-intensive clinker. Some industries have installed new technology to cut emissions, and use filters that improve the quality of the air released into the atmosphere.

Industrial Revolution

• **Category:** Economics, industries, and products

The Industrial Revolution involved a shift from human and animal power to reliance on coal for manufacturing and transportation, and it was marked by an escalating rate of population increase. The early industrial period saw global cooling rather than warming.

• **Key concepts**

carrying capacity: the number of people the environment can support

climate feedback loops: self-reinforcing and self-negating processes that accelerate or retard climatic trends

fossil fuels: combustible products of ancient photosynthesis, such as coal

planetary albedo: the relectiveness of the Earth's surface, including cloud cover, to sunlight

• Background

The Industrial Revolution began around the middle of the eighteenth century in England. Increasingly sophisticated power-driven machines augmented and replaced human and animal labor, greatly increasing individual worker productivity. This led to an overall increase in per capita resource consumption at a time when population was also beginning to increase at an exponential rate.

Some economic historians speak of three or four separate Industrial Revolutions. The first, roughly 1750-1850, centered on mechanization of the textile and metallurgical industries. Mechanization of transportation in the form of railroads and steamships dominated the second phase. The United States overtook Britain as the world's leading consumer of fossil fuels, and Japan became the first non-Western nation to embrace industrialization. The post-World War II era of globalization and rapid growth in information technology has been called a third Industrial Revolution. Finally, some economists call for a fourth Industrial Revolution that would drastically reduce depletion of nonrenewable resources.

Of the revolutions that convulsed Europe and North America in the last quarter of the eighteenth century, the Industrial Revolution arguably had the most profound effect on the mass of people who experienced it. Most of its environmental effects, however, were either local or indirect. Compared with the first half of the eighteenth century and the latter half of the nineteenth, temperatures were cooler. Industrial carbon and sulfur emissions, smoke, and deforestation probably contributed, but their importance relative to other factors is uncertain.

Drax Power Station in Yorkshire, England. The Industrial Revolution radically transformed both the landscape and the air of England and other Western nations. (John Giles/PA Photos/Landov)

• The Process of Industrialization

The roots of Europe's industrialization must be sought in population fluxes and changing agricultural practices of the preceding centuries. Plague caused Europe's population to crash in the mid-fourteenth century. By 1700, the population again reached carrying capacity, supporting urban growth and creating pressure to improve agricultural productivity. Rapid rural population growth also allowed colonial expansion, which in turn provided a source of raw materials for industry.

By 1719, when Isaac Watt patented the first steam engine, London and other English cities mainly used coal for domestic heating. Pithead steam engines used to pump water from coal mines greatly increased production capabilities. Not long afterward, a series of innovations in the textile industry set the stage for massive movement from cottage-based industries to factories relying on external power sources. Other key inventions included improvements in iron founding, mechanization of tool machining, gas lighting, efficient papermaking and printing, and Portland cement, as well as the birth of the chemical industry.

• Energy Consumption

Prior to about 1790, the mechanized textile industry in Britain relied upon water power. After 1790, coal-fired steam engines powered most factories. The use of coal to produce gas for illumination and cooking began in the first decade of the nineteenth century. Steamships started to replace sail for river and coastal traffic by 1820, while the first passenger railroad opened in 1828.

In the United States, consumption of fossil fuels was negligible before the Civil War. The textile industry used water power, and heating and transportation relied on wood from seemingly limitless forests.

The carbon dioxide (CO_2) content of the Earth's atmosphere remained nearly constant from 1700 to 1850, which correlates with a lack of observable greenhouse effect in temperature measurements from this period. Explanations for this stability in the face of greater fossil fuel use include sequestration in oceanic carbonates and an increased level of photosynthesis. In any event, although the rate of increase in fossil fuel consumption was impressive, the absolute numbers are low. The 45 million metric tons of coal consumed in 1850 are dwarfed by nearly 5.4 billion metric tons of coal consumed worldwide in 2006.

• Other Environmental Effects

Historically, industrialization stimulated population growth. In early eighteenth century Britain, improved food production and better control of epidemic disease reduced infant mortality. Employment in cities and the opportunity to emigrate to colonies meant that these children married early and produced large families. While the population of the world as a whole roughly doubled between 1750 and 1860, that of Great Britain went from 7,500,000 to 23,130,000, and that of the United States went from 1,500,000 to 31,400,000. While the effects of immigration dominate U.S. statistics, the bulk of it was from the British Isles. Industrialization played a significant part in creating the expanding resource base making such growth possible. Although per capita resource consumption among the working poor did not begin to rise significantly until after 1850, the rise in numbers meant it took more energy and raw materials to support the population.

Contemporary accounts of early industrial cities paint a vivid picture of belching smokestacks and sulfurous fumes. Pollution controls were nonexistent. This large volume of pollutants tended to offset any greenhouse effect due to CO_2. Pouring quantities of soot and sulfur dioxide into the atmosphere produces atmospheric cooling. Although sulfur dioxide (SO_2) is a greenhouse gas (GHG), it rapidly combines with water to form sulfuric acid, which reflects sunlight. Soot particles also reflect solar radiation. Both can serve as nuclei for cloud formation, increasing planetary albedo and producing additional cooling. Thus, a single pulse of sulfur and particulate matter, injected into the atmosphere, has the potential to set up a climatic feedback loop.

Particulate matter remains in the atmosphere less than a year, and sulfuric acid no more than three or four years, whereas CO_2 builds up over decades. Consequently, the dirtier and more polluting an industry, the less its energy consumption will contribute to global warming in the short term.

This helps explain why there is no global warming effect due to industrialization in the early nineteenth century.

The period 1750-1850 also saw at least two massive volcanic eruptions that contributed to global cooling: Laki in Iceland in 1783-1784 and Mount Tambora in the East Indies, which precipitated 1816's "year without a summer." Neither eruption set up a feedback loop which would account for the generally depressed temperature levels recorded in Europe and confirmed by Greenland ice cores and North American tree ring data for the entire period 1780-1850.

• Context

Comparison of industrialization rates, temperature profiles, and CO_2 levels in the period 1750-1850 with more recent trends suggests an insight into why global temperatures have not responded in a linear fashion to increases in atmospheric CO_2 levels, but instead show a marked acceleration in the 1980's, when acid rain became an environmental issue of grave concern, and western countries began aggressively curbing sulfur emissions from coal-fired electrical plants. Once the natural SO_2 pulse from Mount Pinatubo cleared the atmosphere, the Earth experienced the full effect of GHGs unmitigated by pollution. The importance of SO_2 pollution in counteracting greenhouse warming has also been recognized by British scientists studying drought cycles in the Amazon basin.

Information Council on the Environment

- **Category:** Organizations and agencies
- **Date:** Established 1991

• Mission

The Information Council on the Environment (ICE) was a skeptic organization created to promote the idea that there is no scientific consensus on global warming. ICE was a public information group funded by the Edison Electrical Institute, the National Coal Association, and the Western Fuels Association. Its mission, supported by a $500,000 advertising budget, was to "reposition global warming as theory rather than fact," according to internal documents of Cambridge Reports, the Council's polling firm. The group employed a scientific advisory panel comprising geography professor Robert Balling, research physicist Sherwood B. Idso, and climatologist Patrick J. Michaels, as well as environmental scientist S. Fred Singer, to promote skepticism in television and newspaper interviews, opinion columns, and advertisements. The polling firm advised the council to emphasize that "some members of the media scare the public about global warming to increase their audience and their influence."

• Significance for Climate Change

In addition to the messages carried by its spokespersons, ICE conducted polls about global climate change and greenhouse gas emissions, purporting to gauge public opinion about these issues. In fact, according to strategy documents, pollsters targeted "older, less-educated men from larger households who are not typically information seekers" and "young, low-income women" in areas whose electricity was generated by coal, in an attempt to skew the poll results in favor of less regulation of coal.

ICE also purchased magazine and newspaper ads in key sections of the country, including one that ran in Minnesota reading, "If the earth is getting warmer, why is Minneapolis getting colder?" Another ad showed a ship sailing off the edge of the Earth, with an open-mouthed dragon waiting to catch it. The caption read, "Some say the earth is warming. Some also said the earth was flat." The Arizona Public Service Company declined to join ICE, declaring that the ads over-simplified a complex issue.

ICE was disbanded after only a few months, after a packet of internal memos describing the organization's public relations strategies was leaked to the *Energy Daily*, a trade publication, and follow-up stories appeared in the *Arizona Daily Sun*, the *National Journal*, and *The New York Times*. After the press stories, Balling and Michaels broke with the council. In 1999, a former board member of ICE expressed regret that the campaign had not lasted longer, writing that ICE had resulted in a "dramatic turnaround in how people viewed the issue of global warming."

Institute for Trade, Standards, and Sustainable Development

- **Categories:** Organizations and agencies; economics, industries, and products
- **Date:** Established 2001
- **Web address:** http://www.itssd.org

• Mission

The Institute for Trade, Standards, and Sustainable Development (ITSSD) advocates sustainable development without absolute protection of natural resources and discounts anti-global warming measures as not scientifically or economically justified. Headquartered in Princeton, New Jersey, the ITSSD is a nonprofit organization dedicated to educating government, industry, and the public about science, technology and innovation policy, private property rights, and international trade. It is operated by its chief executive officer-president, vice president, and secretary and has a seventeen-member advisory board. The officers write white papers and articles, serve on a variety of discussion panels, administer an internship program for university students, and publish journals on economic freedom, intellectual property rights, trade barriers, the United Nations Convention on the Law of the Sea, "pathological communalism," and women's property rights.

The ITSSD's principal policy calls for positive sustainable development, which, it argues, has a general capacity to create well-being for present and future generations. This sustainable development is positive in that it eschews regulation "devoid of scientific and economic benchmarks" and "disguised trade barriers premised solely on cultural preferences" in favor of strongly protected property rights, free market (neoliberal) economics, decentralization, economic growth, and local, regional, or national (rather than supranational) institutions encouraging individual initiative. The ITSSD contends that regulations and standards must be developed "based on empirical science and economic cost-benefit analysis" under public scrutiny and free of the dominating influence of scientific fashion or sociopolitical ideology.

• Significance for Climate Change

Informing its stance on climate change, ITSSD relies on the arguments of global warming critics, including (according to ITSSD) "established scientists." Most prominently cited is British businessman, politician, and inventor Christopher Monckton, who argues that global warming derives from natural cycles and is misrepresented by the scientific community. In the white paper "Europe's

Warnings on Climate Change Belie More Nuanced Concerns" (2007), ITSSD president Lawrence A. Kogan accuses leaders of sidestepping what he portrays as the ongoing scientific debate. This debate concerns the extent to which certain human activities can be shown to cause measurable global warming or merely to correlate with a barely observable rise in global temperatures that may or may not prove to be cyclical in nature. The failure of European leaders to discuss this issue in the ITSSD's eyes suggests a nuanced effort to base intergovernmental regulatory policy on popularly fanned fears about largely hypothetical, unpredictable or unknowable future natural and anthropogenic hazards that have not yet been shown to pose direct ascertainable risks to human health or the environment.

Intergenerational equity

- **Category:** Ethics, human rights, and social justice

- **Definition**

The principle of intergenerational equity is strongly embedded in the U.N. Framework Convention on Climate Change. Historically, it owes its recognition to the Brundtland Report, *Our Common Future* (1987), which popularized the principle of "development that meets the needs of the present without compromising the ability of future generations to meet their own needs." The Declaration of Rio on Environment and Development (1992) adds a rights-based perspective to the principle, suggesting that "the right to development must be fulfilled so as to equitably meet development and environmental needs of present and future generations."

- **Significance for Climate Change**

The moral concerns over intergenerational equity have strong implications for climate-change-related policy making. The concept of intergenerational equity acknowledges the obligations of present generations in protecting the opportunities of future generations as well as the rights of future generations in enjoying the same level of opportunities and stocks of assets. This concept raises questions about how the interests of current generations are weighed against those of future generations and about the costs of inaction. Economists use discounting factors to address climate change by attempting to weigh the costs and benefits of alternative policies to different generations. The Stern Review, a report released by the British government in 2006, uses a similar approach to calculate optimal policy response and to highlight the consequences of inaction for future damage.

The concept of intergenerational equity is not without problems. It is hard to know the precise magnitude and distribution of the effects of climate change because of scientific uncertainty, as well as limited current knowledge about the future aspirations of particular societies. For instance, it is not clear how evenly the impact of climate change would be distributed over successive future generations. There is potential conflict between intragenerational and intergenerational needs. If current needs have not been met, this creates a dilemma about whether there is an obligation to meet future needs. Furthermore, countries have different capacities in meeting present and future needs. There are doubts about the reliability of discount rates. Research shows that unless the discount rate is very low, the benefits of climate change mitigation policies in future centuries are almost worthless in present value terms. There is also an implicit asymmetrical power in the concept. While current generations can influence how future generations live, future generations cannot exercise such an influence on presently living people.

Interglacials

• **Categories:** Climatic events and epochs; cryology and glaciology

The question of when the current interglacial period will end and a new glacial period will begin is of paramount importance when attempting to predict the future of Earth's climate.

• Key concepts

Holocene: the current interglacial, which began 11,700 years ago

isotopes: variants of an element that are chemically identical but have different atomic mass numbers and vary in radioactivity

marine isotope stage: half of a glacial cycle, as identified in the oxygen isotope data from ocean cores; advances are given even numbers, and retreats are given odd numbers

Milanković cycle: cyclical variance in Earth's orbital parameters, including axial inclination, climatic precession, and orbital eccentricity

MIS 11: an interglacial that may be the best analogue for the Holocene; also called the Holsteinian or Termination V

MIS 5e: the most recent interglacial before the Holocene, also known as the Eemian, LIG (Last InterGlacial), or Termination II

O^{18}/O^{16} ratio: ratio between two oxygen isotopes that is altered by the advance and retreat of continental glaciers

• Background

How does the present climate compare to the climate during other interglacials? Are current temperatures, sea levels, and carbon dioxide (CO_2) concentrations unprecedented, or should they be considered within the expected range? When, if ever, is the current interglacial going to end? These are among the important questions that climate science seeks to answer. Ice cores, loess deposits, pollen analysis, and other data and techniques provide information that comes together to form a detailed picture that will help answer them.

• Biological Data

Over the last three million years, there have been forty to fifty glacial/interglacial cycles. Scientists have sought to characterize conditions during these periods using a variety of approaches. Plant remains, particularly pollen, have been analyzed to estimate temperature and humidity. The carbonate shells of planktonic marine organisms, preserved as fossils in the sediments beneath the sea, have been analyzed to infer sea surface temperatures. It is difficult to separate regional effects from global ones, and often data from different time periods is only available in different locations, so acquiring a global picture is not easy.

In general, interglacial climate is seen as being quite similar to the current climate. In fact, the term is often restricted to periods during which temperatures were at least as high as they have been during the Holocene, the name given to the current interglacial.

• Ice Core Data

Cores have been drilled out of the ice in Greenland and Antarctica. Within the ice are bubbles of air that have been preserved since the ice was formed. The deepest core, from an area called Dome C in Antarctica, has samples of air from 800,000 years ago. These core samples provide detailed information on eight complete glacial cycles. Ratios of oxygen istopes O^{18} to O^{16} are used to infer how much of the Earth's water was tied up in glacial ice, since glaciers sequester O^{16} and thereby increase the proportion of O^{18} in the ocean. The concentration of deuterium (H^2) in a sample, moreover, can be used to infer the temperature of the air when the snow formed. Age is determined by combining depth, snow accumulation rates, ice flow rates, compaction rates, and so on, in a complex but reproducible way and calibrating the results by using radiometric dating techniques on volcanic dust incorporated in the ice. Dust is examined in detail, and often its place of origin can be determined. While no two cycles are identical, they all share a number of traits.

Each cycle has a saw-tooth shape. A glacial advance ends abruptly, with rapid melting of the ice and a rapid rise in air temperatures. For example, in MIS 9, the temperature rose 13° Celsius in eight thousand years. This warming can stop abruptly, with cooling starting almost immediately, or it can taper off, warming at a slower rate for perhaps a dozen millennia, before cooling begins. Of the eight previous terminations in the Dome C core, four started cooling immediately and four tapered off. Once cooling begins, it is far more gradual than is warming, continuing, with some reversals, for about 100,000 years. Ice is sequestered as cooling occurs, and CO_2 levels fall.

The air temperatures in Antarctica were higher than the average for the current millennium during each of the last four interglacials, but lower during those more than 500,000 years old. The Holocene (MIS 1) began 11,700 years ago. The three most recent interglacials before the Holocene (MIS 5, 7, and 9) had durations of about twelve thousand years or less, so simply by looking at the ice core data one might guess that the next glacial advance may be imminent. However, a theory proposed by Milutin Milanković suggests things may not be this simple.

Periodic variations in some of the orbital parameters of the Earth are known to control the timing of glacial cycles. One past interglacial during which those variations were similar to today's was MIS 11, which lasted for twenty-eight thousand years and had warming taper off after an early rapid rise. However, MIS 19, which also had similar orbital variations, saw cooling right after its initial warming and was of shorter duration. Perhaps the Milanković cycles are similar to lit matches thrown into the woods. When they are thrown will determine the timing of the fires produced, but the scale and intensity of the fires are dependent on how much fuel is available, how dry it is, the weather, relative humidity, and a host of other factors.

• Context

The Earth is currently in an interglacial state and has been in that state for nearly twelve thousand years. Geology and oceanography have shown that over the last three million years the Earth has switched between glacial and interglacial states some forty to fifty times. With no anthropogenic influence, one would conclude that continental glaciers will advance again, the only question being when. In the presence of anthropogenic influences, however, it is not clear that the Earth will return to another glacial state.

Although there is some discussion over whether the orbital conditions for triggering a glacial advance have already occurred or are yet to occur, it is still prudent to examine the conditions on the planet today to evaluate the risk posed by another glacial advance. Of particular interest is why, during times of elevated CO_2 and elevated temperatures, former interglacials succumbed to the minor fluctuations of solar energy produced by those orbital conditions.

Intergovernmental Panel on Climate Change

- **Categories:** Organizations and agencies; meteorology and atmospheric sciences
- **Date:** Established 1988
- **Web address:** http://www.ipcc.ch

Since its creation in 1988, the IPCC has proven to be one of the most credible sources of information regarding the state of scientific knowledge about climate change, its impacts, and possible policy responses. Its input has been instrumental in the global effort to reduce GHG emissions.

• Key concepts

anthropogenic: caused by human activity

greenhouse gases (GHGs): gases that allow solar radiation to reach Earth's surface but trap heat, preventing it from escaping into space

International Council for Science: a global nongovernmental organization that fosters cooperation between national and international scientific unions and organizations in the advancement of science

Kyoto Protocol: an international treaty in which industrialized signatories made legally binding commitments to reduce their GHG emissions

United Nations Environment Programme (UNEP): a United Nations agency that promotes sensible environmental policies as the key to sustainable development in developing nations

United Nations Framework Convention on Climate Change (UNFCCC): an international agreement creating the overall context for future agreements designed to reduce GHG emissions

World Meteorological Organization (WMO): a United Nations agency charged with assessing the effects of atmospheric changes on weather, climate, and seas

• Mission

The first call for an international effort to study the effects of anthropogenic climate change on the global community was issued by the World Meteorological Organization (WMO) at its 1979 World Climate Conference. The statement urged world governments to use scientifically generated knowledge to direct policy initiatives designed to slow the progression of global warming. In 1985, the Advisory Group on Greenhouse Gases (AGGG) was established by the International Council of Scientific Unions (ICSU; later the International Council for Science), the WMO, and the United Nations Environment Programme (UNEP). The group was to periodically evaluate scientific data relating to climate change, following a joint conference. These events created the impetus for the establishment of the Intergovernmental Panel on Climate Change (IPCC).

In 1987, the WMO and UNEP agreed that an organization should be created to coordinate an ongoing international effort to evaluate the results of scientific research on the climatic and socioeconomic effects of greenhouse gas (GHG) emissions. This organization would both evaluate research findings and suggest appropriate and effective policy responses based on those findings. The WMO established the IPCC in 1988 and gave it its mission. The panel was to develop a strategy to increase scientific information on global warming, use that information to assess possible policy initiatives for addressing climate change, evaluate policies already in place or proposed, and report its findings to governments and international organizations. UNEP and the United Nations General Assembly endorsed the IPCC.

The IPCC convenes annually in meetings that include hundreds of government officials and researchers from government agencies and nongovernmental organizations (NGOs) from countries that are members of the WMO and UNEP. At these meetings, the IPCC's objectives and activities are determined, the election of its chair is held, and members of its bureau, Task Force Bureau, secretariat, working groups, and Task Force on National Greenhouse Gas Inventories are selected. The thirty-member bureau, with representatives from all regions of the world, oversees the three working groups, and the Task Force Bureau directs the work of the task force. Working Group I (WG I) analyzes the scientific evidence regarding the causes of climate change, Working Group II (WG II) deals with the effects of climate change, and Working Group III (WG III) examines possible ways to reduce the negative effects. The task force is charged with developing better ways of measuring and reporting countries' GHG emissions. In addition, temporary special topic groups may be formed as necessary. The secretariat oversees and organizes all IPCC functions.

• Activities of the IPCC

The main activities of the IPCC involve producing assessment reports (ARs) and methodology reports. The First Assessment Report (FAR) was requested by the U.N. General Assembly in 1989 to form the basis for the creation of the United Nations Framework Convention on Climate Change (UNFCCC). The FAR was completed in 1990. WG I concluded that anthropogenic GHG emissions, principally those of carbon dioxide (CO_2), would increase and would be responsible for global warming and sea-level rise during the twenty-first century. WG II asserted that this would have negative impacts on land and water ecosystems, coastal areas and cities, forestry and agriculture, and weather. WG III suggested short- and long-term policy responses. An IPCC supplementary report, prepared in 1992 to provide updated information for the newly created UNFCCC, supported the conclusions of the FAR.

Further IPCC ARs were published in 1995, 2001, and 2007. Each contained the three working group sections, with summaries for policy makers, as well as a synthesis report that summarizes the overall findings. These ARs reiterated and expanded the findings of the FAR and expressed greater confidence in the accuracy of the simulation models used to project future climate change, including the ability to better distinguish between natural and anthropogenic GHG emissions. The findings of these improved models indicated that human activity is the primary cause of past and future increases in global warming.

The Fourth Assessment Report, *Climate Change, 2007* (AR4), was the most strongly stated, asserting that mostly anthropogenic global warming will likely result in significant increases in global temperatures, ocean levels, hurricanes, droughts, heat waves, and other negative effects during the twenty-first century. It further stated that these effects will continue for hundreds of years under all simulated scenarios, even if GHG emissions could be limited to their current levels. All ARs undergo a rigorous review and revision process by the working groups, government officials, expert scientists, and the panel before receiving final approval.

In addition to the ARs produced by the working groups, the task force produced *Revised 1996 IPCC Guidelines for National Greenhouse Gas Inventories* to inform governments about the available methods for measuring GHG emissions. In 2006, an updated version was prepared that detailed improvements in software and methods for measuring emissions. The IPCC sponsors expert meetings and workshops to find more effective ways to do its work. It also creates special topic and function groups, such as the Task Group on Data and Scenario Support for Impacts and Climate Analysis, which provides the latest data from climate change studies that use different models for use by those who evaluate their impacts and develop response strategies.

• Controversies Involving the IPCC

The IPCC's activities and processes have not been without their critics. Some have said that the ARs are inaccurate, alarmist, and politically driven. For example, Christopher W. Landsea, science and operations officer at the National Hurricane Center, resigned from participation in AR4 in protest when a lead author of both the 1995 AR and AR4, Kevin E. Trenberth, director of the Climate Analysis Section at the National Center for Atmospheric Research, asserted that increased hurricane activity was caused by global warming, which Landsea strongly disputed. Landsea claimed that AR4's conclusions were a product of political pressure and scientific community consensus, and that they stated the research questions as though they had empirical support, which, in his opinion, they did not. In 2005, the British House of Lords expressed concerns that the IPCC was exaggerating the future magnitude and impacts of global warming. It commissioned a report to perform a more objective cost/benefit analysis regarding the IPCC's suggested responses and the expense of possible damage. Ironically, the resulting Stern Review concluded that IPCC ARs and reports from other sources had underestimated the future risks of global warming.

In fact, another general criticism of the IPCC has been that it is too conservative in its analytical approach and downplays the need for immediate aggressive action. Critics cite other analyses that forecast higher future increases in GHG emissions, global temperatures, and sea-level rise than do the IPCC. Some claim that political pressure from the United States resulted in Robert T. Watson being replaced by Rajendra K. Pachauri as IPCC chair in 2002, because the latter was seen as being more desirable by conservative politicians and large oil companies. At the heart of these concerns are the IPCC review, revision, and acceptance processes, which are viewed by some as being unnecessarily cumbersome, leading to more conservative, bureaucratically acceptable findings.

Critics have objected to line-by-line reviews and revisions of the summary sections of the ARs by the panel, with some saying that they downplayed and distorted findings that had been validated through the peer-review process. The heads of major atmospheric research and meteorological organizations have responded by saying that this was a media campaign attacking rigorously reviewed data compilations and summarizations because of the biases of the critics. The IPCC has stood by its position that the revisions make the ARs more understandable, rather than being politically motivated, and that the strength of the AR processes lies in its objective, cautious, analytical approach, following the ideals of the scientific method.

Critics have also asserted that the submission deadlines for AR material are too far in advance of their publication. As a result, in order to allow for the lengthy review processes, the latest research findings are excluded. On the eve of the release of AR4, Pachauri responded by acknowledging that important research that projected more pronounced future global warming had been completed since the submission deadlines, indicating that aggressive policy initiatives should be initiated sooner than recommended in the report.

• Context

The goal of the IPCC is to foster international cooperation between scientists working on climate

From left: Yvo de Boer, head of the United Nations Framework Convention on Climate Change, Rajendra Pachauri, chair of the Intergovernmental Panel on Climate Change, and Hungarian minister of environment and water management Gabor Fodor hold a press conference in April, 2008. A banner celebrating the IPCC's receipt of the 2007 Nobel Peace Prize hangs in the background. (AP/Wide World Photos) modeling, those assessing climate impacts, and policy advisers in order to determine the causes and dangers of climate change and develop sensible response strategies. This has proven to be a challenge because of the disagreements and debates among scientists and the frequent tension between political dynamics and research findings and conclusions. Nevertheless, the IPCC's work has had significant impacts.

Since 1988, multitudes of scientists have volunteered to participate in the panel's work without compensation, resulting in a dramatic increase in global warming research, and the IPCC has ensured that participants are from both developing and industrialized countries. Over 3,750 contributing and lead authors and expert reviewers from more than 130 countries contributed to AR4. The FAR brought about the creation of the UNFCCC and the Koyoto Protocol, which has been ratified by 183 nations.

Criticisms notwithstanding, a strong consensus of support for the IPCC has emerged within the global scientific establishment. A majority of scientific organizations from all parts of the world, including the United States' National Research Council, the Network of African Science Academies, the European Geosciences Union, and the Royal Meteorological Society have voiced strong support for the IPCC, calling it the foremost authority on the state of scientific knowledge relating to climate change. IPCC's ARs have become a primary source of information in climate change policy debates worldwide, and many conservative political factions that had denied the existence of anthropogenic global warming for decades have now conceded that it is real, in the face of the growing body of scientific evidence.

In 2007, the IPCC was awarded the Nobel Peace Prize for its efforts to compile, analyze, and disseminate scientific data about climate change as the basis for formulating strategies for mitigating against its negative global impacts. The co-winner of this award was former United States vice president Al Gore, who was also recognized for his work on global warming. The IPCC will undoubtedly continue to be an important force in the ongoing international efforts to understand and counteract the current and future effects of climate change. The Fifth Assessment Report (AR5) is scheduled for release in 2014.

Intergovernmental Panel on Forests

- **Category:** Organizations and agencies
- **Date:** 1995-1997; succeeded by the Intergovernmental Forum on Forests, 1997-2000
- **Web address:** http://www.un.org/esa/forests/ipf_iff.html

• Mission

As a U.N.-sponsored body on which all United Nations members were entitled to representation, the Intergovernmental Panel on Forests (IPF) strove to reach a consensus among all its members that could have provided the basis for a world forest convention. Discussions of the role played by forests in controlling climate change, specifically global warming, began in earnest at the United Nations Conference on Environment and Development (UNCED), which took place in Rio de Janeiro in June of 1992. This meeting highlighted the existence of two opposing groups in discussions of the role of forests in global warming. The object of U.N. climate discussions had already been defined as "sustainable development" by the Brundtland Commission of 1987, but the meeting in Rio brought the two opposing camps face to face, as developed nations advocated for a convention that would constrain deforestation while developing countries, notably Brazil and Malaysia, opposed the idea of a world forest convention. Their opposition rested on the fact that much of the deforestation then taking place was occurring in the developing world.

Following the meeting in Rio de Janeiro, a United Nations body was formed called the Commission on Sustainable Development (CSD), which authorized the establishment of the IPF to conduct research that could be used to provide a factual basis for a convention on forests. Such a convention could devise rules that would constrain further deforestation and thereby slow the addition of carbon dioxide to the atmosphere. The CSD began with fifty-three member states, but other U.N. members were free to join.

Meetings of the IPF, which continued to function as a subsidiary of the CSD, received input from a variety of other bodies, especially the Food and Agriculture Organization (FAO), which hoped to take the lead in defining the framework issues of a forest convention. Other bodies, including nongovernmental organizations (NGOs) representing various indigenous tribes, also sought to take part in the discussions. The result was a divisive set of meetings that was dominated by the fundamental division between the developed countries and the developing countries. Since the rules governing the CSD called for a consensus to be reached before a convention could be created, little if any progress was made.

In 1997, the CSD replaced the IPF with another body, the Intergovernmental Forum on Forests (IFF). Like its predecessor, the IFF was an "open-ended" body, which meant that any U.N. member could take part in its discussions. It met four times, in October, 1997, in New York; from August to September, 1998, in Geneva, Switzerland; in May of 1999 in Geneva; and from January to February of 2000 in New York. Discussions by the participants ranged over many issues, including the causes of deforestation, economic issues related to forests, and particularly how to value the services that forests provide. These services include not just possible climate stabilization but also biodiversity (especially in tropical forests) and preservation of indigenous cultures.

A consensus that could lead to a forest convention with terms that might be legally enforceable proved as elusive to the IFF as it had to the IPF. Meanwhile, deforestation of tropical forests continued, while at the same time the United States joined the developing nations in opposing any convention or binding agreement on the grounds that participation had to be "voluntary." Canada led the developed nations, including the European Union, in advocating for a binding convention. In 2001, the IFF was effectively replaced by the U.N. Forum on Forests, a subsidiary of the Economic and Social Council, where discussion of forest issues continued.

• Significance for Climate Change

The IPF and the IFF served to publicize the environmental impact of deforestation of tropical forests, and even though they did not develop a consensus that could lead to a convention on forests, they did bring to light a great deal of factual information about forests and their role in climate change. Forests cover about 30 percent of the world's land mass, but the percentage is declining. Between 15 and 30 percent of the carbon contributed to the atmosphere globally results from the reduction of the world's forests. Tropical forests contain almost as much carbon as do the temperate and boreal forests combined. Stopping deforestation could do much to stabilize Earth's climate.

International agreements and cooperation

• Category: Laws, treaties, and protocols

• Definition

International law connects nation states in a framework of agreements that implement recognized principles, norms, rules, and procedures. Subjects of public international law include sovereign nation states, international organizations, and movements of national liberation. Sources of international law are customs, accepted standards of human behavior, and treaties. The design of international agreements is voluntary, but once concluded they are binding instruments to achieve collective benefits that states would not achieve unilaterally. To either open a new set of options that offer beneficial opportunities or to restrain options that are recognized as harmful, state governments abide by the terms of an international agreement, which in either case is a recognition of mutual interdependence. An ultimate goal of international law is to facilitate win-win solutions through cooperation.

The importance of international agreements is well demonstrated by the prisoner's dilemma in game theory. Here two actors are in a better situation if they both cooperate rather than do not cooperate. If either side individually gives up cooperation for individual benefits, the joint outcome is worse for both. To prevent actors from non-cooperation to maintain mutual benefits requires agreement based on communication, verification, and enforcement. To discourage violations of an agreement, they need to be detected and the expected benefits from violation to be denied. It is often efficient to transfer the tasks of verification and enforcement to institutions that are not bound by individual capabilities and interests.

• Significance for Climate Change

International agreements are essential in climate policy to address the tragedy of the commons regarding the atmosphere. They impose emission constraints for each member state and create opportunities for technology cooperation, capital flows, and trading markets.

The law of treaties defines the rules for legally binding agreements between states, which is codified in the 1969 Vienna Convention on the Law of Treaties. A treaty is a written agreement between two or more sovereign states in which the parties involved agree to abide by certain specified procedures and standards of conduct, which include the *signature* by an authorized State representative; the *ratification* process by parliamentarian bodies to enter a treaty into binding national legislation, independent of the political leadership; and the *entry into force* upon fulfillment of specified conditions, such as the number of ratifying states. During this process, the status of a member state changes from a negotiating state to a state signatory, ratifying state, and ultimately state party after entry into force. A state that has signed a treaty is bound to it and is obliged to refrain from acts that would defeat the object and purpose of a treaty even if it has not yet ratified it. A state can change agreements before ratification and announce that it is withdrawing its signature, after which it is no longer bound.

After ratification, a state is obligated to announce to the world in advance that it plans to withdraw from a treaty, following the advanced notice required. Usually treaties hold for a limited number of parties (bilateral, trilateral, multilateral) and for a given period (for example, the Kyoto Protocol, with obligations for industrialized countries by 2012). Rules of treaties are binding, regardless of the name (for example, protocol, accord, covenant, convention, memorandum of understanding, or exchange of letters or notes). A challenge for international agreements is to design mechanisms that strike a balance between the required commitments and the degree of support for an agreement.

Source: Pew Center on Global Climate Change.

The threat of climate change cannot be resolved or prevented by a single nation, but requires an unprecedented degree of international cooperation to foster emission reductions and technological change in the energy sector. Instruments of international law define the rules of emissions, climate impacts, and policies to diminish the risks and enhance cooperation, providing mutual assurance that policies are pursued in an integrated, coordinated, and effective way. An adaptive regulatory framework would address the collective action problem in long-term climate policy, designing efficient legal mechanisms to improve the effectiveness of institutions, to reduce conflict and codify cooperation and compliance, including the international transfer of investments and technologies to shift the composition and learning rates of the energy system toward emission reductions. Coalitions are emerging where individual action is insufficient or inefficient—for example, in achieving a critical number of votes, a critical mass of investment to realize projects, or a threshold of emissions.

The legal framework of climate policy has been defined by the 1992 U.N. Framework Convention on Climate Change (UNFCCC). With the signing of the Kyoto Protocol in 1997 and its entry into force in 2005, the international community has established a first set of instruments through a combination of cooperative governance and market-based incentives. A lack of agreement on the underlying causes, expected risks, and required actions related to long-term climate change, as well as the expected costs and partial interests, has impeded progress during the past decade. To overcome the hurdles for post-Kyoto agreements, an evaluation and negotiation process across all levels is needed, involving citizens, firms, institutions, and states in a multi-stakeholder environment, which became visible during the Bali climate summit in December 2008. Moving beyond Kyoto is a challenge for the legal and policy process that is supposed to implement the longer-term objectives and manage the potentially severe implications in case of failure. It is also a challenge for the scientific community, which becomes involved in value judgments that require innovative integrated approaches.

International Atomic Energy Agency

• **Categories:** Organizations and agencies; energy
• **Date:** Established July 29, 1957
• **Web address:** http://www.iaea.org

• **Mission**

The International Atomic Energy Agency (IAEA) promotes the peace, health, and prosperity of the people of the world through the use of atomic (nuclear) energy. The IAEA is independent of the United Nations but reports to the United Nations General Assembly, and if violations involving nuclear materials are detected, it reports to the U.N. Security Council. The agency, headquartered in Vienna, Austria, has over twenty-two hundred trained personnel and their support staff. Member nations pay a fee each year as part of their membership but there is also a voluntary fund, the Technical Cooperation Fund, that is used especially in developing countries. The mission of the IAEA is based on three work areas: safety and security, science and technology, and safeguards and verification.

In the safety and security area, the work is focused on helping countries develop standards and procedures for nuclear safety and security. That involves training sessions for untrained personnel, meetings for experts to share information, and planning sessions and training for emergencies. IAEA's budget is geared to the sharing of information with anyone needing nuclear information.

The science and technology area works toward the use of peaceful applications of nuclear science and technology to solve problems in health, poverty, pollution, and other areas of life. The work can be described in three components: technical cooperation, research and development, and energy and electricity. The technical cooperation includes expert advice, personnel, materials, and equipment to support projects that benefit people in developing countries socially or economically. The research and development includes not only the joint research done with IAEA, but also the support of research by different groups all over the world. Any area in which nuclear technology can be valuable is researched but issues in health, environment, poverty, and food are the main focus points. The energy and electricity area of work includes dealing with the energy needs of a country. If the needs can be met with nuclear power, IAEA provides support in equipment, personnel, training, and materials. Ideas that are innovative are especially encouraged in this work. In 2004 IAEA developed the Program of Action for Cancer Therapy (PACT) to aid developing countries in cancer detection and treatment using radioisotope and other nuclear techniques.

Safeguards and verification is the area of IAEA's mission that is most important for world peace. For over fifty years, IAEA has monitored the use of nuclear materials all over the world. The monitoring is not only to check that countries are not using nuclear materials to build weapons, but also that the nuclear materials used in a peaceful manner are used, stored, and secured in a manner that causes no chance of radiation exposure to humans. The United Nations Security Council has requested that IAEA keep a watch on Iran and its use of nuclear materials. The IAEA and its director were awarded the Nobel Peace Prize in 2005.

• Significance for Climate Change

The use of nuclear energy to generate electricity does not generate greenhouse gases to cause global warming. It does not generate smog-producing materials. The use of nuclear energy should not cause any change in the climate unless a disaster spreads radiation into the atmosphere. After the Chernobyl disaster in 1986, the IAEA increased its focus on nuclear safety.

International Council for Science

- **Category:** Organizations and agencies
- **Date:** Established 1931
- **Web address:** http://www.icsu.org/

• Mission

The International Council for Science (ICS) was formerly known as the International Council of Scientific Unions (ICSU). It is a nongovernmental organization of research councils or scientific academies, which are national, multidisciplinary bodies, and scientific unions, which are international, disciplinary organizations. These two complementary types of groups provide a wide range of scientific expertise. The mission of ICS includes research, information access, information exchange, and scientific freedom. The research area includes coordinating research by interdisciplinary groups in topics important to mankind's well-being. Climate change is one of those topics.

The ICS develops Internet Web sites to disseminate data and technology and publishes newsletters, books, journals, and proceedings. It supports over six hundred meetings of discipline-specific scientists, as well as multidisciplinary, topic-driven meetings. Support for science education and for exchange of ideas is also part of the group's mission, as is initiation of regional networks of scientists. Scientific freedom is supported by ICS, which defines it as the freedom to research scientific topics without gender, racial, economic, or geographical limitations. ICS cooperates closely with many other national, international, governmental, and nongovernmental groups, especially the agencies of the United Nations.

The funding for ICS comes from member contributions, grants, and contracts. The grants and contracts come from foundations, agencies, and other bodies that financially support scientific research and information sharing. Each member is part of the General Assembly, which elects an executive board and a slate of officers. The officers are members of the executive board and are responsible for the day-to-day operation of ICS. The officers are supported in the day-to-day operations by the Secretariat, the officers, advisors, and staff of ICS located in Paris, France. To expedite scientific research and education in developing countries, ICS is creating four regional offices for Africa, Latin America and the Caribbean, Asia, and the Arab region.

• Significance for Climate Change

With part of its mission to research areas that affect the well-being of the world's population, climate change is one of the major areas of study by the ICS. One of the major committees of ICS is the Scientific Committee on Problems of the Environment (SCOPE). SCOPE not only researches different factors concerning the environment but also publishes reports on the different factors. Other reports, such as *Invasive Alien Species*, *Sustaining Biodiversity and Ecosystem Services in Soils and Sediments*, and *Interactions of the Major Biogeochemical Cycles*, all deal with the environment; many deal with the climate and man's interaction with the climate, both how humans change the climate and how humans adapt to climate change.

In 2008, ICS initiated a major research program on natural disasters, including those caused by weather and climate. The study is designed to help countries plan for disasters, and to determine changes in lifestyle that will reduce loss of life and lessen economic impact of disasters. The study will also research how man may cause or increase the extent of disasters. Weather and climate disasters include events such as droughts, floods, hurricanes, tornados, cyclones, mudslides, and pollution. Another major study initiated in 2008 is to research the human impact on Earth's life-support systems. This study is to fill in the gaps in the knowledge about the global ecosystem, including the climate.

In each regional office, there are programs about climate or the ecosystem. In the Africa region, one of the four science plans is on global environmental change. The plan includes both climate change and adaptation to climate change. The plan is to develop projects in six areas: degradation of land and biodiversity and how it affects humans, the effect of climate change on rainfall, food system resilience, water resources, atmospheric change, and the effect of the ocean on Africa. The Latin

America and the Caribbean regional office held a conference on sustainable energy and another on the world's geosphere/biosphere. The Asia regional office held a meeting to form plans for the coastal cities to adapt to climate change. Other meetings were for sustainable energy and changes in the ecosystem. Training sessions were held for individuals to learn to study environmental problems.

International Geosphere-Biosphere Programme

- **Category:** Organizations and agencies
- **Date:** Established 1987
- **Web address:** http://www.igbp.kva.se

• Mission

The International Geosphere-Biosphere Programme (IGBP) is an international research program devoted to the study of global environmental change, with a focus on the interactions between the solid Earth and its living organisms. The IGBP's purpose is to work toward improving the sustainability of Earth's biosphere. A central secretariat, hosted by the Royal Swedish Academy of Sciences in Stockholm, Sweden, coordinates IGBP's scientific program. The organization has seventy-six member countries and international project offices in North America, Europe, and Australia.

The IGBP studies the interactions occurring among Earth's natural biological, chemical, and physical processes and the effects human activities have on these processes. Sponsored by the International Council for Science, the IGBP collaborates with other programs to gain and disseminate knowledge regarding global environmental change and to make recommendations regarding how best to respond to it. The IGBP, which emphasizes networking and integration, seeks to enhance scientific understanding by encouraging scientists to transcend disciplinary, institutional, and political boundaries in their research.

The International Council for Science established the IGBP in 1987. The international scientific community had recognized that the research efforts of a single country, region, or scientific discipline would not yield sufficient understanding of global environmental change; there was a clear need for international collaborative research. Key findings from the IGBP's initial studies (IGBP-I, 1990-1999) provided the foundations for a second phase of research (IGBP-II, 2004-2013). Phase II, like Phase I, concerns the Earth systems of land, ocean, and atmosphere and the interfaces among them.

• Significance for Climate Change

As of early 2009, IGBP research comprises nine projects: four focused on the major Earth system components of land, ocean, and atmosphere; three on the interfaces between those components (land-ocean, land-atmosphere, and ocean-atmosphere); and two on system-wide integration (Earth system modeling and paleoenvironmental research). The Global Land Project (GLP), cosponsored by the International Human Dimensions Programme on Global Environmental Change (IHDP), looks at how humans transform terrestrial ecosystems and landscapes. The Global Ocean Ecosystem Dynamics (GLOBEC) project studies the effects of global change on the abundance, diversity, and productivity of marine populations. Integrated Marine Biogeochemistry and Ecosystem Research (IMBER) studies how marine ecosystems and biogeochemical cycles react to global change over time periods ranging from years to decades.

Both marine projects are cosponsored by the Scientific Committee on Oceanic Research (SCOR). International Global Atmospheric Chemistry (IGAC), a project cosponsored by the Commission on Atmospheric Chemistry and Global Pollution (CACGP), focuses on the atmospheric chemistry issues facing society. The project seeks to gain an understanding of the role of atmospheric chemistry in the Earth system while determining how changing regional emissions and depositions, long-range transport, and chemical transformations affect air quality.

Land-Ocean Interactions in the Coastal Zone (LOICZ) studies the coastal zone—an interface where land, atmosphere, and ocean interact—as a key player in the functioning of the Earth system. The project is cosponsored by IHDP. The Integrated Land Ecosystem-Atmosphere Processes Study (iLEAPS) concerns the physical, chemical, and biological processes that transport and transform energy and matter at the land-atmosphere interface. These processes are tightly coupled and highly responsive to climate change. The Surface Ocean-Lower Atmosphere Study (SOLAS) looks at how the key biogeochemical-physical interactions and feedbacks between the ocean and atmosphere affect and are affected by climate and environmental change. Cosponsors are CACGP, SCOR, and the World Climate Research Programme (WCRP).

System-wide integration projects include Analysis, Integration, and Modelling of the Earth System (AIMES) and Past Global Changes (PAGES). AIMES focuses on the use of models and observations in reaching a better and more quantitative understanding of the role human action plays in biogeochemical cycles. PAGES supports study of the Earth's past environment as a means for making sound predictions regarding the future.

In addition to its project cosponsors, IGBP collaborates with a number of other international science organizations. IGBP participates in global assessments such as the Intergovernmental Panel on Climate Change (IPCC) and the Millennium Ecosystem Assessment (MEA), and it is part of the Earth System Science Partnership (ESSP).

In July, 2001, during the Global Change Open Science Conference in Amsterdam, the Netherlands, IGBP joined IHDP, WCRP, and the international biodiversity program DIVERSITAS (all ESSP members) to issue the Amsterdam Declaration on Global Change. The statement acknowledged the increasing effect of human activity on food, water, clean air, and the environment and likened some anthropogenic changes to great natural forces in terms of their extent and impact. Warning of the possibility of abrupt, irreversible, and inhospitable environmental changes in response to human actions, the declaration called for a new, multidisciplinary, multinational, and multicultural system of global environmental science to respond to the complex challenges of global change with good and ethical stewardship of the Earth. IGBP was one of the convening organizations of the Second Symposium on the Ocean in a High-CO_2 World, held in Monaco in October, 2008.

International Human Dimensions Programme on Global Environmental Change

- **Category:** Organizations and agencies
- **Date:** Established 1996
- **Web address:** http://www.ihdp.unu.edu

• Mission

The International Human Dimensions Programme (IHDP) is an umbrella organization that funds and coordinates studies relating to the human impact on all biological, physical, and chemical systems and how those impacts relate to patterns of human social organization. An international, interdisciplinary science program specializing in a social science perspective on global change, it is a joint program of the International Council for Science (ICS), UNESCO's International Social Science Council (ISSC), and the United Nations University (UNU).

All IHDP projects address three major questions:

- How do human lifestyle choices and patterns of consumption contribute to global environmental change?
- How are humans affected by changes in the natural environment?
- How can humans reduce their negative effects on natural ecosystems necessary to support continued human existence?

• Significance for Climate Change

IHDP brings together scientific researchers as well as social scientists and political and economic policy makers in order to consider all aspects of human contributions to pressing environmental problems, probable consequences of continued anthropogenic stresses on a variety of ecosystems, and possible response to mitigate and even eliminate some anthropogenic environmental problems. All IHDP programs share a mission to help translate scientific research on environmental change into practical advice for policy makers. These programs and research projects may be local, regional, or global in scale.

IHDP administers six core scientific research projects. Earth System Governance (ESG) studies anthropogenic changes, local to global, in all physical and biological systems on the planet. The overarching goal of all research projects under ESG is to construct appropriate sustainable development responses that can actually be implemented. Some finds of sponsored research projects are published in the journal *Climate and Development*, as well as in the IHDP publication *Institutions and Environmental Change*.

Global Environmental Change and Human Security (GECHS) studies the impact of environmental changes on vulnerable human populations primarily located in the developing world. Flooding, drought, soil erosion, conflicts over access to natural resources, and human population issues are all research topics sponsored by GECHS, which publishes its research reports in the journal *AVISO*. GECHS encourages cooperation and communication between climate researchers and political leaders in the developing world.

The Global Land Project (GLP) sponsors projects on local and regional levels to study how human interact with both land and water-based systems. GLP projects also give direction on how humans might interact with those systems in more sustainable ways. The GLP projects also consider the negative impact global economic changes produce on local and regional environmental systems, primarily in the developing world.

Industrial transformation (IT) research initiatives look for ways to reduce the negative impact technology developments will continue to have on the natural environment, specifically in the developing world. IT-sponsored projects target energy production, distribution and usage, food production and consumption patterns, and urban development.

Land-Ocean Interactions in the Coastal Zone (LOICZ) is more narrowly focused than the other IHDP core projects. LOICZ research projects focus on coastal communities that are among the first to feel negative effects of environmental changes in the form of soil erosion, depletion of fishing stocks, increased water salinity, overdevelopment, decreased freshwater supplies, and increased vulnerability to catastrophic weather events.

Urbanization and Global Environmental Change (UGEC) projects study urban planning and lifestyle choices as well as patterns of consumption of energy, food, and goods and services. The research results are then used to suggest planning policies that would allow urban areas to become more environmentally sustainable and reduce the impact of environmental change on the urban poor.

In addition to the six core scientific research projects and their subprojects, IHDP shares joint responsibility with Earth System Science Partnership (ESSP) to promote research into climate change, agricultural responses and food security. IHDP also funds smaller pilot projects that allow younger researchers opportunities to secure funding and collaborate on an international scale. The goal of many of the pilot projects is to seek ways to reduce carbon production. IHDP also participates in a variety of research networks. The four primary research networks include the Mountain Research Initiative (MRI), Population and Environment Research Network (PERN), System for Analysis Research and Training (START), and Young Human Dimensions Researchers (YHDR) including students associated with research teams. The development of research networks allows researchers in developed countries to share funding, access to research information, and expertise with colleagues in the developing world. IHDP specifically funds research projects on issues of concern to societies in both the developed and developing world.

In its second decade, 2006-2016, IHDP looked forward to increased funding for pilot projects in order to increase the scale of the projects until some could become additional core scientific projects. As environmental concerns become more urgent and the capacity and economic feasibility of sustainable technologies more widely available, IHDP anticipates playing a wider, more public role in drafting policy positions related to environmental change and its impact on the human community.

International Institute for Applied Systems Analysis

- **Category:** Organizations and agencies
- **Date:** Established 1972
- **Web address:** http://www.iiasa.ac.at

• Mission

The International Institute for Applied Systems Analysis (IIASA) is an interdisciplinary organization founded in 1972 with the aim of promoting East-West cooperation during the Cold War. It now devotes its efforts to complex systems problems of international or global scope. Through its various programs, IIASA conducts research into major economic, demographic, social, and environmental issues, including global climate change. The scope of IIASA research projects is huge, beyond the capabilities of any one country or national research institution to manage. IIASA research projects collect massive amounts of data on a variety of factors, such as the connection between climate change and air pollution, and then build computer simulations and statistical models based on various "what if" future scenarios. Since the days of its founding in the midst of the Cold War between the United States and the Soviet Union, IIASA has maintained a position of strict political neutrality in its research projects. At the same time, IIASA tries to build scientific consensus in order to present credible research findings to technical advisors for political policy makers.

IIASA is financially supported by contributions from fifteen member countries in both the developed and the developing world. In the past, IIASA conducted research projects of topics requested by member countries. Increasingly, however, IIASA is shifting its expertise in quantitative modeling and computational technologies to focus on problems of more urgency for the developing world. This allows IIASA to assist in the construction and implementation of policies relevant to global change. Most research projects focus on one or more problems and interconnections between climate policy, energy production and consumption, water management, agricultural policy, sustainable development, pollution studies, and the interplay between environmental and economic policies. IIASA devises models to reduce future uncertainties about the consequences of current policy options. IIASA divides its core research projects into three very broad categories: energy and technology, population and society, and environment and natural resources.

• Significance for Climate Change

Since the 1990's, IIASA has helped develop models of global energy production, consumption, and pollutant emissions. As developing economies become increasingly industrialized, IIASA provides information on the economic and environmental consequences of these changes, particularly how rising air pollution will affect the ability of boreal forests to function as carbon sinks to mitigate negative impacts of climate change. IIASA projects also provide models to forecast the environmental impact of changes in the global economy, particularly as previously centrally planned economies move in the direction of free-market economies.

IIASA projects under this heading study and analyze the very complex interdependence among population groups, economic development, and environmental impact. Computer simulations indicate the probable social, political, economic, and environmental consequences of probable population projections. Water management, long-term food security, biodiversity, and other environmental impacts related to population change are forecasted and analyzed. Research projects in this category also study age disparity among various national populations and what economic scenarios will be necessary to fund the social security, pension obligations, and health care costs of those populations.

IIASA research projects in this category study all aspects of the human impact on the natural environment, including climate change. Since its foundation, IIASA has been involved in forestry research and the impact of land use and land cover change research. IIASA continues its long-range studies on the global management of boreal forest areas and its impact on global carbon emissions. Recently IIASA projects have focused on cost-effective methods to reduce air pollution, particularly in the developing world. One of the larger projects is the Transboundary Air Pollution Project with India and China. Increasingly, IIASA addresses regional environmental problems in order to provide a scientific basis upon which countries can negotiate specific reductions in carbon dioxide, sulfur dioxide, and other greenhouse gas emissions that have a negative impact on the global climate.

All IIASA projects study global change, whether that change is demographic, political, economic, or environmental. Through increasingly sophisticated and comprehensive computer simulations, IIASA provides scientifically credible information on global greenhouse gas emissions, energy supply and demand, population increases and migration patterns, land use change, and transboundary air and water pollution. It then forecasts probable consequences of both current policies and various policy options to mitigate the harmful effects of anthropogenic impacts on all aspects of the natural environment.

International Policy Network

- **Category:** Organizations and agencies
- **Date:** Established 2001
- **Web address:** http://www.policynetwork.net

• Mission

A nongovernmental, nonpartisan organization that is charity-based in the United Kingdom and a nonprofit in the United States, the International Policy Network (IPN) highlights the dangers of linking environmental regulations to trade rules. The IPN claims to achieve its vision by "promoting the role of market institutions in certain key international policy debates: sustainable development, health, and globalization and trade." In the area of sustainable development, the group takes the stand that, too often, sustainable development involves policies that may, in fact, perpetuate environmental problems and poverty. Although acknowledging a relationship between health, wealth, and a clean environment, IPN believes that sustainable development policies focus too much on sustainability at the expense of development.

To achieve its mission, IPN pursues a number of activities: It supports individuals and groups who profess similar beliefs with Web sites, advice, and small grants. It sponsors workshops, seminars, and conferences and cooperates with groups to produce books, monographs, and articles that express opinions on issues for the media. At international conferences, it helps coordinate the participation of experts in various fields that relate to the interests of IPN and promotes its partners among the news media.

In the area of health, IPN addresses issues such as access to medicine, barriers that reduce the spread of infectious diseases, and the impact of regulation on modern technologies related to nutrition and health. The group feels that the policies of governments and other agencies are often enthusiastic but not practical, thus wasting funds and labor hours on ill-conceived initiatives that ultimately cost lives. In the area of trade, IPN espouses the benefits of freedom to trade; trade is considered fundamental to eliminating poverty and gaining economic freedom. The organization also, however, sees as dangerous the linking of environmental and labor regulations with trade rules. IPN bases its vision of sustainable development on achieving both environmental and human well-being through eliminating poverty and promoting progress.

- **Significance for Climate Change**

IPN released a report in 2004 saying "climate change is 'a myth'" and that warnings of environmental disaster due to climate change are "fatally flawed." The activities of the organization are focused on resisting attempts to stave off global warming at the expense of economic interests.

International Union for Conservation of Nature

- **Categories:** Organizations and agencies; environmentalism, conservation, and ecosystems
- **Date:** Established October, 1948, as International Union for the Protection of Nature; name changed to International Union for Conservation of Nature and Natural Resources in 1956
- **Web address:** http://www.iucn.org

- **Mission**

The International Union for Conservation of Nature (IUCN), formerly the World Conservation Union, is a hybrid organization of states, state agencies, and nongovernmental organizations that facilitates and encourages the conservation and equitable use of nature and natural resources. It was founded in 1948 and has gone by several names in its history (recently reverting from the World Conservation Union to its former title, the International Union for Conservation of Nature). Its Secretariat is headquartered in Gland, Switzerland, but it has a staff of one thousand experts in sixty nations which coordinates several theme-based programs that focus on issues such as forests, gender, and business and biodiversity. Under the IUCN are six Commissions, the most prominent being the Species Survival Commission, which updates the Red List of threatened species; the Commission on Environmental Law, which has facilitated negotiations on several conservation treaties; and the World Commission on Protected Areas. The IUCN is supported by over eleven thousand volunteer scientists in over 160 nations.

- **Significance for Climate Change**

The IUCN position on climate change is that nations should reduce greenhouse gas emissions by 50 percent below 1990 levels by 2050; use ecosystem-based management to mitigate and adapt to warming; and prioritize efforts on behalf of vulnerable peoples and ecosystems. Its research and communications emphasize linkages between conservation, energy use, globalization, and climate change. Internally, much of this work is coordinated by its Climate Change Initiative.

In its role as an expert adviser, the IUCN has advised members to the UN Framework Convention on Climate Change (UNFCCC), the Convention on Biological Diversity, and other agreements on climate change mitigation, adaptation, and impacts, *inter alia*. It has alerted parties to the UNFCCC that if global average temperature were to rise 2° Celsius or more above preindustrial levels, massive extinctions and profound ecosystem changes would result. As a complement to its Red Lists, the IUCN has calculated the number of species that are currently of favorable conservation status that would be endangered by global warming (for example, 51 percent of currently unthreatened corals could be endangered by climate change).

The IUCN is one of the most prominent international organizations drawing attention to the linkages between warming, conservation, and human well-being. It assesses and promotes natural resource management practices that would aid mitigation and adaptation to global warming. For example, it advocates inclusion of REDD (Reduced Emissions from Deforestation and Degradation) in forthcoming climate agreements.

In conjunction with other organizations, the IUCN has worked to mainstream issues that have been sidelined by the dominant discussion, such as the role of indigenous peoples in climate policy and the relationship between gender and natural resource use.

International waters

• **Category:** Laws, treaties, and protocols

International waters are less regulated than national waters, allowing environmentally damaging activities to occur. In addition, as global warming continues, changes in shorelines and the melting of the Arctic ice cap may create international complications.

• Key concepts

exclusive economic zone: a zone extending about 320 kilometers from a nation's shore in which all economic rights are granted to that nation

freedom of the seas: the principle that outside of water adjoining nations' shorelines, all nations have the right of free passage and use of the ocean's resources

territorial waters: areas within bodies of water that are within a nation's borders and subject to all laws and regulations of that nation

United Nations Convention on the Law of the Sea: an international agreement outlining the rights of nations regarding territorial waters, economic zones, and rights of passage

• Background

Nearly three-fourths of the world's surface is covered by water. Each terrestrial or oceanic ecosystem has developed depending upon the availability of a certain type and quantity of water. Major bodies of water and the atmosphere work together to form a circular system. The atmosphere affects glaciers, ice caps, rivers, lakes, seas, and oceans, while simultaneously these bodies of water affect the atmosphere. Changes in one directly result in changes in the other. Because international waters lie outside national boundaries, caring for them is often a low priority.

• Pre-Twentieth Century History

With the Portuguese and Spanish explorations of the fifteenth century, Europeans began to have aspirations for global dominance. New claims over the ocean were put forward, first by Portugal and Spain, which were quickly followed by the British and Dutch. In the early seventeenth century, to reduce conflict, Dutch jurist Hugo Grotius put forward the freedom of the seas theory, that all oceans and adjoining seas could be used by everyone for any purpose. By the beginning of the eighteenth century, this principle was accepted by all European nations, with the provision that each nation controlled the first 4.8 kilometers of water adjacent to its shoreline. In certain strategic straits, all vessels were allowed to travel. This was the norm for the next two hundred years. The assumption during this period was that the oceans were so vast that nothing people could do would cause any harm to them.

• Changes in the Twentieth Century

By the dawn of the twentieth century, it was becoming clear that not all the ocean's resources were inexhaustible. Not wanting to lose resources, in 1945 the United States claimed the entire continental shelf and all the water above it. Because of this, other countries extended their territorial claims to 19.3 kilometers off their coasts. The United Na-

A Chinese natural-gas drill begins operations in disputed territory of the East China Sea very near the border of Japan's exclusive economic zone in September, 2005. (AP/Wide World Photos)

tions organized the Conference on the Sea in 1958. Two more conferences were held, leading to the negotiation of the United Nations Convention on the Law of the Sea. This agreement recognized new economic realities, as well as assigning responsibility for preserving the ocean's resources to all nations. A 19-kilometer territorial limit from the shoreline was formally recognized, as well as the 320-kilometer exclusive economic zone. The country controlling a given economic zone was formally charged with protecting the oceanic environment within it. Free navigation by all countries was allowed in this zone, in international waters, and through strategic straits. It was formally agreed that in international waters, all nations would share both the right to use environmental resources and the responsibility to protect them.

• Effects of Climatic Changes on International Waters

The assumption that human actions can have little effect upon oceans has been discarded. The direct effect of Earth's oceans upon the climate has become well known, as the global effects of weather patterns such as the El Niño-Southern Oscillation and La Niña have become understood. In the Northern Hemisphere, most of the Atlantic Ocean and much of the western Pacific Ocean increased in temperature by at least 1° Celsius between 1990 and 2004. In some locations, water temperatures have increased by more than 2° Celsius. One of the most visible maritime biological changes is the bleaching of coral and the slow destruction of coral reefs caused by changes in both temperatures and currents.

The currents are a necessary part of the ocean's ecosystem. They help equalize the salinity and other aspects of seawater. Some parts of the ocean are becoming fresher, and some are becoming more acidic. Aquatic life is often more sensitive to subtle environmental changes than are land-based creatures, and changes in their habitats can be devastating both for sea creatures and for the humans that depend on them.

The melting of the polar ice caps also poses potential problems for island nations and for some continental nations that have large amounts of territory close to sea level. Many of the islands in the Pacific Ocean are not very high above sea level. With the projected sea-level rise during the twenty-first century, these islands face the prospect of losing much of their land. This loss will place great pressure on their inhabitants to take drastic steps to survive. It may become necessary for other nations to accept immigrants from these areas.

• Context

The oceans constitute an extremely complex system in themselves, and that system is merely a component in the larger and more complex global climate system. The full effect that climate change will have upon international waters remains unclear. Because historically much less study has been done in the world's oceans than on the land, scientists do not have the breadth of knowledge needed fully to understand physical and biological oceanic systems. Thus, it cannot be said with certainty when climatic changes will have catastrophic effects in maritime ecosystems. However, it is certain that those effects will not respect national boundaries. So much of the oceans lie outside of territorial waters that efforts to protect them must take place largely in international waters.

Climate change is already causing dramatic changes in places such as the Arctic Ocean. This not only affects the plants and animals in the region, but it is also stirring up new conflicts among the nations that border this ocean. Once again, the desire for economic supremacy is pushing nations to enforce their rights in the territorial and international waters of the Arctic. For example, in 2008, Norway detained Russian fishing trawlers that they claimed were in their territorial waters, while Russia claimed the area was open to all nations. Thus, climate change is causing not only physical changes but political changes as well. As changes in other international waters become more pronounced, similar conflicts might arise over resources in those areas that countries believe are vital to their well-being. The effect of climate change on international waters can directly touch people in all parts of the world.

Inter-Tropical Convergence Zone

• Category: Meteorology and atmospheric sciences

• Definition

The Inter-Tropical Convergence Zone (ITCZ) is a low-pressure belt located near and parallel to the Earth's equator, within a few degrees of latitude. Because it is a low-pressure belt and located in the vicinity of the equator, near-surface winds on both sides of this belt tend to converge into the belt. A band of clouds and accompanying precipitation is associated with the ITCZ, which can therefore be easily identified from satellite pictures.

The wind on the north side of the ITCZ comes from the northeast (blowing toward the southwest), and therefore, by meteorological convention, is called the "northeasterly." The obverse wind on the south side of the ITCZ is the "southeasterly." The northeasterly and southeasterly are also historically called "trade winds," because explorers, navigators, and merchant fleets once used these winds to sail to many tropical regions for trade and adventure. Thus, the ITCZ is the belt where the trade winds meet.

The ITCZ migrates slightly, oscillating across the equator with the change of seasons. It is primarily located north of the equator, although during winter in the Northern Hemisphere it sometimes moves to the south of the equator. The ITCZ can often be well organized, in the sense that the low pressure, clouds, and precipitation associated with the ITCZ form a solid band structure and make almost an entire circle around the globe. However, this well-organized structure can break down from time to time. When it breaks down, the ITCZ becomes separated into several blocks or a few segments.

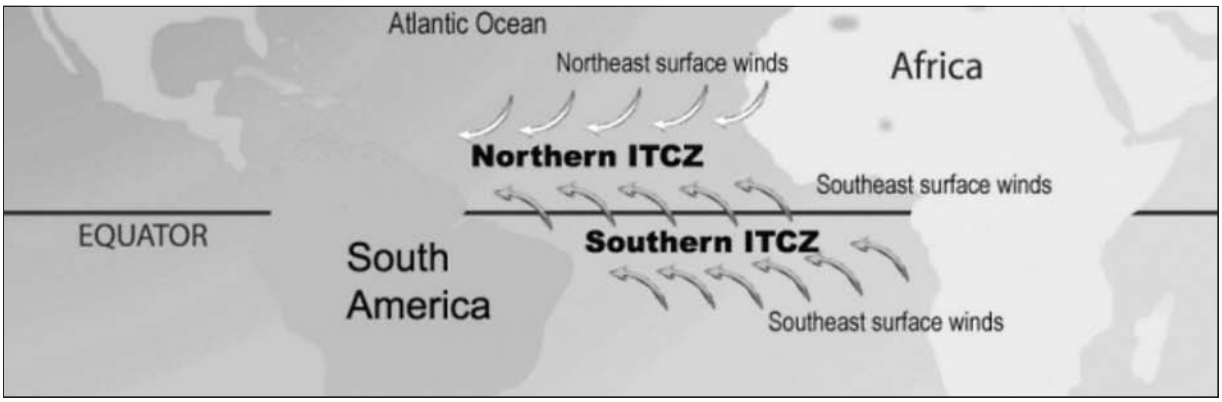
• Significance for Climate Change

The ITCZ is an important atmospheric phenomenon in tropical meteorology. In meteorology, a low-pressure center always draws air flows around it coming in, causes convection, and therefore generates a weather system. The ITCZ serves precisely this role. As the trade winds converge into the low-pressure belt, air starts to ascend to higher altitudes.

Because the ITCZ is typically formed over the tropical oceans, the air in the zone is very moist. The ascending of this moist air in the ITCZ typically leads to cloud formation as the air condenses at higher, colder altitudes. As the air continues to rise and condense, water will eventually precipitate back to the surface. In the ITCZ, this asending stream of tropical air forms the ascending branch of the Hadley cell. This air-circulation cell ascends in the tropics as a result of convection in the ITCZ, moves outward toward the poles, descends in the subtropical regions, and returns inward toward the equator at lower altitudes.

Hadley circulation thus typically transports warm, moist, tropical air to higher latitudes at upper levels. The air gradually cools and dries out as it travels poleward. In the subtropics, about 30° latitude north and south of the equator, the air begins to descend. This effect is believed to cause many of the large deserts in the subtropics, such as the Sahara Desert, because the descending air has lost most of its moisture to precipitation before it descends. Thus, the ITCZ plays an important role in global atmospheric circulation and global climate.

As a driving engine of global atmospheric circulation, the ITCZ plays a great enough role in Earth's climate that any change in the position and intensity of the ITCZ may have significant effects upon the climate. The ITCZ itself comprises the planet's deepest convective cloud systems with the



The northern Inter-Tropical Convergence Zone is created by the collision of the northern and southern trade winds, whereas the southern Inter-Tropical Convergence Zone results from two groups of southern winds squeezing together. (NASA-JPL) most frequent thunderstorm activities and produces the greatest rainfall on the Earth. The Hadley circulation, driven in party by the ITCZ, has a profound impact on a global scale. For example, the intensification of the ITCZ may cause more evaporation of water vapor from tropical oceans and enhance the transport of water vapor to high latitudes.

Many scientists believe that the ITCZ may intensify and produce even more precipitation with the increase of global surface temperature. The position, movement, and intensification of the ITCZ are also influenced by various climate regimes, such as the El Niño-Southern Oscillation and La Niña events. Scientists have also shown that when the ITCZ breaks down, some of its segments can form into tropical disturbances, the initial stage of tropical cyclones, hurricanes, and typhoons. However, it is still unclear whether global warming can cause more frequent breakdown of the ITCZ, thereby producing more tropical storms, although scientists do believe that hurricane intensity will increase as the climate warms.

Invasive exotic species

• **Categories:** Animals; plants and vegetation

With climate change come changes in species distributions. Invasive exotic species in particular can have significant effects upon other species and the structure and function of entire ecosystems.

• Key concepts

exotic species: a species found in an area where it is not native

habitat: an area normally inhabited by a particular species

invasive species: a species whose population grows out of control and negatively affects other species

niche: the role of a species within its ecosystem

preadaptation: the ability of a species to move into a new ecosystem or to assume a new niche as a result of adaptations it already possesses

• Background

An exotic species is a creature found in an area to which it is not native. Species that succeed after arriving in new areas, whose population growth is not limited by natural controls, and that negatively affect other species in their new ecosystems are considered invasive exotics. Such species often evince preadaptations for surviving differences in climate, so global climate change increases the threat they pose of rapidly invading new ecosystems.

Many exotic plants can only exist in new areas with special care and conditions, such as soil fortified with nutrients, a special watering regime, artificial lighting, or protection from cold. Many landscape plants, agricultural plants, domesticated livestock, and pets are exotic plants or animals that benefit humans when brought to new areas. Invasive exotic species spread uncontrollably and become problems for native species and humans. Often, their invasive potential is not apparent until long after they have become established in a new niche.

• Exotics and Global Warming

Global warming is one aspect of the more complex phenomenon of global climate change, and the bigger picture of climate change must be kept in mind relative to invasive exotics. Among other attributes, global climate change can include changes in temperature ranges; timing and amount of precipitation; wind patterns; frequency and intensity of storms; and frequency, intensity, and timing of lightning-started fires. Such changes can dramatically influence living creatures and favor invasive exotics.

Invasive exotic species are often adapted to be effective travelers and colonizers. Many plants can travel on animals, using hooked spines or sticky hairs that allow them or their seeds to adhere to clothes or fur. Lizards and insects may readily enter small openings in packing crates or suitcases and are inadvertently taken to new places. Other plants and animals can be dispersed over great distances by wind. Seeds often survive in the digestive tracts of animals that consume their fruit and are thus dispersed to distant locales. Wood pallets and goods, necklaces made with exotic seeds, and handicrafts made from palm leaves can contain insects and other plant pests or diseases that emerge after arrival at a new place.

Most creatures on the move do not survive the trip. Where they land is unpredictable, and most die, unable to cope with their new environment. They may be unable to reproduce for lack of a mate or appropriate breeding conditions. Those that survive are often adaptable and reproduce rapidly.

• Biodiversity and Interspecies Relationships

Biodiversity is a result of adaptations to local conditions that hone the survival potential of each species. An ecosystem includes a community of living organisms interacting with their physical environment. The species fill unique niches, together fitting into the ecosystem like a hand fits into a glove. Each finger represents a species, and each has a defined space and role within the ecosystem. In a stable ecosystem, species work together smoothly. When a new species is introduced, it is like trying to fit a sixth finger into a five-fingered glove. The exotic species may displace a native species and take its place within the glove, or it may constrict the population of native species so that it carves out a new space within the glove. It may alter the glove in such a way as to form a suitable place in which to exist. These habitat alterations may affect the survival of native species and the ability of the ecosystem to function appropriately. Adaptation to specific conditions is beneficial only so long as those conditions prevail. Changes in the physical environment or in the species composition of an ecosystem can cause minor to major disruptions.

Global climate change reshuffles the deck of biodiversity, and new winners and losers are likely to emerge. Some species hold better cards than others: They are preadapted to specific changes in their ecosystems. Exotic species are often among those; they have already overcome numerous obstacles to establish themselves in their new habitat. Native species, especially specialists with specific adaptations to an existing environment, are often unable to adapt to changed conditions.

• Why Exotics Become Invasive

When exotic plants and animals move or are moved from their native habitat to a new area, they often leave competitors, predators, and diseases behind, allowing their populations to grow unimpeded. If a species produces many offspring and has an easy means of dispersing, its population can grow rapidly, displacing, disrupting, or eliminating other species. In such circumstances, it has become invasive. Native species can become invasive also, but only if changing conditions or human impacts eliminate their natural controls. Invasive exotic species are found everywhere in the world.

• Prognosis

The melting pots of Florida, California, and Hawaii are experiencing severe problems from exotic invasives. They have subtropical climates that favor introduction of exotic plants and animals. Although often for local use, many such plants are also farmed for markets in more northern areas, where they might only survive indoors as pets, house plants, or outdoor perennial plants. Through the pet trade, many species of tropical fish, lizards, and parrots are breeding in Florida.

Interactions among exotics often exacerbate their effects upon an ecosystem, as introduced plants provide important food sources for introduced animals. In Florida, consumption of ornamental plants by exotic green iguanas (*Iguana iguana*), of plants and small animals by black spiny-tailed iguanas (*Ctenosaura similis*), and of animals as large as small dogs and cats by two-meter-long Nile monitors (*Varanus niloticus*) are regional problems that could spread northward with global warming. So, too, could the Burmese python (*Python molurus bivittatus*)—at up to six meters long and weighing ninety kilograms, one of the largest snakes in the world. It has been estimated that this snake could survive in the wild as far north as Washington, D.C. It presently breeds in the Everglades ecosystem, where more than two hundred have been captured. Sources for this population include pets lost or released by owners and some whose escapes were facilitated by hurricane-related damage.

Exotic plants once treasured for their blossoms or other attributes have invaded areas throughout North America and have the potential to spread farther north as the climate warms. Purple loosestrife (*Lythrum salicaria*), a native of Eurasia and widespread as an ornamental, replaces native plants and reduces habitat quality for wildlife as it forms dense stands in wetlands across North America. The Australian paperbark tree (*Melaleuca quinquefolia*) and Brazilian pepper (*Schinus terebinthefolius*), originally introduced as ornamentals, have formed dense monocultures in what had been habitats to a diversity of native plants and animals in south Florida. They are poised to spread northward as the climate warms. Kudzu (*Pueraria lobata*) vines, introduced from Asia to Gulf coast states in the 1800's to control erosion, often blanket ground, shrubs, and trees and are already expanding northward, following mild winters.

Major invasions of marine environments are also occurring around the world, as marine life is transported in the ballast water of ships. These invasions will alter natural ecosystems even further, as global climate change alters the temperature and salinity of the oceans, creating new opportunities for invaders.

Kudzu grows over abandoned vehicles in Tennessee. The invasive plant is extremely hearty and will grow over almost anything that is not moving. (©iStockphoto.com/Roel Smart)

• Context

As ecosystems are altered as a result of global climate change and enhanced invasions of exotic plants and animals, dramatic shifts in the populations of native species will result, causing the extinction of many species that are unable to compete favorably with their new neighbors. Shifts in ranges will vary from species to species, depending on their dispersal abilities, breeding success, and a diversity of habitat needs. A warmer climate might favor extinction of cold-adapted species and northward shifts for southern species, but if favored food plants do not shift at the same time or if a new range includes a predator or disease not previously encountered, the move could mean extinction.

Iran

• **Category:** Nations and peoples

• **Key facts**

Population: 66,429,284 (July, 2009, estimate)

Area: 1,628,554 square kilometers

Gross domestic product (GDP): $842 billion (purchasing power parity, 2008 estimate)

Greenhouse gas (GHG) emissions in millions of metric tons of carbon dioxide equivalent (CO_2e): 288 in 1990; 480 in 2000

Kyoto Protocol status: Ratified 2005

• **Historical and Geopolitical Context**

In 1979, millions of Iranians succeeded in ousting Muhammad Reza Shah Pahlavi (1941-1979), the Shah of Iran and son of Reza Khan, who came to power in 1921 via a coup. While the Shah was popular in the West, some believe he tried to modernize Iran too rapidly and did not adequately adapt his political institutions to the economic and social changes that ensued. Inspired by hopes for democracy, economic prosperity for all classes, gender equality, and a leadership that would not allow Iranian culture to be swallowed up by the West, many Iranian women joined the revolt that stunned the world. The Iranian Revolution was led by Ayatollah R. Khomeini, who had been living in exile in Paris, France.

Today, the Islamic Republic of Iran is a unitary Islamic republic with a sole legislative body, the Islamic Consultative Assembly. Since 1989, the spiritual leader of Iran or Rahbar has been Ayatollah Sayyed Ali Khamenei. The capital of Iran is Tehran, and Farsi (Persian) is the official language. In 2000, crude and refined petroleum composed 85.4 percent of the nation's exports, which totaled more than $28 billion. Trading partners included Japan, China, Italy, and Taiwan. Petroleum and natural gas accounted for 57 percent of $181 trillion in revenues. Since 2005, Mahmoud Ahmadinejad has served as president of the Republic of Iran. While relations with the United States have been shaky, newly elected U.S. president Barack Obama emphasized the importance of communicating with Iran, a country the George W. Bush administration had called "dangerous."

In 2006, the International Atomic Energy Agency (IAEA) demanded that Iran halt uranium enrichment for its nuclear program, which Iran claimed was to be used for peaceful purposes. While Obama eschewed Iran's pursuit of nuclear weapons, he said "it is important for us to be willing to talk to Iran, to express very clearly where our differences are, but where there are potential avenues for progress."

• Impact of Iranian Policies on Climate Change

Iran ratified the Kyoto Protocol in 2005. The decision was endorsed by the Guardian Council, which discussed Iran's plan to adhere to the U.N. Stockholm Declaration regarding sustainable development; the Stockholm Declaration put forth principles that might guide the world's nations to preserve and enhance the human environment. As such, the Office of Climate Change in Iran's Environmental Protection Agency released a report stating that since the Kyoto Protocol came into force in February, 2005, new activities designed to decrease greenhouse gas (GHG) emissions were occurring under the U.N. flexible mechanisms program of the protocol. In addition, it was thought that there was a need to immediately sign the protocol, because an upcoming summit in 2005 was to focus on technology transfer and financial aid to be given by developed, Annex I nations to developing, non-Annex I nations, and only parties to the Kyoto Protocol could participate.

• Iran as a GHG Emitter

Iran is ranked eighteenth of the highest GHG emitters. Developing nations, all of whose emissions rose during the first decade of the Kyoto Protocol, include China (now the top GHG emitter), India, Brazil, Mexico, South Korea, Indonesia, South Africa, and Iran. These eight nations accounted for 30.1 percent of global GHG emissions in 2000; the share of GHG emissions was 40 percent for the developing, non-Annex I countries. The developing countries have been increasing their shares; in 1990, the relative share was 32 percent. For the year 2000, twelve of the top twenty countries were Annex I countries, including seven of the top ten emitters. In 2000, the Annex I countries accounted for about 60 percent of the top-twenty GHG emissions. The number-one emitters of each group were the top two emitters overall: the leading developing, non-Annex I country, China, and the leading developed, Annex I country, the United States, now the second highest of the top-twenty GHG emitters. Together, China and the United States account for over one-third of total global GHG emissions.

While the Organization of Petroleum Exporting Countries (OPEC) Gulf States have the highest GHG emissions, data from 2000 show that—of the top twenty emitters—those with highest per capita emissions were the Annex I countries. Australia, the United States, and Canada ranked fifth, seventh, and ninth, respectively. Their per capita emissions (7.0, 6.6, and 6.1 metric tons per person) were approximately double the emissions of the highest-ranked developing country in the top twenty (South Korea, at 3.0 metric tons), and they were six times those of China (1.1 metric tons). Of note, the population density of Iran is 16 persons per square kilometer in a country that is relatively small.

• Summary and Foresight

It is indeed a paradox that OPEC countries concerned with manipulating the production of petroleum products so as to affect global financial markets have expressed concern with green energy. In January, 2009, Iran inaugurated its first solar energy power plant, adding a modest 250 kilowatts of solar energy to the country's energy grid. The power plant uses parabolic mirrored troughs to gather sunlight where it is used to produce steam and generate electricity. This solar thermal plant is part of 4,075 small-scale solar thermal installations throughout Iran, which comprise 3,781 solar water heaters for residential use, and 294 public baths that are heated with solar thermal energy. Putting an economic value on renewable resources makes Iran, with its abundance of sunlight, rich in "solar energy potential." Iran took its first step toward the large-scale realization of that potential with the inauguration of its first solar energy plant, which was constructed with domestic materials and labor in Shiraz.

Islands

• **Category:** Geology and geography

Global warming causes thermal expansion and ice melt, increasing seawater volume and provoking more frequent and more severe storms. As a result, small, low-lying islands are threatened with ecological degradation and submergence.

• **Key concepts**

brackish water: mixture of freshwater and seawater
calving: separation of a large portion of ice from a glacier or ice shelf, creating an iceberg
coral atoll: an island or islet composed of a lagoon encircled wholly or partly by a coral reef
methane: a gas whose greenhouse effect is considerably stronger than that of carbon dioxide
nissology: the study of islands
thermal expansion: a heat-induced increase in the volume of a liquid or gas

• **Background**

Global warming threatens the survival of low-lying islands, deltas, and beaches. Over two thousand scientists, in conjunction with the United Nations, have estimated that by the year 2100 sea levels will rise by between 9 and 88 centimeters. Rising sea levels threaten human, animal, and plant life, as arable land and potable water are compromised. Refugee migrations and species extinctions result.

• **Conditions**

For millennia before the nineteenth century, Earth's sea levels remained relatively stable. However, as the pace of industrialization and urbanization accelerated around the globe, sea levels began to rise by milliliters per year. Tide gauges and satellite monitoring indicate that this rise has increased in recent decades. Two factors contribute to increases in sea volume. One is thermal expansion, whereby warming waters increase in volume. The other is the melting of ice sheets and glaciers at the North and South Poles and in the mountains of the Andes, Alps, and Himalayas.

Retreating ice has been noted in all these regions. Ice melt in Greenland begins earlier each summer, leaving ever smaller areas to refreeze by winter. The runoff water from the melt penetrates glaciers, loosening their attachment to rock surfaces. Large chunks then break away, in a process known as "calving," launching masses of ice several square kilometers in area that float away, eventually melting in warmer waters. The snow and ice of ski fields in Switzerland have disappeared, as the snow line rises in altitude. Less snow and ice on the surface of the Earth reduces the deflection of sunlight, or albedo, thereby causing more warming in a

Millennium Island, Kiribati, as seen from the International Space Station. The island, no part of which is more than 6 meters above the ocean, has been identified by the United Nations as being at significant risk from rises in sea level. (AP/Wide World Photos)

postive feedback loop. Furthermore, thawing allows the escape of methane gases that have been locked in the frozen Earth, further strengthening the greenhouse effect.

- **Consequences**

Islands are bodies of land surrounded by water, ranging in size from continents to tiny atolls. They can be found on all continents, oceans, and seas. One type of island rises from an underwater, oceanic volcano, as the tip emerges above the water surface to form the island. The other type is an elevation of land on a continental shelf that rises above surrounding waters. Hawaii is an example of the former; the British Isles are instances of the latter. The smaller and lower in height an island is, the more vulnerable it is to rising seas. In addition to threats from rising sea levels, small islands are endangered by tropical storms, including hurricanes and cyclones. If the frequency and ferocity of these storms increase, the risk to islands does as well.

The consequences of this vulnerability are devastating in several respects. In addition to being submerged, small land bodies are being eaten away at their edges by erosion. Moreover, as salt water penetrates an island, salinity enters the water table below the island's surface. The more salinity that freshwater absorbs, the less potable it is for drinking. Moreover, brackish water stunts or kills crops, reducing the food supply. Not only is the sustenance of humans threatened but that of wildlife is as well.

Some islands are being abandoned by their inhabitants as the sea consumes the land. The two thousand inhabitants of the Carteret Islands of Papua New Guinea are refugees from their devastated habitat. Lohachara Island in the Bay of Bengal disappeared under water in 2006; its residents fled to the mainland. Tuvalu, with a population under ten thousand, is a country of nine narrow coral atolls in the South Pacific. New Zealand has agreed to accept thirty-five of its inhabitants per year as environmental refugees.

- **Prevention**

Small island countries produce negligible amounts of greenhouse gases (GHGs). However, they suffer most directly and critically the consequences of global warming that are due to the major emitters. Small island countries act cooperatively through a number of organizations. The Global Islands Network (GIN) is an information clearinghouse and resources cooperative for islands in all regions of the world. Complementing it is the Small Islands Development Network (SIDSnet), specializing in communications and information technology to support island maintenance and development. Members of the Alliance of Small Island States (AOSIS) coordinate their efforts through their respective U.N. diplomatic missions. The International Small Islands Studies Association (ISISA), which has held ten world conferences, is a professional organization that supports research about small islands. The International Scientific Council for Island Development (INSULA) supports the economic, technical, ecological, social, and cultural programs of the world's islands and publishes the journal *INSULA: The International Journal of Island Affairs*, which specializes in nissology. Another periodical is the *Island Studies Journal*.

• Context

Small, low-lying islands are both idyllic and fragile fragments of the Earth's surface. Somewhat like a canary in a coal mine, their extinction is an early warning sign of ecological danger. Before they submerge, erosion and saltwater intrusion render them uninhabitable. Larger, low-lying surfaces, such as delta regions and beaches, are also threatened. As more islands lose the means to sustain their populations, the number of environmental refugees in the world increases, putting further pressure on the planet's remaining resources.

The inhabitants of small islands have contributed the least to global warming, yet they suffer the worst of its initial consequences. They therefore unavoidably raise issues of social and environmental justice. Global warming admits of several feedback loops. The more the conditions for warming accumulate, the more such conditions are strengthened. For any inhabitant of a low-lying island or mainland surface, the question of the survival of one's physical environment is a daily concern.

Isostasy

• **Category:** Geology and geography

The theory of isostasy allows geologists and cryologists to understand the growth or retreat of ice sheets, based upon the movement of the land in response to its increasing or decreasing glacial load.

• Key concepts

continental crust: the uppermost layer of the Earth, granitic in composition, with a density of about 2,700 kilograms per cubic meter

flexure: the way in which an elastic plate bends

forebulge: an elevated area just beyond the area depressed by an ice sheet

glacial isostatic adjustments: vertical motions of the crust to restore it to preglacial elevations

mantle: the layer of the Earth beneath the crust, peridotite in composition, with a density of about 3,400 kilograms per cubic meter

viscosity: a measure of how easily a material flows

• Background

Earth's continental crust floats on a geological layer called the mantle. A continental ice sheet weighs a great deal, so an advancing ice sheet will cause the crust to subside beneath it. When the ice melts, the land it had depressed will rebound upward. These vertical motions of hundreds of meters control the growth and retreat of the glaciers, as well as the directions in which meltwater drainage flows. Models of mantle deformation based on data from the last glaciation can be applied to areas beneath contemporary ice sheets to better understand their dynamics.

• Theory of Isostasy

During the survey of Mount Everest, investigators found that their plumb bob was not attracted by the mass of the Himalayan mountain range as much as they had expected. They concluded that the mountain range was supported by some sort of mass deficiency beneath it. This led to the theory of isostasy, which holds that Earth's mantle is denser than its crust, which floats upon it; it is thicker or less dense beneath mountain ranges. This theory has been found to be generally true, except for some unusual circumstances such as the trenches near subduction zones. These exceptions have been explained by treating the surface of the Earth as an elastic plate that flexes and spreads out gravitational loads.

The continental ice sheets that developed in Canada and Northern Europe placed enormous loads on the crust of the Earth beneath them. Just as a boat rides lower in the water when fully loaded than when empty, the crust of the Earth sank further into the mantle to accommodate this additional load. The flexure produced by this motion on the elastic plate caused parts of it just beyond the loads to rise up as a forebulge. When the ice melted, the load disappeared, areas that had been depressed began to rise up, and the forebulge started to subside. These changes in elevation are often referred to as glacial isostatic adjustments. Although the ice disappeared thousands of years ago, the crust continues to move vertically today, because the mantle is incredibly viscous. Glacial rebound analysis suggests it has a viscosity between $10^{20.5}$ and 10^{22} Pascal seconds. (For comparison, the viscosity of water is 10^{-3} Pascal seconds, and the vicosity of molasses is 10^{4} Pascal seconds.)

• Application of the Theory

Waves coming ashore often cut terraces, erode cliffs, and produce beaches at elevations close to sea or lake level. If the land rises relative to these levels, a series of terraces may result. Organic remains can be used to date these terraces, and geologists have discovered that terraces of the same age at different locations are not at the same elevation. Those closest to where the glacial load was greatest are higher, as they have experienced greater isostatic rebound. Furthermore, terraces formed long ago will show a greater slope, presently, than those formed more recently. By studying such patterns of strandlines, a history of isostatic rebound can be reconstructed. For example, areas around Hudson Bay, in Canada, have already rebounded over 300 meters, continue to rise at rates on the order of 1 centimeter per year, and probably have another 100 meters of uplift to go before isostatic balance is obtained.

The history of isostatic rebound in a given area can be used to make estimates of mantle viscosity and of how this viscosity changes with depth. Computer models can help fill in the gaps where data are absent. Where there is a significant lack of data, suites of scenarios may be obtained, all of which fit the model equally well, and all of which are internally consistent. As additional data become available, some scenarios will be eliminated, and the preferred scenario can shift rather dramatically. For example, preferred scenarios in the mid-1990's envisioned 4 kilometers of ice in Greenland but only 2.5 kilometers of ice in central Canada during the last glacial maximum. A few new data points led to revisions in 2004 that reversed this distribution and placed parts of Greenland in the area of the glacial forebulge.

These scenarios are used by climate scientists to try to determine how rapidly the ice sheets on Greenland and Antarctica might be shrinking. The elevation of the top of the ice sheets and the gravitational attraction at points above the ice sheets can be determined from satellites. However, to calculate how much the volume of ice is changing, the elevation change of the bottom of the ice sheet must also be considered, and isostatic adjustment models are used to estimate this change.

Isostatic adjustments may also have influenced the growth and retreat of the continental glaciers. The accumulation of ice occurs much more rapidly than can be accommodated by isostatic subsidence. Just as the crust of the Earth is still rebounding thousands of years after the load was removed, it subsided over a period of thousands of years during and after the addition of the load. These changes in elevation, frequently called "bedrock lag," affect local climatic conditions and thus the growth or retreat of the continental ice sheets.

Another important consequence of isostatic adjustment concerns drainage of the large lakes at the southern margin of the continental glacier in North America. The route and ultimate destination of the drainage were likely important factors influencing global temperatures near the end of the last glaciation. These lakes consisted of freshwater, most at 4° Celsius, which would have floated on the more saline water in the North Atlantic. Such a freshwater cap would be unlikely to sink initially, and it would take a long time for the winds to mix it sufficiently to permit sinking. The cap may have slowed or turned off the thermohaline circulation, also called the global conveyor belt or the meridional overturning circulation (MOC). The North American lakes drained into the Atlantic Ocean through the Mississippi River Valley, the Hudson River Valley, and the St. Lawrence River Valley, as well as draining northwest to the Arctic Ocean.

- **Context**

Isostasy provides a theory to explain the vertical movements of Earth's crust as the load of continental ice sheets is added or removed from large areas. It permits us to estimate volume changes of contemporary ice sheets by providing estimates of the crustal movements taking place beneath them. By constraining drainage histories of the glacial lakes that formed near the end of the last glaciation, it makes it possible to determine where and when cold, freshwater pulses may have flooded out over the oceans, with their potential radically to modify Earth's climate.

Italy

- **Category:** Nations and peoples
- **Key facts**

Population: 58,126,212 (July, 2009, estimate)
Area: 301,230 square kilometers
Gross domestic product (GDP): $1.82 trillion (purchasing power parity, 2008 estimate)
Greenhouse gas (GHG) emissions in millions of metric tons of carbon dioxide equivalent (CO_2e): 516.9 in 1990; 582.5 in 2004; 567.9 in 2006
Kyoto Protocol status: Ratified 2002

• Historical and Political Context

Italy has played a major role in the religious, philosophical, and artistic development of the world. For centuries, Italy served as the central point from which empire, religion, thought, and artistic creation emanated. The Roman Empire spread its political system and its culture throughout Europe and the Mediterranean. After its collapse, Rome became the center of Catholicism, and it was in Italy that the Renaissance began in the fourteenth and fifteenth centuries, eventually spreading across Europe and into the British Isles. It revived the thought and art of Antiquity with Humanism and rediscovered the human creative ability.

Politically, Italy has had many periods of political unrest. During the thirteenth century there were fierce battles between the imperial and religious powers. The eighteenth century saw regional factions competing for political power. And again in the twentieth century, Italy's government experienced serious instability. Under the republic established in 1946, some fifty different political groups have been in power. In contrast to its internal political volatibility, Italy is a consistent supporter of international organizations. Italy joined the United Nations in 1955 and is a member of five other international organizations, including the North Atlantic Treaty Organization (NATO), the organization of industrialized nations known as the G-8, and the World Trade Organization. Italy was a founding member of the European Union (formerly the European Community). Italy's main trading partners are in the European Union; the country trades mostly with Germany, France, and the United Kingdom. It also trades with the United States and ranked twelfth among the United States, trading partners in 2008.

• Impact of Italian Policies on Climate Change

Although Italy underwent some industrialization during the nineteenth century, it remained primarily an agricultural economy until after World War II. Agriculture is still important to the country. Italy produces a wide variety of products, including grapes, olives, rice, sugar beets, and soybeans. It is the largest producer of wine in the world. The agriculture sector employs a large portion of Italy's workforce. Approximately 1.4 million people are employed in farming. Tourism continues to be important in the Italian economy. The northern section of Italy where manufacturing is concentrated has one of the highest per capita incomes in the world, while the south remains poor by world standards. After the war, Italy became more and more involved in manufacturing and is now the sixth largest market economy in the world. While Italy possesses few natural resources other than natural gas, which is primarily in the Po Valley and in the Adriatic Sea, it imports a large quantity of raw materials for processing. In addition approximately 80 percent of its energy resources are also imported. Its major areas of manufacturing include precision machinery, motor vehicles, chemicals, and clothing. Italy also has a significant oil refining industry. This activity is one of the main sources of increased CO_2 emissions, amounting to a gain of 2.4 million metric tons. The other major source of increased greenhouse gas (GHG) emissions is road transport with a substantial increase in the consumption of diesel fuel. The increase in the use of fossil fuels to produce electricity has also greatly increased the GHG emissions. Production of the energy supply and energy use accounted for 60 percent of the GHG emissions in 2006. The transport sector was the source of another 23.5 percent.

• Italy as a GHG Emitter

According to data collected by the European Environment Agency (EEA), Italy ranked third among the members of the European Union in GHG emissions. In 1990, the base year for the Kyoto Protocol, Italy had GHG emissions totaling 516.9 million metric tons of carbon dioxide equivalent. Its emissions target under the Kyoto Protocol is 483 million metric tons. From 1990 to 1995, emissions remained more or less the same; the following years were then a period of substantial increase. From 2002 to 2006, Italy's average GHG emissions were 571.4 million metric tons, which was an average increase of 10.6 percent for the period. The amount of GHGs emitted by Italy in 2006 showed a small decrease to 567.9 million metric tons but was still an increase of 9.9 percent over its 1990 emissions and well in excess of its Kyoto Protocol target. Italy was responsible for 11 percent of the European Union's GHG emissions.

• Summary and Foresight

If Italy's amount of greenhouse emissions continues at its present rate, the country will not meet its burden-sharing target of 6.5 percent under the Kyoto Protocol by the 2008-2010 period. Italy expects the policies and measures it already has enacted to reduce its emission to a level 7 percent above the 1990 levels. This would be a reduction of 3 percent from the 2006 levels, which were 10 percent above the 1990 levels. Among the measures and policies already in place in Italy are the use of abatement technologies in the production of adipic acid and the replacement of fossil fuels with biomass for heating in the household sector. Italy plans to initiate additional measures, Kyoto mechanisms, and carbon sink activities to reduce emission further. However, the proposed measures will result in a level only 5 percent below the base year levels and will not meet the –6.5 percent target of the Kyoto Protocol.

Italy has been slow to regulate electrical consumption, and austerity is not a popular idea among the Italian citizens, but the European Union is proposing a program for changing the source of energy production to that of renewable resources. Other significant reductions in GHGs emitted by Italian industries should result from the restrictions that will be placed upon them under the European Union Emission Trading Scheme. Reduction of GHG emissions and control of global warming is important to Italy, which is already seeing the effects of global warming on its land area. The melting of Alpine glaciers is causing problems in regard to the Swiss/Italian border, which will probably need to be re-delineated.

Japan

- **Category:** Nations and peoples
- **Key facts**

Population: 127,078,679 (July, 2009, estimate)
Area: 377,873 square kilometers
Gross domestic product (GDP): $4.348 trillion (purchasing power parity, 2008 estimate)
Greenhouse gas (GHG) emissions in millions of metric tons of carbon dioxide equivalent (CO_2e): 1,154 in 1990; 1,223 in 2000; 1,216 in 2006
Kyoto Protocol status: Ratified 2002

• Historical and Political Context

A strong Asian island nation fiercely protective of its national identity and independence, Japan always sought to be at least on equal footing with the known leading nations of the ages. Thus, when industrialization with its attendant side effect of massive emission of carbon dioxide (CO_2) into the atmosphere gave Western nations a decisive military and economic edge by the middle of the nineteenth century, Japan chose to rapidly catch up and industrialize during the Meiji Restoration announced in 1868.

On the other hand, when concern for global warming led the leading nations of the world to seek for means to reduce the negative impact of their industry and consumers and traffic on the Earth's atmosphere by the end of the twentieth century, Japan took a leading role in researching and committing to less environmentally damaging alternatives. It certainly spoke to the Japanese self-understanding as a leading innovative nation that the decisive protocol to the United Nations Framework Convention on Climate Change was adopted in Kyoto, an ancient capital of Japan, on December 11, 1997. Known since as the Kyoto Protocol, the agreement represents a strong international commitment to combat global warming.

In a pattern still typical by the early twenty-first century, once Japan decided to industrialize, the government worked very closely with private enterprise and could draw on a well-educated, hard-working and frugal workforce. This public-private partnership contributed to Japan's fast industrial rise, albeit at the price of environmental damage.

Japan's first encounter with industrial pollution occurred in 1878. Runoff water contaminated with inorganic copper compounds from the privately owned Ashio Mine north of Tokyo caused copper poisoning among farmers and villagers living downstream. Tanaka Shozo, the local member of the lower house of Japan's new parliament, publicly raised the issue. As a result the company paid compensation, and the government erected runoff prevention, yet some problems remained. Well into the middle of the twentieth century, most Japanese pollution cases followed this pattern of privately caused pollution, public reaction, and increasingly vigorous financial, governmental, and legal redress.

An extremely negative side effect of Japan's drive to industrialization despite a surprising lack of natural resources such as coal, oil, iron, and nonferrous metals was its embarkation on imperialism and colonialism. Copying the West, Japan created a colonial empire that at its peak in 1932 encompassed Korea, Taiwan, and the puppet state of Manchukuo, carved out of Northeast China. Conflict with the United States over Japan's war in China after 1937 led to an American oil embargo of Japan in 1941 that persuaded Japanese militarists to attack the United States at Pearl Harbor on December 7, 1941, drawing the Americans into World War II. After surrendering unconditionally on August 15, 1945, Japan lost its colonies. To become an economic leader again was a major challenge.

• Impact of Japanese Policies on Climate Change

Japan's post-World War II political decision to promote Japanese economic recovery included a broad national consensus to rebuild and expand Japan's industry. This national aim was aided by the United States, who wanted a strong Japan as a free world counterpart to communist aggression in Europe and Asia during the Cold War. With virtually no natural fuel resources such as oil and coal, Japan had to import these from abroad, as well as almost all raw materials for industrial production of steel and industrial manufacturing. In this situation, Japanese policy promoted manufacturing of consumer goods, chemicals, and machines primarily for export to pay for its import of fuel and raw materials.

The strong pro-industry policies of Japan led to an initial postwar neglect of environmental protection and the outbreak of three major pollution incidents in 1956, 1961, and 1965. There was strong public reaction to these incidents. Two involved mercury poisoning, and the 1961 case resulted in poisonous smog created by unregulated burning of petroleum and crude oil waste by the Showa Yokkaichi Oil Corporation. As a result of public pressure and successful lawsuits based on irrevocable scientific evidence for the anthropogenic cause of the pollution incidents, Japan's public policy shifted toward more effective environmental protection.

In 1970, Japan passed six environmental laws and put much more teeth into eight existing ones. In 1971, the Environmental Agency was established and given a broad mandate to protect Japan's environment from air, soil, water, and other pollution. Exhaust by cars was also addressed aggressively and industrial polluters were held accountable by passage of the 1973 Pollution Health Damage Compensation Law. Ironically, the drastic oil price increases of the first oil crisis of 1973 forced Japanese companies, utilities, and consumers to find immediate means of conserving fuel to survive economically in the face of Japan's near total dependency on fuel imports. Its industry became more fuel efficient with lower emissions.

The first white paper of Japan's Environmental Agency in 1984 strengthened environmental awareness among Japanese corporations and citizens, as did further policy papers, campaigns, and surveys. The 1993 Basic Environment Law of Japan explicitly restricted industrial emissions considered harmful for the climate, as well as calling for improved energy conservation, recycling, and pollution control programs.

Indicative of Japan's serious commitment to environmental protection including addressing and combating climate change, in 2001, the Environmental Agency was upgraded to the Ministry of the Environment. In 2008, Tetsuo Saito became its Minister. He was chosen because of his scientific background, holding a Ph.D. in physics, and his knowledgeable commitment to clean energy technology.

• Japan as a GHG Emitter

According to Japan's emission statistics reported to the United Nations in 2008 for the years from 1990 to 2006, with 1.22 billion metric tons of greenhouse gases (GHGs) emitted in 2006, Japan was the world's fifth largest emitter of CO_2 and its equivalents. By comparison, the top two emitters were the United States with 6.37 billion metric tons in 2006, a figure closely matched or perhaps even surpassed by 8 percent by the People's Republic of China, according to a 2007 estimate by the Netherlands Environmental Assessment Agency. When Japan's emissions were compared to the size and output of its national economy, the Japanese economy proved remarkable emissions-effective. This was particularly in contrast to the number three and four GHG emitters, India and Russia. In 2008, Japan created with $4.84 trillion the world's second largest gross domestic product, just behind the United States, and remained in place five of the GHG-emitting countries.

Under the complex United Nations measuring system for GHGs, nations can earn some credit or debit to their overall emissions when they offset emissions through land use, land-use change, or forestry (abbreviated as LULUCF). This was an incentive for nations to promote reforestation and protect forests, as was done in Japan vigorously since the 1980's. As a result, Japan's overall 2006 emission was lowered by 82.6 million metric tons of GHGs. In addition, only anthropogenic emissions are considered, excluding, for example, CO_2 from volcanic eruptions.

In Japan, as elsewhere, CO_2 was the major GHG emitted, accounting for 1.156 billion metric tons in 2006 (without LULUCF credits). Under United Nations standards, other GHG emissions are added to those of CO_2 with a weighted formula. For example, each ton of methane is multiplied by 21, each ton of nitrous oxide by 310, and fluorocarbons each have specific values. In 2006, Japan emitted a CO_2 equivalent of 21.8 million metric tons of methane, a 23.6-million-metric-ton equivalent of nitrous oxide and just 15.4 million metric tons of CO_2 equivalents of the ozone-layer-damaging fluorocarbons and sulfur hexafluoride (all excluding LULUCF credits).

As an industrialized, Annex I country that signed and ratified the Kyoto Protocol, which became effective on February 16, 2005, Japan has committed to reduce its emissions to 6 percent below their 1990 level no later than 2012. This commitment is slightly higher than the 5.2 percent average for industrialized nations. However, Japan's 2006 data show an increase of 5.3 percent from the 1.154 billion metric tons of GHGs emitted in 1990. When the figures are used that account for possible LULUCF credits, Japan even increased its emissions by 5.8 percent as reforestation and other measures had reached their intended limits in the 1990's and had leveled off.

Japanese politicians and experts have pointed out that Japan had relatively low emission levels in 1990 already. Ever since the 1973 oil crisis, Japan had invested great resources in cleaner factories and power plants. Japan reduced emissions consid-

A man observes a factory smokestack in Kobe releasing pollutants into the atmosphere. (Yuriko Nakao/Reuters/Landov) erably earlier than other countries. Despite this relative disadvantage, Japan ratified the Kyoto Protocol in 2002 and remained committed to its targets.

• Summary and Foresight

As a leading industrial nation creating the world's second largest gross domestic product, behind the United States, and running the third largest economy, behind the United States and the People's Republic of China, if measured by purchasing power parity, in 2008, Japan would continue to emit a huge share of the world's GHGs. Japan has been particularly motivated to earn the money it needs to import its food and fuel, both of which it is lacking, through export of high-value goods that require considerable energy consumption and thus GHG emission in their manufacture. At the same time, Japanese politicians and the populace were seriously committed to combating global warming and willing to spend considerable resources to achieve this aim.

Far from the days of permitting rampant industrial pollution just after World War II, when economic recovery was on the top of the agenda, Japan has become a leader in environmental protection. By 2002, the second environmental performance review of Japan by the Organization for Economic Cooperation and Development (OECD) praised Japan for its highly effective implementation of positive environmental policies and its strict, well-enforced, and seriously monitored regulations. In 2006, Japan's Ministry of the Environment made prevention of global warming, ozone layer protection, and conservation of the air, water, and soil environments issues of top concern.

Japan has become strongly committed to an international approach to Earth-spanning challenges such as global warming. Japan is a founding member of the Asia-Pacific Partnership on Clean Development and Climate founded on January 12, 2006, in Sydney, Australia. In addition, Japan continues to stress environmental protection in the countries of its trade partners.

Japan has been actively involved on the cutting edge of meteorological research. A major scientific project concerns the Earth Simulator, a supercomputer used for developing and running global climate models since 2002 at the Earth Simulator Center in Yokohama. The Earth Simulator is projected to be replaced by an even more powerful model after 2009, indicating Japan's continuous commitment to climate research.

Jet stream

• **Category:** Meteorology and atmospheric sciences

• Definition

A jet stream is a band of high-velocity atmospheric current that encircles the Earth. This band of strong winds is typically found in the upper troposphere and lower stratosphere. In both the Northern and the Southern Hemisphere, there are two distinctive jet streams: one is located just outside the tropical latitudes, in the subtropics; the other is located at the boundary of the midlatitudes and the polar region. In these latitudes, the jet-stream winds are westerlies, blowing from west to east. The two jet streams are named, respectively, "the subtropical jet" and "the polar jet." These jets shift locations seasonally.

The rotation of the Earth around its own axis causes the air that surrounds the Earth to move as a result of the drag exerted by the Earth's solid surface. This movement of air is called "wind." Wind can blow in any direction, even though the Earth rotates from west to east. Two of the major forces in the atmosphere that determine wind direction are the pressure gradient force and the Coriolis effect. Because of differential solar heating between the tropics and a polar region, there is a strong tendency of the atmosphere to move outward from the warmer equator to the colder poles, distributing heat. This tendency would cause winds to blow in the north-south directions in the Northern and Southern Hemispheres at different altitudes.

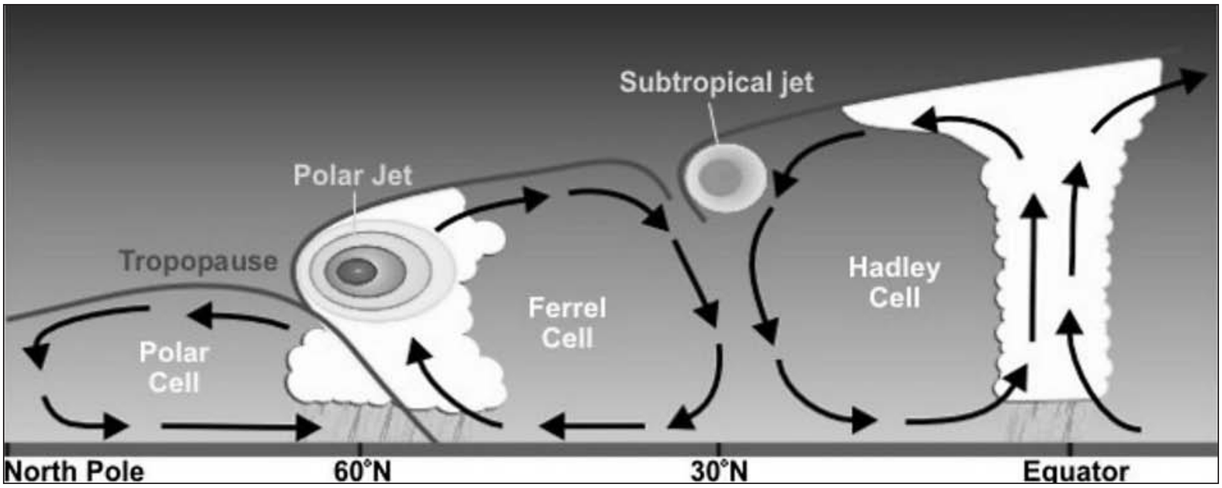
Owing to the Earth's rotation, these two major north-south circulations break up, forming several smaller cells of circulation. These smaller cells include the Hadley circulation, the Ferrel circulation, and the polar circulation, listing them from the equator to the poles in each hemisphere. At upper atmospheric levels, when air travels to the north in the Northern Hemisphere, the Coriolis effect turns this airstream to its right, turning a southerly wind into a westerly wind. Furthermore, because the Coriolis effect becomes stronger as air travels further north and the effect of Earth's surface drag is smaller at upper atmospheric levels, these westerly winds become very strong. As a result, jet streams form outside of the tropics, toward high latitudes, at upper atmospheric levels.

• Significance for Climate Change

Because it is a high-velocity wind current, a jet stream can be an important energy source for extratropical cyclones and storms. The position of a jet stream serves as an important indicator for the location of surface front and storm development. Both the subtropical and the polar jet are located at the boundaries of two different air masses. The boundaries of different air masses are the locations of surface fronts, at which extratropical cyclones develop. Therefore, a jet stream is an important component of a synoptic weather system.

Inside a jet stream, there is often a core region where winds become even stronger than they are in other parts of the jet. This core region is called the "jet streak." Because winds increase toward the jet streak, large horizontal and vertical wind shears exist at the boundaries of a jet stream. The sheared winds can cause a flow current to become curved and unstable. Therefore, in the vicinity of a jet stream, atmospheric waves and turbulence are often generated. Upper air turbulence may threaten aircraft.

Several studies have indicated that global warming tends to cause jet streams to move poleward.



This cross-section of the polar and subtropical jet streams illustrates their relationship to Earth's major atmospheric circulation cells. (NOAA)

The implication of this migration is that extratropical storms or "storm tracks" will extend poleward as well. Furthermore, the combined effects of global warming and the poleward movement of jet streams leave a larger spatial area in which tropical storms may develop. Therefore, the area of coastal land that is vulnerable to hurricanes may increase.

Some scientists have pointed out that, as a result of a continuous increase in Earth's average surface temperature and of the temperature throughout the troposphere, the temperature gradient from the equator to the poles may be decreased. This possibility seems to suggest that the jet stream's intensity may decrease as the climate warms. The weakening of jet streams may in turn decrease the activity of extratropical cyclones. However, other scientists have argued that global warming may not lead to a warming of the entire troposphere and a corresponding decrease in jet-stream intensity. Moreover, because global warming would also tend to increase atmospheric humidity, latent heat release may supply additional energy for extratropical cyclones despite a decreased global temperature gradient.

Journalism and journalistic ethics

• **Categories:** Popular culture and society; ethics, human rights, and social justice

The changing nature of journalism, including the competition between objective coverage and advocacy, has played a key role in the public perception of global warming.

• Key concepts

code of ethics: an unofficial standard for proper journalistic behavior

media bias: presentation of news or information that favors one side of a particular issue

Society of Environmental Journalists: a group of media professionals who focus wholly or in part on a wide range of environmental stories and issues

Society of Professional Journalists: a voluntary association of journalists who try to further the profession

• Background

American journalism is regarded as the Fourth Estate, or a final check and balance on government. Media professionals claim to have evolved a tradition of neutrality in news stories, but both the reality and the ideal of neutrality have been called into question. Journalists themselves are unsure of the role they should play in global warming debates. At the same time, the nature of journalism has blurred with the rise of the Internet and the focus on immediacy in news coverage.

• Traditional Media Approaches to Reporting

Over time, American journalists have evolved an unofficial code of ethics that calls for unbiased or neutral reporting. This concept is integral to ordinary reporters being seen as chroniclers rather than advocates. The ideal has gained widespread but not universal acceptance.

Journalists use several means to enforce neutrality in stories. The traditional approach would include editors removing any comments that are not objective from a given story. Journalists also seek the help of professional organizations to support unbiased reporting. The Society of Professional Journalists says reporters must distinguish between advocacy and news in their reporting. The Society of American Business Editors and Writers tells its members to simply avoid any action that might “appear” to harm objectivity. The Society of Environmental Journalists has been criticized for taking sides in the global warming debate.

Many newspapers also have their own codes of behavior for journalists. *The New York Times* urges staff to remain free of any bias, as do many other organizations. Some media outlets even employ ombudsmen to serve as reader representatives. Media outlets also have detailed correction policies.

There are flaws in all of these approaches. Editors do not catch every instance of bias. Organizations are voluntary and do not police a code. News outlets also use codes as guidelines, but public examples of enforcement are rare. Ombudsmen generally lack any real authority in a newsroom.

Every one of these strategies is at issue in the global warming debate. Scientists and other experts complain that biases are present in news stories. The other methods of controlling bias, from policies to ombudsmen, are unable to keep up with a sophisticated and scientific debate involving professionals who often know far more than reporters or editors.

• Other Strategies

The traditional approach is not the only approach. The term “news media” itself has become fluid. It encompasses alternative weeklies, freelance journalists, and opinion media that take an advocacy role. Even the mainstream media have a strong strain of advocacy. Many media outlets have long employed journalists who advocate for positions—from environmentalism to a higher minimum wage. There is a journalistic tradition that reporters should "afflict the comfortable and comfort the afflicted." That plays out in the climate change debate, as journalists try to show the potential harm of global warming—from species loss to climate disaster.

Several journalists have spoken out and complained about the neutrality requirements. Columbia Broadcasting System (CBS) reporter Scott Pelley famously compared global warming skeptics to Holocaust deniers. Other reporters and editors have taken an activist stand on the issue, claiming that too many lives are at risk because of global warming. *Time* magazine has repeatedly put global warming on its cover, warning that something must be done to stop it.

All major news outlets have found navigating the issue to be difficult. Fox News, whose motto is Fair and Balanced, was criticized by supporters of anthropogenic global warming theory for including too many skeptics. When Fox News ran a special that included their side, skeptics complained and Fox News then produced a second documentary highlighting flaws in the alleged global warming consensus.

• Context

The issue of media neutrality is central to how ordinary Americans see global warming. Do they view it as an imminent threat or as debated science? Journalists have been much criticized by readers, as well as by advocates on the Left and Right.

The issue of media bias about global warming has become almost as big a story as climate change itself. Scientist James E. Hansen complained that the George W. Bush administration censored his work, but he received a great deal of media attention as a result. Skeptical scientists have complained about being either ignored or undermined in stories. *Time* magazine modified the famous photo of the Iwo Jima flag raising to replace it with a tree in a push for global warming action. That decision resulted in thousands of reader complaints as well as criticism from photojournalists. Because global warming is such a controversial issue, it highlights the many flaws in journalistic neutrality. That, in turn, undermines the idea that reporters are objective in other areas of news coverage.

Kilimanjaro

- **Category:** Geology and geography

During the political debates over global warming, Kilimanjaro's vanishing ice cap became an iconic image of the negative consequences of anthropogenic climate change, but climatologists and glaciologists have discovered that decreased snowfall, enhanced exposure to solar radiation, ice-sheet locations and shapes, and other factors are more important than climate change in explaining the disappearing ice.

• Key concepts

ice cap: semipermanent glacial crown of ice atop a mountain or other geologic formation

sublimation: the conversion of a solid directly into a gas, bypassing its liquid state

volcano: a usually mountainous rift in Earth's crust caused by magma erupting through fissures onto the planet's surface

• Background

Kilimanjaro—which, at 5,895 meters, is Africa's highest mountain—is of volcanic origin, based in its location alongside a rift zone created by the Earth's spreading crust. Its trio of volcanic peaks gradually became inactive, first Shira, then Mawenzi, and finally Kibo, the highest. Ice and snow gathered on Kilimanjaro's upper slopes during the late Pleistocene epoch, about eleven thousand years ago. Ice cores taken from the mountain's glaciers have revealed a history of expansions and contractions of the ice cap, with the contractions occurring during periods of drought eighty-three hundred, fifty-two hundred, and four thousand years ago. Periods of expansion resulted from climatic conditions that were warmer and wetter than those of today. Recently, Kilimanjaro's ice sheets have been confined to Kibo.

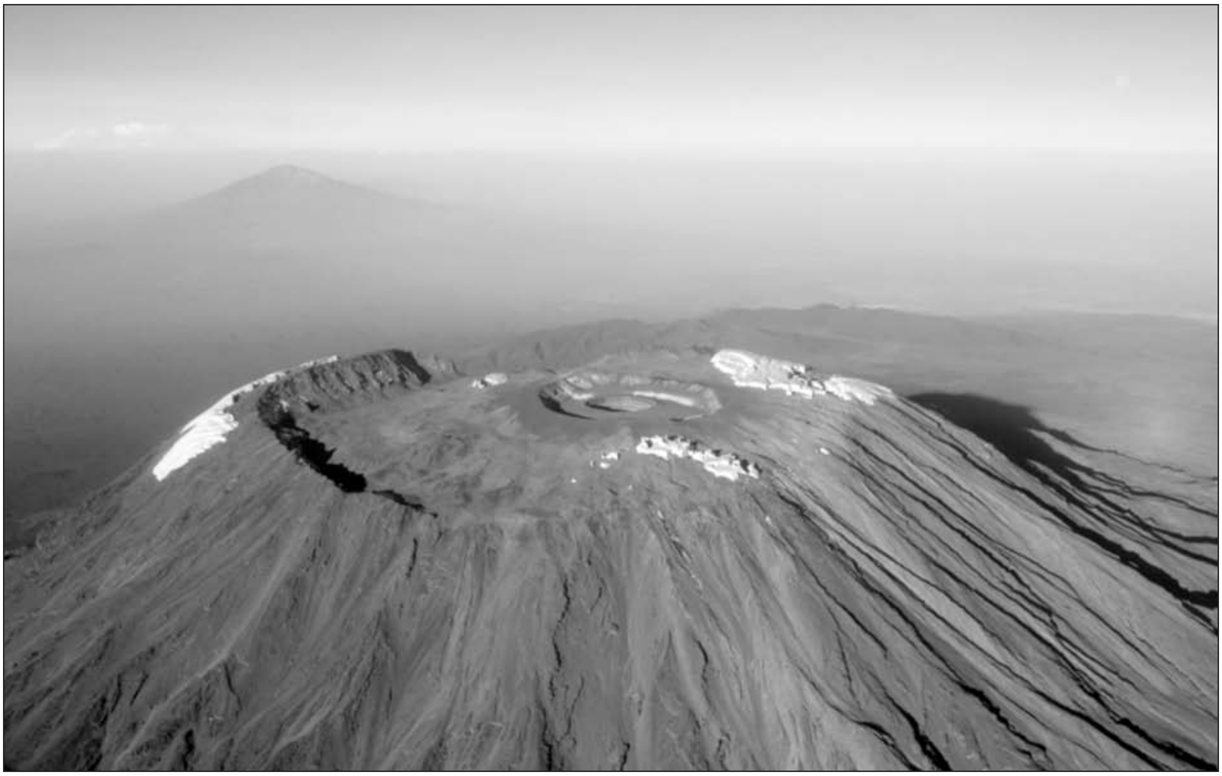
One-half million years ago, early human inhabitants of the Rift Valley first saw this majestic mountain, but its names derive from a much later period. African tribes called it the "white" or "shining" mountain, because of its ice cap. Its present name most likely comes from the Swahili, "Kilima Njaro," meaning "Mountain of Greatness" because of its massive height and bulk. The first European to see the mountain was a German missionary who published an account of his African explorations in 1849. This not only sparked interest in searches for the source of the Nile but also in the scientific study of Kilimanjaro and its ice sheets.

• Vanishing Ice Sheets

In the late nineteenth century, explorers created maps and drawings of the mountain and its environs. From these, scholars derived an estimate that, in 1880, ice covered about 20 square kilometers of Kilimanjaro's principal peak. In 1889, two Europeans were the first to reach Kilimanjaro's summit, and they brought back information about the extent and depth of the ice sheets. In the twentieth century, photographs from the mountain's base and, later, from airplanes, provided benchmarks by which the shrinkage of the ice cap could be measured. In 1912, a precise map was constructed based on photogrammetric evidence. At that time, the ice sheets had diminished to 12.1 square kilometers, though they still existed on all sides and descended to about 4,400 meters. From 1912 to the early twenty-first century, Kilimanjaro's icefields were periodically surveyed, and the data gathered indicated that the time of greatest contraction had been from about 1880 to 1950.

Ernest Hemingway, an American writer, made Kilimanjaro's ice cap world famous through his popular short story, "The Snows of Kilimanjaro," (1936) which was made into a successful Hollywood movie in 1952. By the early 1950's, the mountain's icefields had diminished to 6.7 square kilometers. Sufficient data had been collected to determine that the rarely observed trickles of meltwater were unable to account for the retreating glaciers. Some scientists began to attribute glacial contraction to the sublimation of summit ice into water vapor under the influence of the tropical sun in dry air at below-freezing temperatures. However, during the second half of the twentieth century, as evidence multiplied that midlatitude mountain glaciers were shrinking because of global warming, some scientists extended this explanation to such equatorial mountain glaciers as Kilimanjaro's.

Aerial photographs of Kibo's ice sheets had been supplemented by satellite pictures, and this



Kilimanjaro. (©iStockphoto.com/Alexei Zarubin)

new information showed that, although the ice cap's contraction had slowed since 1953, 75 to 80 percent of its area had vanished during the past century, along with deep reductions in the volume of its ice and snow. Some scientists predicted that the ice cap would be completely gone by 2015 or 2020. Since the "Snows of Kilimanjaro" were famous as well as photogenic, it was natural for advocates of greenhouse gas (GHG) reduction to use dramatic images of the mountain's disappearing ice cap to bolster their cause. Greenpeace advocates held a news conference from Kilimanjaro's summit, and, most significant, former vice president Al Gore argued in a very successful documentary film and companion book, both entitled *An Inconvenient Truth* (2006), that the vanishing ice cap was evidence of global warming. The movie's Academy Award and the book's best-seller status helped popularize the images of Kilimanjaro's vanishing ice, which Gore associated with carbon-dioxide-induced global warming.

• Significance for Climate Change

Although many scientists agreed that temperate-zone mountain glaciers were retreating because of global warming, an increasing number of climatologists and glaciologists believed that the specific case of Kilimanjaro's ice loss was caused by other factors. Data collected from balloons, satellites, and an automatic weather station on one of Kibo's icefields revealed that reduced precipitation of ice and snow in dessicated air, along with extensive exposure to solar radiation in below-freezing temperatures, led to the accelerated sublimation of ice and snow. Fluctuating weather systems in the Indian Ocean, which influenced humidity and cloud cover over Kilimanjaro, may also have played a role.

• Context

Most scientists familiar with the data held that global warming had little or no effect on the ice decline. These scientists chided global-warming enthusiasts for their misuse of Kilimanjaro's vanishing ice cap to support their views on climate change, but they also criticized global-warming deniers who overgeneralized the Kilimanjaro case to include midlatitude glaciers. Kilimanjaro can therefore serve as a cautionary tale of how politics and overheated rhetoric often lead passionate advocates to distort scientific data and images in unacceptable ways.

Kyoto lands

• **Category:** Laws, treaties, and protocols

Kyoto lands are lands within the territory of Kyoto Protocol party nations on which vegetation is planted that acts to sequester carbon. These lands enable protocol parties to earn carbon offset credits to balance their continuing GHG emissions.

• Key concepts

biomass: the organic substance of life-forms, especially plants

carbon fixation: incorporation of carbon atoms into organic compounds within biomass, making it unavailable for CO_2 production

carbon offset credits: credits earned by funding projects that remove GHGs from the atmosphere and that can be used to replace reductions in GHG emissions

carbon sequestration: isolation of carbon from the atmosphere, either by converting it into a form other than CO_2 or by capturing CO_2 and storing it outside of the atmosphere

greenhouse gases (GHGs): trace atmospheric gases that trap heat, preventing it from escaping into space

• Background

Forests and other types of vegetation that store or sequester carbons and are increasing in size are considered to be carbon sinks, or reservoirs. In the main, natural carbon sinks include trees, plants, and organisms that use photosynthesis to remove carbon dioxide (CO_2) from the atmosphere by incorporating, or fixing, carbon into biomass as carbohydrates $(CHOH)_n$ and releasing oxygen (O_2) into the air. Carbon sinks not only rid the atmosphere of greenhouse gases (GHGs) but also, by producing additional CO_2-consuming biomass, can scavenge even more CO_2 from the atmosphere.

The Kyoto Protocol, a United Nations treaty, aims to reduce anthropogenic GHG emissions. It allows member countries to use carbon sinks as a form of carbon offset, gaining credit for their sinks against their continued GHG emissions. These so-called Kyoto lands may then be used to comply with emission-reduction requirements of the treaty.

According to the Intergovernmental Panel on Climate Change (IPCC), if GHG emissions continue to rise at their current rate, global warming will accelerate to levels that will increase both floods and droughts, raise sea levels, and obliterate thousands of plant and animal species. The use of carbon sinks to mitigate the effects of global warming may be useful to countries with large areas of forest or other vegetation for compliance with the Kyoto Protocol. Specific, legally binding quotas for reduction of GHG emissions have been established for the developed nations; developing countries are not compelled to restrict their GHG emissions, which may come, in large part, from land use such as cultivation of lands and destruction of forests. For developed nations, land use would have little effect in meeting Kyoto quotas, since most of their land has already been cultivated. Developing countries may benefit from offsetting their GHG emissions with carbon sinks via land use or green projects, and can help developed countries meet their quotas by trading carbon credits. Usually, an industrialized country will purchase carbon credits from a developing country to meet its quota.

• Implementation

In implementing the Kyoto Protocol, parties to the treaty will most likely base their policy decisions on “defintions, accounting procedures . . . for carbon stocks, and changes in carbon stocks.” Per the protocol, each party “must devise its own method of verifying its carbon emission reductions (CER) to account for carbon sequestration.” In the clean development mechanism (CDM), only afforestation, “the establishment of forest on land that has been ‘unforested’ for a long period, decades to centuries,” and reforestation, the conversion of ‘nonforested’ lands to forest, are allowable methods of producing CERs for the first period of the protocol, 2008 to 2012. Forest conservation or avoidance of deforestation, “the conversion of forest to nonforest,” is ineligible.

The IPCC in its revised *Guidelines for National GHG Inventories* (1997) and the Kyoto Protocol itself call for a strict accounting of the carbon changes encompassing all carbon sinks within a given timeframe; they require that inclusion be limited to “land areas subject to direct human-induced activities.” GHG emissions and removals via land use, land-use change, and forestry (LULCF) may be designed to help parties to Annex B of the protocol meet their obligations. In this case, the *Guidelines* are to serve as the basis for “transparent and verifiable” reportage of changes in forestry and related GHG emissions.

• Significance for Climate Change

Changes in land use can appreciably change the GHG emission levels, with deforestation increasing them and afforestation reducing them. Anthropogenic emissions of CO_2 grew by 2.5 percent to record levels in 2006, as international efforts to fight global warming failed to curb the main gas blamed for rising temperatures. Burning fossil fuels and changing land use together produced 8.8 billion metric tons of CO_2 in 2006. The inclusion of land use as part of the calculations for GHG emissions tends to focus on certain developing nations, notably Indonesia and Brazil, which are significantly raising their GHG emission rankings. Between 1950 and 2000, when land use is taken into account these rankings rose from eighteenth to fifth and from twenty-seventh to fourth, respectively. Indonesia and Brazil have both cleared large parcels of forest, converting carbon sinks into timber and agricultural land and thereby emitting GHGs.

Kyoto mechanisms

- **Category:** Laws, treaties, and protocols

The Kyoto Protocol established three mechanisms for GHG reduction: emissions trading, joint implementation, and the clean development mechanism. The aim of these mechanisms is to provide additional, cost-effective opportunities for industrialized countries to reduce their emissions of GHGs in order to mitigate climate change.

- **Key concepts**

Annex I parties: industrialized nations listed in Annex I of the UNFCCC

assigned amount units: greenhouse gas emission allowances of Annex I parties

certified emissions reductions (CERs): credits for contributing to reduced emissions in developing nations that Annex I nations can substitute for domestic reductions

emission reduction units (ERUs): measurement of the amount of GHG emissions reduced by a joint implementation project

removal units (RMUs): emission reduction units generated by land use, land-use change, and forestry projects

- **Background**

Article 3 of the Kyoto Protocol requires industrialized countries, identified in Annex I of the U.N. Framework Convention on Climate Change, to take on quantified emission limitation and reduction commitments (QELRCs). These QELRCs are set out in Annex B to the protocol and require parties listed in Annex I of the convention to reduce their emissions of six specified greenhouse gases (GHGs). Based on individual targets, Annex I parties are assigned the amount of carbon dioxide (CO_2) equivalent emission units, called assigned amount units (AAUs), they are allowed to emit during the protocol's first commitment period (2008-2012). These parties are obliged to meet their targets primarily through domestic measures. However, recognizing the need for flexibility, the protocol established three market-based mechanisms—emissions trading, joint implementation, and the clean development mechanism (CDM)—that are meant to provide additional, cost-effective ways for developed countries to meet their commitments.

- **Implementation and Participation Requirements**

The mechanisms are under the authority and guidance of the Conference of the Parties to the Convention serving as the meeting of the Parties to the Protocol (COP/MOP or CMP). The relevant articles in the protocol and decisions of the COP/MOP contain the rules and implementation modalities for the mechanisms. Decision 2/CMP.1 contains some general requirements and provides that use of the mechanisms must be supplemental to domestic actions taken by Annex I parties, with these domestic actions constituting a significant element in Annex I parties' efforts to meet their targets. The decision further provides that Annex I parties' eligibility to participate in the mechanisms depends on their compliance with their methodological and reporting obligations under Articles 5 and 7 of the protocol. Participation in the Kyoto mechanisms may involve private or public entities, which must be authorized by a party to the Kyoto Protocol to participate in any of the mechanisms.

- **Joint Implementation**

Under joint implementation, Article 6 of the protocol allows Annex I parties to earn or buy emission reduction units (ERUs) generated from emission reduction or removal projects implemented in other Annex I parties. These ERUs, each representing one metric ton of CO_2 equivalent emission reduction, can be used by Annex I parties to contribute to meeting their targets under the protocol. A joint implementation project could, for example, involve installing solar panels in homes in a developed country to replace power generation from fossil fuels. The use of these solar panels will result in reduced GHG emissions, and the investor can use the reductions achieved, issued in the form of ERUs, toward its own reduction target. The joint implementation mechanism is overseen by a supervisory committee.

The protocol sets out some of the eligibility criteria for participating in joint implementation. Article 6.1 provides that joint implementation projects must have the approval of the parties involved and must result in a reduction in emissions by sources, or removal by sinks, additional to what would have occurred in the absence of the project. The detailed participation requirements are set out in the Annex to Decision 9/CMP.1.

- **Clean Development Mechanism**

The CDM was established by Article 12 of the protocol. Under the CDM, Annex I parties can finance or invest in emission reduction or removal projects in developing countries. These projects generate certified emissions reductions (CERs), which Annex I parties can add to their assigned amounts and use toward meeting their targets under the protocol. Again, each CER represents one metric ton of CO_2 equivalent emission reduction. A CDM project could involve the same activities as a joint implementation. The only differences would be that the project would be implemented in a developing country, and the emission reductions would be issued as CERs. The CDM is overseen by an executive board.

Article 12 sets out some of the participation requirements for the CDM. It provides for the certification of emission reductions resulting from project activities by operational entities, on the basis of

A Madagascar nursery grows seedlings that will be used to plant new forests. The forests' carbon-fixing ability will be converted to credits and sold on the global market created by the Kyoto Protocol. (AP/Wide World Photos) voluntary participation of the parties involved; real, measurable, and long-term benefits related to the mitigation of climate change; and emission reductions additional to those that would have occurred in the absence of the project activity. The Annex to Decision 3/CMP.1 further provides that participants must be parties to the protocol and must designate a national authority. These requirements are additional to the general participation requirements described above.

• Emissions Trading

Article 17 of the protocol provides that parties with QELRCs may participate in emissions trading in order to fulfill their Article 3 commitments. Emissions trading involves Annex I parties trading in their AAUs. Here, Annex I parties who have not used up all their AAUs are allowed to sell them to other Annex I parties. These other Annex I parties are generally parties who either have exceeded or believe they will exceed their assigned amounts. Under the emissions trading scheme, Annex I parties can buy or sell any of the emission reduction units, including AAUs, CERs, ERUs, and removal units (RMUs). RMUs are ERUs generated under land use, land-use change, and forestry projects. This trade in emission reduction units or carbon credits has led to the creation of what is called the carbon market, where carbon emissions are traded like other commodities.

The rules governing emissions trading are contained in the Annex of Decision 11/CMP.1. In addition to the general participation requirements, Annex I parties are required to maintain a commitment period reserve of at least 90 percent of their assigned amounts. They are not allowed to make any transfer that would result in their holdings falling below this reserve.

• Context

The United Nations recognized that differing circumstances exist in different countries. Some countries may be relatively energy efficient, making it more difficult for them to reduce their GHG emissions sufficiently to meet their targets. In some countries, the potential cost of reducing their emissions may be very high. The need for flexibility was recognized, although the protocol provides that the use of the flexible mechanisms must be supplemental to domestic actions taken by Annex I parties. The Kyoto mechanisms were established to provide this flexibility, to enhance Annex I parties' ability to achieve their targets, and to provide them with cost-effective means of achieving these targets. In addition, other advantages of the mechanisms include contribution to the sustainable development of recipient countries through technology transfer and enhanced investment flows.

Kyoto Protocol

- **Category:** Laws, treaties, and protocols
- **Date:** Entered into force February 16, 2005

The Kyoto Protocol establishes clear targets for reducing GHG emissions, along with accounting mechanisms that encourage nations to undertake projects that reduce emissions. It balances national economic development plans with emissions reductions and sets up free market mechanisms to achieve the targets set by intergovernmental negotiations.

• Key concepts

Annex I nation: an industrialized nation listed under Annex I of the UNFCCC and committed to achieve a certain level of GHG emissions reduction within a specified period

certified emissions reduction (CER): a unit of GHG reduction, equal to 1 metric ton of carbon dioxide emissions, certified by the UNFCCC and tradeable on the carbon market

clean development mechanism (CDM): a system accounted by the UNFCCC, whereby an Annex I country sponsors a greenhouse gas reduction project in a developing country to earn CERs

joint implementation: a system in which Annex I countries can earn CERs by working on CDM projects in an economically transitional nation, generally one of the former Soviet or Balkan nations

United Nations Framework Convention on Climate Change (UNFCCC): an agreement between nations to participate in reducing anthropogenic effects on the climate

• Background

By the early 1990's, anthropogenic emissions had been identified as a significant contributor to the concentrations of greenhouse gases (GHGs) in the atmosphere and to climate changes. Such GHG emissions are generated by industrial activities, especially the burning of fossil fuels for energy, as well as agricultural processes in both developing and industrial nations. Thus, the United Nations sponsored the framing of the U.N. Framework Convention on Climate Change in 1992 and the

Gines Gonzalez Garcia, the president of the Tenth Conference of the Parties to the United Nations Framework Convention on Climate Change, declares the entry into force of the Kyoto Protocol on February 16, 2005. (Kimimasa Mayama/Reuters/Landov)

Kyoto Protocol to the UNFCCC in 1997 to address and mitigate the generation of GHGs by the signatories to those treaties.

On a per capita basis, the industrialized nations are by far the more intense of the world's emitters. The per capita carbon footprint, or the number of metric tons of carbon dioxide (CO_2) or other equivalent GHG emissions per year per person, is a useful metric for comparing national emissions. The per capita carbon footprint of the United States, for example, is around 18 metric tons, while Australia's is 25.5 metric tons. The world average is around 2.8 metric tons, China's is 2.4 metric tons and India's is 0.87 metric ton.

When the world's nations began negotiating a response to the perceived threat represented by anthropogenic GHG emissions, it was soon decided that the brunt of the effort would have to be borne by industrialized nations. This decision was not without controversy, but most parties to the negotiations believed that developing nations could not incur the costs of cutting emissions. It was argued that the industrialized nations, which were largely responsible for the rise in GHG concentrations, could not expect developing nations to curtail their attempts to improve their own people's standards of living by industrializing, nor could industrialized nations disavow their own primary responsibility for rising GHG levels and therefore their obligation to make amends. As a result of this decision, the United Nations Framework Convention on Climate Change (UNFCCC) divided its parties into Annex I (industrialized) nations and non-Annex I (developing) nations.

Annex I of the UNFCCC not only lists the industrialized parties to the convention but also commits them to reducing their GHG emissions by a specified date. It was left to the successor document, the Kyoto Protocol, to determine the details for each nation. That document spelled out the obligations of each party nation, as well as the specific accounting mechanisms that would be used both to measure a nation's progress toward reducing its emissions and to assign credits in lieu of actual reductions for certain complementary activities.

To meet the overall target of a 5.2 percent reduction in global GHG emissions from 1990 to 2012, the mandated reductions for individual nations are as large as an 8 percent reduction from the nation's 1990 emissions level. Some nations, including Australia, negotiated allowances for a rapid rate of growth and were allowed to increase their emissions by as much as 10 percent over their 1990 levels. They could also sell any unused portion of that quota as credits to other nations unable to meet their own reduction quotas. Countries set up national registries validated by the UNFCCC to monitor their emissions.

Each signatory to the Kyoto Protocol undertook to adopt policy measures to enhance energy efficiency; protect and enhance sinks and reservoirs of GHGs; and promote forest cover, sustainable forms of agriculture, and research on renewable energy and sequestration technologies. The signatories agreed progressively to remove policies and other incentives that support or encourage GHG emissions; to reduce emissions in the transport sector; and to reduce methane emissions through recovery and use in waste management. Emissions were also to be reduced in the production, transport, and distribution of energy.

Emissions Trading

Article 6 of the Kyoto Protocol, reproduced below, establishes the basic framework for parties to the treaty to trade pollution credits with one another, thereby employing market principles to drive international emission reductions.

1. For the purpose of meeting its commitments under Article 3, any Party included in Annex I may transfer to, or acquire from, any other such Party emission reduction units resulting from projects aimed at reducing anthropogenic emissions by sources or enhancing anthropogenic removals by sinks of greenhouse gases in any sector of the economy, provided that:

(a) Any such project has the approval of the Parties involved;

(b) Any such project provides a reduction in emissions by sources, or an enhancement of removals by sinks, that is additional to any that would otherwise occur;

(c) It does not acquire any emission reduction units if it is not in compliance with its obligations under Articles 5 and 7; and

(d) The acquisition of emission reduction units shall be supplemental to domestic actions for the purposes of meeting commitments under Article 3.

2. The Conference of the Parties serving as the meeting of the Parties to this Protocol may, at its first session or as soon as practicable thereafter, further elaborate guidelines for the implementation of this Article, including for verification and reporting.

3. A Party included in Annex I may authorize legal entities to participate, under its responsibility, in actions leading to the generation, transfer or acquisition under this Article of emission reduction units.

4. If a question of implementation by a Party included in Annex I of the requirements referred to in this Article is identified in accordance with the relevant provisions of Article 8, transfers and acquisitions of emission reduction units may continue to be made after the question has been identified, provided that any such units may not be used by a Party to meet its commitments under Article 3 until any issue of compliance is resolved.

- **Primary GHGs**

The specific gases covered by the Kyoto Protocol are listed in Annex A of the protocol. They are carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), and sulfur hexafluoride (SF_6). The contribution of each gas to the greenhouse effect is converted to that of an equivalent amount of CO_2 for easy comparison. This standardized measure of a GHG's climatic effects is known as its global warming potential. Methane, for example, has a global warming potential of 20, meaning it is twenty times as potent per unit mass as CO_2 over a specific time horizon.

GHG emissions arise from fuel combustion, energy industries, manufacturing industries, construction, and transportation. High-value targets for reduction include fugitive emissions from stored fuels, such as oil and natural gas; industrial processes in the metal and chemical industry, such as solvent and other product use; and direct production of halocarbons and sulfur hexafluoride. In agriculture, enteric fermentation, manure management, rice cultivation, prescribed burning of savannas, field burning of agricultural residues, waste incineration, and wastewater handling are all targeted activities.

- **Parties in Annex I**

The parties included in Annex I of the UNFCCC are Australia, Austria, Belgium, Canada, Denmark, the European Community, Finland, France, Germany, Greece, Iceland, Ireland, Italy, Japan, Liechtenstein, Luxembourg, Monaco, the Netherlands, New Zealand, Norway, Portugal, Spain, Sweden, Switzerland, the United Kingdom, and the United States. Countries listed in Annex I as undergoing transitions to market economies are Bulgaria, the Czech Republic, Estonia, Hungary, Latvia, Lithuania, Poland, Romania, the Russian Federation, Slovakia, Slovenia, and Ukraine. Annex I nations have agreed to limit or reduce GHG emissions from aviation and marine bunker fuels and to ensure that their aggregate anthropogenic emissions of the GHGs listed in Annex A of the protocol do not exceed their assigned amounts. Each party included in Annex I was to have made demonstrable progress by 2005 in achieving its commitments under the protocol.

- **Credits Versus Taxes**

The Kyoto Protocol did not institute taxes on carbon emissions. Instead, it created a system of credits and trading as the favored mechanism to reduce GHG emissions. By turning emissions into tradeable market commodities, the protocol enabled businesses to better manage their emission reduction strategies. The carbon market sets pricing, and market growth is driven by investors. Using flexible mechanisms, the Kyoto Protocol ensures that investments contribute to genuine, sustainable carbon reduction schemes.

- **Certified Emissions Reductions and the Carbon Market**

One certified emissions reduction (CER) unit, also known as one carbon credit, is equivalent to 1 metric ton of equivalent reduction in CO_2 emissions. CERs can be sold privately or in the international market. Each international transfer is validated by the UNFCCC. The European Commission also validates each transfer of ownership within the European Union. Climate exchanges provide a spot market in allowances, as well as futures and options markets, to discover the market price and maintain liquidity.

Trading in CERs is done through at least four exchanges: the Chicago Climate Exchange, the European Climate Exchange, Nord Pool, and PowerNext. The carbon market has exceeded 60 billion euros and is projected to grow beyond 1 trillion euros within a decade. As the need to meet national quotas intensifies, the value of CERs may rise, encouraging more investment in generating new CERs. Speculation and derivatives trading in the value of CERs contributes to rising market activity.

- **Clean Development Mechanism, Joint Implementation, and International Emissions Trading**

Annex I countries earn CERs for financing projects in less developed countries, including projects started ahead of the Kyoto trading period. Under the clean development mechanism (CDM), a developed country can sponsor a GHG reduction project in a developing country, where the cost of GHG reduction activities is usually much lower than it is in the developed country itself. The CDM is administered through an executive board, based in Bonn, Germany.

Joint implementation refers to CDM projects implemented by Annex I countries with the transitional economies of Eastern Europe and the Balkans. Carbon projects can be created by a national government or by an operator within the country. Under international emissions trading, countries can trade in the international carbon credit market to cover their shortfall in allowances.

• Progress Since the Kyoto Protocol

A 4 percent reduction in GHG emissions had been achieved overall by 2004. Large reductions came from former Soviet states that were transitioning to market economies. As of May, 2008, 182 countries had ratified the Kyoto Protocol, representing 61.6 percent of global emissions of GHGs. The United States and Kazakhstan had signed but not yet ratified the treaty. Afghanistan, Andorra, Brunei, Chad, Iraq, the Palestinian Authority, the Sahrawi Arab Democratic Republic, San Marino, Somalia, Taiwan, Tajikistan, Vatican City, and Zimbabwe had not expressed any position.

• U.S. Approach to Kyoto

In 1997, the U.S. Senate voted 95-0 against ratifying the Kyoto Protocol unless several conditions were met. The vote reflected lawmakers' concerns that American manufacturing would be severely affected by the costs of compliance, at a time when strong economic growth was driving emissions up. There was, moreover, widespread skepticism about the claims regarding anthropogenic global warming. The government took the position that since China and India, whose overall emissions are large despite very low per capita emission levels, were not subject to reduction requirements, the United States should not participate in the agreement.

On March 29, 2001, President George W. Bush withdrew the United States from the Kyoto Protocol. By 2004, the country had showed a 15.8 percent rise in emissions, against the target of a 7 percent reduction. Early studies projected a 4.2 percent drop in U.S. gross domestic product (GDP) if Kyoto requirements were met. Subsequent studies have projected far lower effects.

The U.S. approach at the beginning of the twenty-first century focused on using federal tax credits to encourage reduction in GHG emissions, accompanied by a phase-out of the most harmful products such as chlorofluorocarbons. Several states adopted so-called Green Tags, or renewable energy certificates. A renewable energy certificate is earned for each 1,000 kilowatt-hours of electrical energy produced from renewable sources. Some large renewable energy projects, such as wind farms on Native American reservations, have been funded partially through the sale of long-term rights to Green Tags. Green Tags can be used by corporations to reduce their net emissions profile.

A sharp rise in fossil energy prices beginning in 2004 created new market realities in the United States. Nuclear energy, which despite its other problems is a clean source from the GHG perspective, seemed poised for a comeback, along with an increased push toward renewable energy. Coupled with the drive toward efficiency in using costlier fossil fuels, the United States was moving along the path needed to bring GHG emissions down.

• Context

The ambitious aspiration of the Kyoto Protocol is to hold anthropogenic emissions of GHGs at the levels of 1990, as the world economy grows. The technological and policy improvements required to achieve this goal imply dramatic changes in the way the world operates. Fundamentally, the emission of waste heat and hot gases implies thermodynamic inefficiency. The Kyoto Protocol provides the urgent motivation, means for accurate accounting, and substantial funding to improve efficiencies, which in turn reduces the need for energy.

Energy efficiency, as a cost-saving rather than a cost-inducing measure, is also more likely to gain favor among industrialized nations and businesses doubtful of their ability to compete globally while reducing GHG emissions. As the nations of the world begin to negotiate the successor treaty to the Kyoto Protocol, a new sense of urgency combined with a new belief that green technologies may become an economic growth sector may make the next treaty negotiated under the UNFCCC more successful than the Kyoto Protocol has been.

Lamb, Hubert Horace

English climatologist

Born: September 22, 1913; Bedford, England
Died: June 28, 1997; Holt, England

Lamb was a pioneer in examining climate change from a historical perspective.

• Life

Hubert Horace Lamb spent much of his life as a working climatologist engaged in long-range weather forecasting and examining climate change with the United Kingdom Meteorological Office. In this capacity, he spent time in Antarctica, North Africa, and Malta, as well as becoming a member of the World Health Organization Working Group on Climate Fluctuations. In 1971, he became the founding director of the Climatic Research Unit in the School of Environmental Sciences at the University of East Anglia. As the director of the Climatic Research unit, Lamb did a great deal to encourage historical research into climate change as well as research into recent climatic developments. Among other awards, he received the Royal Meteorological Society's Darton Prize in 1964.

• Climate Work

A prolific writer, Lamb authored or coauthored 145 publications in a career beginning in 1939 and lasting through the second edition of his *Climate, History, and the Modern World* (1982), which appeared in 1995. Although he wrote six books, *Climate, History, and the Modern World* is Lamb's most far-ranging and influential work. This book has served as a model of the interdisciplinary perspective necessary for historical climate research. Even though some of his conclusions may be disputed, his work along with E. LeRoy Ladurie's *Times of Feast, Times of Famine* introduced scholars and nonscholars alike to the importance that climate has played in human events.

Almost all of Lamb's written work has dealt with some aspect of climate change. Some of his publications are technical works written for scientists, while others are written for broader audiences. Gradually, Lamb turned to an examination of historical climate as a means to understanding climate change.

In 1982, the initial edition of *Climate, History, and the Modern World* laid out a research program for the historical study of climate that influenced many later works. In this book, Lamb first provided scientific background on how climate works and how it fluctuates. He then provided a useful discussion of the sources used by historical climatologists, such as meteorological records, chronicles, grain prices, archaeological material, pollen analysis, radiocarbon dating, tree ring data, and ocean bed deposits. By emphasizing the use of multiple sources, Lamb made it clear that reliance on one type of source could be misleading and that achieving a comprehensive record of past climate is often difficult. In carrying out his analysis of past climate change, Lamb often extrapolated from his sources, such as written records or tree ring data, to achieve a more complete picture.

The bulk of *Climate, History, and the Modern World* is devoted to an examination of climate from the time of early civilization to 1950 and beyond. Two highly influential chapters posited a medieval warm era that lasted until the end of the thirteenth century and a period encompassing the sixteenth and seventeenth centuries that he labeled the Little Ice Age. These chapters have spawned numerous other works dealing with topics such as the Medieval Warm Period or the Little Ice Age that have used Lamb's analysis as starting points for further work. Subsequent analysis has modified some of Lamb's conclusions, but his work remains the starting point for research.

As a practicing climatologist, not a historian, Lamb provided more of a discussion of the changing climate and how humans have affected climate than of the impact of climate on human affairs. In contrast to Le Roy Ladurie, Lamb argued that climatic changes have had an impact on humankind, a view that has come to be generally accepted. The final section of the book dealt with the human influences on climate change, forecasting future developments in the light of the past, and a chapter dealing with the lessons to be learned from the impact of humans on the climate and what can be done to lessen this impact. The second edition included a final chapter on more recent developments.

Lamb may be criticized for a narrowness of focus because he dealt primarily with Western Europe in his work. Although documentation is better for this region, there have been some interesting works that deal with other areas of the globe, such as China and North America. In addition he tended to paint with a broad brush, emphasizing climate change in general rather than dealing with climate change in a particular region that might even run counter to the overall trend that Lamb was describing.

Lamb deserves credit for helping to open up the historical study of climate change and human impact on climate and climatic impact on human endeavor. Although some of his interpretations have been superseded, he helped to pioneer a field and has helped enhance knowledge of the factors that have contributed to climate change.

Land use and reclamation

• **Categories:** Economics, industries, and products; environmentalism, conservation, and ecosystems

Land use and reclamation affect and are affected by climate change in complex ways. The creation of new land from sea- or riverbeds or the restoration of an area to its previous natural state has the potential to shape the complex interaction between land cover and the atmosphere, an interaction that affects climate change as much as do GHG emissions.

• Key concepts

anthropogenic: due to human sources or activities

greenhouse gases (GHGs): trace atmospheric gases that trap heat, preventing it from escaping into space

land reclamation: modification of unsuitable land to allow for some form of human use or for a return to its original natural state

land rehabilitation: restoration of land that has suffered environmental degradation

• Background

The different types of land surface affect differently the interaction between the Earth and the atmosphere. Land cover and land-use patterns are affected by the distribution and density of human population, by its activities, and by natural causes. Land-use changes in urban and peri-urban areas, including land reclamation, often drive environmental change, reducing or increasing greenhouse gas (GHG) emissions. In turn, land use and land cover are affected by climate change through erosion, desertification, drought, heavy precipitation, ocean warming, sea-level rise, salinization, heat waves, increases in wind intensity, decline of glaciers and snow cover, and drying of wetlands, among other processes.

The role of land-use change in overall climate change is not well understood. However, if most of the observed increase in temperatures in recent decades can be attributed to GHG emissions, then urban and industrial land uses can be seen as coresponsible for global warming.

• Land Creation, Land Rehabilitation, and Soil Remediation

Land reclamation as a vehicle of land-use change can be one of two different processes. One consists in the creation of new land where there was once water, either in the sea or in a riverbed. Many cities

A section of jungle in southern Mexico lies scorched after being cleared by fire for agricultural use. (Jami Dwyer)

on all continents have used this process to create new residential or business areas, harbors, airports, and other infrastructure. Land reclamation also includes the construction of artificial islands for tourism-related activities or the creation or restoration of beaches in areas affected by beach erosion. Another form of land reclamation is the draining of seasonally submerged lands to convert them to agricultural uses and, in some places, also to control the agent of malaria.

The other form of land reclamation, also called land rehabilitation, consists in restoring an area after it has suffered physical degradation. Such degradation may be natural (for example, erosion) or anthropogenic (for example, pollution, soil contamination, or mining operations). Land can be rehabilitated to allow a new use, such as housing or commercial development, or it may be restored to its natural state in the interests of conservation. In the latter case, knowledge of the land's original soil, flora, and fauna characteristics will facilitate their restoration. Soil remediation, a soft form of land rehabilitation, is the removal of industrial contaminants in soil and water to reduce the risks for human health and for the ecosystem.

- **Land-Use and Climate Change**

GHG emissions and other anthropogenic and natural factors have the capacity to affect climate change. Urban and peri-urban areas have probably the greatest influence on climate change, being responsible for most GHG emissions. This influence is expected to increase, according to United Nations projections of urban population growth and urban sprawl. Outside urban areas, changes in land cover—including deforestation, reforestation, agriculture, and irrigation—affect temperatures, precipitation, and atmospheric circulation. Replacing a rain forest with agricultural lands reduces evaporation and consequently raises temperatures, while irrigation increases evaporation and, eventually, precipitation. Similar changes can be associated with reforestation of snow areas, with planting trees as carbon sinks, and with the creation of new areas for growing crops for fuel.

A changing climate can in turn affect land cover and land use. Climate change affects land cover by creating new risks associated with temperature rise, flooding of low areas, dike collapses, sea-level rise, storms and other natural disasters, erosion of coastal areas, salinization, droughts, the quantity and quality of groundwater resources, water scarcity, air quality, land subsidence, and deterioration of soils. These events can lead to habitat destruction, invasion by alien species, ecosystem fragmentation, and species loss, with profound and irreversible impacts on biodiversity. Climate change also directly affects many other economic and social activities that in turn affect land-use patterns. In some parts of the world, for example in small island states, the forecasted climate change and sea-level rise will make land one of the rarest and most vulnerable resources. In this context, cities will probably be the land-use type most affected by climate change, especially cities located on low coastal zones.

• Land-Use Planning in Adaptation and Mitigation Strategies

The interaction between climate changes and land-use calls for innovative adaptation and mitigation measures. Land-use planning can have an important role in climate change adaptation strategies at the local level, and can contribute to wider mitigation strategies as well. These measures include, for example, the coordination of public and private stakeholders involved in land-use and land reclamation processes, tax benefits, innovative financing mechanisms, and other incentives for the use of renewable energy.

Building codes can also be changed to incorporate norms for GHG emissions in public buildings, green roofs, energy efficiency within household dwellings, and energy conservation to prevent the production of carbon dioxide. Land-use planning strategies, including land zoning, must discourage automobile use, provide adequate incentives for mass transit, promote mixed land use and infill development in sites previously used by other urban functions (including land rehabilitated or areas subjected to soil remediation), and promote higher densities and compact urban layouts, stimulating walkability.

• Context

The interaction between landuse and land reclamation, on one side, and climate change, on the other, is exceptionally complex and is still insufficiently understood. However, the evidence available suggests that changes on each side of this relation affect the other, and, consequently, failure to consider these interactions and to act accordingly may have long-lasting negative consequences for the environment and for the economy and society. For that reason, measurable, verifiable, and reportable actions on adaptation and mitigation, in the field of land-use planning, must be taken sooner rather than later, in all countries, to reduce the environmental, economic, and social effects that would otherwise result from inaction. Special support for adaptation measures, including technology transfer and innovative finance, should be provided by the international community to the poorer and more vulnerable countries.

La Niña

• **Category:** Meteorology and atmospheric sciences

• **Definition**

Two large weather anomalies alternate south of an equatorial band across the middle and eastern portions of the Pacific Ocean. One is El Niño, characterized by warmer-than-average surface waters; the other is La Niña, marked by cooler surface temperatures (the two are collectively designated as the El Niño-Southern Oscillation, or ENSO). La Niña is defined as Pacific surface temperatures of 0.5° Celsius or more below average for a period of at least five months. The cooling occurs as stronger-than-usual eastward trade winds blow across the Pacific, churning cold water from the ocean depths to the surface.

The Spanish names of these weather events originate from the appearance of El Niño off the coast of Peru at Christmastime; *niño* (boy child) refers to the birth of Jesus. The opposite pattern is termed *niña* (girl child), although at one time it was called El Viejo (the old man). ENSO does not occur on a scheduled basis but does happen regularly with vehement, widespread consequences.

• **Significance for Climate Change**

No definitive link has yet been made between global warming and ENSO, the causes of which are only incompletely known. A great number of ambiguous variables impede conclusive evidence of such a link. To obtain more data and understand long-term weather patterns, a monitoring system in the Pacific collects data from buoys, satellites, and computer models. Hotter or colder surface Pacific waters alter overhead trade winds, thereby shifting the North American jet stream. Altering the track and strength of the jet stream produces exceptional rain or drought. The cold, heavy air from La Niña pushes the jet stream to the upper part of the United States.

On average, a La Niña event may last from nine to twelve months, appearing at the end of one year and extending into the next. Consequently, in the southeastern portions of the United States, winter temperatures are warmer and dryer than normal. In northwestern regions, they are cooler and wetter. Hurricanes in the Atlantic and tornadoes in the United States tend to increase in number and force during La Niña events. In South America, dryer-than-usual conditions prevail in southern regions.

El Niño events occur more frequently than do La Niña events, in a ratio of approximately two to one. However, La Niña events last longer. One such event lasted, with a brief interlude, from mid-1998 to early 2001. Another occurred during the latter half of 2007 through the first half of 2008, provoking epic rainfall in Australia and record snowfalls in parts of China.

Last Glacial Maximum

• **Categories:** Cryology and glaciology; climatic events and epochs

• **Definition**

The Last Glacial Maximum, also called the Wisconsin Glacial Stage, commenced about 35,000 years ago and ended about 12,900 years ago. At that time, the Earth entered the current interglacial stage of warming. The Last Glacial Maximum reached its peak of cold about 20,000 years ago, when the continental glaciers reached their maximum extent of southern advance. In the Northern Hemisphere during the Last Glacial Maximum, continental glaciers flowed out over the land surface from three main centers, northern North America, Greenland, and Scandinavia. Much of the Northern Hemisphere was covered with ice, including the northern Atlantic Ocean. Similar effects occurred in the Southern Hemisphere.

During the maximum, global sea levels dropped by as much as 120 meters below present levels. This drop had profound effects on the locations of shorelines, the gradients of rivers, and the hydrologic cycle on Earth. Sea level was much lower than present as a result of the amount of water that was locked up in the world's ice sheets covering the land.

Continental ice sheets of the Last Glacial Maximum consisted of individual large lobes, which expanded and contracted at different rates. Action of the individual lobes resulted in deposition of vast layers and mounds of rock, sand, and fine sediment, as well as erosive scour of the land. The Great Lakes of the United States and Canada formed as a result of such scour during the Last Glacial Maximum. Glacial ice covering the northern latitudes reconfigured the land's surface and largely removed preexisting drainage patterns, which were reestablished after the ice melted away.

• Significance for Climate Change

The presence of so much ice on the land had a huge effect on global climate and local weather. As a result of the uptake of water by glaciers, many arid areas of the Earth became much more arid. An example of this occurred in the Sahara region of Africa, where deserts greatly expanded during the era. Rain forests, which were plentiful before the Wisconsin Stage, shrank considerably and were fragmented into small areas. One effect of this fragmentation of the rain forests was isolation of animal groups such as gorillas into separate geographic areas, where the various isolated populations diverged.

Reduced evaporation from cooler seas generally made the Last Glacial Maximum much dryer, but there were areas where this was not the case. For example, in parts of North America, heavy rains from moist winds flowing over continental glaciers caused much heavier precipitation to occur in areas not covered by ice. For this reason, vast continental lakes formed in areas where lakes are not found today, such as the Great Basin of the United States. The largest such lake, Lake Bonneville, was the forebear of the Great Salt Lake.

The onset of the Last Glacial Maximum may have been triggered by the development of the Isthmus of Panama. Prior to the uplift of rocks and volcanic activity that formed the isthmus, waters of the Atlantic and Pacific Oceans freely mixed, and the salinity of these waters was therefore kept nearly equal. After the Isthmus formed, dry winds from Africa evaporated Atlantic Ocean water and raised the Atlantic's salinity slightly. Mixing could no longer mitigate this effect, so Atlantic Ocean water that moved toward Earth's northern pole, which had helped warm that area in past, no longer reached the pole. Instead, the higher density resulting from the water's greater salinity caused that water to sink north of Iceland. The resulting cooling of the northern pole area is thought to have been enough to trigger the initial ice buildup that started the glacial development of the Last Glacial Maximum. Once the process of ice buildup began, increased reflectivity of the ice (known as albedo) sent increasing amounts of solar energy back into space, and the cycle of global cooling began to accelerate.

The history of the Last Glacial Maximum shows what happens when the Earth descends into a glacial episode of ice accumulation and cooling. All global systems, both living and nonliving, are affected by this climate change. In many ways, the contemporary Earth is the result of many vast changes that occurred during the Last Glacial Maximum, as well as the effects of the current interglacial episode of warming.

Sea-level rise since the end of the Last Glacial Maximum has caused nearly all of the world's coastlines to move and reestablish themselves. Most of the high-latitude rivers and streams have established new channels and drainage patterns since the continental ice sheets melted away. Temperature and rainfall patterns are now mostly different from those during the last glacial episode. Therefore, modern ecosystems have entirely shifted in most instances over the past 12,900 years. In many instances, populations of plants and animals have been dramatically affected by this climatic shift. As a result, mass extinctions have occurred in some groups of organisms, and changes have occurred in others. For example, the Ice Age fauna of North America, including the saber-toothed cats, mammoth and mastodon, giant ground sloths, and small native horses—all of which were once plentiful—are now entirely gone. The physical and biotic changes related to the onset, duration, and end of the Last Glacial Maximum serve as reminders that the world and its living systems can be profoundly changed by global climatic shifts such as the ones that occurred as recently as 12,900 years ago.

Latent heat flux

• **Category:** Chemistry and geochemistry

• **Definition**

Water can exist as a liquid, solid, or vapor. The latent heat flux (expressed in joules per kilogram) is the rate at which energy is released or absorbed when water changes from one to another of these three states. It is latent by contrast with the sensible (or dry) heat flux caused by the movement of air. The energy involved in the various phase changes of water are known as the latent heat of vaporization (evaporation and condensation of gas and liquid), latent heat of fusion (melting of ice) and latent heat of sublimation (transition of ice directly to vapor). Evaporation of water, melting of ice, and sublimation of ice are heat-absorbing processes. The heat energy used is held in a latent or dormant (hidden) state until it is released back into the atmosphere when freezing, condensation, or the sublimation of vapor to ice occurs.

• **Significance for Climate Change**

A rise in the concentration of greenhouse gases (GHGs) in the atmosphere makes available more energy at the Earth's surface. This additional energy can be used either to heat the atmosphere by way of the sensible heat flux (increased warming) or evaporate water at the Earth's surface via the latent heat flux. If water is present, the latent heat flux will always be larger than the sensible heat flux, meaning that energy otherwise available to heat the atmosphere is used in evaporation. Given that over 70 percent of the Earth's surface is water, most of the additional energy at the surface due to GHG radiative forcing is used in an enhanced latent heat flux. The resulting warming of the atmosphere would be less in this case than if all the additional available energy was accounted for by the sensible heat flux alone.

The heating of air by the sensible heat flux at the Earth's surface causes the air to become buoyant and, as a result, to rise and mix with the cooler air above. Moisture is entrained in this rising air. As a result, the mean annual global climate impact of increased energy available due an enhanced greenhouse effect will manifest itself both as an increased sensible heat flux (warming) and increased evapotranspiration via the latent heat flux. The latter is dormant heat energy that can be transported great distances by wind and over time without loss. The impact on climate may occur in regions far from its source. This dormant heat energy does not radiate back to space until condensation occurs and returns the heat to the air.

Lavoisier Group

- **Category:** Organizations and agencies
- **Date:** Established 2000
- **Web address:** http://www.lavoisier.com.au

- **Mission**

The Lavoisier Group is an independent, nonprofit organization that aims to promote debate within Australia on the science of global warming and climate change and the perceived need to reduce fossil fuel consumption through national and international regulation. The group's activities are motivated by the belief that some of the science on which national and international climate policy is based is not beyond reproach. In light of this belief, the organization encourages dialogue within Australia on the scientific merits of climate policies and agreements such as the Kyoto Protocol, as well as their economic consequences. The organization also seeks

> to explore the consequences which any international treaty relating to global decarbonisation targets, and the methods of policing such treaties, would have on Australian sovereignty and independence, and for the World Trade Organization rules which protect Australia from the use of trade sanctions as an instrument of extraterritorial power.

The group is run by volunteers comprising mainly active and retired earth and atmospheric scientists, engineers, and other professionals.

The Lavoisier Group is named after Antoine-Laurent Lavoisier, a French scientist, economist, and public servant. Although he is best known for his discovery of the role oxygen plays in combustion, Lavoisier was politically liberal and persuaded of the need for social reform in France during the years leading up to the French Revolution. At age fifty, during the Reign of Terror, he was found guilty of *incivisme* (avoiding civic responsibility) by the French revolutionists and put to death by guillotine. Eighteen months after his death, Lavoisier was exonerated by the French government when it was formally declared he had been falsely convicted.

- **Significance for Climate Change**

The Lavoisier Group highlights noteworthy developments in climatology, publishing information on its Web site and inviting speakers on the subject. The topics most frequently covered in the organization's site and seminars include greenhouse gas theory, solar and planetary influences on Earth's climate, predictions and projections of future climate, the history of climate change, the economics of energy and technology, energy security, the role of the Intergovernmental Panel on Climate Change in promoting global warming hysteria, and the response of Australia's governments to the decarbonization campaigns of the environmentalist movement and the media.

Levees

- **Category:** Economics, industries, and products

- **Definition**

Levees are embankments or engineered structures near bodies of water; they are designed to prevent flooding of the land behind them. Permanent levees are used along rivers, such as the Mississippi and Sacramento Rivers, and in coastal areas, such as New Orleans, Louisiana. Once constructed, lev-

A reinforced section of New Orleans's 17th Street levee, which was breached during the floods associated with Hurricane Katrina. (AP/Wide World Photos)

ees are protected from erosion by planting them with vegetation such as grass or willows on the river side. Concrete abutments may also be used on the river side of a levee to protect the structure from strong currents. A breech occurs when a section of levee is washed away, letting water onto the adjacent land. On large floodplains, levees are built in a series, stepping back from the river, to provide an extra measure of protection against a breech.

Levee systems along coasts and rivers are built and maintained by a variety of state and federal agencies, including the U.S. Army Corps of Engineers (USACE), state and tribal levee boards, and private groups. For example, in Missouri, a group of private landowners who own a majority of the land in a wetland or another region where flooding occurs may create their own levee district, obligating themselves to pay taxes to finance the building and maintenance of levees.

The National Levee Safety Act (NLSA) of 2007 includes several provisions related to the oversight of levee safety and maintenance—including of nonfederal (state and private) levees. One provision of the NLSA authorizes the USACE to develop a plan to create a national levee safety program and to inventory and inspect all federal levees. Nonfederal levees can be added to the USACE inspection and inventory program at the request of local levee boards, but the maintenance and safety of those levees remains the responsibility of the local board. The NLSA also created a National Committee on Levee Safety (NCLS), which consists of representatives from USACE; the Federal Emergency Management Administration (FEMA); and state, regional, and tribal levee boards and is charged with creating a national levee safety program.

• Significance for Climate Change

The U.S. levee system is a large, complex patchwork of many different structures that have been built by a variety of organizations over many years. Some of the oldest levees in the United States were built more than 150 years ago. Most levees are earthen structures, built with a tapered profile, at a width-to-height ratio of seven to one. Thus, a maximum height must be determined by the time construction begins, based on analysis of historical data regarding maximum local flood heights and storm surges and the recurrence interval of these events.

Results of climate models, notably those used by the Intergovernmental Panel on Climate Change (IPCC), predict that future increased global temperatures will lead to higher sea levels, increased precipitation rates, and a greater potential for large hurricanes. Also, a report released by Environment Texas in 2007 concluded that weather data from 1948 to 2006 demonstrated that extreme precipitation events had increased by 24 percent. Together, such weather events have the potential to lead to higher flood levels and storm surges. For example, during the Upper Mississippi Valley flood of June, 2008, peak flows were approximately 1.8 meters above those previously recorded. The storm surge from Hurricane Katrina on August 29, 2005, was 7.6 meters. A report by University of California, Berkeley, scientists concluded that flooding in New Orleans was a result of the levees not being built high enough; however, this conclusion has been disputed by the USACE and independent investigators.

Following Hurricane Katrina, the United States Congress passed the Water Resources Development Act of 2007, which authorized creation of the National Levee Safety Program. The law mandated the formation of the National Committee on Levee Safety. The direct effects of global warming on levee safety have not been considered in initial plans for levee safety standards. A further concern for levee safety in coastal Louisiana, and in other cities located on deltas, is the combined effects of ground subsidence and projected sea-level rise. One potential solution is to replace levees with other flood control technologies, such as the movable water gates employed in Japan, England, and the Netherlands.

Level of scientific understanding

• **Category:** Science and technology

• **Definition**

The Intergovernmental Panel on Climate Change (IPCC) is a scientific body that represents a hybrid of science and government. Its members strive for maximum reliability in their measurements, but they are keenly aware of the virtual impossibility of reaching that goal. Earth's climate is simply too vast a system to allow for carefully controlled experiments. Rather than ignore the problem, IPCC workers have designed a compromise system that specifies the degree to which workers in the field are confident of the validity of reported data. A level of scientific understanding (LOSU) designation is applied to assessments of each of the influences on the Earth's temperature. These radiative forcing factors include the greenhouse gases (GHGs), aerosols, mineral dust, and contrails.

Each of the radiative forcing factors is given an assessment of A to C depending on the evidence supporting it and an assessment of 1 to 3 for the degree of consensus among climate scientists. LOSU is assigned on the basis of these two evaluations. The terms used are high, medium, medium-low, low, and very low. This scale and its terminology were deliberately chosen to avoid confusion with the measures of confidence associated with statistics. IPCC reports clearly state that such statistical precision is not possible in the present state of climate science. The LOSU designation is designed to avoid the unwarranted impressions of understanding.

• **Significance for Climate Change**

Central to all scientific discussions is the reliability of the measurements that are used to support one's position. In the case of climate change or global warming, there are a number of extremely complex issues seldom encountered in scientific studies. These include the size of the system being studied; the constant changes undergone by that system; the large number of scientists conducting partial studies, each of whom has a particular objective; the lack of power to demand that specific procedures be followed; and so on. By contrast, scientists are accustomed to designing experiments with particular objectives and carrying them out under carefully controlled conditions. Added to these difficulties is the obvious necessity of collecting enormous amounts of data on a worldwide scale and attempting to draw from them meaningful leads for further investigation.

These problems pale in comparison to the realization that these scientific studies are conducted in a highly charged political arena. Imagine a range of scientists with little training and personal sympathies or antipathies toward policy makers presenting tentative conclusions to officials with little scientific background, and perhaps even a jaundiced view of civilians who never have to stand for reelection. Even assuming both groups earnestly desire to benefit humanity, it is clear that differences of viewpoint will often lead to discord over the appropriate strategies and tactics.

Those who disagree with a general position on global warming argue that science must not involve consensus and that the LOSU is therefore fatally flawed. This conclusion is based on a red herring and a profound lack of knowledge of the history of science. The most important reason for publication of the outcome of scientific experimentation is to allow other scientists to fulfill their obligation to question any new proposal. This is how new ideas are tested through peer review. The normal outcome of this process is debate over the validity and utility of that idea, and it inevitably leads to a mixture of acceptance, reservation, and rejection. It was long after John Dalton had proposed the atomic hypothesis that the majority of chemists accepted the existence of atoms. Even after an idea becomes textbook science and is accepted by nearly everyone, at least as a working hypothesis, it may still be modified or rejected when the consensus is broken. A consensus existed that the inert elements did not form compounds, until it was shown that they do. Science depends on consensus at every stage of its evolution.

With these technical and political problems in clear view, the IPCC has sought to bring common sense to bear on its mission. Nowhere is this effort clearer than in the LOSU approach. By considering both the strength of the evidence offered by scientists and the degree of acceptance it obtains from the scientific community, the group offers the public and the policy makers its best estimate of the real-world situation. It has been said that the only simple systems are those that have not yet been studied. It appears clear to informed people, scientists, and policy makers that the problems of climate change must be resolved using the best ideas and technology available. The level of scientific understanding represents a useful approach to evaluating and disseminating the current state of this aspect of climate science.

Liberalism

- **Category:** Popular culture and society

Liberalism has an important impact on the modern mindset regarding the human relationship with nature. Liberal individualist viewpoints affect debates about global warming in diverse and sometimes contradictory ways. Examining liberalism is crucial in interpreting U.S. public policy regarding global warming.

• Key concepts

civil society: a voluntary community composed of individuals who share similar values and norms and who work to improve their collective welfare

complex interdependence: a situation in which intensive interconnections between transnational actors necessitate cooperation among those actors

faction: a group of individuals with common goals who work primarily to attain their interests within a larger political framework

liberty: the ability of individuals to act according to their own will without external coercion

natural law: the concept that some laws are given by nature and apply to everyone at all times in all places

neoliberalism: the liberal school of thought in economics that stresses the importance of free markets and minimal government intervention in economic matters

private property: the individual or group ownership and control over objects that have value and can be exchanged

reason: the use of logic and analysis to formulate and evaluate propositions and arguments

• Background

Liberalism is a political philosophy founded during the Enlightenment in Europe. Prominent liberal philosophers include John Locke, Adam Smith, Jean-Jacques Rousseau, Immanuel Kant, Jeremy Bentham, and John Stuart Mill. As a theory, liberalism represents a wide range of thought. At its core, liberalism is optimistic toward the ability of humans to use reason to achieve social progress. To pursue progress through reason, the individual must be autonomous, that is, free from unnecessary coercion and threat. The rise of liberalism coincides with the rise of the modern nation state. Liberalism justifies the authority of the nation state on the grounds that the nation state is a necessary social institution to protect individual rights and liberty. These rights are often defined as the right to enjoy one's property. Governments have a legitimate role in defending property rights and one's freedom to enjoy property according to one's will. Legitimate government to liberals is unbiased, representing no faction while equally protecting the rights of all citizens. Liberalism holds an optimistic view of human nature and enlightened self interest. Individual rights are central to the liberal outlook.

• Private Property

The liberal emphasis on the importance of private property has had a profound impact on modern society. Private property, according to John Locke, is the basis of self-preservation. Locke argues that the person who applies labor to nature to create value is the rightful owner of that value, or property. The industrious create value where there was previously none. In this view, nature is not valuable in itself, but only as a means toward providing for human ends. According to Locke, however, humans should take from nature only that which they can reasonably use. Humans should not allow value derived from nature to spoil. With the invention of money, however, this spoilage can be reduced. Money allows for the accumulation of wealth and enlargement of private property, because it does not spoil.

It should be noted, however, that classical liberalism also informed critics of private property. Many socialist, communist, and anarchist social theories operated under classical liberal principles of human freedom, liberty, and progress. This attests to the wide range of ideas and social movements inspired by liberalism.

• Civil Society

Liberalism emphasizes the importance of civil society. Civil society is achieved by the voluntary submission of each free individual to an objective power that can judge social conflicts arising between self-interested people. The primary force in civil society is the legislature. The legislature makes the laws that form the common bonds and rules among individuals. Civil society is necessary because prior to civil society people exist in the state of nature. The state of nature is one of mutual fear and danger. To enforce legislative bonds, an executive must possess the power to execute laws and punish those who fail to abide by the rules of civil society, or the social contract. Liberal democracies operate under social contracts, an example being the United States Constitution.

- **The Danger of Factions**

The end of civil society is to promote peace and to preserve private property. Sometimes however, legislative and executive power fall prey to the interests of factions. Factions view government as a means to pursue their own interests rather than the interests of the whole country. When factions become too powerful, civil society falls into despotism and possible dissolution. If powerful factions rule unjustly, those who are unjustly ruled are justified to resist. This liberal concept is explicitly stated in the reasoning of the Declaration of Independence of the United States written by Thomas Jefferson. Problems associated with factions are also a central concern in the *Federalist* papers, written by the early American statesmen Alexander Hamilton, James Madison, and John Jay.

- **Context**

Liberalism affects the economics and politics of global warming in diverse and contradictory ways. Much of this diversity and contradiction arises from the various ways in which principles of liberalism are interpreted. For example, liberals who accept the theory of climate change argue that rational people can work together to solve this collective problem. The enlightened self-interest of the individual enables one to cooperate with others to solve collective problems. Civil society would call upon government to address the problem of climate change through legislation and executive action. In the academic field of international relations, liberal theorists cite the importance of cooperation between nation states to achieve common goals. Liberals argue that common goals and interests promote peace between nation states. Liberal scholars in international relations recommend international agreements and institutions to address collective problems such as climate change. Climate change is a good example of a global problem that will require cooperative behavior among the nation states of the global system.

Locke on Property

John Locke's Two Treatises on Government *is one of the founding texts of liberalism. In the Second Treatise, excerpted below, he sets forth the liberal philosophy of property rights that continues to govern the understanding of most Western governments of the relationship between individual humans, society, and the environment. It is within the context of this ideology that most discussions of climate change and public policy take place.*

The earth, and all that is therein, is given to men for the support and comfort of their being. And tho' all the fruits it naturally produces, and beasts it feeds, belong to mankind in common, as they are produced by the spontaneous hand of nature; and no body has originally a private dominion, exclusive of the rest of mankind, in any of them, as they are thus in their natural state: yet being given for the use of men, there must of necessity be a means to appropriate them some way or other, before they can be of any use, or at all beneficial to any particular man. The fruit, or venison, which nourishes the wild Indian, who knows no enclosure, and is still a tenant in common, must be his, and so his, i.e. a part of him, that another can no longer have any right to it, before it can do him any good for the support of his life.

Though the earth, and all inferior creatures, be common to all men, yet every man has a property in his own person: this no body has any right to but himself. The labour of his body, and the work of his hands, we may say, are properly his. Whatsoever then he removes out of the state that nature hath provided, and left it in, he hath mixed his labour with, and joined to it something that is his own, and thereby makes it his property.

To global warming skeptics, however, liberalism is interpreted to defend the inviolability of private property. Skeptics argue that government intervention in the economic process should be kept to a minimum to protect the freedom to dispose of one's private property as one sees fit. Intrusion by governments to address climate change would diminish the liberty of individuals who possess property. The best way to address climate change, if it is a problem, is to allow individuals to create wealth that can then be applied to solve the problem.

Economic neoliberals, who are often political conservatives, are central to skeptical climate change discourse. Some neoliberals are openly hostile to environmentalists, arguing that they represent a new religious movement or reformation of socialism. The skeptical view contends climate change is not a real phenomenon, but a fabrication made by alarmists. These alarmists have a self-interest in promoting climate change theory for they profit from government intervention in the economy. Ironically, contending views of climate change theory allow differing schools of liberal thought to see each other as representing factions that endanger private property, civil society, and natural law.

Libertarianism

- **Category:** Popular culture and society

Libertarianism is a political philosophy that champions individual rights and is suspicious of government restrictions on private property. Many libertarians are skeptical of the scientific basis of belief in anthropogenic climate change. Other libertarians endorse the scientific claims but favor voluntary private-sector efforts at mitigation and adaptation.

- **Key concepts**

geoengineering: the intentional production of large-scale changes to the Earth in order to promote human welfare

laissez-faire: an antiregulation policy that allows markets to operate free of government interference

private property: an institution through which legal rights to most or all tangible economic possessions are assigned to individual owners

revenue neutrality: an approach to fiscal policy in which new taxes (such as carbon taxes) are tied with dollar-for-dollar reductions in other taxes, in order to keep the total tax burden constant

tragedy of the commons: a term describing the perverse collective outcome of self-interested behavior in the absence of property rights

- **Background**

Libertarianism is a political philosophy rooted in individual liberty. It stands in contrast to other political philosophies that place the interests of the nation, state, or other collective group above the interests of the individuals composing the group. There is no list of beliefs shared by all libertarians, though they generally oppose the Drug War and military draft, while favoring large tax and spending cuts. The libertarian position is often described as conservative on economic issues and liberal on social issues, but its proponents believe that libertarianism represents a consistent defense of individual freedoms against government encroachment.

Major Libertarian Think Tanks and Climatological Organizations

- Cato Institute
- Fraser Institute
- Heartland Institute
- International Policy Network

• Strains of Libertarianism

Historically, many different political philosophies have embraced the term *libertarian.* Some libertarians do not have strict rules limiting state power but generally favor reducing the size of government in most areas. Economist Milton Friedman (1912-2006) falls into this camp. Another group of libertarians are principled minarchists, who believe that the only legitimate role for the government is to provide judicial, police, and military services for its citizens. The novelist Ayn Rand (1905-1982) was a famous minarchist libertarian.

Other self-described libertarians are more radical anarcho-capitalists, who call for the abolition of the modern state and the privatization of all legitimate government services, including defense from foreign invasion. Economists Murray Rothbard and David Friedman are anarcho-capitalist theorists. Finally, there are libertarians who reject the system of capitalism as it exists today and believe that private property rights can lead to unjust power relations among the capitalists and the common workers. Pierre Proudhon (1809-1865) and Emma Goldman (1869-1940) are examples. However, in modern American political debate, libertarianism is usually associated with support for private property and laissez-faire capitalism.

• Libertarianism and the Environment

In mainstream political debate, the libertarian position is often associated with the "pro-economy" forces and opposed to the "pro-environment" groups. For example, if there is a conflict between the livelihood of loggers and the natural habitat of the spotted owl, most libertarians would typically support the former. Despite this tendency, many libertarians embrace defense of the environment but believe that market solutions are more effective than government regulations. Such free market environmentalists argue that air and water pollution are not examples of market failure but rather government failure. Free market environmentalists argue that under the common law, a factory dumping chemicals into a river could be prosecuted by the homeowners living downstream. In the late nineteenth and early twentieth centuries, however, British and American courts often threw out lawsuits against big businesses, in order to promote industry.

Libertarians explain environmental abuses using the economics concept of the tragedy of the commons, defined in the essay "The Tragedy of the Commons" (1968) by Garrett Hardin. Historically, when pastureland was treated as common property, herders would routinely allow their animals to overgraze the land, because any individual's restraint would simply allow another herder's animals to eat more grass. Only the introduction of private property boundaries (and barbed wire in the United States) eliminated harmful overgrazing. Likewise, libertarians often recommend the introduction of well-defined property rights as solutions to overfishing, water shortages, air pollution, and other environmental problems typically blamed on capitalism.

• Libertarianism and Climate Change

In the political debate concerning anthropogenic climate change, most libertarians are skeptical of government solutions, which often involve new government powers and hundreds of billions of dollars. Many libertarians have embraced criticisms of the scientific evidence for anthropogenic climate change, especially as the consensus view is promulgated by a worldwide coalition of governments, the Intergovernmental Panel on Climate Change (IPCC). This group of libertarians does not believe continued carbon emissions pose any serious threat and therefore opposes new taxes or regulations because they would impose economic damages with no corresponding benefit.

A smaller but growing group of libertarians endorses the scientific evidence of anthropogenic global warming but supports voluntary, private-sector measures to address the problem. Many in this group rely on the public choice school of economic thought, which demonstrates that democratic systems often lead to unintended consequences. Even if climate change is a serious threat, these libertarians believe, politicians cannot be trusted to implement effective solutions. Instead, they argue that unfettered economic growth will allow mankind to adapt to rising sea levels, higher temperatures, and other possible changes. They also believe that if the situation requires it, the market can provide more extreme remedies such as geoengineering solutions (mirrors in space, aerosols released into the atmosphere, and so on).

Finally, there are some libertarians who believe the nature of global climate change requires a political remedy. Such libertarians usually favor a revenue-neutral approach, in which the revenues raised from a new carbon tax, or from auctioning carbon permits, are used to reduce preexisting taxes.

• Context

There has always been a strong emphasis on individual liberty and suspicion of bureaucratic government in American politics. Since Franklin Roosevelt's New Deal in the 1930's, Republican politicians have generally presented themselves as advocates of fewer taxes and regulations on business. Democrats, in contrast, have generally focused on protecting the rights of minority groups and others with little political power against abuses from employers, the police, and other powerful groups. In modern political debate, libertarians have combined both elements of this suspicion of government, emphasizing the freedom of the individual in both the marketplace and public arena. Because most of the proposed remedies for anthropogenic climate change involve more money and power for the federal government, many libertarians have been very skeptical of the growing calls for government-directed mitigation efforts.

Lichens

• **Category:** Plants and vegetation

• **Definition**

Lichens are very common organisms found in widely diverse habitats, including rock surfaces, trees, and human-made structures. Lichens use structures on which they grow as hosts to support their growth. They are composites, composed of two different organisms, an alga and a fungus, resulting in a symbiotic organism that has a morphology very different from the two original organisms. In lichen symbiosis, the alga provides energy through photosynthesis and the fungus provides protection and support. Lichens come in three types: crustose, a crusty form that grows tightly on rocks or trees; foliose, which resembles foliage; and fruticose, which has the appearance of "fingers." Lichens provide food for animals, such as reindeer living in arctic regions, and habitat for invertebrates. Lichens absorb nutrients from air and rain and are an important part of nutrient recycling. They grow very slowly, with rates less than 5 millimeters per year. Some species even have growth rates of less than 0.5 millimeter per year. Lichens often live for long periods of time, with some species in the arctic estimated to be over five thousand years old.

• **Significance for Climate Change**

Because of their sensitivity to environmental factors, including temperature changes, lichens can serve as indicator species (or canaries in the coal mine) to predict environmental changes. Historically, lichens have been important indicators of pollution and climate changes. Many long-term climate change studies have used lichen growth to estimate changes in environmental temperature over time. Mapping the distribution of climate-sensitive species provides an indication of current climatic conditions, whereas monitoring over time reveals past climate change effects. Lichen growth studies have been an important part of the debate over greenhouse effects by providing data that support climate change and global warming. Because of global warming, arctic-alpine species have been diminishing, while more tropical species have flourished.

Lichens grow at very slow rates, increasing in diameter as they grow. The size of individual lichen patches on rocks can be used to estimate age, with measuring the diameter of the largest lichen on a rock surface a method to determine the time period during which that rock was exposed. The study of lichen growth to determine the age of, or to "date," surfaces is called "lichenometry." The slow growth and longevity of crustose lichens have made them especially useful in lichenometry. Measurement of lichens has been used to document effects of global warming, such as glacial deposits, former extent of persistent snow cover, and avalanche activity. Most climate change studies using lichens have been conducted using a group of crustose lichens of the genus *Rhizocarpon*, which is very abundant in many Arctic environments.

- **Definition**

Liming is the addition of calcium and magnesium to soil to neutralize acidity and increase the activity of soil bacteria. The amount of lime needed to reach the desired acidity depends on the pH and the buffering capacity of the soil. The pH is a measurement of acidity or alkalinity. Buffering capacity refers to the soil's ability to resist change to its pH. Additionally, liming improves nutrient efficiency by encouraging fertilizer uptake. However, there are important limits to liming, as oversupply may cause harm to plant life. The most common liming materials come from grinding natural limestone. Limestone is composed mostly of calcium carbonate ($CaCO_3$) and by most state laws must contain 6 percent magnesium for purposes of liming. In addition to buffering the soil, the main way to reverse acidification in freshwater is through liming the water body or its surrounding drainage basin.

- **Significance for Climate Change**

Carbon dioxide (CO_2) does not absorb the Sun's energy, but it does absorb the heat energy released from the Earth. Some of the released heat energy returns to Earth and some goes out into space. This describes the greenhouse effect of CO_2; that is, CO_2 lets light energy in, but not all of the heat energy can get out. Soil liming can act as either a source or a sink for CO_2. A heat sink absorbs and dissipates the heat energy.

Some studies indicate that rather than all of the carbon in lime becoming CO_2, the lime may sequester up to half of its carbon content, thus becoming an effective carbon sink. If this is so, liming might even be part of the strategy to moderate climate change. Streams draining agricultural watersheds generally show a net CO_2 uptake. However, as nitrate (a common fertilizer ingredient) concentrations increase, lime may switch from a net CO_2 sink to a CO_2 source.

Peat soil contains large amounts of carbon and therefore is a significant emission source of greenhouse gases—especially of methane. When farming acidic peat lands, adjustment of the acidity through liming is essential. However, when adding lime to these soils often rich in carbon and methane, CO_2 production increases. In addition, because of the enhanced decomposition of organic matter through liming, soluble organic carbon increases and may factor into climate change.

Finally, it is important to note that the amount of CO_2 emissions from liming is not completely clear. This is because the amount of carbonate lime applied to soils is unclear, as is the net amount of carbon from liming that is released as CO_2.

Limits to Growth, The

- **Category:** Popular culture and society
- **Date:** Published 1972; updated 2004
- **Authors:** Donella H. Meadows (1941-2001), Dennis L. Meadows (1942-), and Jørgen Randers (1945-)

- **Background**

In 1972, a team at the Massachusetts Institute of Technology led by Donella Meadows developed a computer model called World3 that consisted of a complex set of interrelated differential equations that modeled the global future in terms of human population growth, the global economy, and feedbacks to the environment. The book describing this model, *The Limits to Growth*, was prominent among many publications at the time that raised a clarion call regarding biological productivity, environmental degradation, increasing population growth, and economic activity. The five fundamental variables modeled in World3 were human population, industrialization, food production, pollution, and resource depletion. The model was criticized by many neoclassical economists and others for myriad reasons, including its aspatial formulation, failure to account for technological innovation, and exponential growth assumptions.

Other books were published in the decades leading up to the release of *The Limits of Growth*, including Rachel Carson's *Silent Spring* (1962), Aldo Leopold's *A Sand County Almanac* (1949), and Paul Ehrlich's *The Population Bomb* (1968). Indeed, debates about the sustainable limits of human society harkened all the way back to Thomas Robert Malthus' seminal *An Essay on the Principle of Population, As It Affects the Future Improvement of Society* (1798). The negative effects of humans on the environment seemed to rise in societal awareness in the late 1960's and early 1970's because of the polluted Cuyahoga River catching on fire (1969), oil spills in Santa Barbara (1969), and significant air quality problems in major cities such as Los Angeles. Many contemporary films also presented dystopic visions of the future based on problems associated with limits to growth, including *Soylent Green* (1973), *Silent Running* (1972), and *Logan's Run* (1976).

This heightened awareness of environmental degradation related to limits on sustainable growth contributed to the first Earth Day, which took place in 1970. Soon after, Republican president Richard Nixon signed a great deal of environmental legislation, including the Clean Air Act Extension of 1970 and the Clean Water Act (1972), as well as issuing an executive order establishing the Environmental Protection Agency (1970). The environmental movement laid the foundation for many subsequent considerations of limits to growth. Civilized and uncivilized discussions of the idea of a human population "carrying capacity" increased in frequency and vitriol. Many would argue that Gro Harlem Brundtland's subsequent coinage of the phrase "sustainable development" (meeting the needs of the present generation without sacrificing the needs of future generations) is intimately related to ideas of limits to growth. Nonetheless, discussions of limits to growth and related ideas of carrying capacity remain incredibly controversial today. Perhaps not surprisingly, the specter of present and looming climate change resulting from human activity seems to be rekindling these old and ongoing debates.

Ecological Footprint

In the following excerpt from Donella Meadows, Dennis Meadows, and Jørgen Randers's The Limits to Growth: The Thirty-Year Update, *the authors introduce the concept of an ecological footprint and explain its importance to their argument.*

The term [ecological footprint] was popularized by a study Mathis Wackernagel and his colleagues conducted for the Earth Council in 1997. Wackernagel calculated the amount of land that would be required to provide the natural resources consumed by the population of various nations and to absorb their wastes. Wackernagel's term and mathematical approach were later adopted by the World Wide Fund for Nature (WWF), which provides semiannual data on the ecological footprint of more than 150 nations in its *Living Planet Report*. According to these data, since the late 1980's the earth's peoples have been using more of the planet's resource production each year than could be regenerated in that year. In other words, the ecological footprint of global society has overshot the earth's capacity to provide. There is much information to support this conclusion.

• Significance for Climate Change

Discussions of limits to growth are often centered around the limits represented by the interrelated resources of food, water, and energy. The causes and consequences of climate change are also intimately related to those resources. Most policy proposals regarding climate change involve adaptation to the impacts of climate change or reduction or elimination of its causes. Primary among these causes is the anthropogenic emission of greenhouse gases (GHGs), particularly carbon dioxide (CO_2). Perhaps fortunately, global oil supplies seem to be dwindling. Increasing use of biofuels as a substitute for oil, however, demonstrates the problematic and interconnected nature of limits to growth.

When corn is used to produce ethanol as a substitute for gasoline, food supplies are affected, and the combustion of ethanol still produces CO_2 emissions. When densely populated coastal communities resort to the desalination of ocean water to obtain freshwater, they often burn fossil fuels to generate the energy needed to do so. Global warming also has the potential significantly to alter climate patterns in ways that will negatively affect both food and water supplies. The concepts of carbon footprints and carbon neutrality have gained currency in discussions of climate change. The idea of a carbon footprint borrows from a broader and older idea, than of an ecological footprint, which is itself essentially an analysis of limits.

Typical ecological-footprint analyses compare human demands on Earth's ecosystems and natural resources and contrast them with Earth's ability to provide for those demands through time. Many scholars and researchers are convinced that the present demands of the human population on Earth's resources exceed Earth's ability to provide them and that the human population is therefore in a state of ecological deficit. Increasingly, scholars are conducting various kinds of economic-ecological accounting studies that raise once again some very contentious and controversial questions about the limits to growth. The prospects of climate change, global warming, and their consequences have reignited the interest in and perhaps the urgency of resolving these important questions regarding the limits to growth.

Lithosphere

- **Category:** Geology and geography

- **Definition**

Besides compositional classification, the Earth is separated into layers based on mechanical properties. The topmost layer is called the lithosphere, composed of tectonic plates that float on top of another layer known as the asthenosphere. The term lithosphere is derived from the Greek words *lithos*, meaning rock, and *sfaira*, or sphere. The rigid, brittle lithosphere extends about 70 kilometers and is made up of Earth's crust and the upper part of the mantle underneath. It is broken into a mosaic of rigid plates that move parallel across the Earth's surface relative to each other.

The lithosphere rests on a relatively ductile, partially molten layer known as the asthenosphere, which derives its name from the Greek word *asthenes*, meaning "without strength." The asthenosphere extends to a depth of about 400 kilometers in the mantle, over which the lithospheric plates slide along. Slow convection currents within the mantle, generated by radioactive decay of minerals, are the fundamental heat energy source that causes the lateral movements of the plates on top of the asthenosphere. According to the plate tectonic theory, there are approximately twenty lithospheric plates, each composed of a layer of continental crust or oceanic crust. These plates are separated by three types of plate boundaries. At divergent boundaries, tensional forces dominate the interaction between the lithospheric plates, and they move apart and new crust is created. At convergent boundaries, compression of lithospheric plate material dominates, and the plates move toward each other where crust is either destroyed by subduction or uplifted to form mountain chains. Lateral movements due to shearing forces between two lithospheric plates create transform fault boundaries. Earthquakes and volcanic activities are mostly the result of lithospheric plate movement and are concentrated at the plate boundaries.

• Significance for Climate Change

Volcanic eruptions have severe effects on global climate. The greenhouse effect, icehouse effect, and ozone depletion by far have gained the most attention in climate research and planning. In addition to lava and pyroclastic materials (fragments of hot and molten rocks), volcanoes emit a variety of gases such as water vapor, carbon dioxide (CO_2), carbon monoxide (CO), chlorine, fluorine, and sulfur dioxide (SO_2). Both CO_2 and CO are greenhouse gases (GHGs) that contribute to global warming by creating a shield over the Earth that prevents heat from escaping into the atmosphere.

In contrast, SO_2 gas causes short-term cooling resulting from what is known as the icehouse effect. In the lower atmosphere, SO_2 gas is converted to sulfuric acid (H_2SO4), which condenses to form a thick layer of sulfate aerosol. The suspended aerosols increase Earth's albedo by reflecting the Sun's rays back to space and cause cooling of the Earth's surface. An anomalous increase in SO_2 layers in the atmosphere and decrease in average temperature correlates significantly with several volcanic eruptions. The 1991 eruptions of Mount Pinatubo in the Philippines were responsible for about a 0.5° Celsius decrease in global temperature and an unusually cold summer in 1992 in the intermediate latitude of the Northern Hemisphere.

Although volcanic activity increases the global temperature by adding CO_2 to the atmosphere, a much greater amount of CO_2 is added to the atmosphere by anthropogenic activities each year. Research by Terrence M. Gerlach indicates that anthropogenic CO_2 emissions are about 150 times greater than volcanic CO_2 emissions. A small amount of global warming caused by the GHGs from volcanic eruption can considerably supersede the greater amount of global cooling caused by volcano-generated aerosol particles in the atmosphere. Without such cooling effect, global warming due to GHGs would have been more pronounced.

The lithosphere's plates move at a rate of about 3 centimeters per year. The distribution and relative movement of the oceanic and continental plates across the latitude also have profoundly affected the global climate. The major contributing factors are differences in surface albedo, land area at high latitudes, the transfer of latent heat, restrictions on ocean currents, and the thermal inertia of continents and oceans. According to the present configuration of oceans and continents, the low latitudes have a greater influence on surface albedo because the lower latitudes receive a greater amount of solar radiation than the higher latitudes.

Whereas the continents in higher latitudes receive lesser solar radiation and accumulate snow that consecutively increases the albedo and decreases the Earth's surface temperature, the latent heat of evaporation influences the surface temperature at lower latitudes, where there is greater oceanic surface. The evaporation of water from the oceanic surface, a dominant mode of heat transfer, results in greater heat loss in lower latitudes. Oceanic circulation is a primary mechanism by which the heat due to solar radiation is spread from equatorial to polar latitudes. The continents in between work as barriers that restrict the oceanic heat transport toward the poles, and can influence the area and thickness of polar snow cover. The thermal inertias of continents and oceans are different. The continents respond quickly if there is a change in solar input, whereas oceans have high heat capacity and act slowly. In addition to the present positions of the continents and oceans, the higher elevations due to mountain orogeny also control the global climate.

Little Ice Age

• **Categories:** Climatic events and epochs; cryology and glaciology

A brief cold period may have occurred during the seventeenth and eighteenth centuries. Some researchers think that the lower temperatures resulted from a reduced solar energy output related to the Maunder Minimum in sunspot activity. The possibility that climate variations may be induced by solar activity complicates the conventional theory that human activity is causing global warming.

• Key concepts

luminosity of Sun: the total energy output of the Sun every second, measured in watts

Maunder Minimum: a period from about 1645 to about 1715 when very few sunspots were observed

sunspot cycle: also known as the solar activity cycle, an eleven-year cycle in the number of sunspots and amount of other solar magnetic activity

sunspot minimum/maximum: the time when there is the minimum/maximum number of sunspots during the eleven-year sunspot cycle

sunspots: dark spots on the surface of the Sun caused by solar magnetic activity

• Background

Indirect and anecdotal evidence indicates that it was colder than normal during the seventeenth century in Europe, and possibly worldwide as well. Without accurate weather records for this time period, the exact dates of the Little Ice Age are not known. The coldest period was the seventeenth century, but date estimates range from as early as about 1350 or 1400 to as late as 1850. Indeed, some writers use the term "Little Ice Age" to refer only to that coldest period, while others designate the entire period from 1350 to 1850 with the term. The coldest portion of the Little Ice Age occurred during the time of the Maunder Minimum, a period of virtually no sunspot activity. If the Sun's luminosity is slightly lower during periods of reduced sunspot activity, the Little Ice Age may have been caused by a temporary decrease in the Sun's luminosity.

• Little Ice Age

The Little Ice Age was not an ice age. During the various ice ages, which occurred many millennia ago, glaciers invaded temperate midlatitude regions. The evidence for these ice ages is geologic, because they occurred before recorded history. The Little Ice Age occurred only a few centuries ago. It was colder that normal, but not nearly as cold as the ice ages. Historians know about the Little Ice Age from various anecdotal documents and indirect proxies. There are, however, no accurate weather records for this period, because the instrumentation needed to produce such records had for the most part not yet been invented. Therefore, scientific knowledge of the extent and severity of the Little Ice Age is not precise.

The exact dates of the start and end of the Little Ice Age are somewhat controversial. Authors generally agree that the Little Ice Age encompassed the seventeenth century, but there is some disagreement as to both how long afterward it lasted and how much sooner it started. This disagreement can be understood by examining reconstructed temperatures for the past millennium. The seventeenth century, which was about 0.5° Celsius cooler than the 1961-1990 average temperature, was both the longest-lasting cool period and the coldest period of the past one thousand years. Thus, nearly all researchers agree that this century was part of the Little Ice Age.

The entire period from about 1300 to the late nineteenth century was cooler than normal for the millennium. However, most of this time was not as cold as the seventeenth century, and there were some relatively warm periods during these centuries. The first half of the nineteenth century was colder than normal, but the eighteenth century was about as warm as the average for the millennium. Thus, the Little Ice Age may have lasted as late as 1850, but it may have ended in the early 1700's.

The period from 1000 to shortly after 1200, the Medieval Warm Period, was nearly as warm as the end of the twentieth century. Average temperatures then dropped fairly quickly during the late thirteenth century, making it possible to date the beginning of the Little Ice Age as early as about 1350 to 1400. The middle of the fourteenth and fifteenth centuries were nearly as cold as the seventeenth century, but there were warmer periods about 1400 and during the first portion of the sixteenth century. Thus, the Little Ice Age may not have started until the seventeenth century.

The uncertainty of dating the beginning and end of the Little Ice Age results from the facts that the cool climate from approximately 1350 to 1850 was interspersed with relatively warm periods and that the longest-lasting and coolest period was the seventeenth century. The exact time period of the Little Ice Age is therefore fairly loosely defined.

• Evidence for the Little Ice Age

Thermometers were not invented until the end of the sixteenth century, and widespread, systematic use of accurate thermometers did not occur until much later. There are therefore no accurate weather records to verify the Little Ice Age. Climate researchers must use other lines of evidence, including both various proxies and anecdotal evidence.

The most common proxy studies for climate involve tree rings. The thickness and density of the rings varies with various climatic conditions, including temperature and rainfall. In polar regions, studies of various properties of ice cores provide climate information. The properties include the rate at which ice accumulates, layers that have melted, and isotope ratios. Growth thicknesses and other properties of corals can also provide climate information.

For all of these proxy studies, climate researchers statistically analyze the relationship between the proxy and climate conditions during recent periods for which accurate weather records exist. The researchers then extrapolate the climate conditions back to the dates before accurate weather records. The further back researchers extrapolate, the less accurate the proxy is in reconstructing climate conditions. Hence, climate estimates for the first half of the millennium are less accurate than are more recent estimates. Proxy studies are further complicated by the fact that multiple variables can affect the proxy. For example, tree rings are affected by both temperature and rainfall conditions.

In addition to proxy studies, there is anecdotal evidence for the Little Ice Age. Examples of this type of evidence include such things as diary entries and paintings. Diary entries might include reports of unusual freezings of various bodies of water, extreme snowfalls, and so forth. Paintings in eras when artists strove for realism can also depict frozen landscapes and bodies of water. If the paintings made during a particular time period show a large number of frozen landscapes of locations that seldom freeze now, researchers can conclude that the time period was cooler than normal. These lines of evidence are not scientific, but many reports of a particular time period being colder than normal strongly suggest that it actually was colder, even in the absence of scientifically reliable weather records. These lines of evidence apply primarily to Europe, so the Little Ice Age could have been either a strictly European phenomenon or a global phenomenon.

• The Maunder Minimum and the Little Ice Age

There is fairly strong evidence that variations in the Sun's luminosity related to sunspot activity caused the Little Ice Age.

Sunspots are dark regions on the surface of the Sun caused by solar magnetic activity. Solar magnetic activity also causes bright areas, or faculae, on the Sun's surface. The Sun undergoes an eleven-year cycle regulating the amount of sunspots, faculae, and related solar magnetic activity it experiences. Satellite measurements over the most recent solar cycles show that the Sun's luminosity is a very small amount higher during sunspot maximum than during sunspot minimum. The net effect of the bright areas on the Sun is slightly larger than the net effect of the dark areas, so the Sun is brighter during sunspot maximum.

There are also less well established longer cycles in solar activity. Notably, the Maunder Minimum was a period from about 1645 (possibly as early as 1620) to 1715 when there were very few sunspots. This period corresponds to the coldest portion of the Little Ice Age. If the observation that the Sun emits less energy during periods of minimal sunspot activity holds, then the Sun's lower luminosity during the Maunder Minimum may have caused the coldest portions of the Little Ice Age.

Closer comparison of the sunspot activity and global temperatures over the past thousand years supports this hypothesis. The warm period from 1000 to 1200 corresponds to the Medieval Grand Maximum in sunspot activity: During sunspot maxima, there were many more sunspots than is usual during sunspot maxima. There were also other extended periods of very few sunspots similar to the Maunder Minimum, including the Spörer, Wolf, and Dalton minima. Like the Maunder Minimum, these other minima correspond to the cooler periods of the extended Little Ice Age. It is not proven that variations in the Sun's luminosity caused the Little Ice Age, but it seems to be the most likely explanation.

• Context

Global warming, especially since the later half of the twentieth century, has become a serious worldwide concern. Most climate researchers attribute this global warming to anthropogenic causes, particularly increased emissions of carbon dioxide (CO_2) and other greenhouse gases (GHGs). The extremely hot surface temperatures on Venus clearly demonstrate that CO_2 can warm a planet.

If, however, the Little Ice Age resulted from solar luminosity variations related to long-term solar activity cycles, then there is the possibility that similar solar variations are contributing to current global warming. Some, but not all, late twentieth century sunspot maxima are higher than normal, suggesting the possibility that Earth is entering another sunspot grand maximum similar to the Medieval Grand Maximum. If this is the case, then global warming may have solar variations as well as increased GHGs as a component cause.

Louisiana coast

- **Category:** Geology and geography

The southern third of Louisiana lies no more than 7.6 meters above sea level, and the extensive salt marshes on the central and western coast average less than 1 meter above sea level. Much of the city of New Orleans is below sea level. This land is highly susceptible to the consequences of rising sea levels and increased storm intensity associated with global warming.

• Key concepts

barrier island: an offshore island running parallel to a coastline that protects the coastline from storm surges

bayou: a small, often intermittent, distributary

delta: a network of distributaries through deposited sediments at the mouth of a river

distributary: a branch of a river that removes water from the main river, especially near or in a delta

levee: a natural or human-made raised bank along a river

saltwater intrusion: inland movement of seawater

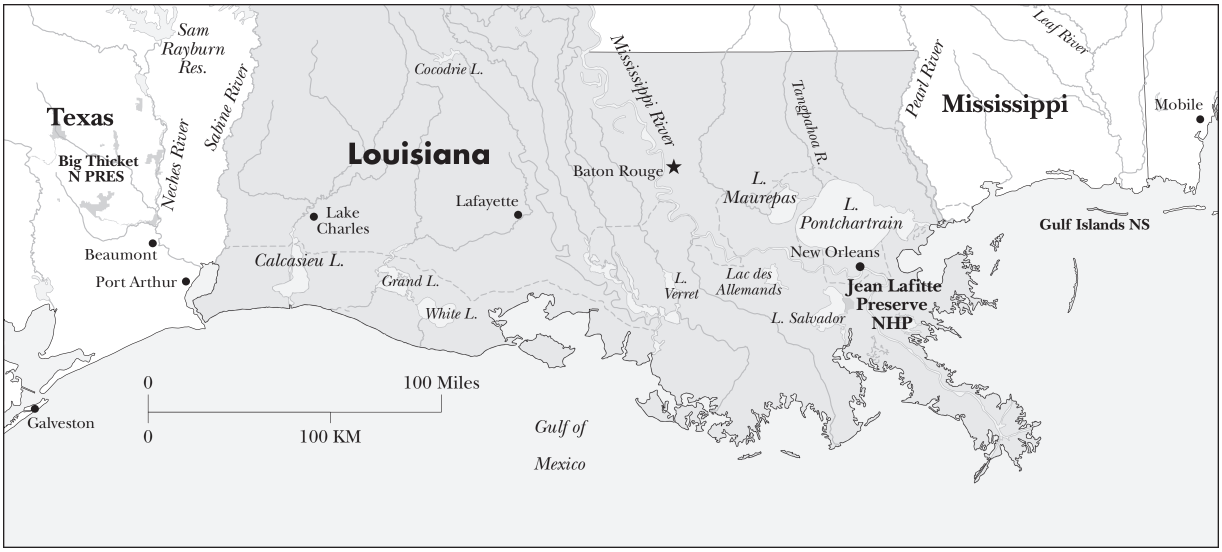
subsidence: land sinkage due to compaction of underlying material

• Background

New Orleans was founded in 1718 on a crescent of land on the east bank of the Mississippi River that was considered high enough to be safe from tidal surges and hurricanes. This high ground, about 5 meters above sea level, was a natural levee produced by sediment deposited during annual floods. Although New Orleans remains the highest land along the entire coast of Louisiana, the extensive salt marshes and river delta that once protected the city have eroded during the past century as a result of "improvements" to the river and development associated with the oil and gas industry.

• Natural Mississippi River

Much of the coast of Louisiana was formed by alluvial deposits of the Mississippi River, and even today the Mississippi and its primary distributary, the Atchafalaya River, have a tremendous impact on the Louisiana coast, carrying 1-2 million metric tons of sediment per day to the Gulf of Mexico. During the past five thousand years, six different outlets formed deltas whose remnants can be identified. The earliest followed roughly the course of the present-day Atchafalaya River and emptied into what is now Cote Blanche Bay. Much of the sediment was carried by the westward gulf current toward the Texas border. The next outlet was further



east, near present-day Terrebonne Bay. The third moved to its westernmost outlet along the general course of today's Bayou Teche. Once again, sediments moved westward, stranding the earlier beaches, called cheniers, behind extensive mudflats.

The fourth delta, far to the east, formed present-day St. Bernard Parish, most of which was underwater during the flooding caused by Hurricane Katrina. The river again moved west along the present course of Bayou Lafourche, and finally, about six hundred years ago, the river moved to its current course and began to form the bird's-foot delta at its mouth. As each delta was abandoned, sediments began to compact, resulting in local land subsidence. The interaction of sediment deposition and wave action formed a series of barrier islands, from the Chandeleur Islands on the east to Marsh Island on the west.

• Managed Mississippi River

Since the time of French settlement, landowners along the Mississippi were required to build and maintain levees, but it was not until major floods in 1849 and 1850 that national concern was raised for controlling the Mississippi River. In 1882, the U.S. Army Corps of Engineers began levee construction. Following the 1927 flood, the federal government committed to a comprehensive flood-control and navigation program that included levees, floodways, channel improvements, and stabilization.

The entire lengths of the Mississippi River and Atchafalaya Basin in Louisiana are confined by levees. Two breaches are designed into the levee system to provide controlled floodways for diverting high flow. The Old River Control Structure, near the natural confluence of the Red River, diverts up to half the flow of the Mississippi during high flood into the Atchafalaya basin. There, it is divided between the Morganza and West Atchafalaya floodways straddling the Atchafalaya River channel. About 24 kilometers above New Orleans, a second floodway, the Bonnet Carre' Spillway, can divert more than 7,000 cubic meters per second from the Mississippi River into Lake Pontchartrain to relieve pressure on the New Orleans levees.

The Atchafalaya River formed from the lower Red River in the 1500's, when a new bend in the Mississippi River captured the Red River and most of its flow. Over the years, the Atchafalaya gradually broadened and deepened until it began to capture Mississippi River water even during normal flow. By 1953, 30 percent of the flow moved down the Atchafalaya, and there was concern that the Mississippi would shift course and strand Baton Rouge and New Orleans. The Old River Control Structures, completed in 1963, regulate flow from the Mississippi. In 1973, part of the structure nearly failed during a major flood. It is likely the Mississippi will change course if and when such a failure occurs.

• Marshes

The broad alluvial plain of the Louisiana coast supports a sequence of four marsh types categorized primarily based on elevation above sea level. They range from 24-32 kilometers wide on the west side of the state to more than 80 kilometers wide south of New Orleans. The first 1 to 24 kilometers from the shore, a total of 3,640 square kilometers, is saline marsh dominated by salt-tolerant species. The salt marsh merges gradually into brackish marsh covering 4,850 square kilometers. Another 2,830 square kilometers are intermediate marshes, which grade into nearly 4,850 square kilometers of freshwater marsh. Because of the levees, annual floods no longer cover the marshes with fresh sediments, and erosion and subsidence exceeds land building along the entire coast, except for the mouth of the Atchafalaya River, which has a growing delta.

• Oil and Gas

Although most of Louisiana's oil and gas production is now offshore in the Gulf of Mexico, the first productive well was about 40 kilometers north of the coast, near the town of Jennings. The easiest way to access well sites was to dredge canals and float equipment to the site. Virtually all of the state's marshland is laced with service canals running from the coast, rivers, bayous, or the commercial Intracoastal Waterway. South of the Intracoastal Waterway, there are more than 7,240 kilometers of canals and 11,590 kilometers of bayous. These waterways permit saltwater intrusion into the heart of freshwater marshes, killing intolerant plant species. They also provide water courses through which storm surges can move far inland, eroding the fragile marshes.

• Context

As a result of human "improvements" in south Louisiana, approximately 155 square kilometers of coastline is lost every year, and what remains is even more susceptible to storm surges that are expected to increase as a result of global warming. New floodways have been opened through the Mississippi River levees south of New Orleans in an effort to flood the marshes with new sediments so they will grow again. However, the region remains increasingly vulnerable to warming-related weather patterns, and if the sea level rises, it will only become more vulnerable still.

Maldives

- **Category:** Nations and peoples
- **Key facts**

Population: 379,174 (July, 2008, estimate)
Area: 298 square kilometers
Gross domestic product (GDP): $1.738 billion (purchasing power parity, 2008 estimate)
Greenhouse gas (GHG) emissions in millions of metric tons of carbon dioxide equivalent (CO_2e): 0.6 in 2004
Kyoto Protocol status: Ratified December, 1998

• Historical and Political Context

Maldives is an archipelago grouped into nineteen atolls located on the Indian Ocean, south-southwest of India. It is an Islamic republic and became independent from England on July 26, 1965. The majority of its people are Sunni Muslims who were originally Buddhists. The official language is Dhivehi, an Indo-European language related to Sinhala, the major language of Sri Lanka.

Maldives became a republic under the 1968 constitution, which established executive, legislative, and judicial branches of government. The Majilis (legislature) is composed of fifty members who serve five-year terms. The judicial system is derived mainly from traditional Islamic law and administered by secular officials, a chief justice and judges on each of the ninteteen atolls. Ibrahim Nasir became the president in 1968 and was succeeded in 1978 by Maumoon Abdul Gayoom.

Maldives has faced no external threat since independence, but has witnessed two internal threats. President Gayoom disclosed in 1980 details of an abortive coup involving Ibrahim Nasir, the first president. The other threat occurred in 1988, when Abdullah Luthufi, a Maldivian businessman, led a group of Tamil militants who invaded the nation in an effort to overthrow the government. Gayoom asked for help from the Indian government, which sent troops to put down the invasion. By 1990, the government had embarked on a democratization program, and the country's security improved.

In 2005, members of the Majilis voted unanimously to legally recognize political parties, and a year later the government introduced a roadmap for reform. A first-ever presidential election under a multiparty system was held in October, 2008. The Maldivian Democratic Party led by Mohamed Nasheed and his running mate, Mohammed Waheed Hassan, defeated incumbent president Abdul Gayoom. On November 11, 2008, Mohamed Nasheed was sworn in as president and Dr. Waheed Hassan as vice president of Maldives.

• Impact of Maldivian Policies on Climate Change

Climate change and rising sea levels are a great concern to Maldives, which is less than 2.5 meters above sea level at its highest point. The country's entire existence is in jeopardy, as global warming causes the polar ice caps to melt and sea levels to rise. Scientists predict that Maldives could sink beneath the ocean surface by 2100 if global warming continues. As a result, the government of Maldives is doing all it can to fight global warming.

The nation was among the first to raise climate change as a serious issue at the United Nations. President Gayoom raised the alarm in 1987, when most nations had not recognized the problem. In 1989, Maldives played a major role in calling and hosting the first small states conference on sea levels. The conference issued the Male' Declaration on global warming and sea-level rise and urged intergovernmental action on the issue. Maldives was also one of the first countries to sign the Kyoto Protocol, written in Japan in 1997. The protocol aimed at tackling the issue of global warming and reducing greenhouse gas (GHG) emissions.

Apart from the county's involvement in several international conferences on climate change, it has also implemented several projects aimed at resisting the rising sea by raising the elevation of some islands. For example, it has completed the construction of a flood-resistant island named Hulhumale, made possible by a $60 million Japanese grant.

• Maldives as a GHG Emitter

According to a United Nations development report, Maldives accounts for 0.0 percent of global emissions, with an emission rate of 2.5 metric tons of carbon dioxide (CO_2) per person in 2004. Maldives' economy is based mostly on tourism and fishing and hence it has little or no industries that pollute. However, that rate was only 0.7 metric ton per person in 1990. As a result, Maldives is not bound by a specific target for GHG emissions. The developed countries, led by the United States, are the greatest emitters of GHGs. With 15 percent of the world's population, they account for almost half of all emissions.

• Summary and Foresight

Tourism is the largest industry in Maldives, taking advantage of the islands' beautiful resorts and beaches. Government revenues from import duties and tourism-related taxes may be threatened by rising sea levels. For example, the 2004 Asian tsunami battered Maldives, forcing the evacuation of thirteen of its two hundred inhabited islands and causing millions of dollars in damage to its resorts and beaches.

Corals are the major ecological component of coral reefs, and elevated sea temperature causes corals to bleach. In 1998, temperature-induced bleaching killed over 95 percent of shallow-water corals in Maldives. The elimination of coral reefs is beginning to affect Maldives, since reefs protect coastlines from storm damage, erosion, and flooding by reducing wave action.

The beaches and shorelines of Maldives are vanishing. They are being washed into the sea, a consequence of global warming. These tiny islands cannot combat this threat alone. They need support from the world community, especially the developed nations that are the major contributors to global warming.

Malthus, Thomas Robert
English demographer and economist

Born: February 13, 1766; The Rookery, near Dorking, Surrey, England

Died: December 23, 1834; St. Catherine, near Bath, Somerset, England

Malthus hypothesized that, while food supplies increase only in an arithmetical progression, populations increase in a geometric progression. Thus, as both entities increase, the food supply would become insufficient for the population, resulting in famines and increased poverty. Malthus's predictions failed to materialize but may become relevant in the context of global warming.

• Life
The British demographer and political economist Thomas Robert Malthus was born in 1766. Malthus was homeschooled until he entered Jesus College, Cambridge, in 1784. He studied English, Latin, and Greek, but his main interest was math. Receiving a master's degree in 1791, he was elected a fellow of Jesus College and ordained an Anglican minister in 1797. Malthus's training as a church leader served him well in describing his ideas about poverty, disease, and famine. These issues and his schooling led Malthus to develop a unique philosophy about God's rule and how populations could be controlled.

Malthus formulated his theory of population growth in the pamphlet *An Essay on the Principle of Population, As It Affects the Future Improvement of Society* (1798), creating a public flurry. Malthus researched many methods of containing catastrophic population growth. He understood that humankind had natural devices, such as crime, disease, and war, for controlling population. The heart of Malthus's doctrine is that an increasing population puts an ever-increasing pressure on natural resources. He was searching for an answer that would allow a balance between population growth and the increase in the world's supply of food.

• Climate Work
Malthus's *An Essay on the Principle of Population* caused immediate debate in intellectual circles. It proposed that population growth would outpace food production, with devastating consequences. The technologies that have allowed food growth to increase in step with population growth may only be an intermediate solution to the problems posed by Malthus. The concept of climate change did not exist in Malthus's world or in his theories, but the effects of climate change today may be more than technology can deal with. Malthus also recognized that human activities could reduce the fertility of natural resources and further impair people's abilities to supply the essential goods needed to survive.

Notable intellectuals have called Malthus's principles of population growth a theory of doom and gloom, yet his work may reveal the need for equal and just allocation and use of resources. Malthus's theory ignited scholarly debate about the balanced use of natural resources

The Premature Death of the Human Race

In An Essay on the Principle of Population *(1798), Thomas Robert Malthus expressed his belief that Earth's limited resources would place a limit on the potential of human societies to thrive or even subsist on the planet.*

The power of population is so superior to the power of the earth to produce subsistence for man, that premature death must in some shape or other visit the human race. The vices of mankind are active and able ministers of depopulation. They are the precursors in the great army of destruction, and often finish the dreadful work themselves. But should they fail in this war of extermination, sickly seasons, epidemics, pestilence, and plague advance in terrific array, and sweep off their thousands and tens of thousands. Should success be still incomplete, gigantic inevitable famine stalks in the rear, and with one mighty blow levels the population with the food of the world.

in order to keep the climate in harmony with the universe. A new factor in the race between population growth and increasing food supplies is the effect of climate change on food production. Climate change is attributed to many causes, primarily human related, including increasing carbon dioxide (CO_2) levels and increasing ozone levels. Malthus's principles of population growth are an important factor in understanding the effects of change and how these changes affect human beings and their climate. The very process of providing the basics of human existence alters the environment that provided these basics, positively or negatively, and may affect Earth's climate.

In spite of living with the ideas and advances of the Enlightenment, Malthus overlooked the technological innovations that were being developed. These innovations were changing lives, altering the environment, and allowing people to survive longer. The science of agriculture made many advances in the 1800's that allowed farmers to make more productive use of their lands. The development of effective contraception also had the potential to check population growth. These events illustrated the flaws in Malthus's theory.

Many developing nations have not adopted improved farming techniques or methods of contraception, however. In the case of these nations, Malthus's theory seems to be coming true. Overpopulation, famine, and war continue to devastate these nations, yet the economic successes of industrializing nations tend to counter Malthus's theory. Economists of the nineteenth and twentieth centuries have criticized Malthus's theory on the grounds that technological advances, the expansion of the market economy, the division of labor, and capital goods have offset large population increases. These developments have made possible the competition between nations for wealth, power, glory, and prestige. This competition, while increasing food and resource supplies, has also resulted in environmental degradation. This environmental abuse has led many environmentalists to claim that continuing resource depletion and waste will lead to a Malthusian end to the recognizable world.

It is sometimes asserted that Malthus was incorrect, because the population grew more slowly than he predicted, while resources have grown at a much faster rate. What is important to his argument is that the population always expands to the limits imposed upon the society. He points out that a growth in population forces an increase in productivity, which causes a larger growth in the population. The same increase in productivity fuels changes to the environment that may cause changes in climate as well.

Manabe, Syukuro

Japanese meteorologist

Born: September 21, 1931; Shingu-Mura, Uma-Gun, Ehim e-Ken, Japan

Award-winning meteorologist Manabe pioneered the use of computer models to simulate the impact of GHGs on climate change.

• Life

Syukuro Manabe was born in Japan, earning a doctorate in meteorology from Tokyo University. After moving to the United States in 1958, he worked as a research meteorologist at the U.S. Weather Bureau's General Circulation Research Section, eventually becoming a senior scientist in the Geophysical Fluid Dynamics Laboratory (GFDL) of the National Oceanic and Atmospheric Administration (NOAA). At NOAA, Manabe contributed his expertise to both national and international panels exploring the global climate. He also held an appointment as professor in the Program in Atmospheric and Oceanic Sciences at Princeton University. In 1997, Manabe returned to Tokyo as the director of the Global Warming Research Program of the Frontier Research System for Global Change. In 2002, he returned to Princeton.

• Climate Work

Manabe concentrates on modeling the atmosphere in order to predict global climate change. He has summarized his work on his Princeton University Web page:

> In the early 1960's, we developed a radiative-convective model of the atmosphere, and explored the role of greenhouse gases such as water vapor, carbon dioxide and ozone in maintaining and changing the thermal structure of the atmosphere. This was the beginning of the long-term research on global warming. . . .

Manabe pioneered the use of atmosphere-ocean circulation models in the analysis of climate disturbances involving greenhouse gases (GHGs). With the aid of a computer, modelers construct a system of mathematical equations that mimics a particular segment of nature. Manabe's equations center on the heat balance of Earth's atmosphere in order to mimic Earth's climate. The goal is to use data from previous years to predict global weather patterns. Even an approximate model allows its users to find the long-term effects of short-term environmental atmospheric inputs.

In 1967, Manabe and Richard Wetherald demonstrated that increased carbon dioxide (CO_2) in the atmosphere would increase the altitude at which the atmosphere reradiated heat into space, thereby lending supporting evidence for the greenhouse theory. In 1969, he and Kirk Bryan issued the first climate models that combined atmospheric and oceanic models. Using these models, Manabe demonstrated how Earth's climate might respond to increasing GHGs in the atmosphere, and his work has formed the basis for many of the assessments issued by the Intergovernmental Panel on Climate Change.

Mangroves

- **Category:** Plants and vegetation

- **Definition**

Mangroves are both a genus of tropical and subtropical trees, the *Rhizophora*, and the family of plants to which the genus belongs, the Rhizophoracae. The term most commonly refers to an assemblage of mangrove trees and other associated trees and shrubs that includes more than one hundred species. Such an assemblage may also be called a mangrove swamp, a mangrove forest, or a mangal.

Mangroves occur in shallow, protected coastal waters, such as flats in intertidal zones, bays, and estuaries in the tropics and subtropics. They cannot survive freezing or even consistently cold water. They are usually canopied forests up to about 10 meters tall, although in rare cases old-growth mangroves can reach 40 meters in height.

Mangroves survive in a difficult niche. They must be salt-tolerant plants (halophytes), and some can thrive in water of twice the salinity of seawater. Mangrove roots can filter salt from water intake, and those growing in the most saline areas excrete salt from their leaves. Mangrove forests shade from the most salt-tolerant species on their seaward side, to the least salt-tolerant species on their landward side, and they shade to conventional forests or freshwater plants.

Mangrove mudflats tend to be oxygen poor (hypoxic), to contain toxic levels of sulfides, to be subject to periodic flooding, and to be very weak for holding trees. Consequently, mangroves have a maze of roots, some of which (pneumataphores) reach up out of the water to get oxygen, while some function as stilts to help brace the trees.

The mangrove niche between freshwater, dry land, and ocean is very small, perhaps only 0.1 percent of the Earth's surface. However, it is very important for three reasons: The maze of roots catches nutrient flows from the land and holds them for gradual release to the sea rather than short, polluting surges. Conversely, the roots protect the land from ordinary erosion and disasters such as hurricanes and tsunamis. Finally, the maze of roots holding leaves and nutrients from shore provides habitat and food for sea life. Young from as many as

Brown pelicans sit in a group of mangrove trees on the Florida coast. (U.S. Fish and Wildlife Service) three-quarters of tropical deepwater fish species live in mangroves.

• Significance for Climate Change

Theoretically, mangroves would benefit from global warming, because their tropical climate area would extend farther toward the poles. More mangroves would increase the capture (sequestration) of carbon from atmospheric carbon dioxide (CO_2) and help reduce the greenhouse effect. Moreover, increased mangrove buffering of nutrient surges washing off the land would release a steadier gentle flow of dissolved organic compounds, allowing plankton and other marine plants to capture more CO_2 from the air and to increase the oceans' reflectivity. Thus, mangroves would create a significant negative feedback retarding global warming.

In practice, however, the decline of mangroves due to human development may be a significant positive driver of global warming. The percentage of Earth's surface covered by mangroves has been cut in half (from 0.2 percent to 0.1 percent) in the last century, mostly as a result of human development. For instance, sand dredged from Biscayne Bay, Florida, buried a mangrove swamp and built a city—Miami. Recent increases in shrimp aquaculture have also caused major destruction of mangroves.

Major warming would also raise sea levels, causing mangroves to retreat from the deeper water and attempt to colonize new inland swampy areas. However, people would likely erect dikes to protect existing structures and agricultural land. Hence, the effective surface area available for mangroves would be constricted even further. This reduction in surface area would decrease the area of ocean fertility, the corresponding amount of carbon sequestration, and the buffering of the land against ocean disasters. Indeed, the damage to New Orleans caused by Hurricane Katrina in 2005 can be partly attributed to reduced swamplands around the city, which left the dikes more vulnerable (although the major causes of bayou losses in New Orleans were subsidence and navigation channels).

A number of groups have tried to replenish mangroves and even establish them in new areas. The best-known of these is the Manzanar Mangrove Initiative, which is backed by the Eritrean government on the East African coast. (It was largely sparked by Gordon Sato, who was interned during World War II at Manzanar, California.) The Manzanar Mangrove Initiative uses small amounts of fertilizer in bags for slow release to vastly increase the area of mangroves and resulting silage for livestock.

An extension of the Manzanar Mangrove Initiative would pump seawater into desert areas to vastly increase mangrove areas, food production, and capture of CO_2 from the atmosphere. However, the required pumping would require major investments in either some form of alternate energy or fossil-fuel-fired power for the pumping. Moreover, skeptics of the Manzanar Mangrove Initiative worry that overzealous fertilization of the mangroves might damage coral reefs further out to sea.

Marginal seas

- **Category:** Oceanography

• Definition

Marginal seas are ocean regions that connect coastal zones to the open ocean. Marginal seas are found as indentations in the continental landmasses and are often separated from the open ocean by an archipelago or peninsula. They vary considerably in size, depth, the nature of their connection to the ocean, and the circulation of water within them.

The Mediterranean Sea is connected to the Atlantic Ocean through the Strait of Gibraltar, which is only 14 kilometers wide. In contrast, the Gulf of Mexico is connected to the Atlantic Ocean via the Caribbean Sea through the Yucatan Channel (271 kilometers wide) and the Florida Straits (180 kilometers wide). The largest of the marginal seas is the South China Sea, with an area of 2.97 million square kilometers, while the Irish Sea is one of the smallest, with an area of approximately 90,000 square kilometers. The Caribbean Sea has the greatest average depth, at 2,400 meters, and the shallowest marginal sea is the Persian Gulf, at 24 meters deep.

Water circulation in marginal seas varies depending on bathymetry, the nature of the connection with the open ocean, riverine input, and local climate. In seas such as the Black Sea, where riverine input exceeds evaporation, surface waters are less saline than is average ocean water. In other seas, such as the Mediterranean Sea, where evaporation exceeds riverine inflow and precipitation, salinity can exceed that of average ocean water. These salinity variations have important implications for the vertical circulation of water in the sea and therefore the chemistry of the bottom waters. Because marginal seas are relatively shallow and small in area compared to the open ocean, they are strongly affected by variations in river runoff, local climate, and direct human impacts, such as nutrient runoff. For example, the sediments of the Arabian Sea are characterized by a regular banding that reflects the annual development of monsoons.

• Significance for Climate Change

Marginal seas represent the buffer between land and the ocean system. They have a major economic impact on those nations that adjoin them as a result of their effects upon tourism, fishing, and the transport of goods. Marginal seas in many regions of the world suffer negative impacts from direct human activities. For example, runoff of fertilizers from agriculture triggers algal blooms in the surface water of many marginal seas. When the algae die and settle to the bottom of the sea, decay of the organic matter consumes almost all of the sea's dissolved oxygen, creating regions devoid of sea life known as "dead zones." A dead zone up to 18,000 square kilometers in area develops every summer in the Gulf of Mexico at the mouth of the Mississippi River. The development of dead zones could be exacerbated, assuming societal activities remain unchanged, in a warmer climate. Increased river runoff and warmer temperatures would lead to a situation in which greater amounts of nutrients are delivered to marginal seas, which generally have lower amounts of dissolved oxygen than does the open ocean.

Marginal seas are also sensitive to rises in sea level, such as those that may accompany global warming. Such a sea-level rise could inundate land that is currently populated. Rises in sea level coupled with changes in runoff to the ocean will affect the hydrologic balance of many marginal seas, with potentially negative ecosystem consequences. For example, decreased freshwater flow into the Black Sea could cause upwelling of the oxygen-depleted, sulfidic bottom waters onto the shelf, causing widespread loss of marine life.

Marginal seas in the Arctic and Antarctic are sites of concern because melting sea ice could contribute to sea-level rise and perhaps also to the shutdown of thermohaline circulation in the Atlantic Ocean. The collapse of the Larsen B ice shelf, in the northwestern Weddell Sea, in 2002, remains a dramatic example of the effects of global warming. The loss of sea ice in marginal seas will have major impacts on many aspects of the Earth system, including ocean circulation, sea level, radiative forcing, biological productivity, and community structure.

Maritime climate

• **Categories:** Oceanography; meteorology and atmospheric sciences

• **Definition**

Maritime climates are generally considered to be those that are moderated by the sea. However, a true maritime climate is in most cases a climate in which it is neither very warm nor very cold, with adequate rainfall throughout most of the year. A typical maritime climate occurs on the coast of Oregon and Washington in the United States, in many parts of New Zealand, in Tasmania, and in much of western Europe. Although surrounded by the sea, tropical islands are not normally considered to have a maritime climate but rather a tropical climate. True maritime climates usually have winter daytime temperatures of about 15° Celsius and winter nighttime temperatures of about 5° Celsius. In the summer, daytime temperatures average about 25° Celsius and nighttime temperatures average about 15° Celsius. Rainfall in a true maritime climate occurs throughout the year, with no pronounced wet or dry season, and averages 10 centimeters per month.

Despite the moderate nature of the true maritime climate, extremes do occur. In many maritime climates, daytime temperatures can reach above 35° Celsius, and occasionally even above 40° Celsius, while nighttime temperatures may reach 0° Celsius, and occasionally as low as –10° Celsius. Sunshine is generally more than adequate for plant growth, and annual bright sunshine hours of two thousand to twenty-five hundred hours are the norm. Rainfall, although generally adequate for plant growth, can vary: Maritime climates can have periods of up to six weeks without any appreciable rainfall, and there is at least one known instance of no rain at all falling during almost every month on the calendar. In contrast, monthly rainfalls of over 20 centimeters in a month are reasonably common, but monthly rainfalls of over 50 centimeters are not impossible. Although a daily rainfall of more than 0.3 centimeter is uncommon, at times, the rainfall in a twenty-four-hour period may exceed 20 centimeters. In summary, a true maritime climate is generally an easy climate to live in for people, plants, and animals, but relatively extreme events do occur.

• Significance for Climate Change

Although the true maritime climate has milder winters, generally cooler summers, and greater temperature ranges from nighttime to daytime than do continental climates, there are many variations from place to place. For example, the climate of New York City, although situated on a coast, has a climate quite different from that of Vancouver, on the coast of British Columbia. Alterations in the true maritime climate brought about by global climate change are likely to be relatively small, and in most places plants and animals should be able to adapt to the change. However, if there is an overall increase in temperatures in the middle latitudes of both hemispheres, where most of the true maritime climates occur, summers are likely to become warmer, albeit not as warm as current continental climates, and winters are likely to have fewer days below freezing. Sunshine hours are unlikely to change, but rainfall extremes, especially on a daily basis, are likely to increase somewhat.

New Zealand is considered to have a typical maritime climate, although there are some areas in New Zealand that are quite dry, with an average annual rainfall of only 30 centimeters. Nevertheless, most of New Zealand, as well as much of western Europe, has a typical maritime climate. Questions arise as to the effects of global warming on the temperature and agricultural production of such a climate. Considering New Zealand as an example, vineyards over the past one hundred years have flourished in many parts of the country, but as yet, in the far south of New Zealand in the Southland district, there are no commercial vineyards. Instead, the district is dairy country, covered with very green pastures and grazing cattle. The Southland District Council and the Southland Regional Council might consider the probable effects on the region of changes predicted in the Intergovernmental Panel on Climate Change's 2007 report. If they did, they might advertise the prospects of the Southland district to become a major grape-growing region in the twenty-first century.

Marsh, George Perkins

American statesman

Born: March 15, 1801; Woodstock, Vermont
Died: July 23, 1882; Vallombrosa, Italy

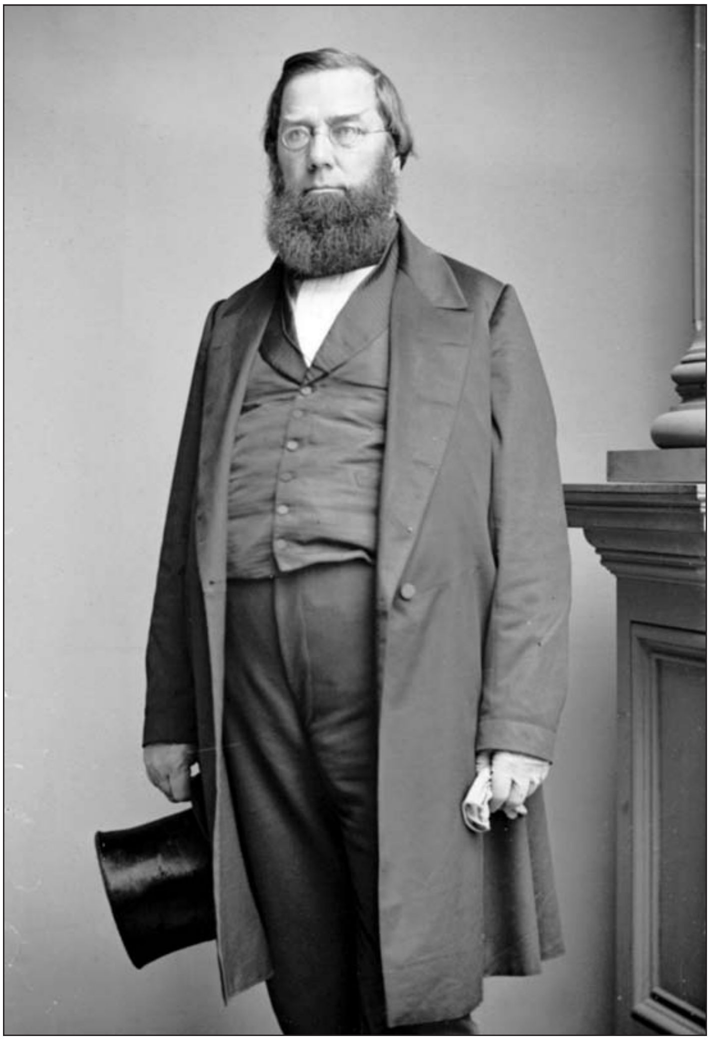
In his seminal work, Man and Nature*, Marsh argued that humans, from their very beginning, have been active agents of environmental change.*

• Life

George Perkins Marsh was born in Woodstock, Vermont, in 1801. In his boyhood years, he took careful note of how this forested region was changing before his eyes as a result of extensive settlement. These early impressions of his cultural geography and his firsthand experiences with the mountains and valleys of Vermont, he would later write, set the tone for his perspective on the impact that humans can have on their environment.

Marsh had a keen sense for the environment and enjoyed the outdoors. His academic interests drew him to Dartmouth College, where he studied languages and law. After moving back to Burlington, Vermont, he set up a law practice, ultimately finding his way into politics and serving as a U.S. representative from Vermont between 1843 and 1849. His interests in science and learning in general provided him with the skills to help organize the establishment of the Smithsonian Institution. His fondness for languages served him well, as he later became a U.S. diplomat to Turkey in 1849 and to Italy in 1861.

Marsh was an avid traveler and, as a nineteenth century naturalist, was well versed in the process of collecting specimens and observing his surroundings. These skills helped hone his understanding of the relationship between humans and their environment. Although he was a prolific writer on a wide range of subjects, it was while he was in Italy that he began his most popular literary work, *Man* *and Nature*, published in 1864. Emerging from an eclectic scientific mix of geography, statesmanship, and common sense, the text, through an exhaustive collection of local case studies, attempted to increase public consciousness of the impact that humans have on their environment. A later edition included the subtitle *Or, Physical Geography as Modified by Human Action*. The book acquired international acclaim, and Marsh would come to be considered the founder of the American conservation movement. He is credited with establishing the first scientific approaches to forest management in the United States.



George Perkins Marsh. (Library of Congress)

• Climate Work

Marsh suggests in *Man and Nature* that the destruction of Earth's forests could have an influence on climate change. Citing scientists from both sides of the question, he puts forth the notion that deforestation, by virtue of its potential to raise soil temperatures and lower humidity, could generate a change in at least regional climate. Extensive historical evidence for the connection of forests and precipitation is presented. He cites some writers who suggest more precipitation is evident over forested lands. Marsh concludes that forests, within their regional setting, influence the humidity of the atmosphere around them.

Marsh goes on to say that forests influence the climates of continental interiors just as the sea influences coastal climates. He cites sources that argue not only that tropical rain forests and other forests increase rainfall and moderate climate but also that their destruction can be linked to the development of hotter regions. Marsh's linking of forests and precipitation may lead readers to conclude that no place on Earth is free of the potential impact of human actions.

Marsh alludes to the impact of humans on climate by introducing a common nineteenth century forestry management practice, now known as clear-cutting. He suggests that regions and countries that clear their forests subject their soils to drying and could see that effect go on indefinitely. Additionally, fallen trees can dam up water courses, creating an environment conducive to higher humidity. These impacts, he concludes, could lead to seasonal temperature changes in both the atmosphere and the soil.

As a naturalist, Marsh had interests in the whole of the environment, not just a singular component of it. His unique consideration of humans as agents of environmental change suggests that they can affect their environment in positive or negative ways. For his time, Marsh's work embraced an unusual environmental paradigm. It represented a drastic departure from the homesteading Romanticists of the 1860's and the notion that humans had a right of dominion over the land such that the rain and the blessings of God would follow the ploughs of settlement. *Man and Nature* is considered to be one of the earliest influential writings on conservation and the environment. Its insights and advocacy of restraint in the use of resources is a clarion call to any society concerned for the future of its natural landscape.

Mass balance

- **Category:** Cryology and glaciology

- **Definition**

Generally, mass balance refers to the net sum between the input and loss of mass to a reservoir. In glaciology, the term refers to the balance between the loss and gain of ice from a glacier, ice cap, or ice sheet. When more ice is gained than lost, the result is a positive mass balance and the overall growth of the ice body. A negative mass balance occurs when more ice is lost than is gained and the ice body shrinks.

Several other terms are used to specify the gain or loss of glacial ice. "Total mass balance" refers to the total net gain or loss of ice from an entire glacier over a single hydrologic cycle. "Specific mass balance," by contrast, refers to such loss or gain at a particular point on the surface of a glacier. Total and specific mass balances can diverge in extremely large ice bodies, such as the Antarctic ice sheets, whose mass balances vary in different geographic locations. The average mass balance per unit area of an ice body is called the "mean specific mass balance." It can be used to compare the amount of ice gained or lost by ice bodies of different sizes.

- **Significance for Climate Change**

Glaciers and other ice bodies are highly sensitive to climate change and are viewed by many scientists as early warning detectors for global warming or global cooling. Ice bodies do not form in a single year or in response to a single snow event. Instead, they form over a sustained period of time, as temperatures remain cool enough that not all of the snow that falls in a given winter melts in the subsequent summer. It is this long-term accumulation of snow that leads to the development of ice and, eventually, a glacier or other ice body. Ice bodies are dynamic, much like rivers. Ice can accumulate at the head of a glacier at the same time that it is being lost from the toe of the same glacier through ablation or iceberg calving. Also, ice bodies can change in size and shape throughout the course of a hydrologic cycle. Thus, to determine whether a glacier is growing or shrinking in size, it is necessary to consider the mass balance, or net sum, of ice that accumulates and is lost throughout an entire hydrologic cycle, rather than simply examining the size of a glacier at two points in time.

Mauna Loa Record

• **Category:** Meteorology and atmospheric sciences

• **Definition**

The Mauna Loa Record (or Mauna Loa Carbon Dioxide Record) is the longest continuous record of atmospheric carbon dioxide (CO_2) concentrations. The level of CO_2 in the Earth's atmosphere is one of the primary determinants of global temperature, and higher levels of CO_2 correspond with warmer global temperatures. The CO_2 data collected at the Mauna Loa Observatory in Hawaii since 1958 has been called the most important geophysical record on Earth.

A carbon dioxide monitoring station at Mauna Loa, Hawaii. (NOAA)

• **Significance for Climate Change**

In the 1950's, continuous monitoring of CO_2 levels represented a break from the conventional view that occasional measurements in selected places would provide enough data. Despite this, scientists at the Mauna Loa Observatory, founded by the U.S. Weather Bureau, decided to maintain continuous records of the CO_2 levels at its location. The observatory is located at an elevation of 3,353 meters on the island of Hawaii, and its CO_2 measurements have been supported by the Weather Bureau and the National Oceanic and Atmospheric Administration (NOAA) ever since. Within only a few years of the project's founding, an annual increase in atmospheric CO_2 concentration was measured.

In 1974, NOAA installed a new CO_2 analyzer that operated parallel to the original analyzer installed by the Scripps Institution of Oceanography. The Scripps analyzer was replaced with a newer model in 2006. The two-analyzer system provides redundancy to ensure the quality of the Mauna Loa Record and the integrity of the global CO_2 measurement network. In the 1960's and 1970's, Scripps added several measurement stations ranging from the Arctic to Antarctica. However, these stations collect flask samples that are analyzed in a lab rather than collecting on-the-spot data via an analyzer, as the Mauna Loa Observatory does.

Despite the project's importance, it has faced numerous budget and staff cuts over its existence, as well as questions of whether it constituted basic research or routine monitoring. Even today, such long-term studies are rare and often poorly supported. Despite the obstacles it has faced, the Mauna Loa project has continued, producing large amounts of valuable data that have led to several breakthroughs in climate science.

A simple graph of the Mauna Loa Record data (called the Keeling Curve after Scripps scientist Charles Keeling, who cofounded the project) shows a steady increase of 2 parts per million (0.53 percent) per year in atmospheric CO_2 since the observatory began collecting data in 1958. According to NOAA's Earth System Research Lab, 63 percent of global warming due to greenhouse gases is due to CO_2.

The record has provided crucial evidence that human activity has changed and is changing the composition of the atmosphere. Climate scientists have used the Mauna Loa data to model the state of the Earth's future climate, affecting political actions such as the drafting of the Kyoto Protocol, a multinational agreement to limit carbon emissions.

The Mauna Loa data also demonstrated for the first time the annual fluctuation in atmospheric CO_2 attributable to biological activity. CO_2 levels reach their maximum in May and their minimum in October. Both of these averages, however, have increased every year since the project began. While the curve is small, it indicates an exponential increase rather than a linear one—the average CO_2 level increases by slightly more each year than the previous year. Atmospheric CO_2 has increased by more than 35 percent over amounts recorded before the Industrial Revolution, and over 6 percent between 1990 and 2009. Comparison with ice-core records suggests that current CO_2 concentrations are unprecedented in the past 650,000 years.

In 1983, Keeling and other scientists began addressing how El Niño weather events affected atmospheric temperature and CO_2 concentration, using the data from Mauna Loa. They were able to identify approximately ten-year fluctuations in temperature correlated with CO_2 fluctuations, leading to a better understanding of long-term global temperature variance.

Skeptics have put forth critiques of the Mauna Loa data, citing the Mauna Loa Observatory's location on an active volcano and increasing traffic near the observatory. However, the project has attempted to minimize contamination through careful sampling and by normalizing to negate local contamination. Atmospheric CO_2 samples from other stations worldwide corroborate the Mauna Loa data, and the Mauna Loa Record continues to form a base data set for crucial research into climate change.

Mean sea level

• **Category:** Oceanography

• Definition

Sea level is the height of the surface of the ocean at any given location. Sea level is highly variable and can undergo very rapid changes due to such events as tides, tsunamis, changes in barometric pressure, wind-generated waves, and even freshwater floods. While these events can produce changes in sea level of several meters, they are local in scale and of a very short duration, generally lasting only for hours. Mean sea level is the average, global height of the sea surface, independent of these local, short-term changes. Changes in mean sea level are on the order of a few millimeters per year.

Mean sea level at specific locations can be calculated using tide gauge records and subtracting the effects of annual changes in atmospheric pressure and long-term changes in tidal ranges, which are driven by astronomical factors. Changes in global mean sea level can be calculated using satellite-based radar altimetry, such as with the TOPEX/Poseidon satellite. The radar altimeter measures the height of the satellite above the ocean, based on the time it takes for a radio signal to travel from the satellite to the sea surface and back. Since the actual altitude of the satellite is known, any changes in the altimeter measurement reflect changes in the height of the sea surface itself.

• Significance for Climate Change

On short timescales (decades to centuries), mean sea level is a function of the amount of water stored as ice in glaciers and ice sheets. As global temperature rises, less water is stored as ice, contributing to a rise in mean sea level. A rise in mean sea level in response to global warming has important societal consequences. First, such a rise contributes to a loss of land, as coastal areas are slowly inundated by water. This is a concern for certain low-lying island nations such as the Maldives or Tuvalu. The Maldives is a nation made up of twelve hundred islands in the Indian Ocean, which has a maximum elevation of only 2.5 meters above current sea level. Thus, the Maldivian population of approximately 380,000 people is highly vulnerable to even a slow rise in mean sea level. For other nations, a rise in mean sea level is also a concern because of increased hazards from flooding during high tides—especially spring tides—and storms. A rise in mean sea level provides a higher baseline upon which tidal fluctuations build. According to the Fourth Assessment Report released by the Intergovernmental Panel on Climate Change, from 1993 to 2003, mean sea level rose approximately 3.1 millimeters per year.

Media

• **Category:** Popular culture and society

The battle over climate change has played out publicly in the media. Conservatives have charged the media with bias against questioning anthropogenic climate change. Liberals have argued that there is a scientific consensus and the media are irresponsible to portray the issue as subject to debate.

• Key concepts

bloggers: people who publish information or commentary known as blogs on Web sites

mainstream media (MSM): an often derogatory term for major journalistic media outlets, including major television networks and newspapers

media bias: valuations made or endorsed by information sources that are supposed to strive for objectivity

• Background

Modern media climate coverage dates to the 1890's. In the late nineteenth century, *The New York Times* warned of a possible return to an ice age. That coverage continued until the 1920's and 1930's, when media outlets cautioned about a warming trend. The coverage again shifted in the 1950's to global cooling, which lasted in some form into the 1990's. The global warming focus, though, began in the 1960's and escalated with publication of Al Gore's book *Earth in the Balance* (1992). Since the release of Gore's movie *An Inconvenient Truth* (2006), the warming debate has become a politicized argument, in which media coverage is scrutinized as much as climate science.

• Media Coverage History

As far back as February 24, 1895, *The New York Times* was warning of the return of an ice age. The paper pointed to scientific concerns about a second glacial period following increases in northern glaciers. Fear spread through the print media over the next three decades. On October 7, 1912, both *The New York Times* and *The Los Angeles Times* cited the worries of Cornell University professor Nathaniel Schmidt about a new ice age. Arctic expeditions added to

California governor and film star Arnold Schwarzenegger addresses the media in June, 2005, exhorting President George W. Bush to accept the reality of global warming. (AP/Wide World Photos)

media coverage and public concern about a cooling climate, but by the time *The Atlantic* was reporting on cooling in 1932, many other outlets had started reporting a warming trend.

The Post discussed a warming Earth in 1930. *The New York Times* told readers in 1933 that America was experiencing the longest warming spell since 1776. Both the *Quarterly Journal of the Royal Meteorological Society* and *Monthly Weather Review* printed articles about humankind having a role in making the planet warmer. Major news media continued coverage of warming into the 1950's, when the trend shifted again.

In 1954, *Fortune* magazine reported that the Earth was growing colder. *Science News* described cooling as a major threat in 1969 and again six years later. The 1975 magazine cover depicted a city in a snow globe, as the magazine ranked the threat of a new ice age as high as nuclear war for potentially harming human life.

The New York Times wrote about global warming in 1969, but there was still little coverage of the topic in the 1970's in major news media. Toward the end of the decade, global warming and the greenhouse effect began appearing in print more than a dozen times in the top newspapers. In the 1980's, that number increased to more than one thousand stories on global warming. *The Post, The New York Times, The Los Angeles Times, The Wall Street Journal*, and *USA Today* all told readers of a looming threat from a warming Earth.

That trend continued through the 1990's. By the end of 1999, *The New York Times* alone had published more than sixteen hundred stories on global warming and *The Post* had published more than thirteen hundred. Throughout the decade, other outlets also devoted broadcast time or pages to the issue. The Public Broadcasting System (PBS), *Newsweek*, and others depicted global warming as an issue of national concern.

Climate reporting continued to gain momentum into the new millennium, but the coverage began to change significantly. More and more, the news stories were criticized for either including or excluding scientists who disputed some aspect of anthropogenic climate change. Reporting on the issue increased in virtually all major news outlets.

Gore and warming appeared everywhere from *People* magazine to *Saturday Night Live* when *An Inconvenient Truth* opened in theaters in 2006. The added attention focused the debate not just on the science but on whether a debate even existed. That trend continued, as television networks from the Cable News Network (CNN) to Fox News to the American Broadcasting Company (ABC) focused their efforts on daily coverage as well as news specials about climate. More than two hundred stories on the issue appeared on the Big Three broadcast networks in just the second half of 2007.

• Spinning the Debate

The two primary sides of the global warming debate agree that the issue is spun by the media, but they do not agree in what way. Environmental groups and liberal media critics claim that the traditional view of journalist as neutral observer has muddled the debate. They embrace a position often repeated by Gore that the debate is over. Conservatives point to numerous examples of activist journalism ignoring scientific disagreement. They complain that reporters hype weather stories as climate change and call for expensive global warming solutions without giving any time to the opposition.

• Mainstream Media

News outlets are the primary source of information about climate. Newspapers have lost their dominance as the primary news source, but newspaper Web sites have gained in popularity at the same time. Thus, newspapers have joined television news and the Internet as the major news media in the early twenty-first century.

Discussion of climate change became easy to find in major news outlets. It was featured repeatedly on the cover of *Time* magazine, on the front page of newspapers, and as the lead story of national network news broadcasts. In most cases, it was reported as an imminent crisis with potentially devastating results. Hurricanes, floods, drought, and a host of minor threats were linked in the press to global warming.

Skeptical scientists and public policy groups roundly criticized what they perceived as media bias in these stories. Journalists who covered the topic, from ABC's Bill Blakemore to *The New York Times*' Andrew Revkin, were often criticized for bias in their reporting. Prominent media watchdog groups and individual bloggers analyzed reporting, while scientists would dissect scientific claims in major news stories.

Other critics attacked any journalist who disseminated stories about climate change skeptics. A conference organized by the Heartland Institute brought together numerous scientists and public policy experts who raised questions about climate consensus in 2008. The event was a metaphor for the debate. The skeptical view received little coverage, and what coverage it did receive was often critical. CNN, for example, compared those who were skeptical to flat-earthers after the world was discovered to be round.

• Alternative Media

The alternative media—including talk radio and nonmainstream Web sites—have had a field day with climate change. Bloggers focus much of their effort on monitoring the news media coverage of the climate. Numerous individuals and groups on the Left and the Right maintain media blogs, and much of their focus has been on environmental coverage. The most famous of these, the Drudge Report, regularly links to climate stories. Whether the topic is snowfall during a global warming hearing in Washington or Gore's own carbon footprint, Drudge and others have driven a significant news agenda. The biggest of such stories can cross over into the mainstream media.

Think tanks, environmental groups, and politicians have all participated in the news media debate on climate change. The ability to link from one to another helped further blur the lines of traditional journalism, as advocacy organizations left and right targeted the other side's positions. The diverse voices also allowed readers and viewers to self-select the information they received. That caused ordinary information consumers to harden positions along ideological lines.

Talk radio also has a significant hand in the global warming debate. In 2008, much of private talk radio remained conservative. Criticism of Gore or climate science was commonplace. Often, talk radio would highlight a story made popular by bloggers such as Matt Drudge or would address a topic that, in turn, would drive the blogosphere. Liberal talk radio, including National Public Radio and Air America, took an opposite approach. Environment and climate stories were prime topics of concern for hosts and listeners alike.

• Entertainment Media

Film and television played a big role in the climate debate. With the rise of global warming as an issue in the 1980's, Turner Broadcasting responded with a cartoon called *Captain Planet*. The cartoon's superheroes protected the Earth from evils such as pollution and global warming.

Several popular movies featuring global warming themes followed. The made-for-television movie *The Fire Next Time* aired in 1993. Kevin Costner's 1995 disaster picture *Waterworld* depicted a world awash in a flood caused by warming. *The Day After Tomorrow* (2004) was one of the most controversial of these films. When it opened, the climate debate was in full force. The movie's title was reminiscent of that of the antinuclear made-for-television film *The Day After* (1983), and it depicted a climate apocalypse brought on by global warming. In the film, the changing climate results in a rapid cooling of the Earth and the onset of a new ice age. The movie was criticized by conservatives for characterizations of a president and vice president similar to George W. Bush and Dick Cheney. It also showed Americans fleeing the freeze being stopped at the Mexican border as illegal immigrants.

Also in 2004, science-fiction thriller author Michael Crichton released a novel critical of the environmental movement. *State of Fear* portrayed murderous environmentalists altering the Earth's climate to force humans into eco-friendly behavior. The novel also included extensive footnotes to raise objections to the idea of anthropogenic global warming. Crichton's book was criticized by scientists such as the National Aeronautics and Space Administration's James E. Hansen and praised in Congress by Republican Senator James Inhofe of Oklahoma.

Film and television portrayals of climate change escalated in 2006. Gore's *An Inconvenient Truth* became one of the top-grossing documentaries of all time. The movie version of his PowerPoint presentation was lauded by environmentalists and widely criticized by conservatives. Either way, it prompted widespread discussion of the topic. The film is shown widely in school systems, but a British court ruled that it contained nine significant errors.

A string of climate documentaries followed Gore's film in 2007 and 2008. They included actor Leonardo DiCaprio's *Eleventh Hour*, *Arctic Tale*, *The Great Global Warming Swindle*, and *Everything's Cool*. Each drew predictable criticism from opponents. Even the SciFi network included global warming as one of ten potentially lethal threats to humankind in its *Countdown to Doomsday* in 2007.

• Context

Despite almost countless news stories, the climate debate remains a major issue in the mainstream media. Polls show a significant number of Americans remain skeptical both about media coverage and about climate science. Because of this, media coverage has become a major topic of concern. Environmentalists continue to criticize skeptics and challenge the media to disregard such voices. Conservatives are joined by a growing and vocal group of scientists who publicly challenge what eco-groups call a climate consensus. Each side tends to complain about the tenor of media coverage of both themselves and their interlocutors.

Medieval Warm Period

- **Category:** Climatic events and epochs

- **Definition**

The Medieval Warm Period (MWP) is a term used to describe a period of several centuries that preceded the Little Ice Age (LIA). The MWP (also the Medieval Warm Epoch or the Little Climatic Optimum) was proposed in 1965 by Hubert Horace Lamb, a British meteorologist and groundbreaking climate historian, who believed it lasted from roughly 900 to 1300 C.E. During the MWP, Lamb believed, the North Atlantic and northern and western Europe experienced warmer conditions on average. He presented evidence drawn primarily from historical documentary data such as the expansion of agriculture to higher-altitude fields in mountainous regions, shifts in the cultivation of certain crops (such as wine production in the British Isles), changes in tree lines, and reports of weather and weather-related events (such as floods and droughts) in historical writings. This period also coincided with the Viking settlement of Greenland and excursions to Labrador, as well as a population boom in Europe, which grew from roughly 35 million to 80 million people between 1000 and 1347 C.E. All of these events seemed consistent with a milder climate and improved agricultural production.

In the decades following Lamb's assertion, temperature proxies were examined to better define the MWP, the transition to the LIA, and the extent to which they were regional or global phenomena. For example, measurements of oxygen isotope ratios in marine sediments from a Sargasso Sea core indicated an ocean temperature around 1100 that was about 1° Celsius warmer than present levels. This was followed by a nearly 2° Celsius decrease between 1100 and 1700.

Dendroclimatology, or the study of climate through tree-ring growth, conducted in the Sierra Nevada and the Great Basin of the western United States suggests periods of increased warmth and later periods of severe drought during the MWP. Similar tree-ring studies in northern Sweden and the Polar Ural Mountains provide evidence of increased temperatures from 971 to 1100 and from 1110 to 1350, respectively. Ice core and borehole studies in Greenland indicate a warm period peaking around 1000, followed by a 3° Celsius decrease into the LIA. Studies of glaciers and their moraines suggest that the MWP generally coincided with glacial retreat and the shift to the LIA with glacial advance. Other types of proxy studies include examining lake sediments, speleotherm (stalactite/stalagmite) growth, and coral growth. Many, but not all, proxy studies of sufficient length do indicate a temperature peak during the MWP and a decrease into the LIA, but with considerable variability in the details.

• Significance for Climate Change

The MWP is a central issue in the debate over climate change, as it is the most recent period of climatic warmth assumed to be free of anthropogenic factors. Likewise, the transition to the LIA is the most recent significant temperature shift before the warming of the twentieth century. The initial estimates by Lamb suggest MWP temperatures were about 0.5° Celsius warmer than those of the late twentieth century. This peak subsequently decreased, as more Northern Hemisphere data sets were combined. While many proxy data sets showed a temperature peak in the MWP, the heterogeneity of the peak locations, magnitudes, and durations meant that averaged temperature changes were reduced from those seen at individual sites.

Even with multidecadal filtering to extract long-term trends during the MWP from year-to-year fluctuations, interludes of cold have appeared in periods of relative warmth. The 2001 report of the Intergovernmental Panel on Climate Change (IPCC) largely dismissed the existence of a distinct, global MWP and LIA, epitomized by the famous hockey stick graph that showed a small, nearly linear decrease in average temperature from 1000 to the late nineteenth century with no distinct MWP to LIA transition. After some controversy, the next IPCC report in 2007 revived the MWP and LIA, using eight proxy-based temperature reconstructions to define a mild Northern Hemisphere temperature peak between 950 and 1100 that was 0.1°-0.2° Celsius cooler than the mean global temperature between 1961 and 1990 and 0.3°-0.4° Celsius warmer than the coolest LIA period.

Attempts to measure the MWP illustrate the challenges of using temperature proxies rather than instrumental temperature readings. Proxies are influenced by effects other than temperature—for example, growth patterns in tree-ring studies can reflect precipitation, diseases, and atmospheric carbon dioxide concentration. Studies that combine multiple proxy data sets must accurately calibrate their results against a common temperature standard, but different researchers use different approaches. Only a limited number of proxy sites extend back to the MWP, with few in the Southern Hemisphere and unbalanced coverage in the Northern. Overall, there is considerable potential error in each reconstruction, such that current views of the MWP are tentative and will likely change with future data.

Interest in the cause of the MWP has been muted by the debate over its nature. If the event was only regional, then changes in regional meteorological features such as the North Atlantic Oscillation might provide a sufficient explanation. If the MWP was more global, solar activity may account for it. Sunspot records do not exist for the MWP, but concentrations of the cosmogenic isotopes carbon 14 and beryllium 10 in tree rings and ice cores suggest that there was stronger than normal solar radiation around 1000 and again between 1100 and 1250. These isotope concentrations are also consistent with evidence of weaker radiation during much of the LIA.

Mediterranean climate

• **Category:** Meteorology and atmospheric sciences

• Definition

Climate is the long-term average weather of a particular location. A Mediterranean climate is characterized by wet winters and dry summers, with mild winter and hot summer temperatures. This type of climate covers just under 2 percent of Earth's land area. It is found only in the middle latitudes (around 35° to 45° north or south latitude) and near an ocean or the Mediterranean Sea. Most of the area included in this climatic zone is the Mediterranean Sea basin, for which it was named. Other Mediterranean climate regions include the coastal regions of central and southern California, central Chile, the west side of the tip of South Africa, and parts of southern Australia, particularly the southwest.

The summer dryness in Mediterranean climates is caused by stable atmospheric high-pressure systems preventing storm systems from entering the area. These semipermanent high-pressure systems move away from the area and toward the equator during the fall, allowing rain-producing low-pressure systems to move in. When high pressure is reestablished in the spring, low-pressure areas can no longer move through the area, and rain-free conditions are reestablished for a number of months.

Because this climatic zone is always near a large body of water and such water bodies moderate temperatures (water heats and cools more slowly than does land), Mediterranean winter temperatures rarely reach the freezing point. Summer temperatures are greatly affected by the relative warmth or coolness of the body of water adjoining the area. The Mediterranean Sea is a warm body of water, causing the Mediterranean basin to be relatively warm in the summer. Other areas, such as California, have relatively cool summer temperatures near the coast, because the Pacific Ocean, for example, is cooler than the Mediterranean Sea. The dryness of summer allows large temperature fluctuations during the day/night cycle. It also contributes to Mediterranean areas experiencing a relatively large number of wildfires, both because the air contains less moisture to resist fire and because the vegetation native to dry areas is itself drier and more prone to burn than that of wetter climates.

• Significance for Climate Change

Mediterranean climates depend for their stability upon a combination of specific atmospheric conditions and the presence of a large body of water. Thus, if the atmospheric conditions are altered by climate change, or if they cease to exist near large bodies of water, Mediterranean climates will disappear. On the other hand, new Mediterranean climates could be established near different water bodies under the right circumstances.

Areas such as California or Chile are on north-south coastlines, and it is possible that climate change could move the climatic zone farther north or south. If the change is not overly abrupt, Mediterranean flora and fauna could migrate along with the climate zone. However, in the Mediterranean basin, a substantial increase in global warming or another climatic change could destroy the ecosystem altogether, because there is no large body of water to the north to which the climate, flora, and fauna could shift. Within Europe, there could be some movement north, as seems to be taking place in the British Isles. The little egret, commonly found in the Mediterranean Sea area, was unknown in England prior to 1996. As southern England has begun to develop a more Mediterranean climate, as of 2008 it was the second most populous heron in the United Kingdom. While birds have the ability to move from the European mainland to Great Britain, however, plants and land animals do not.

Climatic changes have been documented in several Mediterranean and nearby regions. These changes raise particular concerns regarding biodiversity, which is more affected by climate than by other environmental factors. The Iberian Peninsula, for example, has the greatest animal diversity of any region in Europe, and many Iberian species are endangered by global warming. Average summer temperatures in the region are generally rising, which is putting a substantial heat stress upon both plants and animals. Humans are not immune to such factors, and a study documenting a 200 percent increase in the number of extremely hot days on the peninsula concluded that frail people's lives were at risk from the increase.

Desertification is also taking place in the Mediterranean, as rainfall decreases and higher temperatures increase the rate of evaporation. A large number of droughts in the early twenty-first century have contributed to the encroachment of the desert from the south. Although during the past fifty years there has generally been a decrease in the amount of rainfall, in some specific locations there has been an increase in precipitation.

It is estimated that up to 20 percent of plant species live in Mediterranean regions. In some areas, such as California, population growth has played a major factor in decreasing the number and diversity of plants, but changes in the precipitation patterns have also been a contributing factor, as has the resulting increase in wildfires. Even in areas where climate change has not substantially altered the total rainfall, the number of days on which it rains has changed. Many areas have fewer but harder rains than normal, resulting in less moisture being absorbed by the soil. An Intergovernmental Panel on Climate Change study has indicated that Mediterranean climates will very probably experience an increase in severe droughts, heat waves, and wildfires as a result of the changing climate.

Mediterranean Sea

• **Categories:** Oceanography; geology and geography

• Definition

Bounded by Africa to the south, Asia to the east, and Europe to the north and west, the Mediterranean Sea is virtually landlocked. It is approximately 2,510,000 square kilometers in area, has an average depth of 1,501 meters, and reaches a maximum depth of 5,092 meters. It is believed that the Mediterranean was created as a result of interactions over millions of years between the Eurasian and African continental plates.

The major source of the Mediterranean's water is a surface current flowing inward from the Atlantic Ocean at the Strait of Gibraltar in the west. This current increases in salinity as it progresses, eventually sinking in the eastern Mediterranean and reversing course to flow outward along the seabed through the strait. Other important sources of water are the Black Sea (considered by some to be an arm of the Mediterranean) to the northeast, several large rivers (including the Nile), and rainfall. Because of its semilandlocked nature, the Mediterranean has limited tides, and its high rate of evaporation makes it saltier than the Atlantic. The narrow, human-made Suez Canal links the Mediterranean to the even saltier Red Sea in the southeast.

In general, the Mediterranean region is dry and hot during the summer and wet and cool during the winter. It is positioned between rainy, temperate Central Europe and arid North Africa and is sensitive to variations in these regions' normal weather patterns.

• Significance for Climate Change

Climatologists and meteorologists predict that global warming will have a marked negative effect on the Mediterranean Sea and the countries lying on its shores. Existing problems such as flooding, heat extremes, water shortages, and desertification are likely to grow worse.

Global warming may raise the level of the Mediterranean Sea as much as 1 meter by the end of the twenty-first century, covering beaches and inundating coastal communities that are home to millions. The World Bank has warned that the Nile delta, in which one-tenth of Egypt's population lives and in which nearly half of the country's crops are grown, is in particular danger. Some have suggested that the Mediterranean could grow stagnant and that the flow of surface water through the Strait of Gibraltar might even reverse. The sea's resources are already threatened by overfishing, and warmer, saltier water threatens other native species such as corals and sponges, while favoring invasive species that have entered the Mediterranean from the Red Sea by way of the Suez Canal.

According to the United Nations' Intergovernmental Panel on Climate Change (IPCC), annual mean temperatures will probably increase throughout Europe, and the Mediterranean region is expected to experience hotter summers. This increase could have particularly serious consequences along the coast of North Africa. Heat waves are likely to increase in number and intensity, as they did throughout the second half of the twentieth century. The region may suffer from three to six times as many dangerously hot days in the twenty-first century, with France at greatest vulnerability. Rising temperatures will probably also result in increasingly intense storms, and although hurricanes rarely touch Europe, a 2007 study suggests that heat-induced atmospheric instability coupled with warmer sea temperatures could lead to tropical storms forming in the Mediterranean.

Overall, annual precipitation is likely to decrease in all but the northernmost parts of the Mediterranean region. Summers in particular are expected to be drier, with some studies suggesting that summer precipitation over southern Europe may decline by as much as 80 percent. Only in the areas dominated by mountain ranges such as the Alps is precipitation likely to rise, and those areas may lose a greater proportion of moisture due to higher temperatures. Droughts are likely to increase in frequency and severity, especially in the western Mediterranean.

Urban development along the Mediterranean coast of Spain. Significant climate change would pose a threat to such coastal developments. (Heino Kalis/Reuters/Landov)

Water usage in the Mediterranean region doubled in the second half of the twentieth century, and lack of water, already a serious problem in many parts of North Africa and the Middle East because of growing populations, will intensify. Rising sea levels will result in the salinization of freshwater needed for agriculture and human consumption.

Historically, the lands of the Mediterranean region have suffered from anthropogenic deforestation, and the resulting desertification is likely to spread in many areas. The increase in the number of forest fires forecast by the European Spatial Planning Observation Network in 2006 will add to the severity of the problem and will contribute to a loss of biodiversity.

Under conditions of global warming, death rates in the Mediterranean region from storms, heat stroke, air pollution, lack of water, and even malaria can be expected to rise. Many Mediterranean destinations will become too hot for tourists, undermining one of the region's major sources of revenue.

Megacities

• **Category:** Economics, industries, and products

Megacities are vast population centers with equally great effects upon local climate. They both concentrate and require significant amounts of resources, posing unique challenges for sustainability and environmentalism generally.

• Key concepts

megalopolis: a megacity that sprawls over a large area, rather than being concentrated spatially in the manner of traditional cities

urban heat island: an urban region that is significantly warmer than the surrounding rural areas

urbanization: the process of concentration of the human population in cities

• Background

A megacity is a city with a population greater than 10 million. When cities such as Mexico City, Los Angeles, or Hong Kong get this large, it becomes difficult to determine their precise boundaries or true population. The U.S. Census Bureau and the United Nations often disagree in nonsystematic ways about the population of some of the

Construction workers build a new apartment building in Jakarta, Indonesia, one of Asia's fastest-growing megacities. (Supri/Reuters/Landov)

world's largest cities, and the discrepancies between their estimates can represent several million people.

The bureaucracy and infrastructure of megacities can be as complex as those of small nations, and resource allocation within them is particularly difficult. In 1950, New York City was arguably Earth's only megacity. In less than one human lifetime there were at least twenty megacities on the planet. One of the most challenging aspects of this dramatic increase in the number of megacities is that they are increasingly appearing in some of the poorest nations of the world. In 1950, only three of the world's most populous cities were in the developing world. In 2005, about 75 percent of the world's largest cities were in the developing world. The rise of these megacities represents a profound development in the history of humanity, and the challenges they present with respect to climate change may also be among the greatest opportunities to address that change.

• Reality on the Ground

A megacity is a complex structure consisting of a sophisticated built environment that shelters and sustains millions of human agents. These agents, living in close proximity to one another, often represent extremes of human experience, as megacities juxtapose great wealth and poverty, as well as the diversity of human cultures. In their vast urban landscapes, millions of people live and die in sad and tragic conditions of poverty and low life expectancy. At the same time, others live lives of almost unfathomable wealth and freedom to travel about the globe. These urban environments simultaneously represent both a pinnacle of human achievement and a shameful failure to realize human potential.

• Change Challenges and Opportunities

Cities almost always depend on a hinterland beyond their spatial extent to provide food, water, energy, and raw materials to sustain the lives of their citizens. They also increasingly depend on this hinterland to absorb their sewage, solid waste, and greenhouse gas (GHG) emissions. Historically this hinterland was predominantly nearby. Increasingly, however, hinterlands are farther and farther away from megacities, and, in regard to GHG emissions, the global atmosphere itself may be considered part of the hinterland. The hinterland of Los Angeles is global, as the city receives oil from the Middle East, water from the eastern Sierra, and food from Mexico, Europe, and Asia. Mexico City has built vast tunnels to divert sewage to distant hinterlands. Denver, Colorado, uses a network of tunnels to divert water from the western slope of the Rocky Mountains that would normally flow into Mexico's Sea of Cortez.

Almost all of these processes relate to climate change forcing factors in direct or indirect ways. Nonetheless, a fundamental and primary impact of megacites with respect to climate change is the energy used by these cities to provide electricity (often provided by coal-fired power plants) and the energy used to provide transportation (predominantly generated by fossil-fuel combustion). These urban areas are the most densely populated areas of the world. This density is an opportunity for numerous efficiencies with respect to energy consumption for electricity, transportation, and the myriad other related needs of urban residents that require electricity and transportation. Leveraging the energy efficiency opportunities that these densely populated areas represent will be of paramount importance with respect to humanity's collective response to the challenges of climate change.

Meridional overturning circulation

• **Category:** Oceanography

• **Definition**

Meridional overturning circulation (MOC) is an oceanographic term for water flows in the plane defined by the vertical and meridional (or north-south) axes. It is calculated by averaging those north-south, up-down flows from east to west across the width of an ocean basin.

Most discussions of the MOC focus on the deep, overturning circulations that connect the ocean abyss to the surface. Deepwater formation (the "sinking branches" of the deep MOC) occurs in two broad regions of the global ocean: the high-latitude North Atlantic, predominantly in the Labrador Sea and the Nordic Sea, and the southern ocean, near Antarctica. Water's density increases when it is cold and salty. Thus, the densest surface waters occur in the polar regions. Temperatures there are low, and brine-rejection during ice-formation increases the salinity of surface ocean water.

Dense polar water sinks to form deepwater masses that spread out horizontally along the meridional axis to fill most of the global deep oceans. The return branch of this deep MOC is more diffusely distributed. Deep water becomes more buoyant, and it will return back toward the surface if it is heated or made less saline. Vertical mixing with less dense water higher in the water column will decrease the density of deep water, producing a return flow toward the surface. The deep MOC is sometimes referred to as the "thermohaline circulation," a term that is meant to evoke the idea that vertical motions are caused by changes in the temperature and salinity of seawater.

Shallow, wind-driven overturning circulations exist closer to the ocean's surface, the most prominent such feature being the subtropical cells in the Atlantic and Pacific Oceans. The winds blowing over the subtropical oceans force a convergence of surface waters, which pushes surface water downward in a process known as "Ekman pumping." This water travels at depth toward the equator, where the pattern of winds forces surface waters to diverge, bringing the water that was pumped downward in the subtropics back to the surface. Surface winds then force the surface waters back toward the subtropics, completing the subtropical cell.

• Significance for Climate Change

The MOC plays a crucial role in maintaining Earth's climate. The Earth is heated primarily in the tropics. Warm ocean currents move a large amount of tropical heat to higher latitudes in the subtropical cell and the deep MOC. This transfer of heat helps keep the high latitudes warm. The poleward heat flux is particularly strong in the North Atlantic Ocean. Heat brought poleward in the North Atlantic is then advected by large-scale winds eastward, where it warms Europe. Scientists have suggested that the North Atlantic MOC may slow down or shut down completely as a result of global warming; if this happens, the heat flux associated with the MOC would decrease, and Europe would become colder.

A climatic change that warms the high latitudes will introduce freshwater into the high-latitude North Atlantic Ocean as ice sheets melt and precipitation increases. This added freshwater would decrease the salinity of surface waters, reducing their tendency to sink. If polar water stops sinking, the warm surface current that brings lighter water to replace the sinking water would be disrupted, so the flow of heat to the North Atlantic and Europe would diminish or cease entirely.

Geologic evidence supports the argument that the introduction of freshwater into the North Atlantic can weaken heat transport by the Atlantic MOC. During the last ice age, ice sheets several kilometers thick covered a large portion of North America and northern Europe. Around 14,000 years ago, Northern Hemisphere glaciers retreated as a result of astronomically forced changes in Earth's orbit. Temperatures rose, and the ice sheets began to melt. Then, approximately 12,800 years ago, temperatures dropped rapidly back into the glacial range and ice sheets returned for another 1,300 years. This rapid drop in temperatures, known as the Younger Dryas, is believed to have been caused by the rapid input of freshwater into the North Atlantic from the melting North American ice sheet, which dramatically decreased the Atlantic MOC. While there is no large ice sheet on North America today, scientists are concerned that global warming could cause freshwater melt from Greenland to trigger analogous processes.

Mesosphere

• **Category:** Meteorology and atmospheric sciences

• **Definition**

The mesosphere is the region of the atmosphere extending from the top of the stratopause (about 50 kilometers high) to the bottom of the mesopause-lower thermosphere boundary (MLT), about 100 kilometers high. It is the coldest region of the atmosphere. The warmest temperatures in the mesosphere are found just above the stratopause, where air temperatures may be as high as –5° Celsius. Mesospheric temperatures decrease with increasing altitude, with the lowest temperatures, around –125° Celsius, occurring during summer at the mesopause.

• **Significance for Climate Change**

The natural source of water in the mesosphere is oxidation of methane. Atmospheric concentrations of the greenhouse gas (GHG) methane have increased dramatically since the beginning of the Industrial Revolution and may have influenced the appearance of noctilucent clouds. Water vapor emitted by rockets and the Space Shuttle has been observed to form noctilucent clouds. Exhaust from one shuttle mission may increase the appearance of noctilucent clouds by as much as 20 percent. Carbon dioxide (CO_2) in the mesosphere releases heat to space. Solar proton events have been observed to cool the lower mesosphere by causing photochemical reactions leading to ozone depletion, causing an estimated temperature drop of up to 3° Celsius.

Gravity waves are the dominant form of motion in the mesosphere, with wavelengths of around 10 kilometers. Wind speeds on the order of 100 meters per second may occur in the MLT. Gravity wave flux is lowest at solar maximum. Direction of atmospheric transport is from the summer hemisphere to the winter hemisphere.

In the mesosphere, clouds can form only at the coldest temperatures, within about thirty days of the summer solstice at latitudes above 50° north and below 50° south. Because they form at 82 kilometers altitude, the thin filamentous noctilucent clouds (sometimes called polar mesospheric clouds, or PMCs) are illuminated only when the Sun is between 6° and 16° below the horizon.

There has been speculation that noctilucent clouds are a recent phenomenon resulting from anthropogenic activity, as they were not reported prior to 1885, when scientists began studying the colorful twilight displays that followed the eruption of Krakatoa. Soon after the discovery of noctilucent clouds, speculations began that the particles composing the clouds were of extraterrestrial origin. In 1962, rockets launched to investigate noctilucent clouds determined that the cloud particles had nuclei of iron or nickel dust of extraterrestrial origin, which were coated by water ice. One of the most surprising aspects of noctilucent clouds is their strong radar reflectivity. After some study, an explanation was advanced in 2008 that molecules of sodium and molecules of iron form a thin metallic film over the tiny ice crystals. This film reflects radar waves in a special, amplified way that makes the clouds more prominent on radar than if they were a cloud of disordered metal dust. Noctilucent clouds are postulated to remove about 80 percent of the sodium and iron from their environment in the mesosphere.

Water is formed in the mesosphere as a result of the oxidation of methane gas, rather than arising from the Earth's surface. Because methane is released as a by-product of incomplete combustion, as well as through coal-mining activity and anaerobic production from animals, swamps, and rice paddies, its concentration has been rising steadily as a result of anthropogenic activity. The concentration of methane in the atmosphere has increased 150 percent since the industrial age began, around 1750.

After rockets are launched through the mesosphere, their exhaust trails may form artificial noctilucent clouds. These noctilucent trails can form in the mesosphere in temperate latitudes, but ground observations of them are made only when the Sun is between 6° and 16° below the horizon.

After the launch of the STS-107 shuttle mission in January, 2003, it was determined that vaporized iron and water from its exhaust traveled to Antarctica at 110 kilometers altitude in about two days. This exhaust plume went on to form noctilucent clouds in the southern polar summer. Data from this event indicate that a single Space Shuttle's exhaust might cause a 10 percent to 20 percent increase in the appearance of seasonal noctilucent clouds.

Meteorology

• **Category:** Meteorology and atmospheric sciences

Arguably the most important aspect of climate change is its effects on the physical and chemical properties of Earth's atmosphere. Meteorologists can assess those effects and their consequences, informing climate policy decisions.

• Key concepts

climate: long-term average weather conditions

mesoscale: the atmospheric scale between microscale and synoptic scale, ranging from a few kilometers to hundreds of kilometers

microscale: the smallest scale of atmospheric motion, ranging from meters to kilometers

planetary scale: the largest scale of atmospheric motion, covering the entire globe

synoptic scale: the typical scale of weather maps, showing such features as high- and low-pressure systems, fronts, and jet streams over an area spanning a continent

weather: a particular atmospheric state at a given time and place

• Background

Meteorology is the scientific study of the atmosphere, weather, and climate. It combines most of the basic scientific disciplines, such as mathematics, physics, chemistry, statistics, and computer science, and applies them to Earth's atmosphere and its phenomena. Thus, meteorology is a branch of Earth science and of physical science.

Meteorology provides the core knowledge about climate change and global warming. It can be used to analyze planetary climate patterns as well as continental, regional, and local patterns. Meteorologists measure weather and other specific atmospheric phenomena and abstract from those measurements to determine the climate, the long-term average conditions in a given location.

• Dynamic Meteorology

Dynamic meteorology is the core discipline of the atmospheric sciences. It employs dynamics, fluid mechanics, and classical mechanics, coupled with rigorous mathematics, to study atmospheric motion and evolution. Dynamic meteorology treats the atmosphere as a fluid continuum, applying Newtonian principles to atmospheric systems. Modern numerical weather prediction is a result of this approach. Many methods in dynamic meteorology are also extended to study climate systems in the closely related discipline of climate dynamics. Climate dynamics may provide a good tool for studying climate change. Various global circulation models (GCMs) are examples of this application.

- **Physical Meteorology**

In addition to its kinetic properties and dynamic evolution, the atmosphere possesses many other physical properties, such as its thermal content, its humidity, its electrical and optical properties, and so forth. To study these physical properties of the atmosphere, meteorologists incorporate the principles and approaches of physics. A wide range of subjects is helpful in studying such atmospheric phenomena, including cloud physics, thermodynamics, precipitation physics, boundary-layer meteorology, thermal convection, atmospheric electricity, and atmospheric optics.

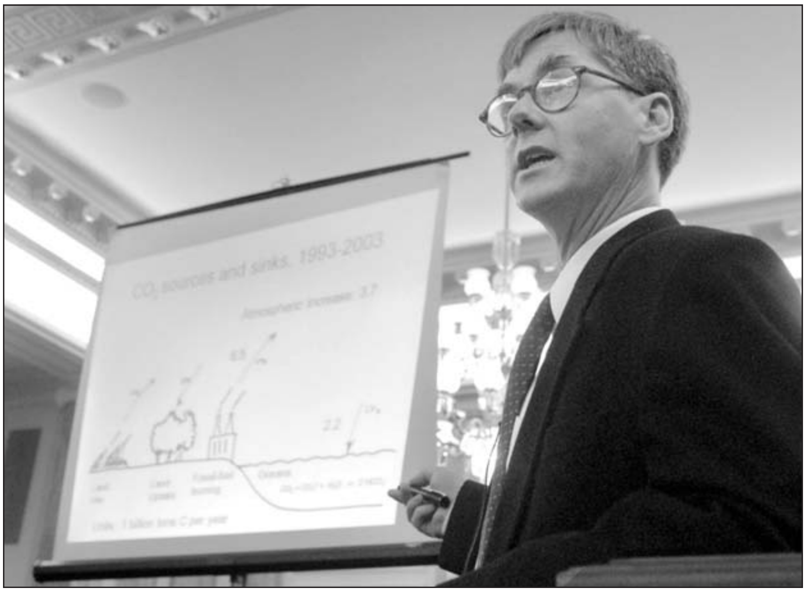
Many atmospheric physical properties are directly related to global climate change. For example, clouds are an important factor in global warming. Clouds play a dual role in the global climate system. On one hand, they contribute significantly to Earth's albedo, reflecting a large amount of solar energy back into space and producing a global cooling effect. On the other hand, they absorb long-wave radiation from the Earth's surface and re-emit it, thereby heating the atmosphere and surface. Increased atmospheric humidity due to global warming will increase cloud cover and influence severe weather patterns as well. Physical meteorology can provide a detailed understanding of these aspects of climate change.

- **Applied Meteorology**

As meteorologists' understanding of the complexity of Earth's climate system has increased, new applied meteorological specializations have emerged. Thus, the field now includes satellite meteorology, radar meteorology, statistical meteorology, agricultural micrometeorology, and climatology. These new subdisciplines are fundamentally interdisciplinary. They not only help translate meteorological concepts and research methods to other scientific disciplines but also strengthen meteorology by incorporating the technologies and methods of its sister sciences. For example, modern technologies, such as radar and satellites, add fresh content to meteorology and provide new observational tools for studying the atmosphere. These new areas are also important for global climate studies. For example, satellites can provide a global view of the global warming effect.

- **Atmospheric Chemistry**

Traditional meteorology is mostly concerned with the physical aspects of the atmosphere. Climate researchers, however, have found that atmospheric chemistry is just as important for understanding



Professor Ralph Keeling addresses members of the American Meteorological Society about the policy implications of natural carbon sinks. (Kevin Dietsch/UPI/Landov) climate change. Greenhouse gases are central to global climate change, and other aspects of atmospheric composition may play similarly important roles. Ozone depletion in the stratosphere is both an atmospheric dynamics and atmospheric chemistry problem that concerns climate change. In addition, Earth's carbon cycle is an important area for climate study.

With an increasing level of global industrialization and urbanization, environmental conservation and protection become more concerned issues. Air pollution and air quality are central to these environmental problems. Acid rain and environmental acidification are also concerns for environment protection and conservation. For all these problems, atmospheric chemistry can provide fundamental understanding.

• Context

Meteorology is one of the primary sciences employed in the study of Earth's climate system. Earth's climate is a complex system, however, that includes five components: atmosphere, hydrosphere, lithosphere, cryosphere, and biosphere. It is the interaction of all five of these components that determines Earth's climatic environment. Therefore, meteorology, although providing a core understanding of global climate and climate change, must be combined with knowledge from other scientific disciplines, such as oceanography, geology, hydrology, chemistry, biology, ecology, astronomy, and glaciology, to address global climate change.

Methane

• **Category:** Chemistry and geochemistry

Methane is among the six GHGs restricted under the Kyoto Protocol. Its global warming potential is more than twenty times that of CO_2.

• Key concepts

alternative fuel: clean or renewable fuel that can replace traditional fossil fuels

archaea: a taxonomic group of prokaryotic, single-celled microorganisms similar to bacteria, but evolved differently

energy from waste: technologies that are designed to produce energy and reduce or eliminate waste at the same time

fuel: an energy source that is burned to release energy

fuel alternative: replacement energy source that can be used instead of fuel

greenhouse gas (GHG): a gas in the atmosphere that traps heat on Earth that would otherwise radiate into space

• Background

Methane is a colorless, odorless gas with the molecular formula CH_4. It is the main chemical component of natural gas (accounting for 70-90 percent of such gas). Natural gas makes up up to 20 percent of the U.S. energy supply. Methane was discovered by the Italian scientist Alessandro Volta, who collected it from marsh sediments and demonstrated that it was flammable. He called it "combustible air."

• Methane as a Greenhouse Gas

As with all greenhouse gases (GHGs), methane in the atmosphere acts similarly to glass in a greenhouse. It allows light energy from the Sun to reach Earth's surface, but it traps heat energy radiated back from the surface in the form of infrared radiation. Since the beginning of the Industrial Revolution in the mid-eighteenth century, methane concentrations have more than doubled in the atmosphere, causing nearly one-quarter of the planet's anthropogenic global warming. Continuous release of methane into the atmosphere causes rapid warming, because methane's contribution to the greenhouse effect is much more powerful than that of carbon dioxide (CO_2).

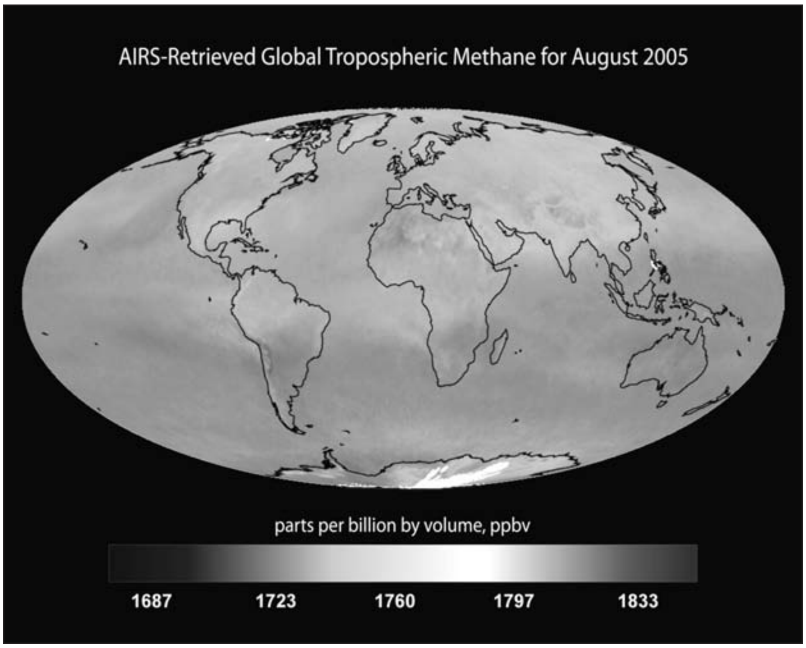
Global warming itself may trigger the release of methane trapped in tundra permafrost or ocean deposits, thereby accelerating climate change in a positive feedback loop. The release of large volumes of methane from such geological formations into the atmosphere has been suggested as a possible cause for global warming events in the past. Methane oxidizes to CO_2 and therefore remains in the atmosphere for a shorter time-period of nine to fifteen years, compared to CO_2, which may remain in the atmosphere for one hundred years.

• Sources of Methane

According to the U.S. Environmental Protection Agency (EPA), about 60 percent of global methane emissions are a direct result of human-related activities. These activities include creating landfills, treating wastewater, animal husbandry (through enteric fermentation and manure production), cultivating rice fields, mining coal, and producing and processing natural gas. For instance, the livestock sector (including cattle, chickens, and pigs) generates 37 percent of all anthropogenic methane. Landfills are the second largest anthropogenic source of methane in the United States.

Natural sources of methane include wetlands, lake sediments, natural gas fields, termites, oceans, permafrost, and methane hydrates. Wetlands are responsible for up to 76 percent of global natural methane emissions. Surprisingly, according to EPA data, termites contribute about 11 percent of global natural methane emissions. In most of these processes, methane is produced by microorganisms called archaea as the integral part of their metabolism. Such microbes are called methanogens, and the route of methane generation is called methanogenesis.

Archaea live in oxygen-depleted habitats, because the presence of oxygen would kill them instantly. For their food source, methanoges use products of bacterial fermentation such as CO_2 and molecular hydrogen (H_2); different acids such as acetate, pyruvate, or formate; or even carbon monoxide. That is why methanogenic archaea usually



A satellite image of the global distribution of methane in Earth's troposphere. (NASA-JPL)

Global Methane Emissions by Sector, 2000

Economic Sector	*Percent of Total Emissions*
Agricultural by-products	40.0
Fossil fuel retrieval, processing, and distribution	29.6
Waste disposal and treatment	18.1
Land use and biomass burning	6.6
Residential, commercial, and other sources	4.8
Power stations	0.9

Data from the Netherlands Environmental Assessment Agency.

exist in consortium with other microorganisms (bacteria). They also live in symbiotic relationships with other life forms, such as termites, cattle, sheep, deer, camels, and rice crops.

• Methane as a Fuel

In the 1985 science-fiction film *Mad Max Beyond Thunderdome* starring Mel Gibson, a futuristic city was run on methane generated by pig manure. In reality, methane can be a very good alternative fuel. It has a number of advantages over other fuels produced by microorganisms. It is easy to make and can be generated locally, obviating the need for long-distance distribution. Extensive natural gas infrastructure is already in place to be utilized. Utilization of methane as a fuel is a very attractive way to reduce wastes such as manure, wastewater, or municipal and industrial wastes. In local farms, manure is fed into digesters (bioreactors), where microorganisms metabolize it into methane. Methane can be used to fuel electrical generators to produce electricity.

In China, millions of small farmers maintain simple, small, underground digesters near their houses. There are several landfill gas facilities in the United States that generate electricity using methane. San Francisco has extended its recycling program to include conversion of dog waste into methane to produce electricity and to heat homes. With a city dog population of 120,000, this initiative promises to generate significant amounts of fuel with a huge reduction of waste at the same time.

Methane was used as a fuel for vehicles for a number of years. Several Volvo car models with bi-fuel engines were made to run on methane, with gasoline as a back up. Methane is more environmentally friendly than are fossil fuels. Burning methane results in production of CO_2 and contributes to global warming, but with less impact on Earth's climate than methane itself would have in the atmosphere, for a net benefit. Even though the use of methane as an energy source releases CO_2, the process as a whole can be considered CO_2 neutral, in that the released CO_2 can be assimilated by archaea.

• Methane Removal Processes

The natural mechanism of methane removal from the atmosphere involves its destruction by the hydroxyl radical (OH). Significant amounts of methane are also consumed by microorganisms called methanotrophs, which use the methane for energy and biosynthesis. These bacteria are prevalent in nature and potentially could be used for methane mitigation.

• Context

Since methane is a powerful contributor to global warming, any efforts to reduce methane emissions will have a rapid impact on Earth's climate. One way to avoid methane release into the atmosphere is to turn it into a fuel. Supply of fossil fuels, particularly oil, is limited and does not satisfy world energy demands, which consistently increase. The extensive use of fossil fuels causes global warming. Methane utilization in place of fossil fuels as an energy source can provide significant environmental and economic benefits. In the future, landfills and wastewater treatment facilities can possibly be redesigned to optimize methane production. However, further research is needed to better understand archaean-bacterial methanogenic communities in landfills and wastewater treatment facilities in order to improve methane generation.

Some technical obstacles exist to efficiently converting landfill wastes that primarily contain plant lignocellulosic material. Lignocellulose is a combination of lignin, cellulose, and hemicellulose that strengthens plant cell walls. Microbial communities in landfills cannot utilize lignin. Creating efficient methane-producing facilities that are also capable of reducing waste is a feasible option for sustainable development to provide fuel to heat homes, run cars, generate electricity, and eliminate powerful GHG and health hazards.

Mexico

• **Category:** Nations and peoples

• **Key facts**

Population: 109,955,400 (January, 2009, estimate)
Area: 1,922,550 square kilometers
Gross domestic product (GDP): \$1.559 trillion (purchasing power parity, 2008 estimate)
Greenhouse gas (GHG) emissions in millions of metric tons of carbon dioxide equivalent (CO_2e): 686 in 2000
Kyoto Protocol status: Ratified 2000

• **Historical and Political Context**

Mexico has experienced political strife throughout its history, including major wars and executions of leaders. The Spaniards invaded the region in 1519, conquering the Aztec and Mayan native cultures. Mexico attempted to declare independence from Spain in 1810, resulting in war and the execution of a number of leaders from Mexico. This war of independence lasted until 1821, when Spain finally granted Mexico its autonomy. The Mexico of 1821 included most of present-day Central America and the southwestern United States.

There was constant strife in Mexico until 1867, especially between a group supporting the centralized federal government required by the 1824 constitution and a group that supported a more localized government. During this time, the constitution was suspended, which resulted in civil war. The Republic of Texas, among others, declared independence from Mexico and was able to defeat the Mexican forces. Later, Mexico lost a war with the United States for control of Texas.

In 1867, Benito Juárez restored the republic of Mexico as a democracy, and he began to modernize the country. His acts reduced the power of the Catholic Church over Mexican politics, required equal rights for all people, and brought the army under civilian control. Porfirio Díaz was the ruler of Mexico from 1876 to 1911. He helped invest in the arts and sciences, and he improved Mexico's economy, reducing economic inequality and political repression. Diaz resigned in 1911 after an election fraud was found, and this event caused another Mexican revolution.

The government entered a chaotic period. A number of elected leaders were overthrown and assassinated. Finally, in 1929, Plutarco Calles founded the Institutional Revolutionary Party, which became the dominant party in Mexican politics until the end of the twentieth century. Mexico became more stable under the party. The economy grew significantly from 1940 to 1980. The government took over mineral rights, including nationalizing the petroleum industry into the organization called PEMEX. The Institutional Revolutionary Party, however, gradually became oppressive and authoritarian. For example, the government in 1968 killed many protestors.

The Institutional Revolutionary Party began to lose its control over Mexican politics in the 1970's, as some non-Institutional Revolutionary Party politicians were elected. In 1989, the first non-Institutional Revolutionary Party governor of a state was elected. It was suspected, however, that the Institutional Revolutionary Party changed the election results in the 1988 presidential elections so that its candidate, Carlos Salinas, won. This infuriated many people. Salinas signed the North American Free Trade Agreement and helped control inflation. By 1994, however, the economy in Mexico collapsed. The United States helped spur the Mexican economy, so that it had rebounded by 1999. In 2000, Vincente Fox became the first non-Institutional Revolutionary Party candidate to be elected president.

• Impact of Mexican Policies on Climate Change

Mexico has a free-market economy with the eleventh highest gross domestic product (GDP) in the world. Mexico has improved railroads, the distribution of natural gas, airports, and the generation of electricity. It has also become the largest producer of cars and trucks in North America. The economy of Mexico tends to be linked to that of the United States, as economic downturns and upturns in the United States have been reflected in Mexico. The country has a large middle class, although there are still significant income disparities among the Mexican people. Many persons live in poverty, especially in rural areas.

Mexico has made a definite commitment to energy conservation to reduce pollutants and greenhouse gases (GHGs) in the atmosphere and to promote energy efficiency. The nation has seven major metropolitans areas with populations over one million. The Mexico City metropolitan area is the largest, with over twenty-two million inhabitants.

The use of refining fuels such as gasoline and diesel, the two most used liquid fuels, has been growing steadily in Mexico. For instance, the use of refining fuels in Mexico grew from 141,000 kiloliters per day in 1988 to 206,000 kiloliters per day in 2000. Lead was eliminated from gasoline, and sulfur in gasoline and diesel fuels was drastically decreased in the 1990's. Fuel oil (4 percent sulfur) and national diesel (2 percent sulfur) have been replaced by gas oil (2 percent sulfur), industrial fuel (1 percent sulfur), and Pemex Diesel Industrial (0.05 percent sulfur).

These improvements in fuel have helped greatly to reduce air pollution, especially from lead and sulfur, in the Mexico City metropolitan area. The metropolitan area lies in a valley, with mountains surrounding much of the region. Pollution settles in this valley for much of the year because of an atmospheric inversion layer that forms over the valley trapping them. This results in a multitude of health effects on the city's inhabitants. The adoption of catalytic converters has also improved air quality. Mexico City's carbon monoxide emissions decreased by 454,000 metric tons per year from 1989 to 1994, reducing the amount of carbon monoxide in the atmosphere by 67 percent. In addition, ozone concentrations decreased by 36 percent from 1991 to 2003.

The use of fossil fuels will likely continue to increase with time in Mexico. Thus, other means need to be found to further re-

duce fossil fuel emissions. For example, public transport needs to be increased so fewer persons drive their own vehicles, and all vehicles need to burn fuel more efficiently.

• Mexico as a GHG Emitter

The GHG emissions of Mexico have grown steadily since 1990. For instance, carbon dioxide (CO_2) emissions were estimated to be 385 million metric tons in 2000 and 438 million metric tons in 2007. During this period, Mexico produced about 1.6 percent of the world's CO_2 emissions. The largest CO_2 emissions are from burning of fuels from industry and in the home (about 32 percent) and from transportation (about 15 percent). Mexico's CO_2 emissions will likely continue to increase as the country remains dependent on fossil fuels and its population grows, unless a more effective means to reduce emissions can be found.

Mexico signed the Kyoto Protocol in 2000. The goal of the protocol was to stabilize GHG emissions (especially those of CO_2, methane, nitrous oxide, and sulfur hexafluoride) to prevent climate change. The industrialized countries agreed to reduce their GHG emissions by 5.2 percent compared to those of 1990. The Kyoto Protocol was put into effect in February, 2005. The treaty divided countries into Annex I (industrialized) countries and non-Annex I (developing) countries. Under the treaty, an Annex I country can invest in projects to help reduce GHG emissions in a non-Annex I country. The Annex I country will earn credit for reducing the other country's GHG emissions that it can use to offset its own emissions in excess of its treaty obligations. For instance, Japan could invest in developing solar energy in Mexico to be used for electrical generation. Japan would then be given credits that it could either use to gain permission to emit more GHGs or sell to a third party.

The major commitment of Mexico as a non-Annex I country is to examine its GHG emissions with time to help limit their emissions. One approach to limiting its GHG emissions might be to add a tax on fossil fuels to increase the costs of the fuels and to reduce the Mexican government's subsidies on fossil fuels. The higher cost of the fossil fuels would reduce the use of the fuels and reduce GHG emissions. For example, it was predicted that if a tax of $10 per ton (in U.S. dollars) had been levied on Mexican fossil fuels starting in 1987, this tax would have resulted in a reduction of about 943 kilograms per person in CO_2 emissions. It would also have increased the Mexican government's revenues by $772 million, or about 3.2 percent. The petroleum, mining, chemical, and construction industries of Mexico would likely stand to lose the most from such a tax. Also, a tax on fossil fuels would encourage the development of more energy-efficient motors in vehicles and the use of more energy-efficient fuels.

Bioenergy sources, such as wood fuels, grain ethanol and other farming fuels, and cattle residues, have been suggested to replace some fossil fuels and reduce GHG emissions. For instance, if Mexico used biofuels (especially ethanol, biodiesel, and electricity generated from biological materials) to replace 16 percent of fossil fuels, then CO_2 emissions could be reduced by 79 million metric tons of CO_2 by 2030.

• Summary and Foresight

The economy of Mexico in the latter half of the twentieth century went from an agrarian economy to a more industrialized economy, increasing national consumption of fossil fuels and production of hard goods such as cars and trucks. Correspondingly, GHG emissions spiraled upward as well. The Mexican government has become more stable in the early twenty-first century than it was for much of its past, as political and police corruption have decreased. Nevertheless, there still appears to be a number of corrupt government officials, including police officers, who are ready to take bribes.

Traffic in illegal drugs appears to be a steadily increasing problem in Mexico. The so-called drug lords have been killing the police, army officials, one another, and many innocent civilians. Some civilians appear to have been held for ransom to obtain more money for the drug lords and some persons appear to have been killed to provoke fear in the general population. Also, some local areas in Mexico have been taken over by those involved with drugs. There may be an imminent danger that much of Mexico could be destabilized if these actions continue, and an unstable society will be much less equipped to institute climate policy initiatives to respond to global warming. Thus, Mexico must curtail these problems to be able to progress as a stable, democratic society. The efforts of Mexico to reduce the GHG emissions could fail if money is channeled elsewhere to stop the activity in drugs.

Microwave sounding units

- **Categories:** Science and technology; meteorology and atmospheric sciences

- **Definition**

A microwave sounding unit sounds (produces a profile of) the temperature and the moisture levels in the atmosphere. The first microwave sounding units were placed on National Oceanic and Atmospheric Administration (NOAA) satellites in 1978. In 1998, the Advanced Microwave Sounding Units replaced the older units. The satellites are polar-orbiting and synchronous with the sun. The satellites will make about sixteen orbits in twenty-four hours. The instruments make a scan every eight seconds, during which time the point on the surface below the satellite will have moved by 45 kilometers. During six of the eight seconds, the AMSU-A instrument is making thirty observations about 3° apart from 48° on one side to 48° on the other. The next scan will be 45 kilometers farther along its orbit. After the thirty observations, the instrument makes an observation of a warm calibration target and an observation of cold space before returning to its original starting position. The AMSU-A instrument is determining temperature of the different layers of the atmosphere. Another instrument, AMSU-B, is scanning in a similar mode but makes three times as many observations and determines water vapor concentration. In 2005, the AMSU-B instrument was replaced by a Microwave Humidity Sounder (MHS). In 2009 or 2010, the Advanced Technology Microwave Sounder (ATMS) is slated to replace the AMSU-A.

The AMSU-A is detecting thermal emissions from atmospheric oxygen. Those emissions are in the microwave region of 23 to 89 gigahertz. The microwave radiation is low-energy and high-frequency. The AMSU-A instrument has several channels. Different channels record different wavelengths of radiation. Groups of channels emphasize different layers of the atmosphere. Combined together a profile of the temperature of the different layers of the atmosphere is produced. Channels 2 through 4 emphasize the surface, channels 5 through 8 emphasize the mid-troposphere, and channels 9 through 14 emphasize the lower stratosphere.

• Significance for Climate Change

The data obtained from AMSU-A includes temperature and water vapor profiles of the atmosphere, snow and ice coverage, cloud water content, and rain rate. With data from other instruments, scientists can produce not only the temperature and water vapor profiles but also a measurement of the ozone, properties of clouds, and the amount of infrared radiation emitted by the Earth in areas not covered by clouds. The AMSU data are used in weather prediction. The more quickly the data get to weather prediction centers, the better the accuracy of the predictions.

It would appear that the data on temperature profiles that have been acquired since 1958 by balloons and since 1978 by MSU would allow for a determination of the increase or decrease of the temperature of the atmosphere. It has not proven to be so simple. Because of a change in equipment, the balloon data have a discontinuity that makes it much less valuable in determining temperature change. The data from MSU are not temperatures but thermal radiation from oxygen molecules. Different scientists use different methods to calculate the temperatures from the MSU data and consequently obtain different temperatures. Two of the groups doing calculations of this type are the Remote Sensing System (RSS) and the University of Alabama in Huntsville (UAH). The lower troposphere temperatures, in which stratospheric cooling has been eliminated, has been measured by RSS with an increase of 0.156° Celsius per decade and by UAH with an increase of 0.13° Celsius per decade. Other scientists have used the RSS data and the UAH data and have derived increases from 0.050° Celsius per decade to 0.20° Celsius per decade. Climate models indicate that the troposphere should warm about 20 percent more than the surface over the entire world and 50 percent more in the tropics. The surface temperature has increased by 0.17° Celsius per decade since 1979. Reconsideration of the data from UAH and RSS has led to corrections that have brought the data into fair agreement and into a not inconsistent agreement with the surface data. Probably the best statement about the data was made in a report by the National Research Council. The report states that whether the two sets of data agree with each other or with surface data, the fact is that there is a warming trend. The amount of warming may be less important than the fact that it exists.

Middle East

- **Category:** Nations and peoples

The Middle East is largely desert, with limited annual precipitation and limited usable freshwater sources. Increased consumption of Middle Eastern petroleum and related fossil fuels appears to be increasing atmospheric CO_2 concentrations, and reliance upon those resources causes the relative political instability of the region to have disproportionate effects on global socioeconomic stability.

• Key concepts:

desalination: removal of soluble salts from water, usually to make it potable or suitable for irrigation

dew point: the temperature at which airborne water vapor condenses

Fresnel lenses: small plastic sheets with very small, patterned, concentric circles stamped or milled into them that concentrate sunlight

orographic precipitation: rainfall caused by rising topography that cools moisture-laden marine air

paleoclimatology: the scientific study of ancient climates

palynology: the study of relict pollen from ancient pollen traps

water rights: the rights of sovereign states or other legal entities to contested water supplies

• Background

The Middle East comprises the sovereign states of the Eastern Mediterranean and North Africa, as well as those states along the Persian Gulf north of the Indian Ocean. Political definitions of the Middle East normally include the states of Syria, Lebanon, Israel, Egypt, Jordan, Saudi Arabia, Iraq, Yemen, Kuwait, Qatar, Bahrain, the United Arab Emirates, and Iran and the quasi-state territories of Palestine. These nations often act as a geopolitical bloc, because many of them are unified by their interests in the global oil market and their largely Muslim populations. The region is more than 92 percent Muslim, and it contains over 60 percent of known global oil reserves, as well as over 40 percent of natural gas reserves.

• Petroleum Production

Middle Eastern oil reserves from both conventional and unconventional sources combined are estimated at over 750 billion barrels. In 2008, the Middle East supplied over 60 percent of all global oil production. Middle Eastern oil reserves may be divided into three categories, in a formula known as 3P: what is provable, what is probable, and what is possible. These are all based on measurable analytic estimates and hypotheses or directly known from instruments used in petroleum exploration.

Saudi Arabia is arguably the most progressive state in the Middle East in the sense that it has declared a long-term goal of preparing for a future without oil. This plan requires Saudi Arabian society to be restructured to find alternative sources of economic wealth and diversification to replace lost oil revenues. The Saudis seek to become self-sufficient in their ability to provide themselves with food and water, among other resources. Nonetheless, Saudi Arabia remains the largest oil producer in the world, producing over 10 million barrels per day, 12 percent of global output.

Climate change represents a significant threat to the peoples and nations of the Middle East. Warming in the region would be likely to spread desertification, and the already marginal vegetation cover would become even more threatened. Ironically, much of the regional Middle Eastern economy is overwhelmingly dependent on oil production, which is seen as one of the major contributors to greenhouse gas (GHG) emissions and global warming, because burning oil releases carbon dioxide (CO_2) into the atmosphere.

• Water Desalination

The peoples of the arid Middle East have been working for decades on increasing freshwater supplies by developing desalination technology. The Middle East accounts for 75 percent of global water desalination. Saudi Arabia—the world's largest producer of desalinated water—has thirty desalination plants that supply 70 percent of national drinking water needs for a 2009 population of 29 million people, although this population is increasing. The Red Sea facility at Shoaiba, for example, a multiflash distillation operation, uses intense hot steam from a local power plant to boil out the salts from water. Its esti-

Anticipating an Israeli raid on Gaza, Palestinians wait in line for water in June, 2006. Water is an even more precious resource in the Middle East than it is in much of the rest of the world. (AP/Wide World Photos)

mated freshwater production is 150 million cubic meters for 2009 and 3 billion cubic meters by 2012.

Israel is also a high-tech leader in desalination, with a volume of 100 million cubic meters of freshwater produced in 2006 at the Israeli Ashkelon desalination facility alone, which uses seawater reverse osmosis (SWRO) technology. This facility, the world's largest SWRO operation, provides 13 percent of Israel's domestic water needs. Overall, the world's largest multiflash distillation operation is at Jebel Ali in the United Arab Emirates, which produces 300 million cubic meters of freshwater per year from the Persian Gulf.

If the Middle East could increase its collective water desalination efforts by 1,000 percent, it could theoretically produce enough freshwater to alter the region's climate. Such a quantity of freshwater would make it possible to sustain significant vegetation and forestation programs that could cause increased humidity and give rise to a sustainable regional hydrologic cycle. If this cycle were achieved, it could transform the desert into a sustainable agricultural region.

Major obstacles stand in the way of such a program, however. The necessary desalination technologies would be extremely energy intensive, practically requiring that they be powered by renewable energy sources such as solar and wind power to avoid depleting even the Middle East's energy reserves. Because the Middle East enjoys high levels of insolution, solar-powered desalination is not beyond the realm of theoretical possibility, and many global pioneering efforts in solar energy technologies are funded by Middle Eastern venture capital.

• Water Rights

Gudea of Lagash, ruler of Neo-Sumeria circa 2100 B.C.E., made a statement four millennia ago that may resonate during the twenty-first century: "He who controls water controls life." This statement is increasingly true in the Middle East, where marginal water sources are increasingly sources of conflict and the United Nations is encountering increasing difficulties in mediating disputes.

Sovereign Middle Eastern states involved in water rights disputes include Israel, Lebanon, Syria, and Jordan, where mountain ranges of the Amana and Hermon Mountains and the Golan Heights lie in the territories of multiple countries. The Amana Mountains are primarily in Lebanon, but their Mediterranean coastal rain shadow extends to Syria. The Hermon Mountain massif is shared between Syria and Israel. The contested Golan Heights are shared between Israel and Syria.

The Jordan River watershed, issuing from the Sea of Galilee, has become a highly charged geopolitical battleground: Jordan has long claimed that the technologically adept Israel supports its agricultural needs by siphoning off at least 70 percent of the watershed above the Jordanian border, leaving little water for Jordan's own agriculture and reducing its potential self-sustenance while increasing its need to import food. If climate change renders the Middle East increasingly arid, water rights will become an even more acrimonious issue, potentially further destabilizing an already tense region where the Jewish state of Israel and its predominantly Muslim neighbors coexist uneasily, and where tensions between Sunni and Shiite Islam and between secular and religious factions and states also cause unrest.

Increasing desertification as a result of climate change is likely, unless growth in regional desalination can compensate for lowering water tables combined with higher demand for rainwater. Overconsumption of water resources (for example, by denizens of the Jordan Valley in the Levant) results in smaller bodies of water (for example, the Sea of Galilee and the Dead Sea), which increases desertification by reducing the available watershed and increases evaporation by increasing the overall land temperature.

• Potential Reforestation

Portions of the eastern Mediterranean landscapes of the Levant now composing Israel were covered in antiquity by dense forests that were lost over time. Palynological studies of remnant pollen verify that this ancient hill forest comprised oak and other hardwoods, among other species. Photographs from the late nineteenth and early twentieth centuries show, however, that the coastal hills were completely denuded of trees in an arid landscape. Systematic, extensive planting of thousands of hardy pine trees, mostly fast-growing Aleppo pines acclimated to aridity, began in Israel in the 1950's.

Meteorological records kept since 1948 show that the annual average Israeli rainfall in the 1950's was around 25 to 30 centimeters. As the new pine forests matured, they cooled the surrounding air and mitigated surface temperatures, drastically altering rainfall. Moisture-laden air off the Mediterranean had previously risen over these hot hills and kept going, since the dew point was too high to cause precipitation. With cooler temperatures from forest cover, there was marked increase in orographic precipitation at lower elevations, as the dew point lowered significantly. Thus, rainfall in Israel increased dramatically over the fifty years between 1950 and 2000, reaching around 1 meter annually. This reforestation practice is thus now known to be effective and could potentially change microclimates all over the Middle East, especially where moisture-laden winds from bodies of water could be "harvested" to produce rainfall for agriculture.

• Solar Energy

Middle Eastern states such as Saudi Arabia and Israel are pioneering solar energy research and experimental projects. The amount of sunlight in the Middle East exceeds that of most other global regions, so solar energy has an extremely high potential there. Near Ashdod and in the Negev area, for example, where 330 sunny days per year are normal, Israel has planned or is building some of the world's most progressive solar energy facilities, with many hectares of solar collectors placed on solar "farms," some using rotating dishes made from mirrors. One Negev site alone is expected to cover 400 hectares when completed in 2012.

Rotating-mirror solar collection can harness 75 percent of incoming sunlight, which is about five times the proportion harvestable using traditional solar panels. The technology also reduces the quantity of photovoltaic cells needed by a factor of about one thousand. Israel is planning to produce about 65 percent of its energy by such means within twenty years. Saudi Arabia also has comparable technology and goals, embodied in its Saudi Solar Village Project, where model solar villages have solar units that use Fresnel lenses to concentrate sunlight. This renewable solar energy source has great potential to reduce dependence on carbon-emitting fossil fuels and also to power desalination for agricultural needs.

• Context

The Middle East is not only a geographic but also a geopolitical bloc that often operates on ideological commonalities reinforced by shared language, culture, and religion. It is predominantly Arabic in language and Islamic in culture. Additionally, its shared climate zone is overwhelmingly arid, bordering on desert, with overall annual precipitation under 20.8 centimeters. Only Lebanon and parts of Syria exceed this annual precipitation average and usually by only a small margin.

The arid Middle East as a geographic and geopolitical unit will be highly influenced by any increased global warming, because it is already under climatic stress. That the region contains a majority of the world's known petroleum reserves only complicates this economic and climatic problem, because its economic health is likely to diminish as a result of decreased global reliance on fossil fuels.

Although models by which one can infer climatic relationships are becoming increasingly sophisticated, one of the most difficult tasks ahead may be to differentiate between correlation and causation in global warming, especially given the increasing fossil fuel carbon footprint. The Middle East, with its enormous but nonrenewable energy reserves, is vital to the future of anthropogenic climate change.

Milanković, Milutin

Serbian mathematician

Born: May 28, 1879; Dalj, Slavonia (now in Croatia)
Died: December 12, 1958; Belgrade, Serbia

Milanković produced a curve demonstrating the variation in intensity of summer sunlight over the past 600,000 years. Once established, the curve enabled scientific explo-

ration of past and future relationships between solar radiation, eccentricity, and climate.

• Life

Milutin Milanković is credited with developing the concept of astronomical cycles that affect global climate and the timing of ice ages. In December, 1904, he received a doctorate of technical science from the Vienna University of Technology. Late in 1909, he was offered a professorship at the University of Belgrade, where for almost a half century, he would lecture on rational mechanics, theoretical physics, and celestial mechanics. Around 1915, he began to study the astronomical explanation for the Pleistocene epoch ice age. This work examined long-term solar radiation at various latitudes and seasons to determine the influence of the astronomical input to Earth's climate. The research was completed in the 1930's, culminating in the 1941 publication of *Kanon der Erdbestrahlung* (*Canon of Insolation and the Ice Age Problem*).

• Climate Work

Milanković proposed that if incoming solar radiation cyclically varies, then those variations of solar energy may be correlative with glacial and interglacial ages, which may arise from the orbital geometries between the Sun and Earth. About every 100,000 years, Earth's orbit around the Sun changes from a near-circular orbit to a slightly elliptical orbit, a variable known as eccentricity. Circular orbits are said to exhibit low eccentricity (around 0); more elliptical orbits have a high eccentricity (around 0.07).

An additional orbital cycle is the tilt (obliquity) of Earth's rotational axis relative to the ecliptic. The tilt varies from 22° to 25° over a period of forty-one thousand years and increases seasonal cycles at high latitudes, whereas lower latitudes undergo a reduced seasonal effect. The greater the obliquity, the more warmth high latitudes receive in summer, and the less they receive in winter. Only the eccentricity cycle affects the amount of solar radiation reaching Earth, so when Earth's eccentricity is at a maxim (causing less solar input) and its obliquity is at a minimum (resulting in less warmth in high latitudes), Milanković proposed that the onset of glacial conditions would occur.

An additional cyclic variation is the precession of the equinoxes, which has two components that regulate the seasonal change of the distance between Earth and the Sun. One component is elliptical precession, which relates to Earth's rotation around one of the foci of the orbit, having a periodicity of twenty-six thousand years; the other component is the "wobble" of the Earth on its rotational axis. Recall the slowing motion of a stationary top: It spins around its rotational axis, but the top of the top also wobbles (orbits). The effects of combining these two components of precession are present at the low latitudes (with periodicities of nineteen thousand and twenty-three thousand years).

With these three major variations in operation, the essence of Milanković's theory is demonstrated: Cooler summers would retard the melting of winter snow and ice; in turn, the relative mildness of winter at low latitudes would lead to sizable evaporation, which would produce abundant snowfall at middle and high latitudes. As snow and ice accumulate on land and remains, the icy surface reflects more energy back into space; over time, this snow and glacial ice can develop into continental ice sheets and mountain glaciers. Also, due to reduced insolation in the cooler, middle- and higher-latitude oceans, less greenhouse gas (GHGs) is available. Less GHG allows more long-wave radiation to leave the Earth, further cooling the planet.

Until the 1960's, Milanković's astronomical explanation for the presence or absence of glaciers was disputed because of a lack of geologic evidence. However, a complex study using climate-sensitive microorganisms in deep-sea sediments was undertaken to establish a chronology of temperature changes over the past one-half million years. The microorganisms used were foraminifera ("forams"), a protozoa that secretes a shell and whose shell, upon death, is deposited on the ocean floor, mixing with other sediments. The foram shell contains specific percentages of oxygen 18 (O^{18}) and oxygen 16 (O^{16}). Since ordinary oxygen (O^{16}) is atomically lighter than heavy O^{18}, during evaporation of ocean water O^{16} would go into ice formation in ice sheets and O^{18} would remain in ocean waters. Thus, when forams with shells rich in O^{18} were plentiful in ocean sediments, Earth was in a phase of glaciation.

Using isotope analysis, temperature variations over time can be compared. The established climate-time scale was then compared to the astronomical calculations of eccentricity, obliquity, and precession to determine whether there was a correlation. The conclusion of Milanković's mathematically complex research is that major variations in climate are closely linked to periods of obliquity, precession, and orbital eccentricity.

Research into future climate regimes investigates the relationship between solar radiation and eccentricity. Studies have demonstrated that for the next twenty-five thousand years, insolation will increase only 25 watts per square meter as received at 65° north latitude in June. Eccentricity will approach 0 for the same period, which will subdue the variations of precession. With these values (which do not consider anthropogenic changes to climate), the present interglacial cycle may continue into the future for twenty-five thousand years. Climate modeling that considers CO_2 input from anthropogenic sources and insolation variation over the next 100,000 years suggests that CO_2 concentrations over 220 parts per million volume will lead to protracted interglacial periods—about fifty thousand years into the future. An overview of most climate models confirms that future global climates will be similar to the warmest portions of the last few tens of millions of years. If the models are correct in predicting long, warm interglacial periods, the additional heat of global warming may strongly modify Earth processes and severely stress living organisms.

Military implications of global warming

• **Category:** Nations and peoples

Climate change is an emerging global threat that may aggravate conflicts and undermine security in many regions of the world. Climate-related impacts and shocks could trigger military responses and absorb resources for risk reduction, disaster mitigation, and conflict resolution.

• Key concepts

conflict: discord between opposing or incompatible values, interests, or actions of individual or collective actors

crisis: a potential turning point to the worse in a difficult situation

disaster: a drastic disruption in the functioning of a system with severe implications

instability: a state in which one or more normally constant, essential features of a system are in flux

risk: an indicator used to evaluate possible dangers that combines possible damages and the likelihood of their occurrence

vulnerability: susceptibility of a social system or group to pressures and stresses

• Background

Global warming not only affects the lives of individual human beings but may also have larger societal consequences. By triggering a cycle of environmental degradation, economic decline, social unrest, and political instability, climate change may become a crucial issue of geopolitical security and conflict. In some parts of the world (notably in Africa, Asia, and Latin America), the erosion of social

In eastern Chad, a dried up river filled with sand sits in the midst of a land already troubled by warfare related to competition for scant resources. (Finbarr O'Reilly/Reuters/Landov)

order, state failure, and violence have traditionally gone hand in hand. In the most susceptible regions, conflicts that begin within one state or between two states may spread to other neighboring states—for example, through refugee flows, ethnic links, environmental resource flows, or arms exports. Such spillover effects can destabilize entire regions and expand the geographical extent of a crisis, overstretching global and regional governance structures.

• Policy Debate on Climate Security

In 2007, the United Nations Security Council held its first discussion on the security risks of climate change, and the U.N. secretary general warned that climate change may pose as much of a danger as war. With its 2007 joint award of the Nobel Peace Prize to Al Gore and the Intergovernmental Panel on Climate Change (IPCC), the Nobel Prize Committee emphasized that extensive climate change could result in "increased danger of violent conflicts and wars, within and between states." A panel of experts that included, among others, former U.S. director of central intelligence James Woolsey and Nobel laureate Thomas Schelling asserted that climate change "has the potential to be one of the greatest national security challenges that this or any other generation of policy makers is likely to confront."

The German Advisory Council on Global Change (WBGU) concluded in its 2007 comprehensive analysis that, without resolute counteraction, climate change will overwhelm many societies' adaptive capacities in the near future, resulting in a level of instability that could jeopardize national and international security. In a 2008 report, the Office of the European Union High Representative and the European Commission suggested that "climate change acts as a threat multiplier, worsening existing tensions in countries and regions which are already fragile and conflict-prone." In particular, the warming of the Arctic region opens up new avenues for potential cooperation, but also for possible territorial disputes.

• Water Stress and Conflict

Climate change will likely exacerbate water scarcity for hundreds of millions of people. Uneven water distribution may induce migration or the quest for resources from neighboring regions. Individual case studies suggest that water scarcity undermines human security and heightens competition for water and land resources. According to Peter Gleick's chronology, water has been a factor in at least forty-two violent conflicts since the beginning of the twentieth century, but only in a few cases was the exchange of fire involved. By contrast, the Basins at Risk project at Oregon State University has concluded that water scarcity does not increase the likelihood of interstate conflicts but rather strengthens cooperation through transboundary water agreements and institutions.

In the Middle East, water scarcity is intertwined with the region's general conflicts. The arid climate, the imbalance between water demand and supply, and the ongoing confrontation between key political actors exacerbate the water crisis of the Nile, Euphrates, and Jordan Rivers. Global warming—together with population growth, overexploitation, and pollution—is projected to increase the likelihood and intensity of droughts in the region, undermining the conditions for peace and human security. However, statements on "Water Wars" in the Middle East have been questioned. The region's conflicts are largely determined by political differences, where hydrological matters represent an additional dimension of conflict as well as cooperation. Further progress of the water talks is connected to the fate of the Middle East peace process.

Central Asia is another region vulnerable to water conflicts, and the IPCC projects a sharp temperature rise in that region. Agriculture largely relies on irrigation and accounts for 20 to 40 percent of the gross domestic product (GDP) of most central Asian nations. Electricity in the region is based almost completely on hydroelectric power, which depends on glacier meltwater from mountain ranges. Some of the glaciers in the region have already declined in the past decades, and by 2050 about 20 percent of the glaciers in some mountains may disappear. The states of central Asia are characterized by largely closed markets, extreme social disparities, and weak state structures, making them unable to cope with these changes. Struggles over land and water resources have already played a major role in this region, and they have been aggravated by ethnic disputes, separatist movements, and religious-fundamentalist groups.

• Land-Use Conflicts and Food Insecurity

Reduction of arable land, water shortages, diminishing food and fish stocks, increased flooding, and prolonged droughts already threaten food security in many parts of the world, and climate change will aggravate this trend. With global warming, a drop in agricultural productivity is anticipated that will be reinforced by desertification, soil salinization, and water scarcity. More frequent extreme weather events may trigger regional food crises and further undermine the economic performance of weak and unstable states, thereby exacerbating destabilization, the collapse of social systems, and violent conflicts.

Particularly vulnerable will be Africa's food production, which has been in decline per capita for more than twenty years. Around 34 percent of the African population lives in arid regions, and about one-third of the population in sub-Saharan Africa is malnourished or undernourished. By 2020, in some African countries, yields from rain-fed agriculture could decline by as much as 50 percent, severely compromising agricultural production and access to food. Food crises impair the livelihoods of subsistence farmers and increase unemployment and migration for millions of people. As a result of migration from rural to urban areas, slums in African cities grow and become breeding grounds for crime and violence. Growing numbers of marginalized people could join riots and armed rebel groups, possibly culminating in civil war and ethnic conflict.

An example of ethnic conflict aggravated by resource scarcity is the 1994 genocide in Rwanda. In Rwanda, soil degradation, population growth, and unequal land distribution gave radical forces an opportunity to escalate ethnic rivalries into a political power struggle. Elsewhere in Northern Africa, a seried of droughts caused Arabic herders to move into the more fertile areas of Darfur, where grazing cattle trampled farmers' fields, contributing to existing clashes and tensions. The Sudan Post-Conflict Environmental Assessment of the U.N. Environmental Programme in 2007 concluded that Darfur is a "tragic example of the social breakdown that can result from ecological collapse."

• Natural Disasters

The IPCC projects that many areas of the globe will experience more frequent and intense extreme weather events and natural disasters, including droughts, heat waves, wildfires, flash floods, and storms. Disasters have dramatic impacts on human lives, generate rising economic and social costs, cause large numbers of fatalities, and temporarily impair or collapse state functions. Regions at high risk from storm and flood disasters generally have weak economic and political capacities, making adaptation and crisis management more difficult. Storm and flood disasters along the densely populated east coasts of India and China could cause major damage and trigger large migration processes. Developed countries are also vulnerable to natural disasters, as was seen during the 2003 heatwave in Europe, when more than thirty-five thousand people died and agricultural losses reached $15 billion.

The record hurricane season of 2005 demonstrated that even the world's most powerful nation is vulnerable and unable to cope with natural disasters. When Hurricane Katrina hit the U.S. Gulf Coast with wind speeds of up to 230 kilometers per hour, it left a trail of destruction over an area as large as the British Isles. In the Gulf of Mexico, 90 percent of oil refinery capacity had to be shut down. When New Orleans was flooded, over fifteen hundred people lost their lives, and hundreds of thousands fled their homes. The Earth Policy Institute in Washington, D.C., called this outflux "the first documented mass movement of climate refugees." The city's entire infrastructure was devastated, including water, food, energy, transportation, communications, and sanitation. Public order broke down. Most vulnerable were those living in poor-quality housing in high-risk areas and having few financial resources and no insurance to cope with disasters.

• Environmental Migration

In response to environmental degradation and weather extremes, or their indirect consequences such as economic decline and conflict, people will be forced to leave their homelands for other regions. Most vulnerable are high-risk climate hot spots, especially coastal and riverine areas and areas whose economies depend on climate-sensitive resources. Although most of the affected people in the Southern Hemisphere will remain within their national borders, industrialized regions face substantially increased migratory pressure—Europe from sub-Saharan Africa and the Arab world, and North America from the Caribbean and Central and South America.

The potential pressure on China to resettle large populations from flooded coastal regions or dry areas may put migration pressure on neighboring countries, including Russia. Migration of people can increase the likelihood of conflict in transit and target regions where migrants have to compete with the resident population for scarce resources such as land, accommodation, water, employment, and basic social services. Immigrants are perceived as competitors who change the "ethnic balance" in the region.

Populated mega-deltas in southern and eastern Asia will be at greatest risk due to increased flooding from the sea and, in some mega-deltas, from rivers as well. Climate change would significantly aggravate human insecurity in Bangladesh, one of the poorest and most densely populated countries of the world. Since 1960, about 600,000 persons have died as a result of cyclones, storm surges, and floods. Improved warning systems and shelters have drastically lowered the number of such deaths in recent years. The impacts of projected sea-level rise could be disastrous, threatening the Bangladeshi economy and exacerbating insecurity.

A 1-meter increase in the sea level could inundate about 17 percent of Bangladesh and displace some 40 million people, according to the World Bank. On several occasions, the migration of impoverished people has already caused violent clashes within Bangladesh and between emigrating Bangladeshi and tribal people in northern India, where several thousand people have died. The complex interaction of both anthropogenic and natural trends and their socioeconomic and political implications may further lead to situations of political instability and violent clashes, undermining young democratic institutions.

• Context

The security risks of climate change are determined by the causal links among climate stress factors, human impacts and responses, and societal instabilities. Whether societies are able to cope with the impacts and restrain the risks depends on their responses to change and their ability to solve and moderate associated instabilities and conflicts. While a gradual temperature rise of several degrees will already severely affect national and international security, abrupt and large-scale climate change beyond critical tipping points (for example, the collapse of the North Atlantic thermohaline circulation, the loss of the Amazon rain forest or of the South Asian monsoon, and the melting of the Greenland or the western Antarctic ice sheets with several meters of consequent sea-level rise) will likely have catastrophic consequences that could be comparable to major wars. Addressing the problem will require integrated approaches that combine climate and security policy in a mutually enforcing way. Adaptive strategies for mitigation and adaptation are needed that minimize security risks and mitigate conflicts by strengthening institutions, economic well-being, energy systems, and other critical infrastructures.

Minerals and mining

• **Category:** Economics, industries, and products

• **Definition**

Minerals are naturally occurring inorganic substances with definite chemical compositions and characteristic physical properties. A rock is an aggregate of minerals. Minerals range in composition from native elements and metals, sulfides, halides, and carbonates to complex silicates, which are the most common rock-forming substances. Contemporary society depends on the availability of mineral resources: Metallic minerals such as iron, copper, aluminum, lead, and zinc; nonmetallic minerals such as salt, clay, gypsum, soil, and water; and energy resources such as coal, petroleum, natural gas, uranium, and palladium have all become necessary to the functioning of human civilizations.

With few exceptions, minerals are generally nonrenewable (exhaustible), since mineral resources generally have required long expanses of geologic time to develop and thus are present in effectively fixed amounts in the Earth. Minerals are extracted from the Earth by a variety of mining methods when the resource is economically viable. As world population increases exponentially and that population aspires to and achieves middle-class socioeconomic status, an escalating resource crisis has begun to develop that propels the mining of nonrenewable mineral resources. This industrial mining is coupled with many environmental concerns.

It is believed that Earth may have reached its maximum capacity to absorb environmental degradation related to mining. Potential environmental impacts of mineral mining depend on factors such as mine waste management, mining procedures, local hydrology, climate, rock types, size of operation, and related factors. Mining disrupts the landscape and can instigate mine subsidence, disrupting biological and water resources. Underground mining is generally more hazardous as a result of poorer ventilation and visibility and slope instability along mine walls. Moreover, the dust and toxic gases in mines lead to severe respiratory problems, and the possibility of exposure to radiation poses serious health threats.

Through mining processes, large amounts of material accumulate as waste that needs to be disposed of. Many copper mines, for example, extract ore that contains less than 1 percent copper. For many nonferrous metals, almost all of the mined ore becomes waste. Artisanal mining, such as alluvial mining for gold and diamonds, often has impacts on landscape, which is disrupted by trenches.

These activities can lead to erosion and localized destruction of river banks. The waste also contains dangerous substances, such as heavy metals, which leach into the soil and result in the generation of acid or alkaline mine drainage.

The sulfide-containing minerals in metal mining get oxidized in the presence of air and react with water to form sulfuric acid. The acid mine drainage water contaminates surface and underground water. With the proliferation of the petroleum industry, numerous large-scale oil spills are becoming usual industrial accidents, and oil percolates through the soil and pollutes groundwater. The fuels and chemicals used in the mining industry are potential pollutants too. These chemicals left behind by explosives are usually toxic, and they increase the salinity of water. Small-scale artisanal mining may also affect water where mercury is used to process gold. Excavation and removal of raw ore are only the initial stage in the mining process. The ores are processed at refineries, and the valuable portion is extracted by flotation, gravity, or chemical methods. The by-products of mineral refining are sulfur, arsenic, and radioactive substances that are dangerous if they are released into the environment.

• Significance for Climate Change

The mineral mining industries contribute to the global climate. Fossil fuels are used to generate the energy required for moving mining equipment, mining procedures, ore processing and drying, transportation, and building operations. Burning them generates greenhouse gases (GHGs). The mining industry consumes large amounts of electricity to transport material by huge vehicles or extensive hoisting systems for underground mines. The underground mines become very warm with time, and cooling of deep underground mines is energy intensive. Refining metal ores by smelting also requires large amounts of energy. Surface mines pollute the air through blasting operations. Coal mines release methane, which is a primary GHG. However, methane can be captured through expensive processes to reduce the enhanced greenhouse effect.

Some members of the mining industry use ozone-depleting gases such as chlorofluorocarbons, hydrochlorofluorocarbons, and hydrofluoro-compounds for cooling. Similar to coal mining, the petroleum industry also has severe impacts on climate. The production and use of oil and natural gas makes a significant contribution to global warming by increasing atmospheric carbon dioxide (CO_2) concentrations. Additionally, mining operations cause extensive deforestation, one of the major changes in landscape that lead to increased CO_2 concentration in the atmosphere and promotes warming.

All these impacts can have long-term environmental and socioeconomic consequences and will be extremely difficult and expensive to address through remedial actions. Therefore, the mining industries are moving toward meeting standards of air and water quality set by Environmental Protection Agency (EPA) and other government agencies. At present, wastes from the extractive industries are properly managed in order to ensure the long-term stability of disposal facilities and to minimize water and soil contamination arising from acid or alkaline drainage and leaching of heavy metals.

The coal industries are participating in the Clean Air Acts (1963-1990) and controlling methane emissions, although this is not economically feasible in many locations. Methane is removed from coal mines through degasification systems or mine ventilation systems during mining activities, or after mining has occurred. Over the 1990-2000 time period, the EPA reports that recovery of coal mine methane resulted in a reduction of methane emissions by 30 percent or by the equivalent of approximately 25 million metric tons of CO_2 per year. The terrestrial and geological sequestration of carbon and improvement of carbon uptake of soils are areas of research in mining industries that can reduce anthropogenic CO_2 significantly. Moreover, the mining industries are promoting clean coal technologies to refine emissions reduction. The final goal is the development and implementation of zero-emissions mining industries. This requires both time and research dollars, and several organizations are participating and investing in this cutting-edge research endeavor, along with the potential for emissions savings.

Modes of climate variability

• **Categories:** Climatic events and epochs; meteorology and atmospheric sciences

Modern technologies, particularly satellites and supercomputers, have allowed scientists to view climate from a global perspective, revealing recurrent patterns of climate parameters that affect large areas of the planet over varying periods of time, often years or decades.

• **Key concepts**

El Niño-Southern Oscillation (ENSO): a coupled oceanic/atmospheric seesaw that occurs in the equatorial Pacific but often has global climatic consequences

modes: phases of a climatic seesaw; for example, El Niño is the warm mode of the ENSO seesaw, whereas La Niña is the cold mode

North Atlantic Oscillation (NAO): a seesaw in pressure between the Azores and southwestern Iceland, thought by some scientists to be an expression of the Northern Annular Mode

Northern Annular Mode (NAM) and Southern Annular Mode (SAM): also called, respectively, the Arctic and Antarctic Oscillations, seesaws in pressure between the latitudes near 45° northern (or southern) latitude and the North (or South) Pole

Pacific Decadal Oscillation (PDO): a temperature, pressure, and wind seesaw in the Pacific Ocean

Pacific-North American (PNA) pattern: a seesaw between northern Pacific and North American pressures

regimes: another word for "modes," fitting in with meteorological metaphors such as "fronts"

seesaw: a change in opposite directions, such as high pressure in one region and low pressure in the other

teleconnection: a connection between two widely separated regions of the planet that have highly correlated changes in some climatic parameter, usually resulting from a seesaw

• **Background**

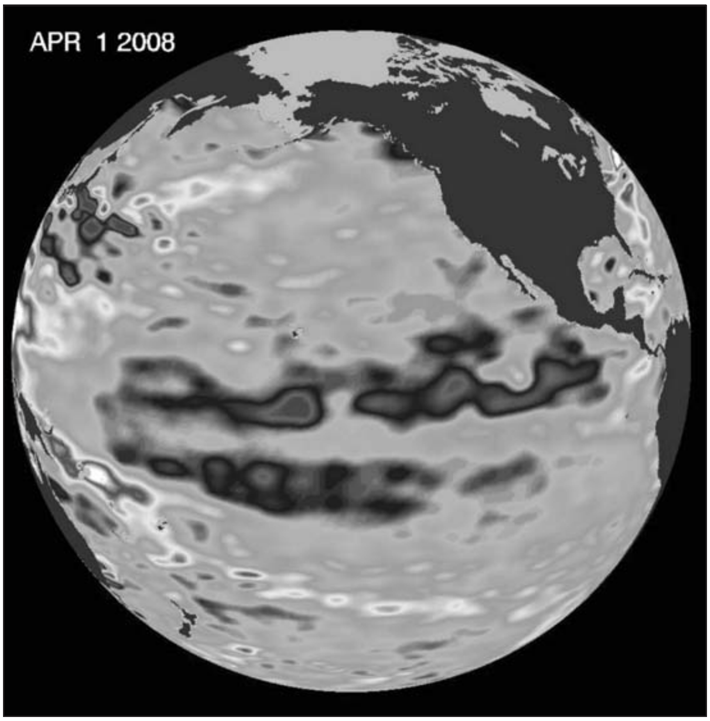
A college town with 2,000 residents that hosts 10,000 students for eight months every year has an average population of 8,666, but it will almost never have that number present. In "academic year" mode, it has a population of 12,000, and in "vacation" mode, it has 2,000. The climate also has modes, and its behavior varies dramatically between them. Temperatures, rainfall, winds, and other climatic phenomena during El Niño are very different from those during La Niña. Recognizing these modes is essential to understanding how the climate operates.

• **Seesaws**

Modes of climate variability are often referred to as "seesaws" because what is missing from one region (such as warmth, atmospheric pressure, or precipitation) is found in excess in the other region. Such seesaws result from the fact that the atmosphere is a finite body of gas that obeys the laws of physics.

By 1924, a number of seesaws had been identified by Sir Gilbert Walker. The data set he presented in 1932 had 183 stations widely spaced across the globe, with multiyear records that permitted statistical analysis. He put his North Atlantic Oscillation (NAO) and North Pacific Oscillation (NPO) on a statistical footing, detailing the strength of correlations between what he called "action centers." He also established the existence of the Southern Oscillation, which he defined in terms of a pressure seesaw. By the 1960's others had shown that this coincided with a pattern of sea surface temperature fluctuations called El Niño, and so it is now known as the El Niño-Southern Oscillation (ENSO).

Additional workers found more seesaws, and often an index was determined by combining the values of some climatological variable at two or more locations in a simple algebraic way: The Southern Oscillation Index was obtained by subtracting the sea-level barometric pressure at Darwin, Australia, from that at Tahiti; the North Atlantic Oscillation Index was obtained by subtracting the sea-level pressure at Iceland from that at the Azores.



The dark area above reveals a cooling trend corresponding to La Niña and the cool phase of the Pacific Decadal Oscillation. (NASA-JPL)

• Statistical Identification of Seesaws

Since Walker's work, the data series from many of his stations have been extended by more than seventy years, hundreds of new stations have been established, and satellite and other remote-sensing techniques have contributed immense amounts of climate information. New statistical techniques involving eigenvector analysis have been developed to analyze these data, particularly Principal Component (PC)/Empirical Orthogonal Function (EOF) analysis.

These techniques take data sets, which can be enormous, and rearrange them into separate, independent components that reveal how the data points are linked. As an example, consider the pressure data for points in the Northern Hemisphere, but outside the tropics (that is, at latitudes greater than 20° north). Eigenvector analysis finds that much of the variability in these data can be explained by two regional seesaws, EOF1, and EOF2. A map of which regions are controlled by each EOF shows that EOF1 corresponds to the NAM, and EOF2 corresponds to the PNA. Because this representation of PNA uses criteria that differ from its original index-based definition, it is often referred to as PNA.

• Context

Teleconnections show that Earth's climate is not entirely random. Spatial patterns exist, and the polarity of the seesaws within these patterns alternates, often with far-reaching consequences. What is less well known is the temporal behavior of these patterns, what causes them to switch polarity, and how they interact.

ENSO is the shortest and best-known seesaw, having an average period of four years, but this period can vary from two to seven years. Efforts to explain why its period should change, or to predict how long a particular El Niño or La Niña will last, have so far been unsuccessful.

The PDO has effects that are geographically similar to those of the ENSO but has a period of twenty to fifty years. Cool before 1924, then warm until 1947, cool again until 1976, and warm again until at least 1998, it has had ambiguous behavior since then. In addition to not knowing why it reverses or when it might reverse again, climatologists do not know whether the PDO causes increased ENSO fluctuations or is caused by them.

Scientists' understanding of the modes of climate variability is incomplete, but most climate scientists agree that they play an important role over periods of years to decades. Our ability to interpret climate data correctly depends on being able to place them in context with respect to these modes. Predictions of climate change would improve if it were possible to predict when these modes will reverse and how strong they would be.

Mold spores

- **Category:** Plants and vegetation

- **Definition**

Mold spores are reproductive structures of filamentous fungi (molds). A single microscopic mold filament, called a hypha, forms a mat that is called a mycelium. Mycelia are visible without a microscope. Molds are very common organisms and can be found where there is moisture, oxygen, and food they need. Molds can be seen on bread, cheese, or fruit. Hot spots of mold growth can be found in basements and bathrooms (especially shower stalls), house plants, and even air conditioners. Molds grow on fallen leaves, rotting logs, certain grasses, and weeds. They also can be found in barns, dairies, bakeries, and greenhouses.

The mold mycelium produces reproductive branches above the surface of the mold. These branches carry spores called conidia that function in distribution of mold by air, water, and animals. Among different molds, spores—employed in asexual reproduction—vary in size, shape, and color. Each spore can germinate to start a new mold, which in turn produces million of spores. Spores are very tough structures: they are resistant to drying, freezing, heating, and some chemicals.

The majority of the mold spores are disseminated by air. A sample of air may contain up to 2 million spores per cubic meter, but on average, about 10,000 spores inhabit one cubic meter of air. The amount of mold spores in the air in some areas is greater than the amount of pollen. Certain types of mold spores can cause various allergic reactions in humans, such as irritations of the eyes, nose, and throat. About 20 to 30 percent of the population develops allergic responses after exposure to these mold spores. The most common allergenic spores in the United States are *Alternaria cladosporium*, *Aspergillus*, *Fusarium*, *Mucor*, *Rhizopus*, and *Penicillium*.

In some people, exposure to mold spores leads to asthma. Some mold spores, if they reach lungs, can cause infections called mycoses. Systemic mycoses are the most serious category of mold infection. The host becomes infected by inhaling spores that germinate in the lungs. In the United States, two of the most common mold infections of that type are coccidioidomycosis, caused by *Coccidioides immitis*, and histoplasmosis, caused by *Histoplasma capsulatum*. Mild coccidioidomycosis may go unnoticed or produce symptoms similar to those of pneumonia or tuberculosis. The human immune system normally destroys mold spores and neutralizes mold infections. In a small number of cases, however, more serious coccidioidomycosis develops and lesions of the skin, bones, joints, internal organs, and brain (meningitis) occur. Progressive histoplasmosis symptoms include lung cavities, sputum production, night sweats, and weight loss.

• Significance for Climate Change

The weather and mold-spore distribution are closely related. Spore count is usually higher in temperate and tropical regions than in the polar and northern regions. In colder climates, molds are present in the air during the period between late winter and late fall. In warmer climates, mold spores are found throughout the year. It is likely that warmer temperatures due to global warming will result in an increase and even abundance of mold spores and, therefore, in considerable increase of allergic reactions. Repeated exposure to a massive amount of mold spores (100 million per cubic meter) can cause serious allergy-related health problems, including chills, fever, dry cough, breathlessness, weight loss, and even permanent lung damage.

Global warming is believed to be a major factor in the explosion of mold-related asthma and mold infections. For instance, the causative agent of coccidioidomycosis can be found in geographical areas with high summer temperatures and mild winters. In the southwestern regions of the United States, where this climate prevails, an estimated 80 percent of inhabitants are currently infected. Infectious disease specialists suggest that global warming will cause the further expansion of the geographic ranges of coccidioidomycosis infection.

Scientists predict that climate change could also increase the spread of histoplasmosis, which at present afflicts about 500,000 people annually. Another example of mold-spore infection spreading as a result of climate change is the infection caused by *Cryptococcus gattii*. Though previously it was only seen in Australia and other subtropical regions, this mold is spreading in Canada's Vancouver Island and the Pacific Northwest. It can cause serious human infection of the lungs and brain.

In addition, molds are the cause of numerous plant diseases. The increase of plant fungal diseases due to global warming may have a negative impact on plants' ability to take up carbon dioxide (CO_2), a greenhouse gas, thereby increasing the CO_2 concentration of the atmosphere and contributing to further warming. Managing mold plant infections may also require pesticides whose production consumes fossil fuels and generates even more CO_2 emissions.

There is another indirect relationship between mold spores and climate change. In nature, many molds are capable of decomposing woody plants such as trees. Cellulose and lignin in these trees are the biological molecules most resistant to decomposition. Molds, however, use cellulose and lignin from woody plants as their source of energy and carbon, and they release CO_2 in the process. Trees function as carbon sinks, retaining carbon for the duration of their lives and sequestering it from the atmosphere. As global climate change increases the amount of mold spores and, eventually, molds, the CO_2 released by decomposition of woody plants by those molds will also increase. Eliminating mold spores is impractical. Therefore, the only solution to keep molds under control is to control global warming.

Monsoons

• **Category:** Meteorology and atmospheric sciences

• Definition

Monsoons are seasonal changes in surface wind and precipitation patterns over the tropical and subtropical continents and surrounding oceans. These changes are due to the differences in thermal properties between land and ocean that give rise to different responses to seasonal changes in insolation.

The specific heat of land is typically less than that of ocean. That is, it requires less thermal energy to raise the temperature of a given amount of land by a given amount than it does to raise the temperature of the same amount of ocean by the same amount. As a result, the summer Sun warms the land more quickly and to a greater extent than it warms the oceans, which remain relatively cool. Typically, low-pressure weather systems form over warm surfaces and high-pressure systems form over cool surfaces. Thus, in the summertime, landmasses often become centers of low pressure, whereas the adjacent oceans become centers of high pressure. Wind blows from high-pressure centers to low-pressure centers, so in summer winds typically blow from the ocean to the land. This phenomenon is called "wind convergence" over land.

When wind converges over land, convection causes clouds to form. Precipitation typically follows the development of these clouds. Therefore, summer monsoons are characterized by winds blowing from the ocean to the land, over which clouds then form and rain falls.

In the winter, the entire process reverses. The lower specific heat of land, which caused it to heat more quickly than the oceans in the summer, causes it to cool more quickly than the oceans in the winter. As insolation decreases, the land quickly loses heat, becoming cold relative to the oceans, which retain much of their heat. As a result, the oceans become centers of low pressure, landmasses become centers of high pressure, and winds begin to blow from the land to the oceans. Clouds and precipitation also move from land to the oceans.

The contrast between the thermal properties of land and seawater is the basic cause of monsoons, but certain topographic features can enhance this effect. Larger landmasses and higher-altitude land surfaces increase the thermal and pressure differentials between land and water. As a result, the world's strongest monsoons are all related to the world's largest mountain ranges: The East Asian and South Asian monsoons are related to the Tibetan Plateau, the North American monsoon is related to the Rocky Mountains, and the South American monsoon is related to the Andes Mountains.

While monsoons are thus caused by contrasts between land and ocean, the atmosphere plays a crucial role in the system as well. The atmosphere couples with both land and sea to mediate and react to the thermal differences between them. It forms different pressure systems over the two bodies based on their temperature differential, reversing the direction of the winds. It also transports large amounts of water from sea to land, first by absorbing evaporated water vapor and then by precipitating the water onto the land.

• Significance for Climate Change

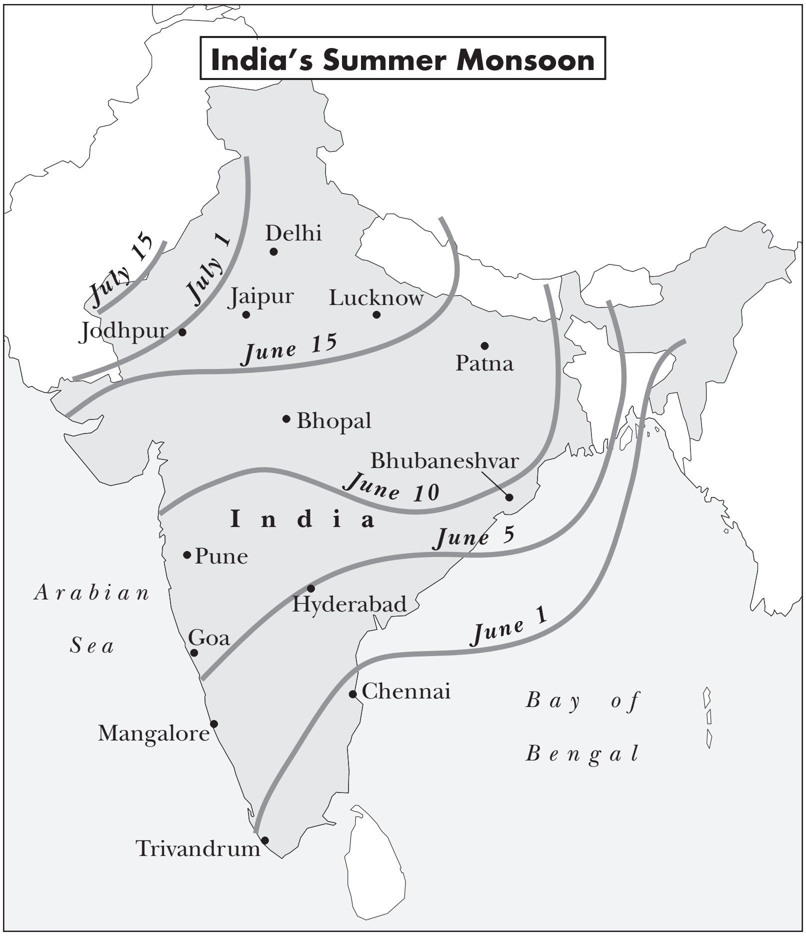
Monsoons form a central part of many regional climate systems. In many parts of the world, monsoonal precipitation constitutes a major rainfall system, providing water resources for regional ecosystems. Many tropical and subtropical climates are dependent upon the monsoonal rains.

Any significant climate change will inevitably affect global monsoon circulations, causing changes in the patterns and intensity of monsoonal rainfall. However, it is a matter of debate among climatologists as to whether global warming will intensify or weaken the monsoons. On one hand, generally warmer climates may reduce the temperature contrast between land and ocean, resulting in weaker monsoons. Evidence to support this hypothesis exists in studies of Himalayan ice cores. Data for the last three hundred years indicate that for every 0.1° Celsius increase in temperature in the Himalayas, there was a decrease of about 100 millimeters in monsoonal rainfall.

On the other hand, global warming may enhance evaporation from the ocean's surface, because warmer air holds more water vapor than does cooler air. An increase in the amount of atmospheric water vapor would likely lead to greater monsoonal rainfall and stronger monsoons. Data from the Tibetan Plateau—where Earth's strongest monsoon is located—indicate that over the last fifty years, total atmospheric water vapor content and total surface rainfall both increased.

Some scientists argue that, rather than strengthen or weaken monsoons, global warming might simply redistribute rainfall without significantly altering average amounts. Such redistribution would entail more severe events at both extremes, as heavy precipitation and flooding would occur in some areas and drought would occur in others. Thus, life in monsoonal areas is likely to change signficantly if global warming continues, but the nature of those changes remains uncertain.

Chungu Lu



The monsoons determine the beginning and end of rainy seasons in many parts of the world, but particularly in the Indian subcontinent. The map above illustrates the progression of rains northward during a typical year, as the summer monsoon moves onto the subcontinent, bringing moist air from the south.

Montreal Protocol

- **Category:** Laws, treaties, and protocols
- **Date:** September, 1987

The Montreal Protocol initiated a process to restore Earth's ozone layer, which protects the planet's inhabitants from dangerous ultraviolet rays. It has been ratified by most of the world's nations.

- **Participating nations:** *1988:* Belarus, Belgium, Canada, Denmark, Egypt, European Community, Finland, France, Germany, Greece, Ireland, Italy, Japan, Kenya, Luxembourg, Malta, Mexico, Netherlands, New Zealand, Nigeria, Norway, Portugal, Russian Federation, Spain, Sweden, Switzerland, Uganda, Ukraine, United Kingdom, United States; *1989:* Australia, Austria, Burkina Faso, Cameroon, Fiji, Ghana, Guatemala, Hungary, Iceland, Jordan, Liechtenstein, Malaysia, Maldives, Panama, Singapore, Sri Lanka, Syrian Arab Republic, Thailand, Trinidad and Tobago, Tunisia, United Arab Emirates, Venezuela; *1990:* Argentina, Bahrain, Bangladesh, Brazil, Bulgaria, Chile, Ecuador, Gambia, Iran, Libyan Arab Jamahiriya, Poland, South Africa, Zambia; *1991:* Botswana, China, Costa Rica, Malawi, Philippines, Togo, Turkey, Uruguay; *1992:* Algeria, Antigua and Barbuda, Barbados, Croatia, Cuba, Cyprus, El Salvador, Guinea, India, Indonesia, Israel, Republic of Korea, Kuwait, Mauritius, Niger, Pakistan, Papua New Guinea, Paraguay, Saint Kitts and Nevis, Samoa, Slovenia, Swaziland, Zimbabwe; *1993:* Bahamas, Benin, Bosnia and Herzegovina, Brunei Darussalam, Central African Republic, Colombia, Côte d'Ivoire, Czech Republic, Dominica, Dominican Republic, Grenada, Guyana, Honduras, Jamaica, Kiribati, Lebanon, Marshall Islands, Monaco, Myanmar, Namibia, Nicaragua, Peru, Romania, Saint Lucia, Saudi Arabia, Senegal, Seychelles, Slovakia, Solomon Islands, Sudan, Tanzania, Turkmenistan, Tuvalu, Uzbekistan; *1994:* Bolivia, Chad, Comoros, Congo, Democratic Republic of the Congo, Ethiopia, Gabon, Lesotho, Macedonia, Mali, Mauritania, Mozambique, Nepal, Vanuatu, Viet Nam; *1995:* Democratic People's Republic of Korea, Latvia, Lithuania, Micronesia, Morocco; *1996:* Azerbaijan, Estonia, Georgia, Liberia, Madagascar, Republic of Moldova, Mongolia, Qatar, Saint Vincent and the Grenadines, Yemen; *1997:* Burundi, Suriname; *1998:* Belize, Kazakhstan, Lao People's Democratic Republic, Tajikistan, Tonga; *1999:* Albania, Armenia, Djibouti, Oman; *2000:* Angola, Haiti, Kyrgyzstan; *2001:* Cambodia, Cape Verde, Nauru, Palau, Rwanda, Sao Tome and Principe, Serbia, Sierra Leone, Somalia; *2002:* Guinea-Bissau; *2003:* Cook Islands, Niue; *2004:* Afghanistan, Bhutan; *2005:* Eritrea; *2006:* Equatorial Guinea, Montenegro; *2008:* Holy See, Iraq; *2009:* Andorra, San Marino

- **Background**

In September, 1987, representatives of most of the world's nations met in Montreal, Quebec, to draft a protocol that called for a cessation in the production of chlorofluorocarbons (CFCs) and hydrochlorofluorocarbons (HCFCs). By July, 1996, this protocol had been subscribed to by representatives of 158 nations. The Montreal Protocol grew out of a concern among most of the world's nations about the depletion of the ozone layer, a thin invisible band in the stratosphere ranging from 10 to 40 kilometers above the Earth's surface. The ozone layer is crucial to the survival of life on Earth, because it filters out most of the deadly ultraviolet rays the Sun produces, permitting moderate temperatures and allowing visible light to get through. Without this natural filtration system, Earth would not be habitable.

Scientists have studied closely the four levels of the atmosphere—the troposphere, the stratosphere, the mesosphere, and the thermosphere—since the 1960's, using weather balloons and satellites to determine what gases are present. The ozone in the atmosphere was first measured in 1956 by scientists working out of Halley Bay in Antarctica.

The earliest weather satellites were launched in the 1970's. In 1978, the United States launched Nimbus 7, the first satellite designed to measure the ozone in the stratosphere in order to ascertain how profusely distributed the ozone atoms are and to determine the extent of the ultraviolet rays the ozone is filtering out. Using scientific data from these experiments, Joseph Farman, a British scientist, concluded in 1985 that the ozone layer had become extremely thin. People began to refer to an ozone "hole," a somewhat inaccurate designation. By this time, earlier researchers had discovered that CFCs, widely used as propellants in aerosol cans, were causing substantial damage to the ozone layer. The presence of CFCs and HCFCs in the atmosphere tripled between 1976 and 1987.

Halons, which contain bromine rather than chlorine, are produced in smaller quantities than CFCs and HCFCs, but they are extremely threatening to the atmosphere, because they destroy ozone at ten times the rate that these other pollutants do. Halons are widely used for extinguishing vehicular fires.

By 1985, after scientists had determined categorically that the depletion of the ozone layer was much more advanced than they had originally feared, many nations banned the continued manufacture and use of CFCs and other such substances. Reexamining information gathered by Nimbus 7, researchers were startled to find that a serious depletion of the ozone layer began in the 1970's and had continued apace since then with a steady thinning in the ozone layer.

Another source of pollution came from the refrigerants used in refrigerators and in air conditioning systems. The improper disposal of refrigerators released dangerous toxins into the air, so an effort was launched to make sure that refrigerators were disposed of safely. The refrigerants in them began to be reused in new refrigerators, employing a process developed by scientists in Germany. By far the greatest offender in pollution from refrigerants is the automobile, because many air conditioned vehicles have leaking rubber tubes from which refrigerants can escape.

By 1985, the hazards the ozone layer was experiencing from various sorts of pollution were considered so critical that immediate action was essential. This pollution compromised the safety of the entire planet, although it was most pronounced over the Northern Hemisphere. There, the ozone layer was shrinking above industrialized regions, where harmful chemicals were regularly released into the atmosphere as by-products of manufacturing. By the end of the decade that began in 1970, ozone in the stratosphere was found to be disappearing at twice the rate it previously had.

• Summary of Provisions

One of the earliest efforts to control the depletion of the ozone layer occurred in March, 1985, when a group of concerned scientists met in Vienna and drafted the Framework for the Protection of the Ozone Layer. The provisions of this document, signed by representatives of twenty-one countries, set a deadline of August 1, 1988, for the signatory countries to cease manufacturing CFCs and called for bans on the use of these chemicals as propellants in aerosol and spray cans, which were major factors in compromising the ozone layer.

This meeting in Vienna marked an important beginning but did not accomplish the sort of widespread action that the urgency of the situation demanded. In May, 1985, reliable scientific journals published findings clearly pointing to the existence of a substantial depletion of the ozone layer over Antarctica. Because of the speed at which this depletion was taking place, it was argued that the future of life on Earth was endangered.

By July, 1996, representatives of 158 countries had signed the protocol that grew out of the Vienna meeting. Although this meeting was not initially a notable success, it was significant for highlighting a critical problem and bringing it to the attention of the world's governments, which, despite their marked political and ethnic differences, realized that no time could be wasted in moving toward a tenable solution.

The Montreal Protocol on Substances That Deplete the Ozone Layer called for a 50 percent reduction in the production of CFCs by the year 2000. It spelled out how the gradual reduction in the production and use of chemicals that threaten the ozone layer must occur.

The protocol defines procedures for controlling the production of CFCs and specifies limits on their export and import. Many serious, seemingly unresolvable disagreements arose among the many nations participating in the drafting of the agreement. Representatives from industrialized nations were pressured by industrial lobbyists to resist approving any actions that might harm industry. In the United States, the Ronald Reagan administration, which was fiercely probusiness, viewed the protocol as a dangerous infringement on free enterprise. Most of Europe's industrial nations had vested interests that ran counter to the provisions of the protocol.

Representatives from countries in the Southern Hemisphere had other concerns, with many representatives of developing countries that teetered on the brink of insolvency resisting measures that might disturb the delicate equilibrium that characterized their economies. Special provisions and alterations in deadlines as they pertained to developing countries were enacted. Provision was made in the protocol to establish the Ozone Fund, which was subsidized by the industrialized nations for the benefit of developing nations. By 1996, this fund exceeded $500 million.

Despite the numerous quibbles that the organizers of the Montreal meeting had to address, the development of the Montreal Protocol moved forward. Annual meetings of those who participated in the Montreal Protocol were held in various venues, including Helsinki, Copenhagen, Beijing, Nairobi, Bangkok, and Vienna. The Montreal Protocol, signed in September, 1987, went into effect in 1989. It created mechanisms to regularly review parties' adherence to the protocol, taking into

Preamble to the Montreal Protocol

The Parties to this Protocol,

Being Parties to the Vienna Convention for the Protection of the Ozone Layer,

Mindful of their obligation under that Convention to take appropriate measures to protect human health and the environment against adverse effects resulting or likely to result from human activities which modify or are likely to modify the ozone layer,

Recognizing that world-wide emissions of certain substances can significantly deplete and otherwise modify the ozone layer in a manner that is likely to result in adverse effects on human health and the environment,

Conscious of the potential climatic effects of emissions of these substances,

Aware that measures taken to protect the ozone layer from depletion should be based on relevant scientific knowledge, taking into account technical and economic considerations,

Determined to protect the ozone layer by taking precautionary measures to control equitably total global emissions of substances that deplete it, with the ultimate objective of their elimination on the basis of developments in scientific knowledge, taking into account technical and economic considerations and bearing in mind the developmental needs of developing countries,

Acknowledging that special provision is required to meet the needs of developing countries, including the provision of additional financial resources and access to relevant technologies, bearing in mind that the magnitude of funds necessary is predictable, and the funds can be expected to make a substantial difference in the world's ability to address the scientifically established problem of ozone depletion and its harmful effects,

Noting the precautionary measures for controlling emissions of certain chlorofluorocarbons that have already been taken at national and regional levels,

Considering the importance of promoting international co-operation in the research, development and transfer of alternative technologies relating to the control and reduction of emissions of substances that deplete the ozone layer, bearing in mind in particular the needs of developing countries,

HAVE AGREED [to adopt this protocol.]

consideration the changes that scientific, environmental, technical, and financial factors might dictate in the future.

In 1990, at a meeting in London, the parties to the protocol voted to eliminate controlled substances that endanger the world's atmosphere gradually. At a meeting of the group in Copenhagen in 1992, the schedule for phasing out ozone-depleting elements was accelerated. Specified substances included CFCs, halons, carbon tetracholoride, methyl chloroform, HCFCs, hydrobromofluorocarbons (HBFCs), and methyl bromide.

Parties to the Montreal Protocol organized panels to discuss scientific issues relating to the depletion of the ozone layer, to consider the effects this depletion had on the environment worldwide, and to deal with technical and economic problems that provisions of the Montreal Protocol created. Some of these meetings resulted in amendments to the original protocol aimed at strengthening earlier provisions. As information about new substances dangerous to the ozone layer—such as CFCs, methyl chloroform, and carbon tetrachloride—came to be known, such substances were added to the list of those already banned or controlled.

• Significance for Climate Change

Because of the danger of ultraviolet rays emitted by the Sun, Earth's earliest inhabitants lived under water. Over billions of years, the oxygen released by aquatic plants rose and over eons created the ozone layer. With such a layer to protect Earth from ultraviolet rays, life eventually was able to emerge from the oceans and, over considerable time, to establish itself on Earth. Ozone absorbs all ultraviolet rays with wavelengths less than 290 nanometers and some with wavelengths between 290 and 320 nanometers, but it absorbs almost none with wavelengths above 320 nanometers. It is the latter rays, known as UV-C rays, that are deadly.

Ozone is made continuously in nature, originating mostly above the tropics and then carried by winds toward the Arctic and Antarctic, where ozone concentrations are greatest. Thus, once the phenomenon of the depletion of the ozone layer was recognized, scientists sought to explain this depletion. They determined that such substances as bromine, chlorine, the hydroxyl radical, and nitric acid threaten the ozone layer. It thus became clear that industrial pollutants were the culprits and that the depletion of the ozone layer could cause ultraviolet irradiation of Earth's surface, endangering human and nonhuman life. The actions demanded by the Montreal Protocol offer humankind's most effective hope of averting this irradiation and preserving Earth's ozone layer.

Motor vehicles

• **Categories:** Economics, industries, and products; energy

Passenger vehicles in the United States by 2007 accounted for 40 percent of the country's oil consumption and 10 percent of the world's consumption. Cars and trucks used in the United States burned 15 percent of the world's annual oil production.

• Key concepts

congestion charge: a tax levied for driving in the urban core of a large city

Golden Quadrilateral: India's first superhighway system, linking the country's east and west coasts with Delhi

miles per gallon (MPGs): a fuel efficiency standard for motor vehicles, measuring the average distance traveled on one gallon of fuel

Target Neutral: a carbon-offset plan for drivers in Great Britain

• Background

Motor vehicles consume one-third of the world's oil production. The number of automobiles has been increasing more quickly than population, especially in countries that have just begun to experience widespread industrial development, such as India and China. The tailpipes of motorized vehicles also emit 47 percent of North America's nitrous oxide, a primary component of ozone in the lower atmosphere that also retains heat as a greenhouse gas (GHG).

• U.S. Cities

Cities in the United States and elsewhere have been remade to accommodate automobiles. The U.S. cities that reached maturity after the 1930's—the last decade in which the average person did not own a car—have become energy-intensive, sprawling regions of suburbs and freeways, in which most residents are required to use automobiles for transportation. Outside of a few major eastern cities (New York and Boston being prominent examples), the automobile has become an everyday necessity for nearly everyone in the United States. After the year 2000, urban planners began to deemphasize the automobile in order to reduce GHG emissions. Even General Motors (GM) during 2007 entered a partnership to develop residences in once-abandoned buildings along the Detroit waterfront. One of the selling points for these lofts was the fact that people who live in them will be able to walk to work at GM's headquarters.

In New York City, Mayor Michael Bloomberg proposed a congestion charge for the crowded southern half of Manhattan Island, roughly from 86th Street southward. Under Bloomberg's plan, on weekdays between 6:00 A.M. to 6:00 P.M., trucks would be charged $21 per day and cars would be charged $8 per day to drive in the city. This tax would be in addition to the premium parking fees charged by city-owned and private lots. In 2008, only 5 percent of the people who worked on Manhattan Island and lived outside the island commuted by car. According to Bloomberg's proposal, drivers traveling only within the congestion zone would pay half price; taxis and livery cabs would be exempt, with uncontrolled, free access to the area.

Studies have shown that vehicle speeds on southern Manhattan Island average from 4 to 6 kilometers per hour. Many times, walking is almost as fast as driving. Subways are generally much faster means of transportation in the city. The value of the time lost to congestion delays in New York City has been estimated at $5 billion per year. When the cost is adjusted to include wasted fuel, lost revenue, and increasing costs of doing business, the total rises to $13 billion per year. Bloomberg's plan was defeated by the New York State Assembly in July of 2007.

- **Existing Congestion Charges**

Singapore was the first city to introduce a congestion charge. London introduced such a charge in 2003, followed by Milan, Italy. In London, vehicle speeds have since risen by 37 percent and carbon dioxide (CO_2) emissions have fallen by 15 percent. London's mayor, Ken Livingstone, a major proponent of the charge, was easily reelected in 2004, and in 2006 two-thirds of London residents supported the charge. During January, 2007, London's congestion zone was expanded westward to include most of Kensington, Chelsea, and Westminster. By early 2007, London's congestion charge had reduced private automobile use 38 percent and CO_2 emissions 20 percent in the congestion charge zone.

London also improved its public transport system to offer its residents easier alternatives; many commuters had complained that the buses were slow and expensive. By the time the London bus fleet was upgraded, more than six million people used it daily. The number of people commuting by bicycle in London soared by 80 percent after the congestion charge was implemented.

In the meantime, BP proposed that every motorist in Great Britain sign up for a plan called Target Neutral. Drivers can fund ventures that offset the amount of CO_2 that their driving adds to the atmosphere. Drivers register at a Target Neutral Web site, which calculates the estimated amount of CO_2 that may be produced by their driving over the coming year. Drivers then pay offsets based on the estimate. The typical family car, traveling 16,100 kilometers per year, is likely to cost about £20 ($39) to offset.

- **Stockholm**

Congestion charging in downtown Stockholm was a controversial issue in the Swedish general election during the late summer of 2006. A congestion charge of up to $7 per day was narrowly approved

Traffic grinds to a halt in New York City in May of 2007. Mayor Michael Bloomberg has proposed a congestion charge to help relieve traffic problems in Manhattan. (Xinhua/Landov) by 52 percent in a referendum September 17, 2006. The Stockholm congestion charge reduced auto traffic by 20 to 25 percent, while the use of trains, buses, and Stockholm's subway system increased. Emissions of CO_2 declined 10 to 14 percent in the inner city and 2 to 3 percent in Stockholm County. The project also increased the use of environmentally friendly cars (such as hybrids), which are exempt from congestion taxes. As in London, commuting by bicycle also increased. Following a trial period, the Stockholm congestion tax became permanent during August of 2007.

• **Context**

While some cities restrict automobile use, developing countries' fleets are increasing quickly. In China, by 2008, there were 20 personal vehicles per 1,000 people of driving age; in India, there were 18 per 1,000. In the United States, the same figure stood at 1,148 per 1,000. Between 2000 and 2006, sales of heavy trucks in China increased 800 percent. Sales of passenger cars increased 600 percent. Sales of new passenger vehicles in India tripled (from 500,000 per year to 1.5 million) between 1998 and 2008, a period during which the country built its first interstate highway system, the Golden Quadrilateral, which links Mumbai (Bombay), Delhi, Kolkata (Calcutta), and Bangalore.

If people in India and China drove at half the rate of those in the United States, world oil consumption, 86 million barrels per day in 2006, would balloon to more than 200 million. If drivers in India and China used cars as Americans do, world oil consumption would more than triple, with attendant impacts on its price, as well as GHG emissions.

Mount Pinatubo

• **Category:** Geology and geography

• **Definition**

Mount Pinatubo is an explosive volcano located near the tropics at latitude 15.1° north and longitude 120.4° east, in the Philippine Islands in the western Pacific Ocean. The volcano erupted on June 15, 1991, producing the second largest eruption of volcanic material in the twentieth century. About 10 billion metric tons of magma (molten rock plus suspended crystals) were brought to the surface, along with abundant volcanic gases, including about 20 million metric tons of sulfur dioxide. This was the largest amount of sulfur dioxide injected into the atmosphere since the eruption of the Krakatoa (Krakatau) volcano near Java in 1883.

Part of the hot gas, volcanic ash, and larger rock fragments spewed by the eruption tore down the valleys of Mount Pinatubo as pyroclastic flows. Great quantities of volcanic ash and gases rose soon after the eruption to heights of over 34 kilometers into the atmosphere. Much of the island of Luzon was completely dark during the day, as the dense ash cloud covered around 125,000 square kilometers around the volcano. Volcanic ash covered everything, and many people died when their roofs collapsed under the weight of the ash. Much of the ash became saturated with water from a nearby typhoon that produced large volcanic mudflows. Many previously abundant organisms such as foraminifera were greatly depleted in the nearby oceans after the eruption.

Mount Pinatubo, as it spews volcanic ash and steam during its 1991 eruption. (USGS/USAF/R. Batalon)

• Significance for Climate Change

The eruption of Mount Pinatubo gives some evidence as to how a big volcanic eruption at equatorial latitudes can change the climate. Larger volcanic eruptions that occurred through geologic time should have had an even more drastic effect on climate than did the eruption of Mount Pinatubo. Based on this eruption, volcanic ash quickly settles to the ground, so its effect on climate is short-lived. Only large eruptions such as that of Mount Pinatubo can eject volcanic gases (mostly water vapor, carbon dioxide, and sulfur dioxide) into the stratosphere to affect climate for more than a few days. The sulfur dioxide gas ejected from Mount Pinatubo circled the globe in twenty-two days. Sulfur dioxide gas ejected from erupting volcanoes at higher latitudes generally takes less time to circle the Earth.

Sulfur dioxide injected into the atmosphere by the eruption was rapidly oxidized to sulfuric acid and mixed with water vapor. This reduced the amount of heat absorbed by the atmosphere from the Sun by about 10 percent. Much of the sulfuric acid stayed in the atmosphere for over a year. This appears to have reduced the average temperature close to the Earth's surface by about 0.5° Celsius.

This cooling reversed the trend of global warming for several years after the eruption of Mount Pinatubo. For example, the ice sheet in Greenland did not melt as much as usual during this time. This cooling was not uniform, however, as parts of North America, Siberia, and Europe experienced higher-than-normal temperatures during this time. The warming trend in those regions was due to circulation changes in the atmosphere that are not completely understood, although several climate models to explain these changes were successful.

The generally cooling temperature of the lower atmosphere reduced the temperature of the ocean at the surface by about 0.4° Celsius for several years after the eruption, especially at midlatitudes. This cooling slightly reduced the evaporation rate of the ocean, so there was on the average less precipitation on the land's surface. The slow rise in sea level that occurred before the eruption was somewhat reduced as well, presumably because there was less evaporation from the oceans and less melting of the glaciers.

Various species of chlorine (such as Cl, ClO, HCl, HOCl, and $ClONO_2$), bromine, and iodine catalyze the removal of ozone in the stratosphere. The eruption of Mount Pinatubo liberated a large amount of chlorine species. Thus, the amount of ozone in the atmosphere dropped significantly after the eruption. For instance, ozone in the atmosphere of the tropics was reduced by about 15 percent after the eruption. The ozone hole in the Antarctic became much larger after the eruption.

National Center for Policy Analysis

- **Category:** Organizations and agencies
- **Date:** Established 1983
- **Web address:** http://www.ncpa.org

- **Mission**

An American nonprofit conservative think tank, the National Center for Policy Analysis (NCPA) promotes an environmental regulation program that seeks to solve problems by relying on a competitive private sector rather than on government control and regulation. The NCPA maintains offices in Dallas, Texas, and Washington, D.C. Well over half of its funding comes from foundations, with the rest from corporations and individuals. Acting as an organizer for other conservative groups, the NCPA also conducts its own free-market-oriented analysis of various issues.

- **Significance for Climate Change**

The NCPA's E-Team focuses on environmental policy. The individuals who form the E-Team are climate-change skeptics who opposed the Kyoto Protocol and also oppose any greenhouse gas (GHG) regulation. NCPA scholars hold that the causes and consequences of the current global warming are unknown. Since it would be very expensive to reduce carbon dioxide (CO_2) emissions substantially, they believe doing so would result in economic decline and increased environmental destruction with little or nothing accomplished to prevent global warming, whatever its cause.

A typical project of the group was an analysis of the 2007 Fourth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC). Citing the purpose of the IPCC as being to provide a

> comprehensive, objective, scientific, technical and socio-economic assessment of the current understanding of human-induced climate change, its potential impacts and options for adaptation and mitigation,

the NCPA concludes that, despite dire predictions of world temperature changes that could result in a global sea level rise, tropical disease spread, accelerated rate of loss of glaciers and ice caps, and increased severity of drought and flooding, forecasts in Chapter 8 of the report violate basic forecasting principles and are therefore invalid.

Because the NCPA is principally concerned with opposing government regulation in favor of promoting private alternatives, the group has concluded, for example, that global warming regulation is a key portfolio risk for state and local pension funds and has recommended that pension fund administrators not promote global warming legislation unless they can demonstrate how such regulation will benefit their portfolios.

The 2007 NCPA publication *A Global Warming Primer* maintains that predictions by some scientists that global warming will cause such things as droughts, floods, and hurricanes of greater intensity are not valid. Given its stance, the group recommends "focused adaptation," taking steps to adapt to warmer conditions, rather than implementing measures that it feels would have more negative economic impact than is justified given the facts that the group accepts as valid regarding global warming.

National Climate Program Act

- **Category:** Laws, treaties, and protocols
- **Date:** Signed into law September 17, 1978

The National Climate Program Act created an interagency program that conducts climate research, provides climate information, and supports policy decisions in the United States.

• Background

Following a period of reduced global average temperatures in the early 1970's, and growing out of years of effort by groups of climatologists, several bills were introduced in the U.S. Congress to coordinate climate research, prediction, and planning. One such bill, the National Climate Program Bill of 1975, failed to pass. Two years later, U.S. representative George Brown of California introduced the National Climate Program Bill of 1977, but it also failed, largely because of disagreements between the American Association of State Climatologists and the National Oceanic and Atmospheric Administration (NOAA) over funding priorities. Finally, in 1978, Congress passed the National Climate Program Act, and it was signed by President Jimmy Carter on September 17, 1978.

• Summary of Provisions

The National Climate Program Act (Public Law 367 of the Ninety-Fifth Congress), called for the establishment of the National Climate Program (NCP), as well as the Climate Program Advisory Committee and the Climate Program Policy Board. These entities are to issue periodic reports and plans to "assist the Nation and the world to understand and respond to natural and human-induced climate processes and their implications." The act required the secretary of commerce to establish a National Climate Program Office that would coordinate efforts and develop a series of research and climate services, drawing together the strengths of NOAA and other governmental agencies. These responsibilities were delegated to NOAA. The Department of the Interior and its U.S. Geological Survey are among the other agencies assigned specific roles under the NCP.

• Significance for Climate Change

The NOAA Climate Program conducts research and monitoring related to climate, climate change, and climate impact. It gathers and manages data from surface, marine, upper-air, and satellite observations; issues monthly and seasonal predictions of temperature, precipitation, and other weather indicators; predicts the impact of climate fluctuations on water resources, including fisheries, crop irrigation, and energy demands; and conducts new research. Five divisions of NOAA contribute to these efforts: the National Environmental Satellite, Data, and Information Service; the National Marine Fisheries Service; the National Ocean Service; the National Weather Service; and the Office of Oceanic and Atmospheric Research.

Several climate projects under NOAA have yielded important results. Under the direction of the NOAA administration, the United States is part of the Group on Earth Observations, an international organization developing the Global Earth Observation System of Systems (GEOSS), which will collect and manage data around the world. NCP awards grants and fellowships for outside research on the Arctic, on atmospheric composition and climate, on the global climate cycle, and other topics. It also operates the Regional Integrated Sciences and Assessments program, a partnership with American universities to connect with local and regional researchers and policy makers. The Climate Program Office operates separate divisions for climate observations, research, climate assessments and services, planning, and communications and education.

Although the 1978 act established the National Climate Program Office, the office received only a few million dollars of funding, so for its first five years the program accomplished little. No climate-related bills were introduced in the year after passage of the act, and in 1980 most of the funding for climate research was canceled as a result of a budget crisis. By 1984, pilot programs and new structures, including a strongly linked network of regional monitoring centers, enabled the NCP to produce and disseminate useful climate data. These data were essential in the growing national and international understanding of the causes and the effects of global warming.

As policy makers became more interested in global warming, they were unable to make use of much of the pure science that NCP was conducting, and they pressed for more information in forms that would help them draft policy. In response, in 1990 Congress created the United States Global Change Research Program to increase understanding of and response to global warming through research presented by NCP. Several amendments to the National Climate Program Act have been proposed since the 1980's to provide more funding, to solidify the various roles of the various agencies involved, or to require specific actions based on the data. In 2007, the Climate Change Adaptation Bill was introduced in Congress to amend the National Climate Program Act. It would require the president to draw up a strategic plan to address the impacts of global warming in the United States, and to establish a national climate service within NOAA. The bill was reported out of comittee in June, 2008, but no further action was taken by the 110th Congress.

National Research Council

- **Category:** Organizations and agencies
- **Date:** Established 1991
- **Web address:** http://www.gefweb.org

• Mission

The National Research Council (NRC) is the operating arm of the United States National Academies of Science. It was established in 1916 and made permanent by President Woodrow Wilson in 1918. The National Academies of Science include the National Academy of Sciences (NAS), the National Academy of Engineering (NAE), and the Institute of Medicine (IOM). These are private, nonprofit organizations chartered to provide policy advice to the federal government on science, technology, and medicine. They provide this policy guidance through the six divisions of the NRC. For global warming questions, most of these activities are carried out through the Division of Earth and Life Studies.

The NRC initiates studies at the request of the White House, a department of the federal government, or the Congress by calling together a committee of experts from the academies and from the nation. The committee studies the issue and publishes a public report on its findings, including policy recommendations. The NRC publishes more than two hundred reports and other documents each year.

• Significance for Climate Change

The NRC has been studying climate change since 1992. In 2002, it was charged with providing strategic advice to the U.S. Climate Change Science Program (CCSP), which coordinates the climate change activities of thirteen federal agencies. In addition to the annual advisory reports for CCSP, twenty-five other reports regarding global warming have been issued. The highlights of these reports have been compiled and published as *Understanding and Responding to Climate Change, 2008 Edition.*

The report indicates that available scientific data clearly show that the Earth is warming, and most of this temperature increase is likely due to human causes. Temperatures reconstructed by several different methods indicate that the planet's surface temperatures since the middle of the twentieth century have been higher than in any comparable period since about 1500 and have increased at the same rate as has the emission of greenhouse gases (GHGs). The report states, "Climate change will affect ecosystems and human systems—such as agriculture, transportation, and health infrastructure—in ways we are only beginning to understand." It concludes, "The increasing need for energy is the single greatest challenge to slowing climate change." As a result, the main action that should be taken is to reduce the amount of carbon dioxide and other GHGs that are released into the atmosphere: The world must work together to make use of alternative energy sources and prepare its populations for the effects of higher temperatures during the next decades.

Natural Resources Stewardship Project

- **Category:** Organizations and agencies
- **Date:** Established October 12, 2006
- **Web address:** http://www.nrsp.com

• Mission

As a skeptic organization, the Natural Resources Stewardship Project (NRSP) casts doubt on groups that view global warming as an issue that demands immediate attention, calling this stance a "hypothesis" and arguing that "current climate change is within natural variations." The NRSP is a Canadian, federally incorporated, nonprofit, nonpartisan organization that claims to promote responsible environmental stewardship through media and public relations; consumer education; promotion of private property rights; market-based approaches; and efficient and sensible regulatory and legislative frameworks, particularly at the federal level.

• Significance for Climate Change

The NRSP was established when there was a perception that caring for the natural environment had changed from being about individual responsibility to being about nonaccountable actions of transnational and nongovernmental organizations (NGOs), with negative economic consequences. This perceived change resulted in lessening citizens' initiatives and undermining private property rights. Members felt that many governmental and NGO initiatives followed an agenda not based on science or on rational economics. Overall, they felt that the situation was damaging the economy more than it was helping the environment.

The NRSP defines "responsible environmental stewardship" as prudent use of all resources, minimizing unnecessary pollution, transforming waste into resources, and improving material conditions; formulating practical environmental policies based on logic, scientific objectivity, and an understanding of risk; individual rather than governmental action as the preferred means to achieve goals; an understanding that private property encourages private responsibility; a recognition that regulation of resources is best at the most local level possible; and an understanding that more economic freedom allows more responsible individual action.

A top-priority initiative of the NRSP entitled "Understand Climate Change" used proactive grassroots groups to campaign against the Kyoto Protocol and other greenhouse gas emission reduction schemes and to promote sensible climate change policy. Another project, "The Science Centre," will establish a credible independent auditing mechanism to review scientific studies before they are used as a basis for widespread environmental decisions.

The NRSP addresses climate issues differently from less skeptical groups. They applaud the Canadian government's moving toward reducing greenhouse intensities over the short term rather than in terms of absolute emission caps. Believing that carbon dioxide is "almost certainly not a significant driver of global climate change," they will devote time and effort to studying natural factors, such as changes in the Sun's output. Funds will be used to find ways to adapt to the natural phenomenon of climate change rather to reduce carbon dioxide, and the group will oppose establishing further emission standards except at the most local level possible.

Netherlands

- **Category:** Nations and peoples
- **Key facts**

Population: 16,715,999 (July, 2009, estimate)
Area: 41,526 square kilometers
Gross domestic product (GDP): $670.2 billion (purchasing power parity, 2008 estimate)
Greenhouse gas (GHG) emissions in millions of metric tons of carbon dioxide equivalent (CO_2e): 213 in 1990; 174 in 1999; 217 in 2004
Kyoto Protocol status: Ratified 2002

• Historical and Political Context

By the seventeenth century, the Netherlands was playing a major role in the world's economy. The creation of the Dutch East India Company established the country as one of the major seafaring and trading powers. The mercantile class became extremely influential in all aspects of the country's life. The Netherlands' major trade rival was England and the competition between the countries led to the Dutch Wars, which were resolved in 1667 by the Treaty of Breda. England recognized the Netherlands' right to the Dutch East Indies. During this period, the Netherlands' capital city of Amsterdam became the site of the first stock exchange and was recognized as the wealthiest trading city at the time. In 1652, the Netherlands had become a republic under Jan de Witt. In 1672, the French invaded the country and killed de Witt. This marked the beginning of a decline in the economic prosperity of the country, which lasted throughout the eighteenth century. From 1795 to 1815, the Netherlands was under French control as part of Napoleon's Empire.

The Industrial Revolution of the nineteenth century did not bring about rapid changes in the Netherlands, because the country relied heavily on waterways for transportation and on wind power for energy. Up to the time of World War II, the Netherlands maintained a neutrality and independence from its neighboring countries that adversely affected its economic prosperity. After the war, the country made a dramatic change in policy and began interacting with its neighbors; this new policy brought about renewed economic prosperity. The Netherlands became an important founding member of major international organizations including the Benelux, the North Atlantic Treaty Organization (NATO), and the European Coal and Steel Community. As one of the fifteen founding members of the European Union, the Netherlands plays an important role in Europe's economy and welfare.

• Impact of Dutch Policies on Climate Change

Sea level, rising tides, and the potential of flooding have always been of major concern to the Netherlands since approximately 27 percent of its land lies below sea level. Throughout its history, the country has intervened to protect its land and inhabitants from encroachment by the sea and from flooding caused by overflowing rivers and rising sea levels. The industrialization of the Netherlands has adversely affected the country's situation. With the exception of the natural gas fields near Sloctern, the country has few natural resources and the economy depends on manufacturing and processing for a considerable amount of its wealth. Petroleum refining, food processing, and chemical processing, along with the manufacture of electrical machinery, all increase greenhouse gas (GHG) emissions. This adds to global warming, which may raise sea levels and increase erratic weather patterns that may contribute to the overflow of rivers and flooding. This situation is worsened by the Netherlands' use of intensive agriculture and horticulture, which produce more GHGs.

The coastline of the Netherlands has undergone considerable changes over the centuries. In 1134, a severe storm created the archipelago of Zeeland. In 1421, the Saint Elizabeth flood caused serious damage to the Netherlands. To combat these problems, the Dutch built polders and dikes to control the water levels and prevent disasters. There are three different kinds of polders, which are tracts of lowlands enclosed by dikes. The first is land reclaimed from a lake or the sea, the second is an area prone to flooding that is protected from the sea by dikes, and the third is a drained marsh separated from the surrounding water by dikes. Windmills are used to pump the excess water. Water bodies or home councils, which are groups independent of any government control, supervise the maintenance of the flood prevention systems.

In 1953, the Netherlands experienced one of its worst floods. The country put into effect the Delta Works, which raised 3,000 kilometers of outer sea dikes and 10,000 kilometers of canal and river dikes to a flood-prevention level and closed off the Zeeland sea estuaries.

• Netherlands as a GHG Emitter

As a member of the European Union, the Netherlands ratified the Kyoto Protocol in 2002. According to the data gathered by the European Environment Agency, the Netherlands emitted 213 million metric tons of GHGs in the base year of 1990. In 2006, the Netherlands had reduced its emissions to 207.5 million metric tons, ranking seventh among the EU27 and sixth among the EU15 as an emitter of GHGs. The burden-sharing target of the Netherlands under the Kyoto Protocol is –6 percent, to an annual average of 200.3 million metric tons of emissions between 2008 and 2012. From 2002 to 2006, the Netherlands produced an average of 213.6 million metric tons of GHG emissions, representing an increase of 0.3 percent. The country's 2006 emissions, at 207.5 million metric tons, were 3 percent below its base year emissions but were still above its treaty target. The Netherlands has projected an increase in its emissions to a level just 2 percent below the 1990 levels, as present policies continue in energy supply and use, as well as in transport and agriculture.

• Summary and Foresight

The Netherlands believes that it will exceed its target of 6 percent below 1990 levels by 2012. By implementing carbon sink activities and using Kyoto mechanisms, specifically that of providing funds for projects reducing GHG emissions in other countries under the clean development mechanism, the Netherlands projects a level of GHG emissions 8 percent below those of 1990.

In view of the prospects of continued global warming, the Netherlands is embarking upon a major flood-control project. Projected to continue to the year 2100, the project is estimated to cost about one billion Euros per year. At the core of the project is the planned raising of dikes and reinforcing of storm barriers. Many different approaches are being considered, from amelioration of the protection from the sea at major ports, especially Rotterdam, to extending the coastline of the North Sea as much as 1 kilometer by dumping millions of metric tons of sand into the ocean. The Netherlands is also working to use technology to protect the country from floods. A system of sensors to determine the stability of the dikes is being developed to replace the human volunteers who carry out the inspection. The Netherlands is also working with International Business Machines (IBM) to create software that can analyze weather, provide early warning of flood threats, and help coordinate plans for evacuation. The law approving funding for the massive and costly project and maintaining its funding over the century-long period has yet to be passed, but the Netherlands is convinced that the sea level will rise and significant preventive measures must be in place before 2100.

New Orleans

• **Category:** Nations and peoples

After Hurricane Katrina devastated New Orleans in 2005, the city's experience became a pivotal point for increasing interest in understanding and mitigating the contribution of global warming to future coastal disasters.

• Key concepts

Atlantic Multidecadal Oscillation: cyclical increases and decreases in sea temperatures that last for decades

Power Dissipation Index: a measure of the total annual energy output of all hurricanes in a region

Saffir-Simpson scale: a scale that ranks hurricanes from category 1 through category 5, based on their sustained wind velocity

storm surge: rising water that is caused when a hurricane's winds push the ocean's surface inland

U.S. Army Corps of Engineers: a government agency whose duties include flood control

• Background

New Orleans, the only major American city below sea level (2.4 to 3 meters below in some places), depends on a system of levees and natural buffers, such as coastal wetlands and barrier islands, for flood protection. When Hurricane Katrina's storm surge breached and topped the city's levees in the summer of 2005, 80 percent of New Orleans was flooded. Post-storm queries have sought to determine how to assess and reduce the probability of future New Orleans disasters by better understanding the conditions that caused Katrina's devastation.

• Rising Sea Levels and Hurricane Strength

Whether New Orleans will suffer future catastrophes that are similar or worse in magnitude than the one caused by Katrina depends on a number of factors, including the current and projected effects of climate change. There is a fairly strong consensus among scientists that sea levels have increased because of global warming and will rise another 0.3 to 1 meter over the next one hundred years. Additionally, some scientists have hypothesized that, since hurricanes' high winds, rain, and tornados are created as they push water vapor up into the atmosphere, more sea surface heat should increase the storms' power.

A study conducted at the Massachusetts Institute of Technology combined hurricanes' duration and wind speed to create the Power Dissipation Index to measure their intensity. The research report, which was published a month before Katrina, concluded that an examination of 1,557 Pacific and 558 Atlantic hurricanes over a thirty-year period showed a doubling of storm power, with a strong correlation between rising water temperatures and increasing hurricane strength. Research conducted at the Georgia Institute of Technology similarly showed that, since the mid-1990's, the number of Category 4 or 5 hurricanes on the Saffir-Simpson scale had doubled. A report issued in 2007 by the United Nations Intergovernmental Panel on Climate Change (IPCC) asserts that climate change has created the potential for more intense hurricanes that could threaten the Gulf Coast for the next one hundred years or more.

These and similar studies' conclusions are not accepted by all scientists. Some meteorologists, including National Oceanic and Atmospheric Administration researchers, take the position that the Atlantic Multidecadal Oscillation (AMO) has created decades-long increases and decreases in sea temperatures, and the AMO is more responsible for the recent upsurge in hurricane strength than is global warming. These critics concede, however, that the AMO will cause decades of more powerful hurricanes.

- **Loss of Natural Protections**

Historically, Southeast Louisiana's coastal wetlands and barrier islands have served as natural buffers that reduced hurricane damage to New Orleans (the U.S. Army Corps of Engineers asserts that 4.3 kilometers of wetlands dissipates 0.3 meter of storm surge). Soil subsidence, meanwhile, was counteracted by continuous silt deposits from the Mississippi River. Both human development and climate change have created the potential for extensive damage from future storms. Flood control and navigation projects stopped the land buildup from the Mississippi River in both the wetlands and the New Orleans area, while the channels created by the oil industry sped up the pace of coastal erosion.

The combined effects of sea level rise, land subsidence, and erosion have resulted in the loss of thousands of square kilometers of Louisiana's coastal land, a 1-meter increase in "relative sea level" for New Orleans over the past one hundred years (one-third due to sea rise and two-thirds due to soil compaction), and concerns that New Orleans may be on the coast in another one hundred years. The destruction of barrier islands has also increased (Ka-

A U.S. Coast Guard rescue boat moves through a flooded section of New Orleans during the aftermath of Hurricane Katrina in September, 2005. (Getty Images) trina destroyed half of the Chandeleur Islands located east of New Orleans). Many experts claim that current and proposed coastal restoration efforts would only minimally reduce annual losses.

• Government Responses and Calls for Action

Whether New Orleans can avoid future disasters of Katrina's magnitude will depend on the effectiveness of measures that have been taken and the implementation of additional proposals for better protecting the city. The federal government began increasing the height and strength of the levees shortly after Katrina, and millions of dollars have been spent on coastal restoration programs. Critics argue that these measures cannot begin to counteract the ongoing effects of global warming. They propose that a comprehensive approach that includes billions of dollars in coastal restoration projects and local, national, and global efforts to significantly reduce greenhouse gas (GHG) emissions will be necessary to ensure New Orleans's future survival. Private organizations have rebuilt neighborhoods in New Orleans using green construction to serve as pilot projects to promote energy-efficient housing everywhere and have joined with scientists and legislators in calling for the federal government to end its resistence to both increasing investment in renewable clean energy and participating in international agreements to reduce carbon dioxide emissions.

• Context

Within the debate over the best ways to secure New Orleans's future, there are those who assert that concerns about that city's fate should be viewed as a wake-up call that draws attention to a much broader threat. They posit that, if the future effects of global warming occur as currently projected, all of America's coastal areas, where half of the nation's population resides, would be in danger from catastrophes caused by coastal erosion, higher sea levels, and strong storms. This could result in cities like New York and Miami being below sea level and dependent on levees for protection, as New Orleans's improved levee system becomes obsolete and ineffective. The IPCC report asserts that, during the next century, coastal communities all over the world will be at risk of disasters like Katrina's destruction of New Orleans. This report also states that, beyond the hundred-year projections, current rates of ocean temperature increases could cause much higher sea levels as huge Antarctic and Greenland ice sheets melt.

Nitrogen cycle

• **Categories:** Chemistry and geochemistry; environmentalism, conservation, and ecosystems

• **Definition**

The nitrogen cycle is a natural process by which nitrogen in the air moves into the soil, is utilized by living organisms, and returns to the air. Organisms need nitrogen to make macromolecules, including amino acids and nucleic acids. Air is 79 percent nitrogen gas (N_2). N_2 has a triple bond, making it relatively inert and unable to be used by most organisms. Nitrogen fixation, converting N_2 to NH_4+ (an ammonium ion), is carried out by *Rhizobium* bacteria, which live in root nodules of host plants of the legume family such as peas, beans, and clover. Bacteria get carbohydrates from the plant, and the plant uses some of the ammonium the bacteria fix.

Free-living cyanobacteria also fix nitrogen. Lightning fixes smaller amounts of nitrogen. Plants absorb nitrate or ammonium ions from the soil through root hairs. Ammonium is converted into organic nitrogen compounds by bacteria and by plants. Other organisms get organic nitrogen from what they eat. Organic nitrogen is converted to ammonia as microorganisms decompose dead matter. Soil bacteria, *Nitrosomona*, perform nitrification where NH_4 is converted to NO_2^- (nitrite). NO_2^- is converted to NO_3^- (nitrate) by *Nitrobacter*. Completing the nitrogen cycle, nitrites are converted to N_2 and N_2O (nitrous oxide) in anaerobic conditions by bacteria *Pseudomonas* and *Clostridium*.

• **Significance for Climate Change**

Humans have more than doubled the annual transfer of nitrogen gas into biologically available forms of nitrogen. This has occurred through burning of fossil fuels, manufacture of synthetic nitrogen fertilizers, and widespread cultivation of legumes (soy, alfalfa, and clover). Burning fossil fuels causes formation of oxides of carbon (carbon monoxide, carbon dioxide). The burning of such fuels occurs at elevated temperatures that cause nitrogen and oxygen molecules in air to react to form oxides of nitrogen (NO, N_2O, and NO_2). NO_2 forms smog and mixed with water forms nitric acid (HNO_3), contributing to acid rain.

The Haber-Bosch process fixes N_2 using hydrogen, high temperature, and pressure to form ammonia. Synthetic nitrogen fertilizers (ammonia, ammonium nitrate, and urea), applied directly to the soil, have led to a huge increase in agricultural productivity. The applied fertilizer not utilized by plants leaches out of soil and accumulates in water. N_2O and CO_2 are greenhouse gases (GHGs) that contribute to global warming by absorbing energy from the Earth's surface, stopping the loss of this energy, and raising the Earth's temperature. NO_2 is not as abundant as CO_2, yet it is an important, stable GHG that absorbs infrared energy about 270 times more strongly than does CO_2. Nitrogen cycle influence on global warming is complex, as an increase in biologically active nitrogen stimulates plant growth, which increases uptake of CO_2.

Nitrogen fertilization

• **Categories:** Plants and vegetation; economics, industries, and products; chemistry and geochemistry

• **Definition**

Nitrogen fertilization is a phenomenon in which plant growth is unusually stimulated by the addition of reactive nitrogen compounds, such as ammonia and nitrate. Nitrogen compounds are usually applied as fertilizers to soil for uptake by plant roots. They are also often applied through air deposition from the atmosphere to foliage for uptake through leaves and to surface soil for plant-root uptake. Nitrogen fertilizers are usually manufactured through chemical processes, such as the Haber-Bosch process, to produce ammonia. This ammonia is applied directly to the soil or used to produce other compounds, including ammonium nitrate and urea. Reactive nitrogen compounds in the atmosphere are side-products of fossil fuel combustion.

Nitrogen is an essential element of all proteins, enzymes, and metabolic processes for the synthesis and transfer of energy. Nitrogen is also an element

The Cherepovets nitrogen fertilizer plant in Cherepovets, Russia. (Smirnov Vladimir/ITAR-TASS/Landov)

in chlorophyll, the green pigment of plants that facilitates light harvest and photosynthesis. Thus, nitrogen is essential for plant survival, growth, and reproduction. Many experiments have shown that photosynthesis is linearly correlated with nitrogen concentration in leaves. Increased nitrogen availability via fertilization or deposition generally increases photosynthetic carbon fixation and stimulates plant growth.

• Significance for Climate Change

Nitrogen is very abundant in the Earth's atmosphere but mostly not active for plants to use. Most plants take up only reactive nitrogen compounds, mostly from soil, for photosynthesis and growth. In natural ecosystems, inactive nitrogen in the atmosphere is converted to biologically useful forms mainly via nitrogen fixation by lightning or by a limited number of plant and microbial species. Anthropogenic activities, such as manufacture of nitrogen fertilizer, cultivation-induced nitrogen fixation, and combustion of fossile fuels, have accelerated the addition of reactive nitrogen to ecosystems, roughly doubling the rate of introduction. It is expected that conversion of inactive nitrogen in the atmosphere and in fossils to reactive nitrogen will increase another two- to threefold in the future.

Nitrogen addition, particularly through fertilization and deposition, has profound implications for climate change and global warming. Nitrogen deposition has been suggested to be a major mechanism underlying terrestrial ecosystem carbon sequestration. Extensive experimental evidence supports the theory that plant growth is limited by nitrogen in almost all ecosystems, and nitrogen addition to ecosystems often stimulates plant biomass growth and increases carbon storage in plant pools. The nitrogen limitation is usually persistent in ecosystems, largely because of the transient nature of biologically available forms of nitrogen. Biologically available nitrogen enters natural ecosystems primarily by biological fixation, but it is highly susceptible to loss by leaching and volatilization.

Although nitrogen stimulates biomass growth and carbon storage in plant pools, the effects of nitrogen fertilization on soil carbon storage are controversial. In several studies, nitrogen addition did not significantly affect soil carbon storage. It caused significant increases in soil carbon content in European and North American forests, and it stimulated substantial carbon loss from soil in other ecosystems. Nitrogen addition not only stimulates plant biomass growth and carbon input to the soil systems but also potentially stimulates microbial decomposition of litter and soil organic matter. Particularly in forests, most litter and soil organic matter have high carbon contents and low nitrogen contents.

Microbial activities are strongly limited by nitrogen availability. Nitrogen deposition can relieve nitrogen stress and stimulate microbial activities. As a consequence, soil carbon content can decrease with additional nitrogen input from deposition. In an ecosystem with low carbon content and high nitrogen content in litter and soil organic matter, nitrogen-induced increases in plant biomass growth and carbon input can result in increases in soil carbon sequestration. Since carbon in terrestrial ecosystems is mostly stored in soil, the inconsistent, often opposite responses of soil carbon storage to nitrogen addition suggest that stimulation of carbon sequestration in terrestrial ecosystems by nitrogen deposition may be minor.

Nitrogen fertilization and deposition may indirectly affect land-surface energy balance and then feedback to climate change. Nitrogen addition usually results in increases in leaf chlorophyll content and greenness of plant canopy and land surface. Green land surface has low albedo, so it readily absorbs solar radiation, and its high transpiration levels influence local and regional water vapor dynamics and air circulation.

Nitrogen fertilization and deposition can cause emissions of nitrous oxide (N_2O), ammonia gas (NH_3), and nitrogen oxides to the atmosphere, leading to greenhouse effects. The production and application of nitrogen fertilizers also consume energy and emit carbon dioxide (CO_2) into the atmosphere. Reactive nitrogen in the atmosphere can influence tropospheric aerosols and stratospheric ozone, resulting in cooling effects. Moreover, nitrogen-induced increases in tropospheric aerosols can reduce plant carbon uptake and ecosystem carbon storage.

Nitrogen fertilization and deposition can result in degradation of ecosystems. Runoff with nitrogen-rich compounds from high-deposition regions and fertilized fields causes eutrophication in rivers and lakes and hypoxia in coastal zones.

Nitrous oxide

• **Category:** Chemistry and geochemistry

• Definition

A colorless gas with a sweet odor, nitrous oxide is one of the many oxides of nitrogen. Sometimes called laughing gas, funny gas, nitrogen suboxide, or dinitrogen monoxide, it was first manufactured by Joseph Priestley, an English chemist, in 1775. It can be used to render a person insensible to pain in short surgical procedures; if inhaled for too long a period, it will cause death. It is also used as a propellant in aerosals and as an oxidizer to increase a racing-car engine's power output.

• Significance for Climate Change

Nitrous oxide is a trace gas produced by human industrial activity that affects the environment as do the other greenhouse gases (GHGs) and, as such, is limited by the Kyoto Protocol. (The other nitrogen oxides are not considered to be GHGs.) Another source of nitrous oxide is nitrogen fertilizers. Nitrous oxide also occurs naturally as a by-product of the bacteria in soil and water, particularly in tropi-

Global Nitrous Oxide Emissions by Sector, 2000

Data from the Netherlands Environmental Assessment Agency.

cal forest areas, and in animal waste products. Nitrous oxide may have slightly less effect than the halocarbons, as nitrous oxide reacts naturally with soil and water, so is less likely to make its way into the atmosphere. However, one molecule of N_2O in the atmosphere has two to three hundred times the warming effect of one molecule of CO_2.

As light from the Sun enters the atmosphere, some of that light gets scattered by molecules in the air or gets reflected from clouds back into space. Some of the light that reaches Earth is reflected back into space, such as light that bounces off snow or ice. Much of the light that reaches Earth is absorbed into the Earth and retained as heat. The Earth's surface warms and emits infrared photons, which make several passes between the Earth and the atmosphere, warming the atmosphere and the Earth as they go back and forth. Eventually, these infrared photons return to space.

The GHGs, including nitrous oxide, all have three or more atoms. They are able to absorb infrared photons as they pass, transferring the energy from the photon to the molecule and affecting the way these infrared photons are able to warm the Earth by trapping them. Eventually, this absorption of energy affects the net change in the Earth's energy balance. The effect caused depends on the radiative force associated with the gas.

This balance is also affected by the global warming potential (GWP) of the gas. Some gases stay in the atmosphere much longer than others before any natural process is able to remove them. Some gases can stay in the atmosphere for hundreds or thousands of years. Gases with long lifetimes continue to affect the warming of the Earth and its atmosphere. This warming, in turn, affects changes in weather, sea levels, and land.

These gases can be removed from the atmosphere through condensation and precipitation or by chemical reactions in the atmosphere. However, due to their long lives in the atmosphere, they are, generally speaking, accumulating more quickly than they can be dispersed.

Because of their effects on the global climate, the retention of these gases in the atmosphere could lead to melting of glaciers and polar ice caps, flooding and droughts becoming more severe, rising sea levels, increases in the salinity of freshwater, more devastating tropical cyclones and tidal waves, and erosion of beaches on the coasts.

These effects on the global climate could also help increase food production. As the Earth becomes warmer, growing cycles lengthen, more land becomes available for food production, and more and different varieties of food are able to be grown.

Climate change from the greenhouse gases, including nitrous oxide, could also lead to more insect-borne disease spreading further throughout the world. As mosquitoes and other pests are able to survive in more and different areas, malaria, dengue fever, and cholera could spread further.

Noctilucent clouds

- **Category:** Meteorology and atmospheric sciences

- **Definition**

At very high latitudes, usually farther than 50° from the equator, very thin, extremely high-altitude clouds sometimes form during the summer. These clouds are very difficult to observe directly from Earth. They are easiest to see at the end of twilight, when darkness has settled on the surface of the Earth but sunlight is still shining at very high altitudes: The ultra-high-altitude clouds appear to shine after dusk, so they are called noctilucent clouds (German for "night-shining" clouds).

Noctilucent clouds form in the mesosphere, an upper layer of Earth's atmosphere, at an altitude of about 85 kilometers. At that altitude, the air is exceedingly thin and cold. Dust and tiny ice crystals form the clouds, but the ice crystals require exceedingly cold temperatures, typically colder than –120° Celsius, which occur during the summer months in the polar regions (when surface temperatures are warmest). As a result, the technical name for noctilucent clouds is polar mesospheric clouds.

The first known reports of noctilucent clouds followed the 1883 explosive eruption of Krakatoa, when the clouds were extensively studied by Jesse Otto. Initially, it was believed that the clouds were simply a by-product of the volcanic eruption. However, the clouds persisted long after the ash from the eruption had dissipated. Otto and subsequent researchers were able to determine very little about the clouds. They are too high for balloon studies and have prompted satellite missions to study them, including the Aeronomy of Ice in the Mesosphere (AIM) mission.

Though little is known about nocticlucent clouds, scientists have observed that they are somewhat more frequent after meteor showers. Some

An artist's rendering of the satellite Glory, *which measures the effects of noctilucent and other clouds, as well as those of particles and solar energy, upon climate change.* (MCT/Landov) rocket exhausts, such as those of the Space Shuttle main engines, have also been implicated in the formation of nocticlucent clouds. Despite over a century of research, the nature and actual cause of noctilucent clouds is still not known.

• Significance for Climate Change

Because noctilucent clouds were not reported until 1883, some have speculated that they did not exist before then, but that claim is unsubstantiated. Many subtle phenomena were first studied scientifically in the nineteenth century, but that does not mean that they did not exist beforehand. Noctilucent clouds have also been more commonly reported over the course of the twentieth century, leading to claims that these clouds are becoming more common. That claim, too, is disputed. Noctilucent clouds have been more widely publicized over the course of the last century, so there may have simply been more people looking for them or recognizing and reporting them when they saw them. Concerted and in-depth scientific investigations of noctilucent clouds have been fairly recent, so there is little long-term data.

Not only have noctilucent clouds been observed more frequently in high latitudes, but they have also been observed at lower latitudes than before, with reports of noctilucent clouds from as far south as Colorado. The apparent increase in noctilucent cloud reports appears to correlate with the reported increases in global temperatures over the last century. Since noctilucent clouds require extremely cold mesospheric temperatures, sighting these clouds at lower latitudes may suggest a cooling of the mesosphere. This has led to claims that noctilucent clouds are in some manner related to global warming, which may also relate to cooling of the upper atmosphere. However, these claims are difficult to substantiate, because the nature of the noctilucent clouds is still not understood, nor is the mechanism by which these clouds form.

Some theoretical models indicate that certain greenhouse gases, such as methane, may provide hydrogen to the mesosphere that can oxidize to form water from which the clouds can form. One of the mysteries about noctilucent clouds is the source of the water in the mesosphere, one of the driest parts of Earth's atmosphere. An increase in methane could be one explanation. However, other sources for the water in the mesosphere could also result in noctilucent clouds. Major volcanic eruptions or impacts from icy bodies from space could also impart water to the mesosphere, but impacts should occur at fairly consistent rates, and there have been no major volcanic eruptions of the order of Krakatoa in the last century.

In recent years, it has been discovered that noctilucent clouds could be monitored from the ground by radar even when they were not visible. The ice crystals forming the clouds seem to act as attractors for iron and sodium ions in Earth's thermosphere. These metal ions are believed to come from meteoroids burning up in Earth's upper atmosphere. Satellite detection of noctilucent clouds is also now possible. These new methods of study may answer questions about the origins of the clouds and any possible link between them and global climate change.

Nongovernmental International Panel on Climate Change

- **Category:** Organizations and agencies
- **Date:** Established 2007
- **Web address:** http://www.sepp.org

- **Mission**

The Nongovernmental International Panel on Climate Change (NIPCC) is an international panel of nongovernmental scientists and scholars assembled to address the causes and consequences of global climate change. The NIPCC was established by the Science and Environmental Policy Project (SEPP). The SEPP was founded in 1990 by eminent atmospheric physicist (and former director of the United States Weather Satellite Service) S. Fred Singer,

> on the premise that sound, credible science must form the basis for health and environmental decisions that affect millions of people and cost tens of billions of dollars every year.

NIPCC set out to produce an independent evaluation of the available scientific evidence on the causes of climate change. Motivation for this grew out of widespread dissatisfaction with the global climate assessment reports of the United Nation's Intergovernmental Panel on Climate Change (IPCC), in particular the Fourth Assessment Report (2007).

SEPP brought together an international panel of nongovernmental scientists and scholars who were not predisposed to believe that climate change is caused mostly by human greenhouse gas emissions. The organization's report, *Nature, Not Human Activity, Rules the Climate* (2008), focused on evidence that the NIPCC felt that the IPCC had ignored. The report stems from an international climate workshop in Vienna in April, 2007, organized by the NIPCC.

- **Significance for Climate Change**

The NIPCC's 2008 report aims to provide an independent, nongovernmental second opinion on the global warming issue. NIPCC claims

> the central problems for policymakers in the debate over global warming are (a) is the reported warming trend real and how significant is it? (b) how much of the warming trend is due to natural causes and how much is due to human-generated greenhouse gases? and (c) would the effects of continued warming be harmful or beneficial to plant and wildlife and to human civilization?

The report presents evidence that helps provide answers to all three questions.

The NIPCC could find no convincing evidence or observations of significant global climate change from other than natural causes. The authors sum up their findings as follows:

> This NIPCC report falsifies the principal IPCC conclusion that most of the reported warming (since 1979) is "very likely" (that is, 90-99 percent certain) caused by the human emission of greenhouse gases. In other words, increasing carbon dioxide is not responsible for current warming. Policies adopted and called for in the name of "fighting global warming" are unnecessary.

C R de Freitas

Nongovernmental organizations

- **Categories:** Environmentalism, conservation, and ecosystems; ethics, human rights, and social justice

• **Definition**

Nongovernmental organizations (NGOs) are broadly defined as private, philanthropic, and nonprofit organizations that aim to provide services for needy people and to challenge sociopolitical inequalities at local, national, or international levels. Oxfam, Greenpeace, the Red Cross, Save the Children, and Doctors Without Borders are a few high-profile NGOs that have been active in shaping climate change policies.

• **Significance for Climate Change**

An increasing number of NGOs have showed their growing interest and influence in putting the environment on the global agenda and pressuring governments, business, and international organizations to take climate change seriously. Climate change affects both developed and developing countries, but many NGOs pay extra attention to the needs of vulnerable groups in developing countries since the climate-change-induced destruction falls disproportionately on them. These impoverished people rely heavily on natural resources, such as land and sea, for survival, but climate change would cause more floods, droughts, and extreme weather, and that will destroy their livelihoods and worsen poverty. However, the adaptive capacity of developing countries is low, and their governments are not strong enough to respond effectively to the challenges posed by climate change. Some NGOs, such as Oxfam, take an environmental justice perspective, arguing that rich countries control access to carbon and are capable of protecting themselves from the ravages of climate change. In contrast, poor countries are least responsible for greenhouse gas (GHG) emissions, but they pay the price for industrial growth in rich countries. They highlight the implicit power imbalance between rich and poor countries and between carbon haves and have-nots.

NGOs have comparative advantages in global environmental politics. First, global warming is a crisis on a global scale and requires global coordination to provide a solution. Most international NGOs have dense networks, and they often work together in coalitions and coordinate their lobbying efforts in order to maximize the impact. Second, donors do not always trust governments in the developing countries. They prefer offering development aid through NGOs, which are seen as transparent, accountable, and trustworthy. Third, NGOs can respond more quickly than many governments to the needs of local communities. They are also sensitive to gender and power dynamics.

Maarten van Aalst, the International Red Cross's leading climate expert, discusses the consequences of climate change for people and property during a press conference in April, 2007. (AP/Wide World Photos)

Therefore, NGOs try to build bridges for local people, governments, and international communities. Apart from raising public awareness and engaging affected communities in the decision-making process, NGOs are keen to advocate mitigation and adaptation policies. They launch campaigns to cut GHG emissions in order to reduce global average temperature. They also help poor countries to develop alternative livelihoods, to improve global humanitarian systems, to increase emergency aid, and to reduce risks of disaster by building long-term social protection. They build local capacity by focusing on disaster preparedness and recovery plans. They also help identify new funding sources for the Adaptation Fund, the largest potential source of funds for climate adaptation in poor countries. Furthermore, they build partnerships with other organizations to provide essential services, such as water and sanitation, to local people.

It needs to be noted that NGOs are a diverse group with varied goals, structures, and motivations. These differences mark heterogeneous policy design, priority, and response to climate change. Different targets, priorities, and strategies show the disparities in history, resources, leadership, expertise, networks, and visions. While some focus more on targets for national CO_2 emissions, financial mechanisms, and technology transfer, others are more concerned with humanitarian work and disaster preparedness. For example, Doctors Without Borders focuses on the health implications of higher temperature on disease patterns, while the International Red Cross, in contrast, emphasizes community-based self-reliance, early-warning operation, risk-mapping, and vulnerability assessment. Oxfam takes a rights-based perspective, arguing that the excessive GHG emission of rich countries has violated the human rights of poor people in developing countries.

NGOs have faced a number of challenges. First, NGO relationships with local governments in developing countries can be rough. Some NGOs suffer from excessive government interference. Second, NGOs rely on financial support from donors. Donors can make unreasonable demands and put their own agendas above the needs of recipient communities. Third, the legitimacy and governance of NGOs are sometimes questioned because the public wants to know how funds are allocated. Finally, local NGOs feel cash-rich international NGOs imposing their agendas on them, without building their capacity for dealing with local issues. Local NGOs are concerned that overreliance on foreign NGOs will create a culture of dependence, and that is not conducive to the healthy development of NGOs in developing countries.

Nonlinear processes

• **Category:** Science and technology

• Definition

In science, a process is a series of changes of one or more variables that represent properties or states of an object or a system. Examples of physical, chemical, and biological processes include evaporation, land erosion, oxidation, cell division, germination, dispersion, growth, accumulation, and global warming. In addition to the processes themselves, the study of the relationship between causes and effects of changes accounts for a major portion of scientific research. There are many ways to classify a process, based on properties of the process itself or the cause-effect relationship behind it. For example, a process can be continuous or discrete, stable or unstable, convergent or divergent, and linear or nonlinear.

A process is nonlinear when its effect is not simply proportional to its cause. For example, water evaporation is a nonlinear process, because water being boiled will not vaporize until the temperature reaches the critical threshold of 100° Celsius, causing a change in water's state from liquid to gas.

- **Significance for Climate Change**

The global climate system includes a variety of nonlinear processes that are subject to positive feedbacks, as well as complex interrelations between numerous factors affecting the climate. Such complexity exposes the Earth to a high risk of abrupt climate changes.

A positive feedback loop worth noting is the Arctic permafrost melt, which can speed up the cycle between the accumulation of GHGs in the atmosphere and temperature growth. The greenhouse effect contributes to global warming and higher temperature leads to melting frozen soils in the Artic region. The ice melting can release vast amounts of carbon dioxide (CO_2) and methane trapped in the permafrost soils. Estimates show that billions of metric tons of methane—a greenhouse gas twenty-one times more potent than is CO_2—can be emitted into the atmosphere and amplify the greenhouse effect.

Another important positive feedback loop is the Arctic albedo change. The albedo of a surface is the percentage of incident light that it reflects back into space. Since ice masses have high albedos, the ice covering the Arctic Ocean and land surfaces can help the Earth absorb only a small fraction of solar energy. As the Arctic ice melts due to global warming, the uncovered surface assimilates more solar energy and as a consequence intensifies the warming effect.

Besides permafrost melt and the Arctic albedo change, rain-forest decline, water scarcity, land degradation, ocean decline, and persistent toxins have the potential to cause abrupt climate change. Studies of the effects of the nonlinear processes, as well as their interactions with other elements of the climate system, are in progress to resolve uncertainty about abrupt and irreversible climate changes.

North Atlantic Oscillation

- **Category:** Oceanography

- **Definition**

The North Atlantic Oscillation (NAO) is the dominant pattern of atmospheric circulation in the North Atlantic region ranging from central North America to Europe and northern Asia. The NAO is usually developed in the winter and is caused by fluctuations in atmospheric pressure between a subpolar, low-pressure center near Iceland and a subtropical, high-pressure center near the Azores-Gibraltar region. The NAO is generally described by the North Atlantic Oscillation index, which is a weighted measurement of the difference between the subpolar low-pressure zone and the subtropical high-pressure center during the winter season of the North Atlantic region.

The positive NAO index phase corresponds with time periods when a stronger subtropical high-pressure center and a deeper-than-normal subpolar low-pressure zone exist in the North Atlantic region, increasing the atmospheric pressure gradient in this region. During positive-NAO-index years, the western subtropical North Atlantic Ocean is warm. Strengthened westerly winds blow warmth and moisture into north-central Europe. The warm, moisture-bearing winds arriving from the subtropical Atlantic Ocean make Europe warmer and wetter. In the meantime, northern Canada and Greenland experience cold and dry winters. Cooler temperatures occur off the west coast of Africa. Strong trade winds send more dust out across the ocean toward the Caribbean Sea. The eastern United States undergoes a mild and wet winter season.

The negative NAO index phase corresponds with time periods when both the subtropical high-pressure center and the subpolar low-pressure zone are weakened, which would reduce the atmospheric pressure gradient in the North Atlantic region. As a result, fewer and weaker winter storms occur in this region. More moist air is brought to the Mediterranean, and cold air is brought to northern Europe. Northeastern Canada and Greenland experience mild and wet winters and the eastern United States undergoes a cold and dry winter season.

• Significance for Climate Change

The NAO index varies from year to year and has evidenced a cyclicity of decadal scales over the past 150 years. The NAO index was persistently positive in the early 1900's, negative in the 1960's and 1970's, and considerably more positive during the 1980's and early 1990's. Since the heat capacity of the ocean is much greater than that of a continent, the NAO accounts for approximately one-third of the changes in average winter surface temperatures in the northern hemisphere. Variations in the NAO have significant impacts on many aspects of North Atlantic societies and the environment, such as agricultural harvests, water resources, fishery yields, industrial energy production, and ecosystems. Significant changes in the NAO may in turn influence climatic changes, including changes in sea surface temperature (SST), ocean circulation patterns, and Arctic sea-ice coverage.

Many mechanisms have been proposed to account for NAO index variability, including atmospheric response to changes in SST, variability of atmospheric convection in the tropics, internal and nonlinear dynamics of the extratropical atmosphere, and anthropogenic forcing caused by greenhouse gas (GHG) emissions and ozone depletion. Tropical heating has been proved to influence the atmospheric circulation over the North Atlantic region. Since tropical convection is sensitive to the underlying SST distribution, recent warming of the tropical oceans may lead to persistently positive values for the NAO index.

Some scientists think that changes in atmospheric circulation associated with the NAO index have contributed to the winter warming of the Northern Hemisphere in recent decades. Recent statistical evidence has demonstrated that the forcing of increased GHG concentration in the atmosphere may have affected the long-term variability of the NAO. Recent comparisons of NAO index records between the 1800's and the late twentieth century demonstrate that global warming may cause the increased variability of the NAO. Even though studies have linked climate change to the NAO, however, the mechanism of the NAO is still not fully understood. The NAO needs to be further investigated to advance understanding of the linkages between anthropogenic forcing and NAO variability.

North Korea

- **Category:** Nations and peoples
- **Key facts**

Population: 23.5 million (2008 estimate)
Area: 122,762 square kilometers
Gross domestic product (GDP): $40 billion (purchasing power parity, 2008 estimate)
Greenhouse gas (GHG) emissions in millions of metric tons of carbon dioxide equivalent (CO_2e): 71.8 in 2004
Kyoto Protocol status: Ratified 2005

• Historical and Political Context

In the aftermath of World War II in 1945, Korea was divided into two countries in accordance with a United Nations arrangement. North of the 38th parallel, the North Korean government, or the Democratic People's Republic of Korea (DPRK), was formally established in 1948. The Korean Workers Party, supported by the Soviet Union, became a ruling party. The government established a centralizing system and nationalized all properties. Economic activities were conducted under state control. In June, 1950, North Korea entered the Korean War against South Korea, and the war lasted until July, 1953. After the war, the government emphasized heavy industry, along with a centralized, planned economy.

North Korea developed a political ideology, *Juche* (self-reliance), whose goal was to strengthen the country economically and militarily and finally to make North Korea immune to foreign invasion and capitalist intervention. This ideology has prevented the nation from keeping technological pace with other industrialized countries and has made North Korea one of the poorest nations in the world.

In 1994, Kim Jung-il succeeded his father, Kim Il-sung, as general secretary of the Korean Workers Party. In July, 2002, North Korea started to open its border and to adopt capitalism. The government set up a free-trade zone near its border with China. However, the government still maintained a firm political control of the economy and denied access to foreign media. North Korea declared that it had developed nuclear weapons, and six-party talks began that were aimed at finding a peaceful means to curb the North Korean nuclear program.

• Impact of North Korean Policies on Climate Change

After the Korean War, the government moved toward a command economy and nationalized all assets. Since then, all economic activities have been conducted under state control. The centralized, planned economy grew significantly in industrial production and made significant progress in social infrastructure. The government has consistently promoted economic development policies that place top priority on heavy industry, including electricity production, steel production, and machine building. In turn, unreasonably one-sided promotion of heavy industry has deepened structural imbalances between North Korean industries. This "heavy industry first" policy has made North Korea unable to catch up to new technological developments or to phase out its coal-and-steel-based economy. The government also pursues military strength while striving to develop its economy.

In the 1970's, environmental pollution became a serious issue after two decades of industrialization emphasizing heavy industry and reckless development of natural resources. However, the government did not regulate this pollution until the Environmental Protection Law, established to prevent pollution and promote environmental preservation in 1986. Other environmental policies have also been implemented to establish air and water pollution standards. In 1996, the government established the State Environmental Protection Bureau to implement the Environmental Protection Law. North Korea has also participated in the United Nations Environment Programme (UNEP) since 1992.

In spite of North Korea's efforts to restore its environment, environmental degradation in the country is getting worse. This is primarily because of the government's policies emphasizing development in areas of heavy industries and an increase in food production, rather than environmental protection, as well as the lack of investment in the environment due to the weak economy.

• North Korea as a GHG Emitter

The Carbon Dioxide Information Analysis Center (CDIAC) reported that North Korea emitted almost 72 million metric tons of greenhouse gas

(GHG), in carbon dioxide (CO_2) equivalent, in 2004. The CO_2 emission as a percent of global CO_2 production is about 0.3 percent. CO_2 emissions of North Korea had been significantly increased by the early 1990's. Then, the emission sharply decreased; it stabilized in the early twenty-first century. CO_2 emission is primarily from the manufacturing industries and construction sector (78.6 percent), as well as the electricity and heat-production sector (15.9 percent). Less than 5 percent of CO_2 emission is from transportation and residential use.

Because of its self-reliance policy, North Korea avoids dependency on foreign energy sources, but it heavily relies on its own coal as a primary source of energy. North Korea uses coal with high sulfur content to produce heat and to generate electricity. Therefore, besides CO_2, other air pollutant emissions such as SO_x are also significant. North Korea's use of coal is projected to increase fivefold from 2005 to 2020. However, the use of obsolete industrial technology with poor energy efficiency, lack of exhaust gas purification technology, and lack of renewable energy alternatives induces a great deal of GHG emission. North Korea's inability to deal with this GHG emission, even from its power plants and refineries, has led to accelerated air and water pollution.

To cooperate in international efforts to protect the global environment, North Korea ratified the Kyoto Protocol in 2005. The government has also signed several international environmental agreements, such as the Convention of Biological Diversity. The government established the State Environmental Protection Bureau to implement environmental laws and regulations.

• Summary and Foresight

North Korean environmental degradation results from enforcement of misguided economic policies such as putting heavy industry first and engaging in the parallel development of military strength and the economy. Furthermore, North Korea's self-reliance ideology rendered the government unable to carry out reforms of its closed economy. However, North Korea has recognized the serious environmental degradation that has taken place over the past several decades. By adjusting its legal and administrative framework, the government has designated environmental protection as a priority over all other productive practices. The government established environmental laws and regulations and improved environment management systems.

North Korea has demonstrated its willingness to engage with the global community through organs such as UNEP to protect its environment. The government also attempts to strengthen cooperation with international societies such as the United Nations Development Programme (UNDP) in order to overcome economic hardship, to acquire economic support, and to lift the economy. The nation has adopted a pragmatic strategy. The government also emphasizes the need for foreign trade and economic cooperation with other nations. Proclamation of a Free Economic Zone and enactment of the Law on Attraction of Foreign Investment are good examples of the recent changes in North Korea. The country, however, continues its self-reliance policy and confronts contradictions between protection of national security and economic development, although diplomatic relations are ac-

tive. Thus, the government needs to make internal changes to facilitate and acquire international support.

Because of a lack of energy, economic growth in North Korea may need to scarify its environment like other developing countries, developing abundant but poor-quality coals to meet energy demands. International organizations also need to respond to North Korea's effort to protect its environment by supporting the improvement of North Korea's economic condition and by establishing environmental cooperation to promote environmental infrastructure, such as clean coal combustion, purification technologies, and renewable energy alternatives.

Northwest Passage

• Categories: Geology and geography; oceanography

• Definition

In the 1400's and early 1500's, Portuguese and Spanish navigators developed routes to the rich oriental spice trade going south of Africa and South America, respectively. Their rivals, England and France, hoped to find another, shorter route. They sought a way west at the north end of North America—the Northwest Passage. Many expeditions failed, often tragically, to find an ice-free northwest passage through the maze of islands west of Greenland in the Canadian north. Their attempts pitted them against the polar cold and floating pack ice of the Arctic Ocean.

Finally, in 1903, Roald Amundsen allowed his small ship, *Gjoa*, to be locked in ice and drift westward for three years, until it melted free on the Alaska side. That was an exploring feat, but it had no commercial potential. Likewise, the 1969 passage of the supertanker *Manhattan* was a nautical triumph but a commercial failure, because it required assistance from two icebreakers and repairs afterwards.

Since then, two things have changed: The climate has warmed, and the Arctic's energy resources have become better known and more sorely desired. The Little Ice Age reached its coldest point in the early 1800's, and world temperatures have moved generally higher ever since (with cooling retreats such as the 1880's to through about 1910 and the early 1940's through the mid-1970's). Beginning in the mid-1970's, temperature increases resumed and increased more steeply. This increase has been ascribed to the greenhouse effect of global warming caused by higher levels of carbon dioxide (CO_2), which slows the escape of heat through the Earth's atmosphere.

By the mid-1980's, cruise ships began making summer cruises through many Northwest Passage waters. In 2007, the summer melt reduced the extent of Arctic ice to its smallest area since comprehensive satellite data were collected beginning about 1970. The Northwest Passage was largely ice

Satellite imagery of the Northwest Passage, free of ice and navigable by ships, taken in August of 2008. (ESA/dpa/Landov)

free for several weeks before the cold returned. Moreover, those open summer waters replace the near total solar reflectivity of polar ice with the near total solar absorption of dark, open water. Several climate models suggest that all of the Arctic pack ice may melt in summers by 2100, or even much sooner.

Beside climate change, development is coming to the entire Arctic region, because world demand for petroleum and natural gas may soon exceed production both because of continued economic growth and exhaustion of a number of existing deposits. Meanwhile, about a quarter of the world's hydrocarbon deposits ring the Arctic from the Norwegian Sea through Siberia, Alaska, and northern Canada.

• Significance for Climate Change

The fabled Northwest Passage may soon become a functional reality because of the confluence of climate warming, the resource wealth of the Arctic, and the Arctic's central position between Europe and East Asia. These factors could make a navigable Arctic Ocean "the Mediterranean of the north." However, there is still doubt about a functioning Northwest Passage. A minority group of climatologists suggests that most of the warming in the Arctic since the early 1800's is due to natural cycles. They posit that the mechanisms of global change are still only dimly understood and that computer modelers are applying mere decades of firm data against processes that operate over millennia. Consequently, the recent melting could be replaced by cold and increased pack ice comparable to the 1800's or beyond any in recorded history.

Still, the general pattern of two centuries has been of warming climate and decreased ice. This suggests that offshore drilling and even coal mining will progress northward into the various seas of the Arctic Ocean. It suggests that thousands of ships will ply that waterway, either through Canadian waters or through a longer but serviceable route north of Russia (the Northeast Passage). Once in place, it may be a factor for increased global warming for four reasons.

First, incidental pollution and accidental spills are inevitable. Pollution tends to melt ice. Soot on ice or snow increases melting by increasing absorption. Any major petroleum spills would result in black, absorbing areas on, in, and beneath the ice for decades, because petroleum-digesting bacteria function slowly at near freezing temperatures.

Second, major industrial development also brings thermal pollution that could significantly increase melting of the pack ice. Moreover, there is a major limitation to cooling waters compared to temperate regions. The Arctic Ocean has an unusual thermal structure, with warm salty Gulf Stream water reaching the Arctic Ocean but diving under a major layer of less-dense freshwater. The deeper waters are often a degree above freezing, and they are more saline, which hinders them from freezing. Thus, bringing cooler waters from the depths is not an option.

Third, industries and governments making sizeable investments in ports, icebreaking ships, and mining facilities would not gladly surrender those treasures to returning ice. The first two mechanisms could be applied deliberately to melt ice. Fourth, activities to enforce sovereignty claims, such as building bases, would also contribute to warming.

The sheer volume of Arctic ice makes it difficult to predict the full climatological consequences of its melting. One climate theory has held that an ice-free Arctic in winter would provide sufficient water vapor for vastly increased snowfall on surrounding lands, perhaps enough to generate a new ice age.

Nuclear energy

• Category: Energy

Nuclear energy may offer a partial alternative to fossil fuels. Nuclear power generates no GHGs, but adequate measures to dispose of nuclear waste have yet to be developed, and the long lead time required to construct a nuclear power plant precludes using nuclear energy as a global replacement for GHG-emitting energy sources in the short term.

• Key concepts

fission: the splitting of a heavy nucleus (such as in a uranium atom) into two, with a release of a relatively large amount of energy

fossil fuels: fuels, including coal, gas, and oil, based on compressed, ancient organic materials

fusion: the combination of two light nuclei to produce a heavier nucleus; if accomplished in a contained setting, this is infinitely sustainable

greenhouse gases (GHGs): gases emitted by burning fossil fuels that trap heat in Earth's atmosphere

high-level waste: extremely radioactive fission products and transuranic elements such as plutonium, often produced by fission processes

A crane operator stands in front of the containers used to transport nuclear waste from the reactor site at La Hague, France, to a storage site in Gorleben, Germany. (Kay Nietfeld/dpa/Landov)

• Background

Since the 1950's, countries such as the United States, the Soviet Union (now Russia), and France have relied on nuclear power as an energy source. Electric power is generated in nuclear power plants by fission reactors that heat water to turn turbines. Nuclear fission produces no greenhouse gases (GHGs). Mining uranium to power the reactors causes some environmental degradation, but the most significant drawbacks of nuclear energy are the high cost of reactor construction, the long lag time required to build reactors, and the difficulty of safely disposing of the nuclear waste generated by the reactors.

• Nuclear Energy as a Power Source

When several countries began to build nuclear reactors to generate electric power in the 1950's, nuclear energy was haled as the energy of the future. Uranium was and still is in plentiful supply, and supporters of nuclear power indicated it would provide inexhaustible electric power in the future. A few countries, most notably France, engaged in extensive reactor construction, and approximately 80 percent of France's electric power now comes from nuclear power. Other countries, such as the United States, initially built several reactors. Support for nuclear power declined in the United States, however. No new power reactors were ordered after 1978. Approximately 20 percent of the electric power produced in the United States in the first decade of the twenty-first century came from nuclear energy.

Worldwide, approximately 16 percent of all electric power is generated by nuclear energy. In the first decade of the twenty-first century, some 440 nuclear power reactors were in operation in thirty countries. Six different types of power reactor were in operation, with research underway to expand this number. The most common reactor was the pressurized water reactor (268 reactors), followed by the boiling water reactor (94 reactors).

In spite of its initial problems, nuclear power may offer some advantages in dealing with climate change generated by burning fossil fuels. The operation of fission reactors does not generate any GHGs. Uranium is in plentiful supply, both from mines throughout the world and as material reprocessed from old nuclear weapons. Nuclear reactors can be constructed to fit existing needs, with electric power capacities ranging from nearly 2 gigawatts per reactor to much smaller capacities to serve small communities. Once in operation, a power reactor may be expected to operate for forty to sixty years.

Although challenging, it may be possible to generate as much as 1 terawatt of electric power per year with nuclear energy by 2050. If this goal is accomplished, it will be possible to achieve a substantial reduction in carbon emissions by mid-century. The technology to build nuclear reactors already exists and does not have to be invented; new advances, however, can lead to increased reactor efficiency. The construction of nuclear power reactors is a feasible alternative to fossil fuel power plants.

One criticism that has sometimes been levied against nuclear power is that it is not safe. Some critics indicate that reactors may leak radioactive matter. Power reactors in Western countries such as the United States, the United Kingdom, and France have had minimal leakages with no health risks. Other critics indicate that power reactors may have major accidents, including core meltdowns, pointing to accidents at the Three Mile Island Nuclear Power Plant in the United States in 1979 and the Soviet reactor at Chernobyl in 1986. The Three Mile Island accident led to a radiation leak of less than 50 curies of radiation, and no health issues have been traced to this incident. The Chernobyl accident was far more severe, with a release of 100 million curies of radiation, numerous deaths, and continuing health problems resulting from the accident, as well as lingering health problems in the region. Western countries do not use reactors of the Soviet design, which had limited containment around the reactors. The safety claims regarding most Western power reactors are generally overstated. In many ways, nuclear power produces fewer health problems than do coal-fired power plants.

All existing nuclear power reactors are fission reactors. The potential exists, however, eventually to construct fusion reactors. Such reactors would produce much less radioactive waste and operate more efficiently than fission reactors. Although advocates over the last thirty years have repeatedly indicated that fusion would become the energy source of the future, the technology remains relegated to the laboratory for the near term. No means of sustaining the temperatures required for fusion (about 100 million° Celsius) has yet been found. In addition, questions involving the high costs of construction and the production of the tritium gas necessary for a fusion reaction must be addressed.

Several environmentalists and other advocates of nuclear energy argue that the United States and other Western countries should reconsider its use. They point to the negative impacts of coal and oil plants, such as acid rain and GHG emissions. In addition, some economists predict that oil will become increasingly expensive, making nuclear energy more cost-effective.

• Drawbacks and Liabilities of Nuclear Energy

Most of the twentieth century problems with nuclear energy remain, and some new issues have been raised as well. As fears of terrorism and so-called suitcase devices have increased, the need to control even relatively small amounts of nuclear material has become more urgent, and even well-protected nuclear power plants pose security risks. Although terrorists might prefer more high profile targets than reactors and upgrading nuclear fuel is difficult, the security threat may sway public opinion against expanding nuclear energy.

Moreover, there are no ideal methods of nuclear waste disposal. Wastes with low levels of radioactivity are currently being stored underground in the United States and elsewhere. The greatest source of concern is high-level radioactive waste, such as spent fuel rods, piping, and the like. France has long followed a policy of reprocessing and reusing spent fuel rods. This is an attractive solution, but the process produces weapons-grade plutonium as a by-product. The United States and most other countries have not adopted this practice, in part out of fear that some plutonium might fall into the wrong hands.

The United States and most other countries that use nuclear energy have not solved the problem of spent nuclear fuel as yet. The United States is developing an underground storage facility at Yucca Mountain in Nevada, but it is controversial and is unlikely to be operational until 2015 at best. Until the Yucca Mountain site becomes operational, American nuclear power facilities are storing spent fuel on site. This approach is also being followed by most of the other countries that operate nuclear power reactors. The Russian Federation stores spent fuel on site but also engages in a limited amount of reprocessing at Chelyabinsk-65, and another facility at Krasnoyarsk is scheduled to start operation in 2015. The former Soviet government also engaged in extensive injection into the ground of a good deal of its lower-level waste such as cesium 137 and strontium 90. This injection occurred at three Soviet sites, producing several environmental problems.

Nuclear waste storage on site remains an option for nuclear power facilities, but the waste issue will need to be resolved if extensive use is to be made of nuclear energy in the future. The French and possibly the Russians seem to be comfortable with reprocessing. France and the United Kingdom are engaged in a joint project to develop a means to recycle spent nuclear fuel without producing weapons-grade plutonium. Most other countries are trying to develop underground sites, as Finland is doing at Olkiluoto, or shipping their nuclear waste to countries such as the United States for storage. Because of the long period of radioactive decay of some of this waste (several million years in some cases), developing safe, permanent storage facilities remains a challenging issue.

• Timetables for Nuclear Deployment

Nuclear energy may provide some help in mitigating global warming, but its impact is unlikely to be felt in the short run. In the United States, for example, the time required to obtain a permit to build a power reactor had increased to three and one-half years by the time the last reactor was permitted in 1978. Once a permit was issued, construction required around ten additional years. Although reactors have been constructed in other countries such as France or Russia in much shorter periods of time, they are complex facilities that cannot be constructed in short order. In some nations—such as Germany or the Scandinavian countries, where power reactors have been shut down—the largely antinuclear public will have to be convinced to allow new nuclear facilities to be contructed before any such project can be considered.

A large-scale expansion of nuclear energy is not likely until the 2020's, if then. In the United States, sixteen utilities had announced plans for potential reactor construction by 2007, but it would be several years before any of these facilities could go online. Elsewhere, the situation was much the same.

• Context

Nuclear energy has much to offer as an alternative to fossil fuels. Utilization of nuclear energy can help to provide a middle-term solution to the need for clean energy until ways can be found to enable cleaner, renewable sources such as solar energy to satisfy humanity's energy needs. In addition to environmental factors, the increasing cost of oil will help make nuclear energy more attractive. Fears of terrorism, radiation leaks, and the difficulties surrounding nuclear waste disposal are obstacles to a resurgence of nuclear energy. The length of time required to build an operational reactor negates any advantages of nuclear energy as a short-term solution to energy-related GHG emissions. Public opinion appears to be becoming more favorably inclined toward nuclear energy, but a good deal of opposition remains. As with many issues concerning global warming, the longer the wait before construction of power reactors begins, the more costly the process will be, and the less help the reactors will provide in combating the increasing emission of GHGs.

Nuclear winter

- **Category:** Climatic events and epochs

• Definition

"Nuclear winter" was the term coined in the 1980's to describe the global climatic effects of a major nuclear weapons exchange between the United States and the Soviet Union. The concept arose from scientific theories attempting to explain the extinction of the dinosaurs. Evidence to suggest an unusual geological event was found at the boundary between the Cretaceous and Tertiary periods (65-70 million years ago). An iridium-rich layer of sediment separated the dinosaur-fossil-bearing layers below from the dinosaur-fossil-lacking layers above. It was theorized that this amount of iridium could only have come from a collision with an asteroid-sized object, at least 10 to 16 kilometers in diameter.

If such an object had hit the Earth, the impact would have had a global effect on the planet's environment. Rock and ash debris would have been thrown high into the atmosphere, and the impact would have ignited huge forest fires. Ash from these fires, combined with the fine dust from the impact, could have remained in the atmosphere for several years and altered the Earth's albedo. Less sunlight would reach the surface, as the dust-laden atmosphere reflected it back into space. Those life forms surviving the initial impact would have to adapt to a rapidly changing environment. Less sunlight would affect photosynthesis, and the food chain would be disrupted as the Earth entered into a long global winter.

Some scientists saw a correlation between this scenario and the possible aftermath of a massive nuclear weapons exchange. The smoke and ash coming from the hundreds of burning cities and forests would pollute the atmosphere and alter weather patterns. Scientists envisioned an Earth enshrouded by dust-laden clouds that would block out sunlight and lower surface temperatures. The summer days would be cloudy, cooler, and wetter, with a short growing season. Winters would be cold and brutal. It was estimated that within three years of the nuclear conflagration, over one-half of the Earth's population would face starvation.

• Significance for Climate Change

The end of World War II in 1945 saw the beginning of the Cold War between the United States and the Soviet Union. During the war, the United States and the Soviet Union had been allies fighting against a common enemy in Nazi Germany. Although the two countries had different political ideals and agendas, they put aside their differences to win the war.

Once the war was over, each side began to mistrust the other. What made matters worse was the development and use of the atomic bomb.

The United States was the first country to develop a nuclear bomb, which it used twice to end the war with Japan, bombing the cities of Hiroshima and Nagasaki. Conventional bombing raids over Germany and Japan killed more people and damaged more property than a single atomic bomb. However, the psychological effect of one bomb doing the same amount of damage as thousands of conventional weapons made a difference and motivated Japan to end the war. The bomb blasts had unanticipated, lingering effects on the area, however, in the form of radioactive fallout. Tens of thousands of people may have died from the nuclear blast, while perhaps hundreds of thousands more would later die from radiation poisoning.

The nuclear attacks on Hiroshima and Nagasaki demonstrated to the world the horrors of nuclear war. It was hoped that they would serve as a reason for avoiding any further nuclear conflicts. Throughout the 1950's, 1960's, and 1970's, the United States and the Soviet Union each developed sufficient nuclear capability to deter the other from attacking, following a doctrine of mutual assured destruction. It was understood that in the event of a nuclear exchange, the fallout would affect the global community. In an attempt to persuade political leaders to cut back their stockpiles of nuclear weapons, scientists began to study the global environmental effects of a massive nuclear weapons exchange.

Throughout the 1980's and 1990's, scientists and political activists publicized the effects of a nuclear weapons exchange and the threat it would pose to the survival of humankind. Perhaps their efforts played an important role in reducing the stockpiles of nuclear weapons and bringing an end to the Cold War. In the wake of the Cold War, however, nuclear weapons remain. The threat of an all-out nuclear exchange involving thousands of warheads may be a thing of the past, but several nations have the ability to wage a limited nuclear war and are apparently willing to do so.

The possibility also exists of nuclear weapons falling into the hands of terrorists. Even a relatively small conventional engagement such as the 1991 Gulf War has environmental effects. When Saddam Hussein set fire to hundreds of Kuwaiti oil wells, the intense smoke from these fires polluted the environment. While full-scale nuclear war—and thus full-scale nuclear winter—appears unlikely, even a limited exchange would have severe environmental consequences and could affect the global climate in an unforeseeable manner.

Ocean acidification

• **Categories:** Pollution and waste; oceanography

• Definition

Ocean acidification describes the decrease in pH of the oceans due to increased concentration of dissolved carbon dioxide (CO_2). CO_2 is a trace gas found in the atmosphere. The concentration of dissolved oceanic CO_2 is in equilibrium with the gas's atmospheric concentration, such that an increase in the atmospheric concentration leads to an increase in the dissolved concentration, and vice versa. Throughout geologic time, atmospheric CO_2 reflected a balance between various sources and sinks found on land and in the oceans—such as photosynthesis, respiration, chemical weathering of rocks and burial of organic and inorganic carbon. Since the onset of the industrial age, human activities, such as fossil fuel combustion and intensification of agriculture, represent a new source of atmospheric CO_2.

These activities are thought to cause the observed increases in atmospheric CO_2, which in turn lead to increased dissolved CO_2 concentrations in the oceans. Dissolved CO_2 combines with water to form carbonic acid (H_2CO_3), which subsequently dissociates to produce bicarbonate (HCO_3^-) and carbonate ions (CO_3^{2-}) and protons (H^+). The balance among these different reactions is such that increased concentrations of dissolved CO_2 lead to increased proton concentrations (acidity). Since pH is an inverse scale of the concentration of dissolved H^+, the higher the proton concentrations, the lower the pH and the greater the acidity. Modeling experiments using different scenarios to project future atmospheric CO_2 concentrations indicate that by 2100, the ocean's pH will drop by up to 0.45 unit.

Effects of Ocean Acidification on Coral Reef Calcification Rate

b. millimoles per square meter per day.

• Significance for Climate Change

The reactions by which CO_2 and water form H_2CO_3, HCO_3^- and CO_3^{2-} control the pH of the world's oceans. Oceanic pH has important ecological consequences, because many plankton (including the *Coccolithophoridae*, which are marine algae, and the *Foraminiferida*, which are planktic protists) and macrofauna (corals, mollusks, brachiopods, and so on) precipitate the minerals calcite or aragonite (which both have the chemical formula $CaCO_3$) to make exoskeletons, shells, and tests in a process called calcification. Under normal conditions, calcite and aragonite are stable minerals in surface waters, because CO_3^{2-} concentrations are naturally maintained at levels that prevent their dissolution. However, increasing atmospheric CO_2 concentrations lead to decreased oceanic pH values and a concomitant decrease in carbonate ion concentration.

This effect is currently observed in a vertical profile of the oceans, where carbonate ion concentrations decrease with increasing depth. At a depth known as the lysocline, the rate of carbonate mineral dissolution increases rapidly with decreasing carbonate ion concentrations. Thus, in surface and intermediate waters, carbonate minerals are not dissolved. Below the lysocline, carbonate minerals are readily dissolved. Many laboratory experiments seem to indicate that ocean acidification will prove detrimental to many marine ecosystems. This finding has been recently validated by a study of a benthic ecosystem located near a naturally occurring volcanic vent that delivers CO_2 to the surrounding waters. The full-scale consequences of acidification of the global ocean are likely to be numerous, and could include extinctions as food webs collapse due to a loss of calcareous planktonic primary producers and consequences for the strength of the biological pump.

The biological pump is the process by which CO_2 is actively removed from the atmosphere by primary producing phytoplankton who convert the CO_2 to organic matter via photosynthesis. When these organisms die, their hard parts act as ballast to help the organic matter sink to the ocean floor, where it is buried in sediments. Ultimately, this sequesters the CO_2 in rocks for geologic time scales. However, if ocean acidification leads to dissolution of calcareous tests, organic matter will not be effectively buried because it is not dense enough to settle to the ocean floor. Not all scientists agree with the negative predicted consequences of ocean acidification. They argue that carbonate minerals present in sedimentary rocks on the ocean floor should, over time, consume the excess H^+ produced from increased atmospheric CO_2 concentrations, causing ocean acidification to slow or even stop.

The increase in atmospheric CO_2 concentrations appears to be linked to an increase in global temperatures. Temperature is a strong control on the conversion of atmospheric CO_2 to dissolved CO_2 in the ocean. Henry's Law states that the dissolved concentration of a gas is proportional to the partial pressure of that gas in the atmosphere in contact with that liquid. Gases are characterized by different Henry's Law constants that give the proportionality of dissolved gas that will be in equilibrium with the overlying atmosphere. For most gases, including CO_2, the value of the Henry's Law constant decreases with increasing temperature—that is, at higher temperatures, the amount of CO_2 that can be dissolved in the ocean will decrease. This temperature dependence provides a negative feedback on the amount of ocean acidification that could occur. However, this also means that a greater proportion of anthropogenic CO_2 would remain in the atmosphere as global temperature rises.

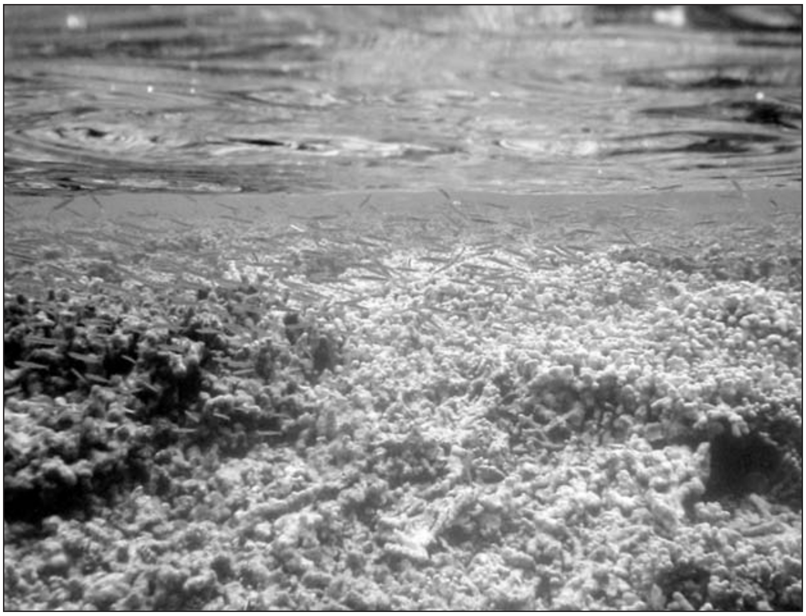
Ocean-atmosphere coupling

• **Categories:** Meteorology and atmospheric sciences; oceanography

• Definition

Ocean-atmosphere coupling describes the interdependency between the temperatures and circulation of water in the ocean and those of air in the atmosphere. Changes in the surface temperature of ocean water produce changes in the atmosphere above the water, which alters wind patterns and leads to further changes in surface ocean temperature. If these changes are significantly large or long-lived, changes in atmospheric patterns capable of producing changes in global weather patterns can result. The most prominent example of this is the El Niño/La Niña weather cycle, which



An image of the point of interface between atmosphere and ocean. (NOAA)

gained notoriety as the cause of numerous climate disruptions in North America during the late twentieth and early twenty-first centuries.

• Significance for Climate Change

The specific heat of water—that is, the amount of energy required to alter water's temperature—is extremely high. As a result, Earth's water systems are a significant stabilizing influence on global surface temperatures. The ocean-atmosphere coupling is among the most significant points of distribution of water in the global hydrologic cycle. Water evaporates from the oceans into the atmosphere, which carries water vapor over land, where it precipitates, providing freshwater to terrestrial ecosystems. This cycle, and particularly the interface between air and sea, both directly affect and are affected by global climate patterns, particularly those involving temperature.

The significance of ocean-atmosphere coupling to global warming increased as cyclical meteorological phenomena, such as the El Niño/La Niña cycle in the southern Pacific and the North Atlantic Oscillation patterns affecting weather in northern Europe and North America, began accelerating in the early 1980's. Of particular concern was the alteration of cyclical El Niño periods, triggered by higher sea surface temperatures in the southern Pacific, and La Niña periods, caused by lower sea surface temperatures in this region. Seven El Niño periods took place during the 1980's and 1990's, while only three La Niña periods occurred. Many scientists regarded this phenomenon as possible evidence of the escalation of global warming.

The study of ocean-atmosphere coupling thus intensified during the late twentieth and early twenty-first century, as scientists sought to determine the causes and extent of global warming, as well as its future duration and potential for escalation. Many of these studies sought to determine whether global warming patterns have human causes, while others attempted to forecast changes in global weather patterns to determine the potential for future extreme weather events such as severe droughts, flooding, and drastic changes in temperature. Long-term studies of patterns of climate variability involving ocean-atmosphere coupling have failed to yield definitive answers to these inquiries, leading many scientists to conclude that these patterns must be examined for longer periods in order to determine their implications for global warming and its causes.

Ocean disposal

- **Category:** Pollution and waste

- **Definition**

Ocean disposal ranges from dumping toxic chemicals, sewage, dredge spoils (material removed during dredging), and bilge water to accidental spills from oil tankers. Dumping of waste and dredge spoils has long been a part of the United States' waste process, as it provides an economically viable option for disposing millions of metric tons of waste. Dumping waste into the oceans has increasingly been shown to adversely affect aquatic ecosystems and contribute to global warming. There are strict ocean disposal regulations in the United States, including the Marine Protection, Research, and Sanctuaries Act (MPRSA) of 1972 and the Clean Water Act (CWA) of 1972; nevertheless, illegal ocean disposal still occurs frequently.

- **Significance for Climate Change**

Toxins from pesticides, as well as heavy metals, phosphorus, and nitrogen from dredge spoils, are a few of the harmful wastes dumped into the ocean. The effects of ocean disposal are not fully understood, but ocean disposal has been shown to cause substantial loss of marine life and indirectly enhance global warming. When plants and animals die, the dead organisms decay and release carbon dioxide (CO_2). CO_2 collects in the atmosphere and traps the Sun's heat, increasing the Earth's temperature. Recent consequences attributed to this climate change include the melting of glaciers, rising sea levels, disruption of coral reef habitats, and more extreme hurricanes.

In addition to the evidence of climate change caused by ocean disposal, hazardous waste disposal, such as nuclear refuse, can cause genetic defects, leading to cancer or death in both humans and marine life. Because of this danger, long-term burial of hazardous waste at sea is controversial. From the 1940's through the 1960's, the United States discarded barrels of radioactive waste in the ocean. The Environmental Protection Agency (EPA) then prohibited all dumping as a result of many of the barrels leaking.

Most of the material being dumped into the ocean is dredged waste. One approach to long-term storage of dredge spoils entails drilling holes into the ocean's floor and saturating the holes with the dredged waste. San Francisco, California, houses one such site approximately 91 kilometers offshore. This site is the deepest ocean disposal site in the United States, covering 22 square kilometers at a depth of 2,500-3,000 meters. The consequences of drilling deep into the ocean floor are not well known, raising questions of the short- and long-term effects of dredge spoils deposited in deepwater sediment on deep-sea biodiversity.

Ocean dynamics

- **Categories:** Meteorology and atmospheric sciences; oceanography

The movement of water in the Earth's oceans is the primary process that transports heat from the tropics to the polar regions, keeps the oceans uniform in chemistry, and transports heat between the ocean's surface and its floor.

- **Key concepts**

gyres: large, rotating loops of ocean current found in all major oceans; they are driven westward by the trade winds near the equator and eastward by the westerlies at high latitudes

meridional: referring to the motion of air or water in a generally north-south direction, that is, along meridians

thermohaline circulation: a vertical circulation in the oceans that is mostly driven by water-density differences, which in turn are governed by temperature and salinity

trade winds: twin wind belts on either side of the equator that generally blow westward

westerlies: belts of wind in midlatitudes that generally blow from west to east

• Background

Motions in the Earth's oceans include tides, which are caused by the gravity of the Sun and Moon; surface currents, which are driven by wind; and thermohaline circulation, which is driven by density differences in seawater. All of these motions move large amounts of water from place to place. In so doing, they also transport heat from equator to pole and from the surface to the deep ocean, and they also transport dissolved chemicals, including greenhouse gases. Although the saltiness of ocean water varies from place to place, the relative proportions of dissolved materials—say, the ratio of sodium to chlorine—are extremely uniform. Ocean dynamics keep the oceans thoroughly mixed and profoundly affect Earth's temperature; hence, they are important in climate modeling. Although waves are the most obvious water motion to most people, the water in waves merely oscillates back and forth; that is, waves do not transport water long distances and thus are not discussed in this article.

• Tides

Tides are the result of the gravitational attraction of the Moon and Sun. Although the Sun is far more massive than the Moon, its much greater distance means that its tidal effect is only about half that of the Moon. Nevertheless, if the Earth lacked a Moon, it would still have appreciable tides.

The continents prevent water from moving freely, so the actual movement of the tides is very complex. In most ocean basins the high and low tides revolve like the spokes of a wheel or the wave in a drinking glass oscillating in a circle. Tides move water through the connections between oceans and are important in keeping ocean water uniformly mixed. In small bodies of water it can take hours for the tides to progress from one end to the other, so tide predictions have to be based on local observations as well as the positions of the Sun and Moon.

Solar and lunar tides affect each other appreciably. Solar and lunar high and low tides can reinforce each other or partially cancel each other out. When the Earth, Sun, and Moon are in a straight line, at new or full moon, solar and lunar tides reinforce each other. The range between low and high tide is large, a condition called spring tide. When the Sun and Moon are 90° apart, as at first or last quarter moon, solar and lunar tides partially cancel each other out. The range between low and high tide is unusually small, a condition called neap tide.

• Ocean Currents

Surface ocean currents are driven by the winds. Generally, water near the equator is pushed west by the trade winds until it strikes a continent. Most of it then is diverted poleward, where it encounters the prevailing westerlies and is pushed east. Once it reaches the eastern side of the ocean, most of the water is diverted toward the equator. Thus, in all the ocean basins there is a large loop, or gyre, rotating clockwise in the Northern Hemisphere and counterclockwise in the Southern.

Around the Antarctic is a unique geography, a belt of latitude consisting entirely of ocean. With no topography to hinder them, the westerly winds in the Southern Hemisphere, called the Roaring Forties, create some of the roughest seas in the world. They also create a globe-girdling current, the Circum-Antarctic Current, that continuously circles Antarctica and is the principal mechanism for transferring water from one ocean to another.

• Thermohaline Circulation

The densest seawater on Earth is found around the Antarctic. The water is dense because it is both cold and salty. The water is salty because freezing of sea ice leaves dissolved salt concentrated in the remaining liquid. This cold, dense water sinks to the bottom and flows northward as a dense layer called Antarctic bottom water. The largest amount of Antarctic bottom water flows beneath the Pacific until it reaches Alaska, where it rises and merges into the surface circulation. It then flows around the North Pacific gyre until it reaches the southwest Pacific, where it has warmed to over 30° Celsius. Some warm water circulates through Indonesia to the Indian Ocean, and even though the amount of water involved is fairly small, the amount of heat transferred is large. Warm Indian Ocean water rounds Africa, cooling somewhat, then warms again in the South Atlantic. Some warm water crosses into the North Atlantic, travels up the eastern coast of North America as the Gulf Stream, then crosses to Europe. Finally, in the Arctic, the water cools and sinks. It then begins traveling south as North Atlantic deep water. Antarctic bottom water is also creeping northward in the Atlantic, colder and denser than North Atlantic deep water. Thus, in the North Atlantic, Gulf Stream water is moving northward on the surface, Antarctic bottom water is moving north along the bottom, and North Atlantic deep water is moving south just above the Antarctic bottom water. Because much of the water movement is northward or southward, thermohaline circulation is sometimes called meridional overturning circulation.

Scientists in the Argo program deploy a float to monitor ocean temperature and salinity. More than three thousand such floats are deployed worldwide. (NOAA)

• Context

Large-scale movements of ocean water affect local and global climate by transporting heat. They also affect climate change by transporting dissolved greenhouse gases into the deep ocean for storage and back to the surface for release. One aspect of thermohaline circulation has received particular attention. Many scientists are convinced that a sudden release of freshwater from glacial lakes in North America covered the North Atlantic with a layer of freshwater that prevented the exchange of heat between the ocean and the atmosphere and caused a sharp cooling event, called the Younger Dryas, about twelve thousand years ago. Some have suggested that melting of the Greenland ice cap might have a similar effect, so that warming of the climate might, paradoxically, produce a cooling episode.

Ocean life

• **Categories:** Oceanography; animals; plants and vegetation

Oceans, which cover 71 percent of the Earth's surface, respond more slowly than land to global warming. This warming, however, may cause damage to Arctic and Antarctic ecosystems due to melting sea ice, bleaching and die-off of reef corals, disruption of ocean currents, and shifting predator-prey relationships favoring reduced biodiversity. Long-term effects could include massive extinctions due to changes in seawater chemistry.

• Key concepts

dead zones: areas of deepwater oxygen depletion due to surface algal blooms or disruption of thermohaline circulation

El Niño-Southern Oscillation (ENSO) events: periodic fluctuation of temperatures and currents in the Pacific Ocean on a four-, ten-, and ninety-year cycle

primary productivity: production of fixed carbon through photosynthesis

thermohaline circulation: the rising and sinking of water caused by differences in water density due to differences in temperature and salinity

• Background

Until quite recently, scientists and the general public considered the Earth's oceans to be impervious to anthropogenic degradation. Oceans cover 71 percent of the Earth's surface and account for a little less than half of its primary productivity, that is, the photosynthetic conversion of carbon dioxide (CO_2) into the organic compounds that make up the bodies of living organisms.

The ocean is far from being a uniform habitat; however, with the exception of some near-shore environments, ecological niches cover wide areas and intergrade, meaning that species can readily adapt by shifting their ranges. In consequence, environmental pressures producing elevated extinction rates on land have a less dramatic effect in the open ocean.

Nonetheless, human activity has had an adverse effect on marine life, from phytoplankton to top marine predators such as sharks. While overfishing, pollution, and damming of rivers that serve as spawning grounds for marine fish have all taken their toll, these are only indirectly related to global warming.

Present effects attributable to elevated land temperatures include displacement of currents and upwelling zones and increased runoff in major river systems. Effects attributable to elevated sea surface temperatures include melting sea ice in the Arctic and Antarctic, reducing habitat for polar bears, penguins, and the many humbler species of plants and animals that thrive at the margins of the polar ice caps. In the tropics, higher sea surface temperatures alter coral metabolism, causing corals to bleach when they lose symbiotic algae (zooxanthellae) critical to their growth. Degradation of coral reefs profoundly affects the many organisms restricted to this habitat.

If atmospheric CO_2 continues to increase, altered seawater chemistry will become a concern. An increase in dissolved CO_2 increases acidity, which in turn inhibits production of shells. Coelenterates such as corals, whose skeletons are made up of aragonite, are more susceptible than are mollusks that have calcite shells. Present-day stunting effects attributable to this cause have not yet been observed in nature, but such stunting is suspected in the geologic record, so coelenterates are being closely monitored.

• Climate Change and Marine Life in the Geologic Record

Scientists recognize at least five major global mass-extinction events, of which the one at the Permian-Triassic boundary, 251 million years ago, was the most devastating. At that time, 95 percent of marine genera and 70 percent of land genera became extinct in three distinct pulses over a period of about eighty thousand years. At least two respected theories suggest that climate change caused these extinctions.

According to these theories, massive volcanic eruptions in Siberia started the catastrophe in motion. Each eruption caused cooling due to atmospheric volcanic dust and sulfur dioxide, followed by warming due to the longer-lived carbon-dioxide, augmented by heightened decomposition. Over the course of a million years, repeated eruptions, dwarfing anything humans have experienced in their brief tenure on Earth, eventually overwhelmed the Earth's capacity to self-correct.

One theory postulates that the ocean depths became increasingly oxygen-depleted, favoring the growth of bacteria that produce hydrogen sulfide. High pressures and cold temperatures in the abyss allowed that gas to build up, only to be released in a gigantic "burp" of highly toxic fumes. Another theory points to the storage of large quantities of methane in the form of clathrates in deep-sea sediments. It suggests that this methane was abruptly released when warming raised the temperature of the deeper regions of the ocean by 5° Celsius. In addition to being toxic and a powerful greenhouse gas (GHG), methane is explosive at concentrations as low as 5 percent.

Whatever the cause, the extinction, which devastated every group of plants and animals, was extremely abrupt by geological standards. Following the cataclysm, sedimentary rocks are nearly bare of fossils for the first ten million years of the Triassic period.

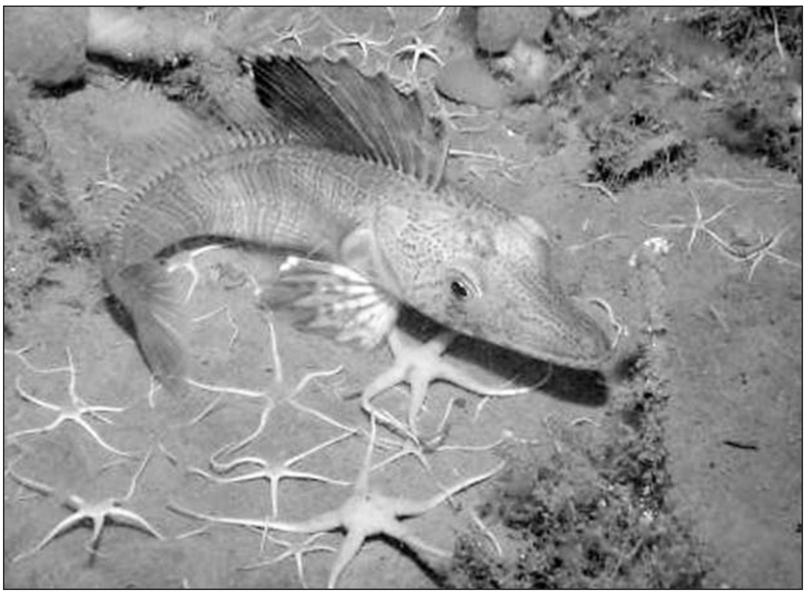
• The Present and Near Future

Unless the most carefully researched models are far off the mark, nothing resembling the devastating geochemical upheavals of the Permian-Triassic period looms in the foreseeable future, even if present levels of fossil fuel consumption persist. These models presuppose that volcanic activity will continue at levels typical of the Holocene and that no asteroids are headed in Earth's direction.

Possible changes due to increasing acidity are being closely monitored, but so far no notable effects on organisms have been observed in nature. Scientists working with a tiny marine snail that is crucial to Antarctic food chains have demonstrated, however, that there is ample cause for concern, because both higher temperatures and increasing acidity inhibit growth and shell production and can be expected to act synergistically. Acidity alone is not expected to reach lethal levels for another fifty years, but temperatures are rising rapidly, and marine organisms in the Antarctic cannot adjust their ranges southward. A wide variety of fish and birds depend on this snail for continued survival.

• Polar Regions

In both the Arctic and the Antarctic, chilled surface seawater sinks, allowing nutrient-rich waters to well up from below and support high phytoplankton productivity. The polar seas teem with life. The lower surfaces of ice sheets also support dense growth of attached algae. Global warming near the North Pole causes the most productive zone to retreat northward and contract in extent. This restricts the number of herbivores and carnivores the system can support. Most polar animals are unable to extend their ranges into temperate seas, because their unique adaptations to frigid temperatures make them poor competitors and susceptible to disease in warmer climates. The situation in the Southern Hemisphere is even more acute, as spe-



A species of fish evolved to thrive in the freezing waters of the Antarctic. (Dr. Julian Gutt/PA Photos/Landov) cies migrating southward encounter the continental margin.

The plight of polar bears has received considerable attention. These huge carnivores prey almost entirely on seals that they hunt on sea ice; they hibernate on land. The seals are declining in numbers and retreating farther from shore as the ice cap shrinks. Bears are starving and failing to reproduce. Whale populations that had begun to recover from overexploitation by the whaling industry are also declining again as a result of low food supplies. Antarctic penguins also face declining food supplies and an influx of predators, including sharks, which are extending their ranges southward.

• Coral Reefs

Reef-building corals, and the numerous species that depend upon them, have a narrow temperature range for optimum growth. They are also vulnerable to changes in sea level due to either global warming or global cooling. During the last Pleistocene glaciation, the resulting drop in sea level exposed much of Australia's Great Barrier reef, restricting this unique ecosystem to isolated pockets. A rapid rise in sea level would damage existing reefs by reducing light levels below those needed by symbiotic algae.

A 2° Celsius rise in surface temperature is sufficient to cause bleaching in corals as the individual polyps eject symbiotic algae. Bleaching initially causes growth to cease and eventually kills the coral colony. In recent years, there have been massive die-offs of corals—80 percent in the Caribbean and 50 percent in the South Pacific—but it is uncertain how much of this is due directly to global warming. The die-off in the South Pacific was associated with a severe El Niño-Southern Oscillation (ENSO) event to which global warming may have contributed. Near-shore pollution also devastates coral reefs in populated areas.

• Dead Zones

In a number of parts of the world, extensive areas of ocean have become depleted in oxygen, turning once productive fisheries into wastelands. Most of these dead zones are associated with rivers draining populated areas; one of the largest lies offshore of the mouth of the Mississippi River. This dead zone owes its existence to influxes of nutrient-laden freshwater to the Gulf of Mexico. These nutrients stimulate massive algal blooms. There is an indirect connection to global warming, in that warming generally causes increased precipitation and therefore increased runoff. Dead zones off the west coasts of the United States and South Africa result from disruption of cold currents and associated upwelling zones and thus may be directly related to global warming.

• Productivity

While global warming due to elevated CO_2 levels can cause local drops in productivity due to drought on land and disruption of thermohaline cycles in the ocean, the long-term predicted effect, on a global scale, of such warming is a net increase in photosynthesis, with an upper limit that far exceeds any projections based on realistic economic indicators. In the long term, this is good news. If the Earth is producing more food, both the numbers and the diversity of herbivores and predators can be expected to increase.

In the short term, however, such changes lead to the proliferation of weedy species with high reproductive rates and broad ecological ranges, loss of diversity, and generally unstable conditions. Species with specialized ecological requirements become extinct, and natural ecosystems increasingly resemble intentional agriculture or aquaculture. A glimpse of the future may be gleaned from the formerly rich fisheries off the West Coast of North America. These have been in decline for several decades, mainly because of pollution and over-fishing. Warmer waters coupled with a persistent dead zone off the coast of California and Oregon have further reduced stocks of commercial and sport fishes, but they have favored proliferation of the Humboldt giant squid, an aggressive predator adapted to warm temperatures and low oxygen levels. Sport fishermen are now being lured with the prospect of landing a 34-kilogram squid that puts up a mean fight.

Rising temperatures can be expected to reduce areas of high planktonic productivity near the poles while expanding them near the equator and at continental margins, threatening polar species with starvation and extinction while increasing numbers in warmer climates without a corresponding increase in diversity.

There are undoubtedly reef-building organisms ready to replace corals should the seas become inhospitable. During the very warm late Cretaceous, rudists, a group of bivalve mollusks related to clams, were the main reef builders. Several types of algae also have limestone skeletons. If any of these groups were to replace corals, the structural integrity of reefs would be preserved, but the beauty and diversity of the ecosystem would be sadly compromised on any conceivable human time scale.

• Context

The main threats to the abundance and diversity of marine life derive from Earth's human population explosion with its concomitant overexploitation and pollution of coastal waters. The exploding population is also a major factor in global warming. In terms of direct threats posed to marine life from rising temperatures, dwindling sea ice in the Arctic and especially the Antarctic is probably the most clear-cut. While anthropogenic warming is undoubtedly a factor in coral reef destruction and the decline of fisheries, it may well not be the principal cause. As scientists learn more about long-term cycles involving ENSO and analogous oscillating pressure and current systems in other oceans, a better understanding of the relationship of current extreme events to long-term trends should emerge.

Offsetting

• **Categories:** Pollution and waste; economics, industries, and products

• Definition

Offsetting is the practice of compensating for pollution from one source or location by reducing or mitigating pollution from another—for example, planting trees to offset carbon dioxide (CO_2) emissions from vehicle use. Individuals have become more conscious of their possible impact on global climate (referred to as their "carbon footprint"), as well as of the difficulties of reducing GHG emissions. Thus, an idea has emerged that increases in greenhouse gas (GHG) emissions from a given source can be mitigated—or "offset"—by parallel activities to decrease emissions from another source or to remove carbon from the atmosphere and store it in sinks.

• Significance for Climate Change

Using vegetation to remove carbon from the atmosphere was proposed as early as 1976 by physicist Freeman Dyson. A decade later, in 1988, one of the first projects to provide an offset for carbon emissions—the planting of 52 million trees in Guatemala—was undertaken at the instigation of the Arlington, Virginia, energy company Applied Energy Services to justify a proposed power station. By the late 1990's, celebrity participation began to popularize the idea of individuals offsetting their carbon-emitting activities by paying companies to engage in tree planting and other green activities.

For example, the Rolling Stones in 2003 highlighted "carbon neutral touring," paying the company Future Forests to plant trees to neutralize the environmental impact of their British concerts: The Edinburgh Center for Carbon Management calculated that one tree for every 60 of the band's anticipated 160,000 fans should suffice. (The following year, questions were raised about how Future Forests was spending its money, and the company subsequently renamed itself the Carbon Neutral Company.) In 2006, former vice president and later Nobel laureate Al Gore applied the idea to his influential book, *An Inconvenient Truth*: "By supporting a new Native American wind farm and a new family farm methane energy project through NativeEnergy, this publication is carbon neutral."

The emphasis on newness reflects the so-called additionality requirement—that any carbon decrease produced by an offset be additional to what would otherwise occur. Such counterfactual claims are notoriously uncertain. Though such offsetting does focus attention on the environmental impact of people's lifestyle choices, critics view it as either confused (because of insurmountable problems in definition and measurement) or self-deceptive (because people are questionably encouraged to believe their environmental impact has really been neutralized).

On a larger scale, analogous issues arise about carbon emissions trading among, or within, nations. In agreements such as the Kyoto Protocol's clean development mechanism, many countries have committed to reduce GHGs by certain future dates, but such agreements sometimes permit targets to be reached through credits for activities that remove CO_2 from the atmosphere (carbon sequestration) or that reduce the amount of CO_2 added to the atmosphere (alternative energy), even if emissions are otherwise increasing. Critics of carbon trading question whether pollution is really offset, pointing to scams, misjudgments, and counterproductive efforts. They also challenge the fairness of offsets, criticizing in the name of environmental justice what has been labeled "CO_2lonialism." (See, for example, the 2004 Durban Declaration against carbon trading.)

"Carbon forestry," Larry Lohmann complained in 1999,

> proposes to lessen the atmospheric effects of the mining of fossil fuels by colonizing still other resources and exerting new pressures on local land and water rights; the community evicted by oil drillers today may find itself displaced by carbon-"offset" plantations tomorrow.

Nearly a decade later, Dyson remarked: "The humanist ethic accepts an increase of CO_2 in the atmosphere as a small price to pay, if worldwide industrial development can alleviate the miseries of the poor half of humanity." The empirical and ethical complexities of the offsetting issue are highlighted by the fact that Dyson and his critics both claim the moral high ground.

Oil industry

• **Categories:** Fossil fuels; economics, industries, and products

The history, globalization, exploration, and geographic distribution of oil reserves, along with their eventual depletion, will affect not only the future of oil markets but also the way humans react to climate change.

• Key concepts

alternative energy: fuels and other energy resources that are renewable, nonpolluting, or both and have the potential to replace fossil fuels and other traditional energy resources

fossil fuels: energy resources formed from decayed organic matter under geological pressures over millions of years

greenhouse gases (GHGs): trace atmospheric gases that trap heat, preventing it from escaping into space

peak oil: the point at which oil availability and production reaches its zenith, before the Earth's oil resources begin either to dwindle or to become prohibitively expensive to exploit

• Background

The oil industry is a capital-intensive industry, and, therefore, its story generally is one of enormous wealth and, through wealth, one of political power and influence. The modern form of oil industry began when John D. Rockefeller's Standard Oil monopoly was vertically integrated, spanning production, refining, transporting, and retailing operations. The industry's fruits were initially spread abroad by Rockefeller's fleet of kerosene tankers. At the same time, Standard Oil was also securing a tight hold on the U.S. oil market. At the beginning of the twentieth century, it already controlled 87 percent of production, 82 percent of refining, and 85 percent of all petroleum marketing operations in the United States.

In short order, however, a brace of developments turned both the U.S. oil market and the petroleum industry into a competitive, global operation. The application of the Sherman Antitrust Act (1890) and subsequent breakup of Standard Oil into its regional components in 1911 forced some of its newly independent, "oil-short" units (notably Standard Oil of New York and later Mobil Oil) to look abroad for the oil that its gas stations had previously acquired from other parts of the Standard Oil trust. At approximately the same time, the conversion of navy ships to oil prompted Britain and the United States to urge their nascent oil companies to explore abroad for secure sources of oil to service their fleets in remote parts of the world. Soon the ancestor of British Petroleum and Standard Oil of New Jersey (originally Jersey Oil and later Exxon in the United States and Esso in Canada), Rockefeller's core unit, were competing with one another for the status of the world's largest petroleum corporation. That competition would endure throughout the twentieth century.

World War I introduced aircraft, tanks, and ambulances to the battlefield, further underscoring the relationship between national security and a healthy oil industry. Taking advantage of that fact, by the time that Henry Ford introduced the assembly-line

A Petro-Canada oil refinery and distribution center in Edmonton, Alberta. (Dan Riedlhuber/Reuters/Landov)

technique for making automobiles an affordable part of the average American's life, the U.S. oil industry had already used the war to turn the government in Washington from a trust-busting foe of big oil into one of its biggest supporters. Except for a few minor disruptions, that relationship lasted throughout the twentieth century, manifested in favorable tax laws, support of oil company efforts to stabilize the markets, and—following the rise of the Organization of Petroleum Exporting Countries (OPEC)—a willingness to allow the major oil corporations to undertake mergers akin to those that the Sherman Antitrust Act had been enacted to prevent. However, even before the rise of OPEC and those mergers, U.S. petroleum corporations had remained major players in the U.S. and global economies. On the eve of the 1973 oil crisis, the American petroleum industry was generating 30 percent of all domestic investment and 40 percent of all American investment in the developing world.

The benefits that the U.S. government offered to its smaller oil companies to go abroad and find new sources of oil to meet the growing demand for oil after World War II ultimately undermined the cartel of private oil companies that had stabilized the international price of oil for two generations. Known as "the Seven Sisters," this cartel—composed of Exxon, Mobil, Standard Oil of California (SoCal, later Chevron), British Petroleum, Royal Dutch Shell, Texaco, and Gulf—accounted for 90 percent of all global production outside the United States and Russia, 80 percent of all refining operations, and 70 percent of all marketing operations in the early post-World War II years. Oil-producing states either sold their oil to these companies at the proffered price or did not sell their oil at all.

Encouraged by government incentives, in the aftermath of World War II, several smaller U.S. oil companies began to explore for oil abroad. More joined the pack when one of the first, Getty Oil, struck it rich by finding oil in Kuwait. Unlike the Sisters, these individual companies had little bargaining power. Gradually they cut into the share of the market controlled by the Sisters (whose control over production outside the United States and the Soviet Union dropped to 70 percent by 1970). More important, their individual operations were usually in one country only, and they either bought their oil from that state on its terms or did not acquire foreign oil at all. As the international oil market grew ever tighter during the 1968-1973 era of Western economic expansion, their host governments demanded—and received from these companies—much better financial payoffs than those offered by the Sisters to their producing states. Given the increasingly tight energy market, the Sisters had to extend the same deals to their host governments. Consequently, even before the October, 1973, Yom Kippur War led to the Arab oil embargo and OPEC's rise to prominence, the Seven Sisters' hold on the global industry was already eroding rapidly.

• OPEC and the Global Economy

The 1973 Arab oil embargo on countries friendly to Israel created panic in the marketplace, as Western states bid against one another for oil that, in some instances, they did not have the storage facilities to accommodate. The price of oil on the spot market jumped from under three dollars per barrel (the Sisters' last posted price on the eve of the Yom

Kippur War) to the twenty-dollar-per-barrel range. In turn, this hysteria allowed OPEC to buy out the Seven Sisters and other Western oil companies and establish itself as the new international cartel in charge of setting the price of oil. Subsequently, both the fortunes of the international petroleum industry and those of the international economy fluctuated with OPEC's fortunes and its ability to keep the price of oil stable and in a price range affordable enough to allow for overall economic growth and the economic development of Third World countries.

In general, OPEC's record has been spotty. The OPEC-endorsed price hikes in the 1970's—to twelve dollars per barrel in 1973 and to more than thirty dollars per barrel in 1979 (following the fall of the shah of Iran and resultant drop in the availability of Iranian oil in the market)—led to a prolonged recession in the oil-importing, economically advanced Western world throughout much of the 1980's, which depressed the price of OPEC oil significantly. As a result, oil was relatively cheap in the 1990's, which not only led to a renewed expansion of the global economy but also enabled both India and China to mount significant development plans fueled by low-cost, imported petroleum. With the tightening of the market at the turn of the twenty-first century and the uncertain market conditions during the first decade thereof, OPEC again allowed the price of oil to soar to recession-inducing levels, slowing the base of globalization and, in many instances, encouraging countries to adopt protectionist policies antithetical to the ideals of a globalized economy.

Meanwhile, partly in order to survive the eras of depressed oil prices, the global petroleum industry reshaped itself, from the dominant Seven Sisters cartel of private oil companies into a complex mixture of private and state oil companies, complicated by the fact that not all of the state-owned oil companies in the world were the economic creatures of OPEC members.

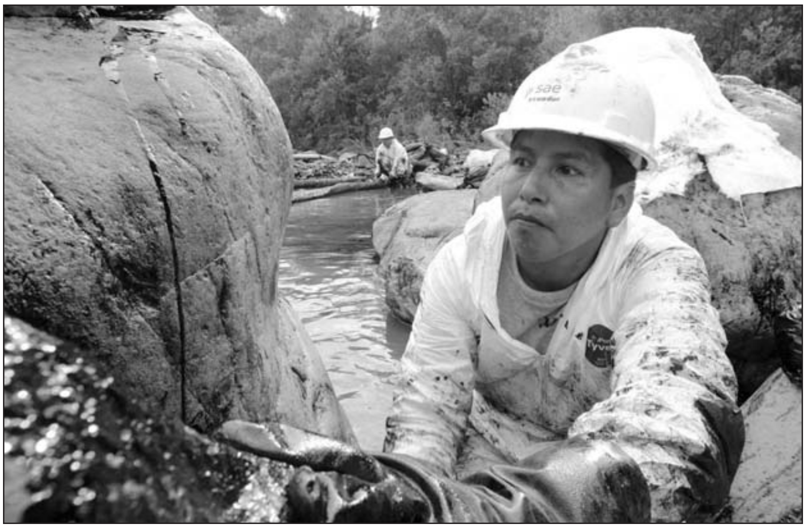
• Diversification, Mergers, and the Western Oil Corporations

When OPEC took over the international oil market in 1973, the possibility remained of discussing Western oil companies in the terminology that had been used for half a century. There were the "majors," the Seven Sisters, and then there were the "independents," that is, the comparatively small producers that included enterprises from family operations like Krumme Oil in Oklahoma to large, multinational oil companies like Getty Oil and Atlantic Richfield Company (ARCO). During the high-price energy era of the 1970's and early years of the following decade, all these companies reaped large profits, and the majors and many of the larger independents reinvested those profits in the pursuit of alternative energy schemes (Exxon, for example, invested five billion dollars in its oil-from-shale project in Colony, Colorado) and the acquisition of holdings in such other energy sectors as coal and uranium. These companies would do much the same vis-à-vis biofuels in the high-cost petroleum era that followed the U.S. invasion of Iraq in 2003.

The downturn in the price of oil in the 1980's caused the majors to shut down most of their alternative energy projects and to seek means for surviving in the lean years of the global recession. As these companies would do in even more publicized ventures during the 1990's, when the price of oil remained in the twenty-five-dollar-per-barrel range, many turned to mergers in order to economize, beginning with the 1984 merger between SoCal and Gulf Oil that enabled Gulf to sell off many of its subsidiaries and service stations and led SoCal to change its name to Chevron. A decade later, what had been exceptional in 1984 became, momentarily, almost commonplace. The process began in December, 1998, when British Petroleum (BP) acquired Amoca (formerly the American Oil Company or Standard Oil of Indiana) for more than fifty billion dollars. The following year the combined corporation purchased ARCO (one of the major players in the discovery of Alaskan oil). Combined with its subsequent acquisition of Burmah Castrol, a lubricant manufacturing company, BP was able to pare approximately twenty thousand jobs worldwide and become temporarily the world's largest oil company.

BP held that distinction for only a few months until Exxon and Mobil merged in November, 1999, into the largest corporation in the world. The transaction enabled the combined corporation to sell off more than seventeen hundred service stations (to Tosco) and trim its payroll by nearly ten thousand employees. The merger mania did not end there, or on the U.S. side of the Atlantic Ocean. In 1999, two giant European petroleum firms, France's Total and Belgium's Petrofina, merged into TotalFina and then acquired France's other major petroleum company, Elf, to make TotalFina the fourth largest petroleum company in the world. Then, in 2001, another Sister-Sister marriage occurred, this time involving Chevron and Texaco.

In short, by the time oil prices began to rise appreciably shortly after the terrorist attacks on New York and Washington, D.C., on September 11, 2001, and especially following the U.S. invasion of Iraq in 2003, a new set of six "supermajors" had emerged in the world of private oil companies: Exxon-Mobil, BP-Amoco, Chevron-Texaco, TotalFina, Royal Dutch Shell, and Conoco-Phillips (whose two units completed their merger in August, 2002). All are vertically integrated and, compared to the "independents," have a commanding share of the market. Unlike that of the Seven Sisters, though, their power is rooted in sales, not in the production of oil: They accounted for only about 10 percent of the oil produced in the early years of the twenty-first century and their combined ownership of oil and gas accounts for less than 5 percent of the world's know oil and gas reserves.



Ecuadoran workers clean up an oil spill on the Santa Rosa River in February, 2009. (Guillermo Granja/Reuters/Landov)

• State-Owned Petroleum Industries

Comparatively speaking, the real "supermajors" are not these private oil companies but the seven largest state-owned petroleum companies in the contemporary world, led by those of Saudi Arabia, Iran, Russia, and Venezuela, but also including the state-owned companies of China, Brazil, and Malaysia. Collectively, these seven account for nearly one-third of the world's gas and oil production and the majority of its know oil reserves. More important, when combined with the production capacity and reserve holdings of other state-owned oil companies, these actors account for the overwhelming majority of the world's oil and gas production and reserves. In that sense they are more analogous to the Seven Sisters than today's "supermajor" private oil corporations. However, unlike the Seven Sisters, they do not collaborate with one another. Quite to the contrary, they sometimes compete with one another for influence inside OPEC (where only Saudi Arabia, Iran, and Venezuela are represented) and for profits in the world's petroleum marketplace.

• Oil Depletion and "Peak Oil"

Because petroleum is a nonrenewable natural resource, the industry will someday face the inevitable depletion of the world's oil supply. In 2007, the BP *Statistical Review of World Energy* predicted that the reserves in the Middle East would last 79.5 more years; those in Latin America, 41.2 years; and those in North America, 12 years. At 2008 production levels, the world's oil reserves would be depleted in 40.5 years.

A theory developed by geologists Marion King Hubbert in the 1940's, known as the Hubbert's peak theory (also known as "peak oil") or the "Hubbert curve," identified patterns of resource use that let Hubbert to predict that U.S. oil production would peak in the early 1970's. The extension of this analysis to world energy production to the prediction that a worldwide energy crisis would occur after production of oil and gas peaked. Research conducted by IBISWorld suggested that biofuels such as ethanol and biodiesel would continue to supplement petroleum but that, because output levels were low, these fuels would not replace local oil production and would play only a minor role in reducing dependence on imported crude oil.

• Peak Oil and Climate Change

Perhaps the most damaging effect of petrochemicals is global warming. The use of fossil fuels releases carbon dioxide (CO_2) and methane, two greenhouse gases (GHGs) that trap the Earth's heat within the atmosphere and lead to warmer oceans, warmer climates, unstable weather, rising sea levels, and concomitant phenomena such as floods, drought, shifts in water flow, forest fires, famines, and extinctions. Such changes have already been noted but do not take place simultaneously or immediately; still they can occur over as short a time as decades, and their ecological and climate impacts are extremely complex and difficult to predict.

There is some consensus, however, that such changes, and their climate impacts, will increase in occurrence and severity, requiring ongoing mitigation and response. The projected effects of climate change are sufficient reason by themselves to seek to reduce fossil fuel dependency and replace energy needs with more sustainable resources. Peak oil will challenge humankind's ability to deal with and adapt to global warming: a decline in global oil supply, paired with an increase in the cost of goods and services, reduces the ability to make the investments in infrastructure that are required in order to respond to global warming in a proactive and coordinated fashion. Therefore, it is imperative that policy makers consider proposed responses to peak oil and global warming in tandem.

Oregon Institute of Science and Medicine

- **Category:** Organizations and agencies
- **Date:** Established 1980
- **Web address:** http://www.oism.org

• Mission

The Oregon Institute of Science and Medicine (OISM) figures in the debate on global climate change mostly because of controversial mailings sent out in 1998 and 2007, and its sponsorship of the Petition Project or Oregon Petition, a petition by scientists opposed to the idea of global warming that as of January, 2009, had more than thirty-one thousand signers. OISM is a small, nonprofit private institution in Cave Junction, Oregon, a small community of about fourteen hundred residents in southwestern Oregon. The Institute was founded in 1980 and as of 2009 had six faculty (though it does not teach classes) as well as a number of volunteers. Most of its stated research efforts involve research on medical subjects, but it also lists as research interests "improvement in precollege education curricula, especially in the sciences; and improved civilian emergency preparedness." In the climate debate it is prominent as sponsor of the Oregon Petition and distributor of papers rejecting the idea of global warming. The late, eminent scientist Frederick Seitz served as spokesperson for some of these efforts.

• Significance for Climate Change

In 1998, the OISM first attracted widespread attention among climate researchers by distributing a mass mailing of a paper casting doubt on global warming. The paper was accompanied by a letter signed by Seitz, who had an illustrious career in solid state physics at the University of Illinois and Rockefeller University that included chairing the United States National Academy of Sciences from 1962 to 1969 and receiving the National Medal of Science in 1973. In 1979, Seitz became a paid consultant to the tobacco industry and led its scientific research program to discredit the evidence linking smoking to cancer and other illnesses. After his connections with the tobacco industry ended, Seitz became a critic of various environmental causes, including climate change.

The article mailed by the OISM looked like a genuine article reprinted by a scientific journal. In fact, the article almost exactly duplicated the format of the *Journal of the National Academy of Sciences.* The academy took the unusual step of issuing a public statement disclaiming any connection between itself and the paper, and many scientists expressed anger that Seitz had used his former connections to the academy to promote a paper that seemed purposely designed to resemble an academy publication. Seitz later claimed to have urged the authors of the paper to submit it for peer review.

In 2007, the OISM sent out another mass-mailed paper, "Environmental Effects of Increased Atmospheric Carbon Dioxide," by Arthur B. Robinson, Noah E. Robinson, and Willie Soon, which had been published in the *Journal of American Physicians and Surgeons.* The *Journal of American Physicians and Surgeons* is published online by a politically conservative medical organization, the Association of American Physicians and Surgeons. The journal specializes in articles critical of government health care regulations, but it also frequently publishes nonmedical articles appealing to political conservatives. The paper by Robinson, Robinson, and

Soon included much of the material from the 1998 paper and was also accompanied by a letter from Seitz.

The other major effort by the OISM to influence the climate debate is the Petition Project or Oregon Petition. The petition reads in part:

> We urge the United States government to reject the global warming agreement that was written in Kyoto, Japan in December, 1997, and any other similar proposals. The proposed limits on greenhouse gases would harm the environment, hinder the advance of science and technology, and damage the health and welfare of mankind.

The Petition Project provides lists of signatories and data on their academic credentials. As of January 23, 2009, the Petition Project claimed:

> The current list of 31,072 petition signers includes 9,021 PhD; 6,961 MS; 2,240 MD [medical] and DVM [veterinary]; and 12,850 BS or equivalent academic degrees. Most of the MD and DVM signers also have underlying degrees in basic science.

One significant problem with the Oregon Petition is that it does not list the institutional affiliations of signers. It also does not verify the credentials of signers. The words "credential" and "credibility" both come from the same Latin word meaning "believe." Credentials are evidence that someone is credible when talking about a subject. A patient may not have the technical training to understand or identify a medical problem, but a doctor's credentials are a strong indication that the doctor's opinion is credible. The doctor may also be well informed about many other nonmedical subjects (like climate change), but without credentials in those areas, there is no evidence one way or the other to judge his or her credibility.

Only 29 percent of the signers of the Oregon Petition have doctoral degrees in science, whereas 41 percent have only a bachelor's degree. A breakdown by specialty claimed 3,697 signers were scientists in the Earth, atmospheric, and environmental sciences, including 578 atmospheric scientists. Only 12 percent of the signers have degrees in Earth, atmospheric, and environmental science, and fewer than 2 percent are atmospheric scientists. The Oregon Petition Web site claims:

> All of the listed signers have formal educations in fields of specialization that suitably qualify them to evaluate the research data related to the petition statement.

Most of the signers, however, are in fields that have no real bearing on climate change, and most do not have the level of training needed to evaluate the research on climate change. They may be perfectly qualified in their own specialties, but they do not have credentials, or credibility, in climate research.

Although there are many uncertainties in predicting future climate changes and in formulating policy on climate change, campaigns such as the Oregon Petition and the Seitz mailings damage, rather than advance, the skeptic cause. Real experts on climate change are not persuaded by the Oregon Petition or the OISM mailings. The use of deceptive mailings and irrelevant credentials may persuade people without expertise in science, but those tactics serve only to erode the credibility of skeptics in the eyes of scientists.

Organization of Petroleum Exporting Countries

- **Categories:** Organizations and agencies; fossil fuels; energy
- **Date:** Established 1960
- **Web address:** http://www.opec.org/

OPEC promotes the use of petroleum and attempts to make oil production profitable for its member countries. Petroleum is one of the three fossil fuels contributing to an increase in atmospheric CO_2, which is a key factor in global warming.

• Key concepts

Arab oil embargo: a 1973 action by Arab members of OPEC to stop exporting petroleum to the United States and other supporters of Israel

Arab states: countries in the Middle East in which Arabs are the primary ethnic group, often incorrectly assumed to include Iran

cartel: an organization that limits competition in a particular industry to increase profitability for its members

fossil fuels: carbon-based fuels derived from decayed plants and animals under geologic pressure over millions of years

founding members: an official designation given to the five countries that formed OPEC

OPEC Conference: the chief authority within OPEC; composed of representatives of all the member states

secretariat: the administrative section of OPEC, which carries out the day-to-day functions of the organization

• Mission

Meeting in Baghdad, Iraq, September 10-14, 1960, Iran, Iraq, Kuwait, Saudi Arabia, and Venezuela formed the Organization of Petroleum Exporting Countries (OPEC). The organization is often referred to as a cartel, with the aim of coordinating petroleum production and policies. Through these actions, the members hope to achieve maximum economic return, without causing a decrease in demand for petroleum. There are seven other active members (Algeria, Angola, Ecuador, Libya, Nigeria, Qatar, and the United Arab Emirates).

• OPEC Organization

OPEC is an intergovernmental organization with its headquarters in Vienna, Austria. Any oil-exporting country may apply for membership, which is granted if the application is accepted by three-fourths of the current members, including all five of the founding members. At the OPEC Conference all members have one vote, and the conference alone has the power to make decisions on all policy issues of substance, by unanimous vote. At its semiannual sessions, the conference also appoints a secretary general who oversees the daily operation of the organization. All sections of the organization are charged with developing an acceptable policy that will match supply and demand for petroleum, allowing for stable prices and supplies. OPEC must take into consideration the effect these policies will have on other oil exporting countries and upon the nations that consume petroleum.

For the first decade of its existence, OPEC had limited opportunities. Large American and European petroleum companies dominated all aspects of oil production and marketing. Around the end of the decade, most members nationalized oil production, giving themselves greater power. This also gave the countries a greater stake in having a stable mar-

OPEC president Chakib Khelil of Algeria prepares to take questions from the press in September, 2008. (Heinz-Peter Bader/Reuters/Landov)

ketplace for trading petroleum. OPEC set production quotas for each country that insured relative stability, since slightly more than half the traded oil originates in OPEC. OPEC prices all of its oil in U.S. dollars.

• The 1973 Arab Oil Embargo

In 1973, American economic problems had caused a decrease in the value of the dollar. Thus, OPEC leaders desired to increase the price of oil. On October 6, the Yom Kippur War was launched by Egypt and Syria against Israel, giving OPEC an excuse to raise prices and make a political statement. Led by the Persian Gulf oil producers, other Middle Eastern states sought to weaken the ties between the United States and Israel. On October 17, OPEC decided to end oil exports to those countries supporting Israel. OPEC cannot force its members to follow its decisions. However, within two days all the Arab states that were OPEC members joined in this action, as did Iran. In just over two weeks, OPEC cut production by one fourth. The actual military conflict was only twenty days in length, but the oil embargo lasted five months. The rising oil prices were a strong incentive for other oil producing countries to increase their production. This caused the resolve of some participating in the embargo to weaken, so with the military conflict ended and the price of oil greatly increased, OPEC could declare victory and stop boycotting the American market.

Even though the Arab oil embargo only affected 7 percent of the oil available to the United States, it sent tremors throughout the United States. The psychological impact of people worrying about the gasoline supply resulted in long lines forming at gas stations across the country. Many areas of the country suffered gasoline shortages. By the end of the embargo, the price of gasoline had increased by about 45 percent nationwide. The threat of another oil embargo led to support for more domestic oil production and exploration and for non-OPEC suppliers. In the United States, the long term effect of the embargo was energy conservation, including mandated automobile efficiency standards. By decreasing dependence upon OPEC oil, the United States was able to decrease OPEC's economic and political power.

• The Post-Embargo Era

The focus of OPEC's work since the mid-1970's has been to stabilize oil prices in a range that is advantageous for its members. About twice a decade an unexpected political or economic situation has affected the oil markets, causing rapid price increases or decreases. OPEC desires stability or orderly petroleum price increases. Since the 1990's a new challenge has arisen: the strong international movement to reduce dependence upon fossil fuels to combat global warming. OPEC fears this could significantly reduce the world's demand for oil. During the 2000's, OPEC produces about 45 percent of the world's petroleum and anticipates this increasing to over 50 percent in the next decade. While it has passed resolutions in favor of environmental responsibility and efficient automobiles, it also lobbies hard against any special taxation of oil, or petroleum products. OPEC believes that in the foreseeable future there is a continuing major role for oil. To offset any contribution oil makes to global warming, it advocates carbon capture and storage technologies, which captures carbon dioxide pollution and stores it underground. It is an advocate for investment in exploration for new oil fields and development of current fields.

• Context

The balancing act that OPEC must undertake between optimal profitability and continued demand for oil products means that the secretariat is very active. The secretariat is constantly trying to forecast the global economic future, while at the same time watching for political activity that might be seen as a threat to the stability of the oil supply. OPEC was formed because there was a strong desire for the governments and citizens of the countries with the oil resources to get a larger share of the profits, rather than having them go to foreign firms. As such, it is only to be expected that OPEC will push hard to retain its markets for oil. With its central focus on economic interests, it should be expected that OPEC will fight hard to stop any movement to greatly reduce the use of oil, even if these changes are part of a process toward ending global warming. To get OPEC support on climate change issues, any proposals must allow continued use of petroleum products.

Donald A. Watt

What to Do About Climate Change (*sidebar*) 190

Volume 2

AIRS-Retrieved Global Tropospheric Methane for August 2005 (*chart*) 717
Annual Global CO_2 Emissions from Burning Fossil Fuels (*table*) 448
Anthropogenic GHG Emissions to Earth's Greenhouse Effect, Contribution of (*table*) 595
Average U.S. Midgrade Gasoline Prices, 1995-2008 (*graph*) 469
Big Five Mass Extinction Events, The (*table*) 415
Climate-Related Disasters, 1900-1999, Global Deaths Due to (*table*) 541
Climate Time Line, Holocene (*time line*) 555
Climatological Organizations, Major Libertarian Think Tanks and (*list*) 673
CO_2 Emissions, by Nation, GHG and (*table*) 611
CO_2 Emissions from Burning Fossil Fuels, Annual Global (*table*) 448
Contribution of Anthropogenic GHG Emissions to Earth's Greenhouse Effect (*table*) 595
Coral Reef Calcification Rate, Effects of Ocean Acidification on (*table*) 780
Cyclone Energy, Years of Greatest Accumulated (*table*) 417
Death of the Human Race, The Premature (*sidebar*) 688
Deaths Due to Climate-Related Disasters, 1900-1999, Global (*table*) 541
Deviations in Mean Global Surface Temperature (*table*) 510
Disasters, 1900-1999, Global Deaths Due to Climate-Related (*table*) 541

Earth's Major Gyres (*map*) . . . 534
Ecological Footprint (*sidebar*) . . . 677
Effects of Ocean Acidification on Coral Reef Calcification Rate (*table*) . . . 780
Emissions Trading (*sidebar*) . . . 655
Extinction Events, The Big Five Mass (*table*) . . . 415
FAO Mandate, The (*sidebar*) . . . 438
Florida (*map*) . . . 435
Footprint, Ecological (*sidebar*) . . . 677
Fossil Fuel Reserves, 2003, World Proved (*table*) . . . 450
Fossil Fuels, Annual Global CO_2 Emissions from Burning (*table*) . . . 448
France (*map*) . . . 454
Gasoline Prices, 1995-2008, Average U.S. Midgrade (*graph*) . . . 469
Germany (*map*) . . . 482
GHG and CO_2 Emissions, by Nation (*table*) . . . 611
GHG Emissions to Earth's Greenhouse Effect, Contribution of Anthropogenic (*table*) . . . 595
Glacial Lake Agassiz (*map*) . . . 484
Glaciation Time Line (*time line*) . . . 490
Global Deaths Due to Climate-Related Disasters, 1900-1999 (*table*) . . . 541
Global Methane Emissions by Sector, 2000 (*table*) . . . 718
Global Monitoring Principles (*sidebar*) . . . 507
Global Nitrous Oxide Emissions by Sector, 2000 (*table*) . . . 762
Global Surface Temperature, Deviations in Mean (*table*) . . . 510
Global Warming Potentials of Major Greenhouse Gases (*table*) . . . 511
Global Warming Potentials of Major HGWP Gases (*table*) . . . 550
Greenhouse Effect, Contribution of Anthropogenic GHG Emissions to Earth's (*table*) . . . 595
Greenhouse Effect, The (*diagram*) . . . 517
Greenhouse Gases, Global Warming Potentials of Major (*table*) . . . 511
Groundwater Movement: Influent and Effluent Streams (*diagram*) . . . 528
Gulf Stream and the North Atlantic Drift, The (*map*) . . . 532
Gyres, Earth's Major (*map*) . . . 534
HGWP Gases, Global Warming Potentials of Major (*table*) . . . 550
Holocene Climate Time Line (*time line*) . . . 555

ENCYCLOPEDIA OF GLOBAL WARMING

Oxygen, atmospheric

• **Categories:** Chemistry and geochemistry; meteorology and atmospheric sciences

The amount of oxygen in Earth's atmosphere is linked to the biological cycling of carbon via photosynthesis and respiration, as well as to the geological cycling of carbon through the planet's crust, oceans, and atmosphere. As a result, periods of high atmospheric oxygen concentration tend to be periods of low concentration for CO_2, an important GHG.

• Key concepts

aerobic: in the presence of oxygen
anaerobic: in the absence of oxygen
endosymbiont: an organism living inside a cell or body of another organism
eukaryote: an advanced cell, containing a nucleus and other membrane-bound organelles
fermentation: the biochemical generation of energy from organic compounds in the absence of oxygen
organic matter: carbon-containing compounds produced by life processes
photosynthesis: the production of food from light energy, carbon dioxide, and water
prokaryote: a primitive cell (bacterium), lacking a nucleus and other membrane-bound organelles
respiration: the biological generation of energy, using oxygen

• Background

Oxygen exists in Earth's atmosphere mainly as dioxygen gas (O_2). It is a by-product of photosynthesis and accumulated in the primordial atmosphere primarily as a result of the photosynthetic activities of cyanobacteria in the oceans. Algae and plants are also important contributors of atmospheric oxygen.

In photosynthesis, organisms take up carbon dioxide (CO_2) from the air and water and minerals from the soil, and, using the energy of sunlight, they convert these substances into chemical compounds from which they build their cellular constituents. The oxygen released in the process is used in respiration by animals, including humans, as well as by plants and many other organisms, to retrieve the energy stored in chemical bonds. CO_2 is given off as a respiratory by-product. In cyanobacteria, algae, and plants, photosynthesis outpaces respiration, yielding a net gain of oxygen by the atmosphere.

• The Early Atmosphere and Photosynthesis

When the Earth formed, some 4.5 billion years ago, the atmosphere contained almost no free oxygen. This early atmosphere probably consisted of CO_2, water vapor, nitrogen, hydrogen, and trace gases. Earth's first living things, bacteria, appeared around 3.8 billion years ago, in the oceans. These early prokaryotes were unable to photosynthesize. They probably derived their nutrients from chemical compounds in seawater, and their energy through fermentation. Some prokaryotes developed the ability to photosynthesize, and, about 2.8 billion years ago, one group of these, the cyanobacteria, began to produce oxygen as a by-product. These microbes still exist today.

• Effects of Atmospheric Oxygen on Life

Oxygen reached appreciable levels in the atmosphere by about 2.3 billion years ago. It changed the course of evolution. Because it is a highly reactive gas, oxygen was a deadly poison to many of the earliest bacteria, but some bacteria harnessed it to break the chemical bonds in their food, yielding energy. Thus, they developed respiration, an aerobic pathway for energy production. Respiration is more efficient than fermentation. It became life's predominant energy-producing pathway.

The build-up of oxygen in the atmosphere aided life in another way: It led to the formation of the planet's ozone layer. Ozone (O_3) is produced by the interaction of the Sun's ultraviolet radiation with O_2 gas. The ozone layer shields terrestrial life from ultraviolet radiation.

About 1.5 billion years ago, the accumulation of abundant free oxygen was accompanied by the evolution of a new, more complex cell type, the eukaryote. Those eukaryotes that acquired photosynthetic endosymbionts became algae. By 600 million years ago, multicellular eukaryotic forms had arisen, and the organismal groups that dominate the globe today—animals, plants, and fungi—became established.

Atmospheric Oxygen and the Geological Carbon Cycle

The countervailing processes of photosynthesis and respiration help stabilize the atmospheric concentrations of oxygen and CO_2 on timescales of single years to tens of thousands of years. Over longer timescales—millions of years—recycling of the Earth's crust regulates carbon exchange between rocks, oceans, and the atmosphere and affects the balance of atmospheric gases. As plant matter and sulfur in rocks and sediments are alternately buried and oxidized, oxygen is added to the atmosphere or removed from it. CO_2's abundance is generally inversely related to oxygen's abundance in these processes.

The concentration of oxygen in Earth's atmosphere is about 20.95 percent. The remainder of the atmosphere consists mainly of the relatively unreactive gas nitrogen, at 78.09 percent. The other atmospheric components are trace gases, which include CO_2, at about 0.035 percent, and water vapor, which fluctuates in concentration. Although a slight decrease in atmospheric oxygen has been recorded during recent decades, attributable to the burning of fossil fuels, the reservoir of atmospheric oxygen is so large that significant change cannot readily occur. Conversely, atmospheric CO_2 is present in such small concentrations that minor changes make a large proportional difference.

There is evidence that, in the distant past, the atmospheric oxygen concentration was not completely stable. About 540 million years ago, oxygen composed about 15 percent of the atmosphere. Then, around 300 million years ago, it reached about 35 percent, as a result of the conquest of the land by plants and the attendant increase in global photosynthesis. Oxygen concentration also increased by the burial of forests in coal swamps, which sequestered vast amounts of organic carbon from the atmosphere. Under normal circumstances, the trees would decay, and their carbon would be oxidized to CO_2 and water, but the swamps prevented this from happening. By around 200 million years ago, the atmospheric oxygen concentration had plummeted back to about 15 percent, accompanied by a major extinction event at the Permian-Triassic boundary.

Context

Oxygen's existence has been known only since 1774, when Englishman Joseph Priestley isolated the gas and noted its special properties, including its ability to make a flame burn particularly brightly. In Priestley's day, the atmosphere was just beginning to be understood as a collection of individual gases, rather than the single, uniform "air" it had been supposed to be. Priestley was also the first to note that plants and animals exist in a reciprocal relationship, mediated by the gases of photosynthesis and respiration.

It took nearly two centuries following Priestley's discovery of oxygen for the origin of this gas to be understood: Only in the 1960's did the idea that photosynthesis was responsible for the build-up of atmospheric oxygen over the eons become widely accepted by scientists.

Oxygen isotopes

- **Category:** Chemistry and geochemistry

- **Definition**

All atoms of a chemical element contain the same number of protons, but they may contain different numbers of neutrons and thus have different masses. Forms of elements with differing masses are called isotopes. Oxygen in nature always has eight protons, but it may have eight, nine, or ten neutrons for a total mass of 16, 17, or 18. Out of every 100,000 oxygen atoms, almost all are oxygen 16 (O^{16}). Only 205 are oxygen 18 (O^{18}), and only 38 are oxygen 17 (O^{17}). Isotopes of an element are chemically identical, but since they differ in mass, atoms of lighter isotopes move more readily than heavier ones. Chemical and physical processes can partially sort isotopes of differing weights, a process called fractionation. Since O^{16} atoms are 11 percent lighter than O^{18} atoms, water molecules with O^{16} evaporate more readily, so that variations in the ratio of O^{16} to O^{18} can be used to trace movements of water in the environment.

- **Significance for Climate Change**

Oxygen isotope analysis is among the most important and most accurate tools available for the study of ancient climates. During ice ages, the evaporation of O^{16}-rich water from the oceans to form ice caps leaves the oceans depleted of O^{16} and enriched in O^{18}, so that shells formed by marine organisms during ice ages are enriched in O^{18}. During warm periods, much less water is locked up in ice, so the oceans are richer in O^{16} and poorer in O^{18}.

Oxygen isotope abundances are described in terms of the Vienna Standard Mean Ocean Water (VSMOW), which is actually an average of ocean water composition adopted by the International Atomic Energy Agency. An older term, Standard Mean Ocean Water (SMOW) is still sometimes used. Scientists measure the abundance of isotopes using an instrument called a mass spectrometer. Atoms or molecules are vaporized, electrically charged (ionized), then accelerated by an electric field. They can be sorted either by measuring their speed (heavier atoms or molecules accelerate more slowly) or by deflecting them with a magnetic field (heavier atoms or molecules are deflected less).

During warm periods (when there is less ice on Earth than now), marine shells are up to 0.3 percent poorer in O^{18} than VSMOW, and during ice ages they are up to 0.3 percent richer. For example, researchers at Woods Hole Oceanographic Institute have used oxygen isotope data on the shells of marine microorganisms to infer that one thousand years ago, during the Medieval Warm Period, the surface temperature of the Sargasso Sea was about 1° Celsius higher than it is at present; it was 1° Celsius lower than present during the Little Ice Age, four hundred years ago.

Ozone

- **Categories:** Chemistry and geochemistry; meteorology and atmospheric sciences

Earth's atmosphere is divided into layers, of which the stratosphere and troposphere are significant to climate change. Ozone is present in both layers. In the strato-

sphere, ozone protects life by absorbing dangerous solar ultraviolet radiation. In the troposphere, ozone is a pollutant that creates smog, affecting air temperature, evaporation, moisture, and precipitation.

• Key concepts

greenhouse gases (GHGs): gases that trap heat in the atmosphere
ozone hole: an area of diminished ozone in the ozone layer
ozone layer: an atmospheric layer that contains a high (over 91 percent) concentration of ozone
stratosphere: the layer of Earth's atmosphere above the troposphere, situated between 10 and 50 kilometers above the planet's surface
troposphere: an atmospheric layer closer to Earth, where weather phenomena occur
volatile organic compounds: substances with carbon backbones that evaporate or vaporize easily at room temperature

• Background

Ozone in the stratosphere absorbs ultraviolet solar radiation; in the troposphere, it creates pollution with other greenhouse gases (GHGs). Stratospheric ozone absorbs the Sun's rays and protects life from harmful wavelengths. It is produced naturally through photochemical reactions and electrical discharges. High-energy, ultraviolet light splits oxygen atoms, which in effect form ozone molecules. Ozone-depleting substances, chlorofluorocarbons (CFCs) destroy the gas and create "ozone holes." Ozone holes transmit ultraviolet solar radiation and increase temperature at the Earth's surface. Tropospheric ozone is produced by the reaction between volatile organic compounds and nitrogen oxide. It creates smog, limiting the ability of solar energy reflected from the surface to escape to the atmosphere.

• "Good" vs. "Bad" Ozone

Ozone in the stratosphere protects Earth's surface from ultraviolet solar radiation. High-energy, ultraviolet rays are absorbed by oxygen and ozone for atmospheric reactions. Oxygen molecules, which are of greater stability than ozone, require energy corresponding to a wavelength of 242 nanometers in the electromagnetic radiation spectrum to split their atoms. Triatomic ozone, which is less stable than is biatomic molecular oxygen, requires energy corresponding to a wavelength of 200-320 nanometers.

"Good" ozone can be depleted by the ozone-depleting substances, which do not undergo chemical reaction in the troposphere, but can be destroyed by ultraviolet radiation in the stratosphere. Ozone-depleting substances derive from Earth's surface, and they are recognized in the Montreal Protocol. They degrade slowly and remain in the troposphere for years, until they reach the stratosphere, where they are broken down by intense solar radiation and release chlorine and bromine molecules, which destroy the good ozone. One chlorine atom can destroy 100,000 ozone molecules.

"Bad" ozone is not emitted directly into the air, but produced in the troposphere through chemical reactions of nitrogen oxide and volatile organic compounds in the presence of sunlight. These compounds are primary air pollutants, emitted from sources that include industrial facilities, electric utilities, motor vehicles exhaust, gasoline vapors and chemical solvents, coolants, foaming agents, fire extinguishers, solvents, pesticides, and aerosol propellants. Ozone, dangerous to vegetation and ecosystems, reduces agricultural crops and tree growth and creates harsh weather.

The Industrial Revolution affected the composition of the atmosphere. The burning of fuels released large amounts of smoke and gases directly into the atmosphere. Among the most important emissions are carbon dioxide (CO_2), nitrogen oxides, sulfur dioxide, and CFCs. Ozone in the stratosphere blocks ultraviolet light from reaching the surface of the Earth, but chlorine and bromine from halogenated compounds are very effective at destroying ozone. The concentrations of these chemicals already present in the atmosphere will continue to affect ozone for a long time.

• Healing the Ozone Layer

Ozone concentration in the lower and higher atmosphere is a result of the temperature and climate change. The pollutants producing bad ozone create a cooling affect on the Earth's surface; at the same time, ozone-depleting substances create ozone holes in the higher atmosphere. A major concern of today's scientists is balance calculations regarding ozone sinks and sources. A few countries, such as the United States, China, India, Malaysia, and Indonesia, are the major polluters. Their amount of pollution significantly affects bad ozone production and good ozone depletion. The discovery of the thinning of the ozone layer led to the 1987 Montreal Protocol, which regulates these harmful substances. The protocol was signed by almost all developed and developing counties.

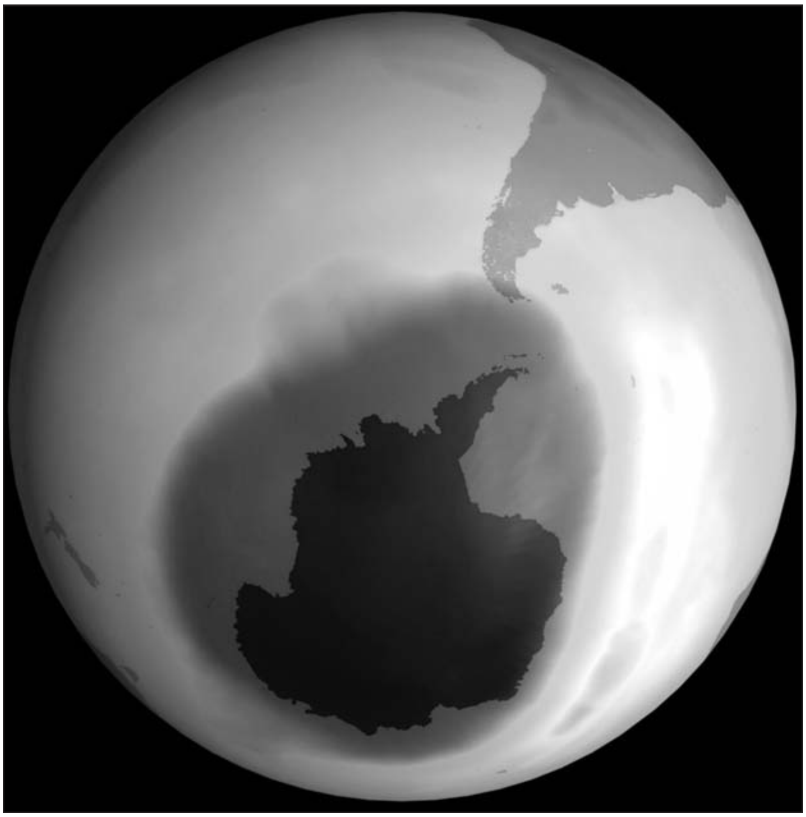
Joseph Farman, a British scientist who discovered the ozone hole over Antarctica, has stated that China, India, and other developing counties such as Malaysia and Indonesia fail to comply with new regulations and are damaging the progress made in healing the Earth's protective ozone layer. Since 1985, governments have stopped or controlled some harmful emissions, such those from aerosol sprays. Progress on the release of ozone-depleting substances has improved, and the ozone hole over Antarctica is not worsening. However, when the harmful substances are in the air, it takes a long time before they are removed. The reduction of the ozone layer is observed above the Arctic and Europe, and it is projected to worsen, according to Nora Schultz.

Ozone, along with methane, is being sucked out of the atmosphere over the tropical Atlantic Ocean, based on the data collected in Cape Verde at the west coast of Africa. The atmospheric observatory there records that 13 percent of ozone is lost each day. This discovery suggests that 50 percent more ozone is being destroyed above the tropical Atlantic Ocean by halogens released by the seawater. More ozone and methane is being destroyed than was thought previously, says Alastar Lewis of the National Atmospheric Science center in Leeds, England. The ozone in the troposphere is the third most important anthropogenic gas, after CO_2 and methane.

• Context

Neil Harris of the European Ozone Research Coordinating Unit at Cambridge University says that it is important to include halogens in climate models to understand their effects on climate change, such as changes in winds, in water temperature, and in ocean productivity. Winds affect how much bromine is released in sea spray. Harris's research indicates that GHG sinks are threatened by nitric oxides released by cars and factories, which increase the production of ozone. Wind affects the fate and transport of compounds in the atmosphere.

In 2007, the ozone hole shrank, but in 2008, it grew again. Thinning of the ozone layer contributes to global warming. The increase of ozone concentration is an effect of the increase of pollution



Graphic of the Antarctic hole in Earth's ozone layer based on data from the Total Ozone Mapping Spectrometer. (UPI/Landov) in the air. This increase has occurred particularly since the Industrial Revolution, which took place in Europe and the United States in the late eighteenth and early nineteenth centuries. The major changes in agriculture, manufacturing, and transportation had important effects on the socioeconomic and cultural conditions, leading to industrialization. The Kyoto Protocol was issued to set the standards for the emission of GHGs. It is still uncertain if the proceeding climate changes can be stopped. The air, water, soil, and the whole Earth environment are already affected by these changes.

Paleoclimates and paleoclimate change

• **Category:** Climatic events and epochs

Reconstructing climates from the Earth's geologic past and human prehistory provides a context for evaluating the extent to which the present global warming trend is an anthropogenic phenomenon. Paleoclimatic records also allow projections of the impacts of global warming on natural ecosystems and human society.

• Key concepts

astronomical forcing: climatic change triggered by changes in solar luminosity, variation in the Earth's orbit, and bolide impact

Milanković cycles: variations in the eccentricity of the Earth's orbit, the tilt of the Earth's axis, and the precession of equinoxes, resulting in climatic variation on a scale of tens of thousands of years

positive climate feedback loops: self-reinforcing climatic processes, such as increased snow cover increasing planetary albedo, promoting additional cooling and therefore more snow cover

proxies: measurable parameters, correlated with climate, that are preserved in the geologic record

• Background

The Earth's climate has not been uniform in geologic or even historic time. Climatic changes form the backdrop for much of human prehistory and are viewed by some as a driving force in the rise and fall of civilizations. Looking further back into the geologic record, the abrupt transitions between eras indicate periods of rapid climatic change. Despite decades of intensive research, there remain many uncertainties and unanswered questions about the causes and impact of climatic change, particularly in remote geologic time.

Paleoclimatology as a science owes its beginnings to the work of Louis Agassiz (1807-1873), who in 1840 tuned his attention from the study of fossilized fish to observations on glaciers in Switzerland and concluded that the presence of characteristic glacial geologic formations in widely separated localities indicated that an ice sheet had once covered northern Europe. At about the same time, systematic study of fossilized plants in Britain, Germany, and Pennsylvania suggested that the climate at a more remote period had been tropical. Paleoclimatology as a scientific discipline remained largely a tool to study ancient ecosystems until the last quarter of the twentieth century, when the focus turned to understanding mass extinctions in the remote past and historical climatic extremes in order to predict and manage global warming in the present.

• Research Techniques

Systematic instrumental records of temperature, precipitation, and wind speed in parts of Europe and North America exist for the last 150 years, with spotty records for the eighteenth century. Data such as timing of the grape harvest in Southern Europe and the maximum extent of the annual flooding of the Nile extend the range of human observations several centuries backward in time, and historic and even legendary sources chronicle catastrophic events throughout human history.

Most paleoclimatology relies on the study of proxies, of which tree rings (dendrochronology) are a good example. If a variation in ring width in historic times correlates with fluctuations in temperature or precipitation, a similar pattern in the more remote past indicates similar fluctuations. Within the roughly four-thousand-year lifespan of the oldest living trees, dendrochronology provides very high resolution of climatic fluctuations. It has helped establish that the El Niño-Southern Oscillation (ENSO) cycle of wet and dry years has occurred for many centuries in coastal Peru and the American Southwest. Some corals and mollusks also develop annual rings that are indicative of fluctuation in water temperature at a given locality.

The type of vegetation and species present in a region are both good climatic indicators. Leaves, woody material, and particularly pollen occur in abundance in bogs, lake sediments, and sedimentary rocks. Plant species and genera have changed very little over the last few million years, making it a safe assumption that the environment in which a fossil was deposited closely resembled the environment where the same species occurs today. The genus *Metasequoia* (dawn redwood) today thrives in wet temperate climates. Its occurrence in a fifty-million-year-old fossil assemblage of the Eocene Age on Ellesmere Island in the Canadian Arctic is one of many pieces of evidence for an unusually warm period in geologic time.

Pollen analysis is a powerful tool, because pollen is extraordinarily resistant to decay, many pollen grains can be identified to genus, and analysis of relative abundance provides a fairly complete picture of the vegetation that produced it. Pollen in bog cores provided the first evidence for the Younger Dryas, an episode of drastic cooling in Europe between 12,900 and 11,500 years ago. The prevalence of pollen of an arctic plant, *Dryas octopetala*, indicated an abrupt return to arctic-tundra conditions within a ten-year period.

Further back in the geologic record, general morphology of plant fossils can be used as a climate proxy. Forest vegetation indicates relatively high precipitation; broad-leaved evergreens, a tropical or subtropical climate; and slow-growing woody plants with small vessel elements, a semiarid ecosystem.

The abundance and species composition of oceanic plankton are highly sensitive to water temperatures. Foraminifera (protozoa) and diatoms (algae) produce distinctive resistant outer coatings. The ratio of stable isotopes of carbon and oxygen in carbonate-containing marine sediments reflects their concentration in seawater. Plants selectively use carbon 12 in photosynthesis, so oceanic sediments become enriched in carbon 13 during warm, moist periods. Evaporated water is enriched in oxygen 16 relative to oxygen 18, leaving seawater with a higher proportion of oxygen 18 during periods of glaciation.

There are many geologic indicators of past climatic conditions. Cool, arid conditions produce deposits of loess (windblown dust). Volcanic ash distributed over a wide area may signal the onset of a cooling period. Low sea levels indicate glaciation, and high sea levels indicate warming episodes. Organic matter accumulates on land during cool wet periods. Continental glaciers produce characteristic scouring of rocks and glacial moraines. Ice-rafted debris found far from the continental margin, especially at low latitudes, indicates extensive glaciation.

The effects of geological and astronomic forcing mechanisms can be modeled based on a knowledge of plate tectonics and changes in the Earth's orbit and solar luminosity, and the results can be compared with proxy measurements. The relative proportions of sea and land mass and the latitudinal distribution of continents have changed substantially over nearly four billion years of life on Earth, but continental drift occurs too slowly to account for dramatic climate changes in the Phanerozoic. Plate tectonics do, however, spawn massive episodes of volcanism, such as those associated with the Permian-Triassic and Miocene-Pliocene transitions. Milanković cycles, which predict changes in the absolute amount of solar radiation reaching the Earth, show some positive correlation with Pleistocene glaciation pulses. Cores taken from glaciers in Greenland and Antarctica provide evidence of climate over the last 400,000 years in the form of rates of precipitation, amounts of atmospheric dust, and concentrations of carbon dioxide (CO_2) in trapped air.

• Climatic Change in the Geologic Record

Scientists who developed the geologic timescale used today based their division into eras and periods on marked discontinuities in both the inorganic constituents and fossils in sedimentary rocks. The discovery of radiometric dating based on decay of uranium isotopes at the end of the nineteenth century allowed an absolute time scale to be superimposed on the stratigraphic sequence. From a climatic perspective, the periods represent spans of millions of years, during which global climate was relatively uniform, divided by much briefer spans that were characterized by climatic extremes, elevated extinction rates, and the subsequent emergence of numerous new taxa.

The geologic record is punctuated by five recognized episodes of catastrophic extinction, when 60-80 percent of the then extant species disappeared in less than a million years. The best-known of these is the end-Cretaceous event marking the end of the dinosaurs 65 million years ago. Most biologists accept that the precipitating factor was an asteroid collision. The end-Ordovician extinctions, 440 million years ago, coincided with a drastic lowering of the sea level, possibly representing extensive glaciation. The causes of the late Devonian and Triassic-

Jurassic extinctions are uncertain. From the point of view of present policy makers attempting to learn from the lessons of geologic history, the Permian-Triassic extinctions, 250 million years ago, are probably the most instructive, both because they were the most profound and because the postulated causes most closely mirror global anthropogenic changes that are rapidly creating what Richard Leakey and others have termed "the sixth extinction."

A somewhat controversial interpretation of late Precambrian geologic formations postulates a "snowball Earth" between 790 and 630 million years ago. This period encompassed three or possibly four major glacial episodes, during which the Earth's oceans may have completely frozen, halting the evolution of multicellular life. At the time, most of the Earth's land mass centered over the South Pole. There is also evidence of major glaciation during the Huronian, 2 billion years ago. The postulated cause is depletion of methane due to release of oxygen by photosynthesis.

For most of the Phanerozoic, temperatures on Earth, as inferred from sea levels, isotope ratios, and vegetation at high latitudes have been significantly higher than they are at present. The late Cretaceous and the Eocene were particularly warm periods, characterized by temperate deciduous forests in Antarctica and the Canadian Arctic, and tropical jungles in Central Europe and the Pacific Northwest. The past 50 million years have witnessed gradual cooling and increasing aridity. Pronounced aridity and a drop in sea level in the Pliocene caused both the Mediterranean and Black Seas to become landlocked and shrink to a fraction of their present size.

• Climatic Change in Human Prehistory

The tenure of modern humans on Earth encompasses the last Pleistocene glaciation and the ten thousand years of the Holocene, during which the Earth's climate has fluctuated, with a temperature maximum roughly six thousand years ago and a temperature minimum, the Little Ice Age, from the fourteenth to early nineteenth centuries. There are many studies correlating prehistoric cultural changes with climatic changes. For agricultural societies, the droughts associated with colder periods are more devastating than lower temperatures themselves. The historic and geologic records contain no compelling evidence of rapid rises in temperature such as the Earth is currently experiencing—global warming in geologic time appears to be a gradual process to which life adapts itself. Cooling, on the other hand, can be extremely rapid and catastrophic. Massive volcanic eruptions cause global cooling by ejecting fine ash and sulfates into the atmosphere. Historic cold episodes beginning in 1470 B.C.E., 535 C.E., 1315, and 1815 are dwarfed by the eruption of Mount Toba on the island of Sumatra seventy-four thousand years ago, which is believed by some to have nearly wiped out the human race.

• Context

Probably the most important lesson to be learned from paleoclimatology in respect to global warming is that of the disruption of North Atlantic currents and resulting deep freeze in Europe in the 8.2ka event. Very rapid melting of the Greenland ice cap and release of freshwater into the Atlantic could well mimic the effects of the rapid draining of glacial Lake Agassiz through the St. Lawrence at the end of the Wisconsin Glaciation. The other lesson to be learned, although it does not so readily translate into international policy making, is that a massive volcanic eruption could, within a period of a few months, cause a substantial drop in global temperatures and global agricultural productivity, a much grimmer scenario in today's overpopulated and environmentally degraded world than in 1315 or 1815.

Parameterization

- **Category:** Science and technology

- **Definition**

In climate models, parameterization is the technique of representing processes that are too complex or otherwise cannot be effectively simulated in the model. Climate models are based on a series of mathematical equations that represent different chemical and physical processes—such as the evaporation of water from the ocean, the condensation of water vapor in the atmosphere to form clouds, and the direction of cloud transport based on wind directions and strengths. While processes such as these can be exactly solved within the climate model, other processes are too complex to treat in this manner. An example of this is local weather patterns such as the development of small-scale rainstorms. In this case, some other variable or data set must be chosen to represent the effects of the rainstorms. Long-term data on the regional average rainfall could be chosen as the parameterization for rainstorms. Thus, rather than a model solving a series of equations to predict when or where future rainstorms will occur, the average regional data is used to predict variations in the total average amount of rain under different climate change models.

- **Significance for Climate Change**

Global climate models are mathematical representations of a large series of complex chemical and physical phenomena. These mathematical models are the basis for future predictions of the potential effects of global warming. Global climate models are created by dividing the whole atmosphere into a horizontal and vertical series of grid boxes. These boxes can vary in size from 2°-10°, latitudinally and longitudally (approximately 200-1,000 kilometers), and tens of kilometers in height.

Certain processes—such as large-scale atmospheric circulation patterns—can be represented by relatively simple mathematical equations that can be solved for every time point and within every grid cell of the model. Other processes, such as small rainstorms or variations in local wind speed, are too complex, are not well understood, or occur on a geographic scale that is much smaller than the grid size of the model. Thus, these processes must be parameterized—or represented by some other type of data in order to let the model run. In effect, parameterization is a type of approximation, but is important in decreasing the complexity of the global climate models, so that climate models can be run using existing computing technology. However, an important part of developing and using a climate model is determining the amount of error that parameterizations introduce to predicted model results.

Particulates

- **Category:** Chemistry and geochemistry

- **Definition**

Particulates, also known as particulate matter, are fine particles of solid or liquid matter suspended in a gaseous medium. The particulates and the gas medium are collectively referred to as an aerosol. Particulates can be of natural or anthropogenic origin. Natural sources of particulates include volcanoes, dust storms, and fires, while anthropogenic sources include by-products of industrial processes, such as the burning of fossil fuels.

- **Significance for Climate Change**

Particulates are known contributory factors of climate change. Anthropogenic aerosols affect the climate by altering the atmospheric radiation field through scattering and absorption mechanisms. Aerosols can both absorb and scatter radiation. Whether a given aerosol is classified as radiation-absorbing or -scattering depends on its net effect and can be expressed by a single scattering albedo (SSA) value. Higher values indicate radiation scattering, whereas lower values indicate radiation absorption. For example, sea salt, a natural aerosol, has an SSA value of 1, whereas soot has an SSA value of 0.23, characterizing its immense atmospheric absorbing potential.

The manner and degree to which solar radiation is affected by atmospheric particulates depends on the chemical composition of both the particulates and the gaseous medium in which they are suspended. Sulfate aerosols, for example, have a cooling effect due to their tendency to scatter light. It appears that the slight decrease in global temperature observed in the middle of the twentieth century can be attributed to sulfate aerosols. By contrast, soot, also known as black carbon or carbonaceous aerosol, has absorbing properties that contribute to a warming effect. According to the Intergovernmental Panel on Climate Change (IPCC), black carbon contributes a global mean radiative forcing (the difference between the incoming and outgoing radiation energy in a given climate system) of +0.2 watts per square meter.

Globally, approximately 10 percent of aerosols are generated as a result of human activity. The health effects associated with particulates and aerosols are well documented. The inhalation of particulates and aerosols has been positively correlated to the development of asthma, lung cancer, and cardiovascular disease. The size of a particle is the key determinant as to which area of the respiratory system it will first contact and primarily affect. Large particles tend to become trapped in the nose and throat and are generally eliminated before harm is caused. However, smaller particles (around 10 micrometers) settle lower in the airway in the bronchi and lungs and can result in adverse health conditions. Particles smaller than 2.5 micrometers, can penetrate the gas-exchanging tissues of the lung, and those smaller than 100 nanometers can enter cardiovascular organs such as arteries, causing vascular disease.

Peer review

- **Category:** Science and technology

- **Definition**

When a scholar completes a research project, he or she is expected to publish the original findings. Before such publication takes place, however, the research undergoes a process known as peer review: Scholars with expertise in the relevant field read prospective articles to evaluate their conformity to the professional standards and conventions of the field. Peer review is employed in all scholarly fields, from the humanities to the sciences, so criteria of evaluation can vary significantly from field to field. For example, scientific papers are expected to present objective, scientifically verifiable data, whereas humanities research is expected to support arguments with evidence but it need not and cannot be purely objective or conform to scientific principles. In some fields, reviewers are strongly encouraged to help authors whose work is deemed acceptable but open to improvement.

While the procedure varies in different journals and fields of study, a journal's central office generally maintains a file of people willing to review articles and their areas of expertise. An editor selects scholars who are most likely to be knowledgeable in the general area of the proposed publication (peers) and requests their assistance (review). The identity of the article's author is often known to the reviewer, but the author rarely knows the reviewer's name. In as short a time as is reasonable (which varies from a few weeks to a year), the editor receives the recommendation concerning publication. The article is designated as acceptable for publication, needing revisions, or recommended for rejection. It is not unusual for an editor to receive conflicting reviews of a manuscript.

• Significance for Climate Change

Scientists working strictly in the area of climate change are relatively few, but there is a large number whose work contributes to the debate concerning the reality, magnitude, and causes of global warming. Furthermore, these men and women come from virtually every field of science and engineering. It follows that they read and publish in a wide variety of learned journals. While the public image of science may not emphasize it, each of these groups has somewhat different expectations and procedures with respect to peer review.

The peer review process is of central importance in all scientific work, but it is more sharply focused in studies associated with global warming, because the relationship between science and politics is more apparent in such studies. Generally scientists and politicians function in separate arenas. The chemist, for example, may submit a research proposal to the National Science Foundation, where it is subjected to peer review and funded or rejected. When the research is completed, an article may be written and submitted to the *Journal of the American Chemical Society*, where it is again subjected to peer review and published or rejected. The new addition to the chemical literature is built upon, modified, or negated by future studies, each of which is peer reviewed.

The politician stands for election on the basis of his or her total record and personality. The review is not by peers, but by constituents. The new legislator works to persuade peers not only that an action is right but also that it is possible and preferable to a number of alternatives. In the debate, the proposal is reviewed by peers; their conclusions and actions are reviewed by constituents in the next election. The legislator may make written arguments in the *Congressional Record* or the *Wall Street Journal*, neither of which is peer reviewed.

These activities possess many similarities along with important differences. In the context of global warming, both frames of reference are crucial. Elegant scientific studies are meaningless without effective policies. International agreements based on mediocre science can do more harm than good. It is useful for discussions about the importance of climate change to refer to both the *Journal of Climatic Studies* and the *New York Times*, but it is vital that interlocutors distinguish between factual studies and policy debates. It is crucial that both what is probably true and what is possible are addressed, but they must be addressed in different ways using different sources.

Penguins

- **Category:** Animals

- **Definition**

Penguins are aquatic, flightless birds that strictly inhabit the Southern Hemisphere. Though popularly associated with Antarctica, penguins inhabit all southern continents, extending as far north as the Galapagos Islands off the coast of Ecuador. In fact, only a few penguin species live in the southernmost regions, and at least ten species live in the temperate zone. Most penguins spend half of their lives on land and half in the oceans. They feed on small marine creatures such as krill, fish, and squid while swimming underwater.

- **Significance for Climate Change**

Cold-species penguins are dependent on Antarctic ice, so temperature increases that thin ice shelves, which are important breeding and feeding sites for penguins, can adversely affect penguin populations. Antarctic warming led to the collapse of portions of the Antarctic Larsen Ice Shelf in 2002, reducing important penguin breeding and feeding areas and drowning thousands of emperor penguin chicks, who were forced to take to the water before they learned to swim. Some scientists believe that cold-species penguins are indicators of the health of Antarctic ecosystems and the consequences of Antarctic climate change.

Global climate changes can perturb the distribution of penguin food sources and harm the health of cold-species penguin populations. During the winter, marine algae freeze into the ice pack. Ice melts during the spring release algae, which are eaten by krill. This increased food source expands the krill population in time for the penguin's spring breeding time. Warming decreases winter ice, which in turn decreases the release of algae and, consequently, the surge in krill population. Less food available for breeding penguins reduces penguin fertility.

A group of penguins gather on a small ice floe in the Antarctic. (©Vladimir Seliverstov/Dreamstime.com)

Not all penguin populations are equally affected by global climate change. Populations of Adélie penguins—the most southerly distributed penguin species, which inhabits the area from South Africa's Prince Edward Islands to the Antarctic Peninsula—are declining. Penguin populations in the Indian Ocean and more southerly regions of Antarctica are thriving. In some cases, penguin populations thrive because they have access to their primary food source earlier in the breeding season. In other cases, shifts in the location of the primary food source forces penguins to forage further to feed, reducing their fertility.

These changes in food availability are due to the Antarctic Circumpolar Current (ACC), which mixes 140 million cubic meters of water from the Indian, Pacific, and Atlantic Oceans and flows from west to east around Antarctica. The ACC is filled with krill and other penguin food sources. Climate change can alter wind patterns and drive the ACC away from or closer to penguin nesting sites, affecting their populations both directly (by increasing or decreasing food supply) and indirectly (because food supply affects fertility).

Perfluorocarbons

• **Category:** Chemistry and geochemistry

• **Definition**

Perfluorocarbons are chemical compounds that are formed when some hydrogen atoms in hydrocarbons are replaced by fluorine atoms. True perfluorocarbons (PFCs) contain only carbon and fluorine atoms and generally include only CF_4 and C_2F_6; PFC derivatives may have other chemical groups attached to them. PFCs are chemically inert. They exist in a clear and colorless liquid form that has two times the density of water because of its high molecular weight. There are also five PFC gases: tetrafluoromethane, hexafluoroethane, octafluoropropane, perfluoro-n-butane, and perfluoro-iso-butane. These gases are formed synthetically and are by-products of aluminum smelting, uranium enrichment, and semiconductor manufacturing, as well as refrigerant blends. They have also been used as substitutes for CFCs in manufacturing.

PFCs are used in medical procedures, such as eye surgery and certain types of imaging procedures. They are being investigated for use as artificial blood, though this application is not yet feasible. However, PFCs are also suspected as agents in human disease and damage, such as breast, liver, prostate, and testicular cancer; hypothyroidism; and other developmental damage associated with toxic chemicals.

• **Significance for Climate Change**

PFCs affect the warming and cooling cycle of the Earth, as do the other greenhouse gases (GHGs) addressed by the Kyoto Protocol. PFCs are part of the class of fluorinated gases, which—along with carbon dioxide (CO_2), methane, and nitrous oxide—are considered to be the major GHGs listed in the Kyoto Protocol. However, they do not affect the atmosphere to the extent that other gases, such as water vapor, CO_2, or methane, do. PFCs also do not affect the ozone layer as some other gases do, and they were introduced as an alternative to ozone-depleting substances.

As light from the Sun enters the atmosphere, some of that light is scattered by molecules in the air or reflected from clouds back into space. Some of the light that reaches the Earth is also reflected back into space by surfaces such as snow or ice. Much of the light that reaches the Earth is absorbed and retained as heat. The Earth's surface warms and emits infrared photons, which make several passes between the Earth and the atmosphere, warming the atmosphere and the Earth as they go back and forth. Eventually, these infrared photons return to space.

The GHGs, whose molecules are all composed of three or more atoms, are able to absorb infrared photons as they pass, transferring the energy from the photons to the gases' molecules and trapping the thermal energy associated with them. Eventually, this absorption of energy effects a net change in the Earth's energy balance. The extent of the net change depends on the radiative force associated with the gas, as well as the lifetime of the gas. These two factors are expressed together by the gas's global warming potential. PFCs can stay in the atmosphere for hundreds or thousands of years. Thus, they continue to affect Earth's atmosphere and climate far longer than other GHGs.

Many GHGs are emitted as a result of human energy use, such as when fuel is used to generate electricity. Though human-made gases, such as PFCs, only account for approximately 2 percent of total GHG emissions, some scientists believe these emissions are enough to tip the delicate balance of the Earth's warming and cooling patterns. PFCs can be removed from the atmosphere through condensation and precipitation or by chemical reactions. However, because of their long lifetimes, they tend to accumulate more quickly than they can be dispersed.

Because of PFCs' effects on the global climate, the retention of these gases in the atmosphere could lead to melting of glaciers and polar ice caps, increased severity of flooding and droughts, rising sea levels, increases in the salinity of freshwater, more devastating tropical cyclones and tidal waves, and coastal erosion. These effects on the global climate could also help increase food production. As the Earth becomes warmer, growing cycles lengthen, more land becomes available for food production, and more and different varieties of food are able to be grown. Climate change from the GHGs, including PFCs, could also lead to more insect-borne disease spreading further throughout the world. As mosquitos and other pests are able to survive in more and different areas, malaria, dengue fever, and cholera could spread further.

Permafrost

- **Category:** Cryology and glaciology

- **Definition**

Permafrost is permanently frozen ground, including soil, sediment, or rock. In order to be considered permafrost, the ground must remain below freezing for at least two consecutive years. Permafrost can persist for tens of thousands of years or more. Depending on the ground temperature, permafrost can be either continuous or sporadic. Permafrost is composed of different layers. Seasonal frost, which thaws during warmer times of the year, is generally present on top of permafrost and is called the "active layer." In the Arctic zone, permafrost may extend more than 100 meters below an active layer. Sometimes, a layer of unfrozen ground, called a "talik," is sandwiched between the active layer and the permafrost.

Permafrost is most commonly found in high latitudes near the North and South Poles. About half of the world's permafrost is found in Russia and Siberia. Permafrost is found in the Arctic, Alaska, and northern Canada, as well as further south in the Rocky Mountains. In the Southern Hemisphere, permafrost is found in Antarctica and the Andes Mountains.

• Significance for Climate Change

Although permafrost can persist for thousands of years, it's temperature is often near its melting point. Therefore, slight changes in ground temperature can quickly affect the distribution and thickness of permafrost. Recent warming trends have caused large sections of permafrost to thaw, decreasing the amount and depth of permafrost observed in many areas. Situations in which the ground thaws deeper than the next winter's freeze can result in a talik forming. This allows heat to accumulate within the ground, accelerating permafrost thaw.

Thawing permafrost can have significant impacts on ecosystems and human infrastructure, as well as potentially contributing to the release of greenhouse gases (GHGs). Roughly one-third of the world's total soil carbon is estimated to be stored in permafrost. GHGs, such as carbon dioxide (CO_2) and methane, are often trapped within frozen ground. As permafrost thaws, these gases may potentially be released into the atmosphere. Permafrost-related GHG emissions can contribute to a positive feedback loop as well: As more permafrost thaws, more GHGs are released, increasing the greenhouse effect and warming the climate. Consequently, permafrost thaw increases, releasing more GHGs.

Significant impacts on infrastructure and ecosystems can result from permafrost loss, as pockets of soil that contain large amounts of ice melt, buckling highways and destabilizing building foundations. Ground underneath forests can also cave in, causing what is referred to as "drunken forests," with trees leaning inward at an angle. Permafrost degradation can also result in erosion and landslides. Ecosystem diversity, composition, and productivity are also impacted by declining permafrost.

Pesticides and pest management

• Category: Economics, industries, and products

• Definition

Pesticides are generally defined as substances intended to prevent, or interfere with, the growth of a given pest (normally an insect, its larval form, or a noxious plant). In the ideal case, the pest is killed, so its descendents can cause no further damage. Most pesticides target more than a single species of pest, and they can be very toxic to animals and humans. Pesticides differ in their chemical structures, and some are difficult or impossible to biodegrade because they are human made and not naturally occurring. Their toxicity and resistance to biodegradation leads to environmental problems, such as runoff and stream contamination, that can endanger livestock, humans, and wildlife.

These challenges have led to growing interest in other approaches to pest management, such as developing alternative physical and biological procedures (called integrated pest management, or IPM); using purely organic techniques, employing no synthetic pesticides or fertilizers; or genetically engineering plants to be pest resistant. For example, the bacterium *Bacillus thuriengensis* is a popular biopesticide. It is found in the soil and produces a protein crystal that is deadly to the larval forms of some insects when consumed. The biodegradable crystal kills only certain insects and does not affect animals, humans, or plants.

Genetic engineers have inserted the gene that codes for protein crystal production in *Bacillus thuriengensis* into the chromosomes of different crop species, such as corn. The resulting plant produces its own toxic crystal that kills insects that seek to consume the plant. This approach to pest control has potential dangers, however, as it has killed not only pests but also beneficial insects such as butterflies. This was documented in a California field test, when pollen from a genetically engineered strain of corn landed on milkweed plants. When Monarch butterfly larvae consumed the infected leaves, they were killed. Another IPM ap-

Nicaraguan banana plantation workers suffering the effects of exposure to the insecticide Nemagon await medical treatment. (Oswaldo Rivas/Reuters/Landov)

proach, biofumigation, involves planting crops such as *Brassica* (cabbage) species that, when plowed, release biocidal substances that kill soil-borne insects and nematodes. When other crops are then planted in the field, the pests are deterred without the use of additional pesticides.

• Significance for Climate Change

Photosynthetic organisms (plants, bacteria, algae, phytoplankton, and so on) capture carbon dioxide (CO_2) and remove, or sequester, it from the atmosphere. Other types of bacteria absorb methane and other substances and further metabolize them. When used properly, pesticides contribute to the survival of photosynthetic plants, making them important devices for combating greenhouse gas (GHG) emission and climate change. However, excessive use of toxic chemical pesticides can prevent natural processes from controlling GHGs. For example, synthetic pesticides and fertilizers inhibit soil fungi (mycorrhizae) that promote carbon sequestration in the soil.

The changes in temperature, wind patterns, and rainfall that accompany global warming facilitate the transfer of pests from one territory to another. They also affect the ability of certain types of native plants to survive changes in their new environment and promote competition between native and exotic plants.

Plant-growth-chamber and greenhouse studies have shown that carbon 3 plants (such as wheat and soybeans) grow more efficiently than carbon 4 plants (such as corn) when the CO_2 concentration is increased, a process known as CO_2 fertilization.

In addition, most weeds (both carbon 3 and carbon 4) grow more efficiently than crops because of their greater genetic diversity and the larger number of weed species. Changes in crop species also lend themselves to potentially new plant and insect pests that may require increased pesticide usage, as well as use of additional types of pesticides.

Rises in global temperatures have also been hypothesized to increase the numbers and efficiency of insect pests, thereby leading to the necessity of increased pesticide use. Warmer climates allow earlier arrival of migrating insects and the appearance of exotic invasive species previously unable to survive in a given area. Many such new species are able to survive longer in altered climates because winters remain warmer. As a result, more generations of a given insect species can develop during a given season, leading to increased pest populations.

Observations made in the northeastern United States demonstrate this trend. Summer temperatures between 1970 and 2000 rose by approximately 0.5° Celsius, and winter temperatures rose by about 2° Celsius. Spring also arrived sooner, and winters became warmer and produced less snowfall. A larger number and variety of insect pests were recorded. These included species not previously seen, such as mosquitoes carrying both West Nile virus and viruses capable of causing Japanese and St. Louis encephalitis. Tree-eating insects that previously would not have survived the winter, such as the hemlock wooly agelid, have also been seen in the region.

Finally, it has been shown that herbicides are not as effective against weeds grown under increasing CO_2 concentrations. Certain insecticides (pyrethroids and spinosad) have also been shown to be less effective at higher temperatures. According to most sources, the GHGs (mostly CO_2) produced during the manufacture of pesticides make only a minor contribution to global warming. The benefits of well-balanced pest management programs can offset that potential harm.

Petroleum hydrocarbons in the ocean

• Categories: Chemistry and geochemistry; oceanography; environmentalism, conservation, and ecosystems

• Definition

Hydrocarbons are organic compounds formed exclusively from the elements hydrogen and carbon and are straight-chain, branched, or cyclic molecules. The types of carbon-to-carbon bonds in hydrocarbons range from single to triple. Very low mass hydrocarbons are gases. Liquid and solid hydrocarbons spread out as a floating layer, if less dense than ocean water, or sink below the ocean's surface, if more dense.

Hydrocarbons in the ocean originate from point and nonpoint sources. Point sources include oil spills from vessels, facilities, pipelines, and rivers. In 2007, 10.6 million liters of oil were released near South Korea in a barge accident. In 2005, more than 26.5 million liters were released from petroleum refining facilities in the aftermath of Hurricane Katrina. Nonpoint sources include vents in the ocean floor and marine transport operations. The National Research Council reported in *Oil in the Sea III*, that 46 percent of oil released in the ocean comes from natural leaks from fissures in the ocean floor. It is a matter of debate whether these hydrocarbons come from biotic or, less likely, abiotic processes.

- **Significance for Climate Change**

Methane, or natural gas, is the most volatile of the hydrocarbons. Over 85 percent of methane released from deep ocean vents dissolves in the water column as a result of the high pressure and low temperature of the deep ocean. In shallow waters, methane bubbles rapidly rise to the surface. Methane is also released from landfills, oil production, and ocean oil spills. Methane is a greenhouse gas (GHG) with twenty-five times the global warming potential of carbon dioxide (CO_2).

Nonvolatile hydrocarbons forming ocean spills may undergo chemical, biological, or physical alteration. Chemical breakdown of surface hydrocarbons in the ocean occurs as a natural photooxidative process in which hydrocarbons, catalyzed by sunlight, react with oxygen. Because hydrocarbons do not absorb light efficiently, the reaction requires other organic matter to absorb and transfer energy to oxygen, which becomes the highly energetic and reactive species, singlet oxygen. Singlet oxygen reacts with hydrocarbons to produce alcohols, aldehydes, ketones, and carboxylic acids in a series of complex reactions. These oxidized products are more water soluble than the parent hydrocarbon.

Less subtle is in-situ burning of oil spills. When immediate removal is important or other oil removal methods are infeasible, an oil spill can be burned to form the products CO_2 and water. However, tremendous amounts of toxic carbonaceous particulate matter are released to the air as a dark cloud of smoke that eventually settles on the ocean surface. Although the combustion product CO_2 is a GHG and causes global warming, the smoky particulate matter deflects radiation and cools the atmosphere.

Biological breakdown of hydrocarbons occurs with bacteria, fungi, and some phytoplankton. The two pathways to breakdown hydrocarbons are oxidative phosphorylation, or respiration, and a detoxification mechanism that oxidizes the hydrocarbons to water-soluble oxygen-containing compounds that are easily excreted. Respiration of simple hydrocarbons results in the production of CO_2, a GHG. Bacteria that have acclimated to environs containing hydrocarbons are faster to initiate biodegradation.

Several physical methods are used to contain and remediate oil spills, including floating boom barriers to surround an oil spill, skimming boats to remove oil, sorbent materials that transfer oil away from water, and chemical dispersants to finely divide and dilute oil spills. The method used depends on the type, amount, and location of spill and also weather conditions.

Some ocean flora and fauna have adapted to live

Oil leaks from the merchant ship Syros *off the Uruguayan coast in June, 2008.* (Reuters/Landov) near sea vents of crude oil and natural gas. However, high hydrocarbon concentration in the ocean is a stressor to other ocean flora and fauna. For example, coral appears bleached after hydrocarbon exposure destroys the pigmented zooxanthellae of coral polyps. Bleached coral, if they survive, evince decreased exoskeleton maintenance, growth, and reproduction. In general, coral bleaching may be due to any number of stressors. Another likely stressor is elevated sea surface temperature associated with climate change. Attributing coral bleaching to specific stressors is complicated.

Although hydrocarbons are present in the marine environment, marine organisms are exposed only to the hydrocarbon that is bioavailable. The amount of hydrocarbon that is bioavailable depends on the partitioning of the hydrocarbon between ocean and tissues such as gills and cell membranes. Hydrocarbons can also be bioavailable when ingested (adsorbed to foods). Bioaccumulation of hydrocarbons in organisms requires desorption of hydrocarbons from foods in the gut and transport of hydrocarbons among cells. Birds and waterfowl are exposed to hydrocarbons that adsorb to feathers, skin, bills, and beaks. Even with sublethal exposure, the fitness of waterfowl may be compromised. For example, waterfowl with oily feathers cannot maneuver well enough to obtain sufficient food to survive.

The long-term effects of hydrocarbons in the ocean on populations, communities, and ecosystems are difficult to determine due to the magnitude of the studies and multiple variables. The effect of climate change must be factored into studies. Changes in CO_2 concentration affect ocean pH while global warming affects ocean currents and ocean temperature. These factors must be included in studies of marine populations and ecosystems.

pH

• **Category:** Chemistry and geochemistry

• **Definition**

pH is a quantitative measure of the acidity or basicity of a solution. The pH scale assigns a value between 0 and 14 based on the concentration of the hydrogen atoms in the solution. The more hydrogen present, the more acidic the solution and the lower the pH value. The fewer hydrogen ions present, the less acidic the solution and the higher the pH value. Pure water, which is neutral (neither acidic nor alkaline) has a pH of 7, which means that the concentration of the hydrogen ion is 10^{-7} gram-equivalent per liter. This mathematical system of stating pH was developed by a Danish chemist, Soren Peter Lauritz Sorenson, around 1909. "pH" is thought to be an abbreviation for the "potential of hydrogen" in English. The same abbreviation makes sense in several other languages, as it could stand for *pondus hydrogenii* or *potentia hydrogenii* in Latin or *potentiel hydrogene* in French.

• **Significance for Climate Change**

Soil pH. Arguably the single most important property of the moisture that is provided to soil is its pH. Soil's acidity determines which kinds of plants are able to grow in that soil. It is possible to adjust the pH of soil or of the water provided to it; acidic soil can be treated with lime to "sweeten" or neutralize it.

Acidic soil is usually considered to be infertile, as most conventional crops will not grow in it. Soil acidity also causes certain metals, such as aluminum and manganese, to become more soluble in the soil; many plants will not tolerate more than tiny quantities of these metals. Of the seventeen essential nutrients a plant needs to grow, it gets fourteen of them from the surrounding soil. The soil's pH is an important factor in the solubility and availability of these nutrients.

Soil acidity can be increased by aspects of the global climate. For example, acid rain (rain with a pH of 5.6 or lower) acidifies the soil upon which it falls. Other contributors to soil acidity include the oxidation of sulfur compounds that occurs when salt marshes are drained to be used as farmland, as well as the addition of fertilizer salts that hydrolyze or the addition of microbes that decompose organic materials. The pH of soil can be determined using a pH meter, a device that uses electrodes in the soil to generate a weak charge that can measure the concentration of hydrogen ions. Indicator dyes are also used in determining soil pH; these dyes are mixed into soil suspensions and matched against a color chart.

Water pH. Acidity is also important in bodies of water. When water becomes polluted, the temperature of the water increases and excess nutrients are formed. This causes greater algal and plant growth in the water, which may increase acid levels. These increased levels can greatly change the solubility of all the chemicals in the water, affecting the entire ecosystem. For example, if changes in pH increase the solubility of phosphorus, that increase may in turn increase plant growth, eventually generating a greater demand for the dissolved oxygen in the water and decreasing the availability of the oxygen to fish. pH is also important in seawater simply because different types of marine plants and animals are able to survive in acidic or alkaline environments, so the pH of an ocean region helps determine the inhabitants of that region.

Bodies of water have a natural ability to buffer changes in the pH, so adding acids or bases to the water does not generally change the pH value as much as one might expect. (The pH values throughout a body of water may vary naturally. At the bottom of a lake, for example, the pH may be lower than at the top, perhaps between 6.5 and 7.5. At the top of a lake during the summer, pH may range from 7.5 to 8.5.) However, the ability of a body of water to buffer changes in pH is greatly affected by acid rain. When the water absorbs great quantities of acid from rain, it loses its buffering ability, and even a slight addition to the water, such as from more rain or from snow melt, will then alter its pH.

Some microorganisms are able to affect the pH of their environment. For example, when a food is pickled, microbes are used to acidify and preserve it. However, microbes used in farming and agriculture can also affect soil and water quality when they acidify the soil or, through runoff, the water.

Phosphorus cycle

- **Category:** Chemistry and geochemistry

• Definition

The chemical element phosphorus is essential for terrestrial life. Plants, animals, fungi, and microorganisms use phosphorus for intercellular signaling. They also use it to make membrane lipids that compose the cell membrane; molecules such as adenosine triphosphate (ATP) that store usable chemical energy and transfer it from one reaction to another; and deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), which store genetic information. Some animals also use phosphorus to make bones and teeth.

The phosphorus cycle is a biogeochemical cycle that describes the movement of phosphorus through rocks, living organisms, and water. Because phosphorus and phosphorus-based compounds are typically solids at terrestrial ranges of temperature and pressure, the atmosphere does not play a significant role in the movements of phosphorus. Phosphorus, therefore, is usually found on land, in rock and soil minerals, and in salts that form oceanic sediments. Since phosphorus-containing compounds are poorly soluble, phosphorus is a limiting factor for plant growth in marine environments.

In rocks, phosphorus is found primarily in marine sedimentary rocks (in the mineral apatite), guano deposits (bird and bat droppings) in tropical caves, and in some calcium-rich volcanic rocks. Erosion of phosphorus-containing rocks redistributes it throughout the soil and water. Plants take up this phosphorus, herbivores eat the plants, carnivores eat the herbivores, and phosphates absorbed by animals eventually return to the soil by excretion of urine and feces and by decomposition after death. Phosphorus enters aquatic ecosystems by means of rainwater runoff, sewage seepage, natural mineral deposits, and industrial wastes. The poor solubility of phosphorus-containing compounds causes them to settle on lake bottoms and the ocean floor. Tectonic uplifting of such sediments and their subsequent erosion returns them to the phosphorus cycle.

• Significance for Climate Change

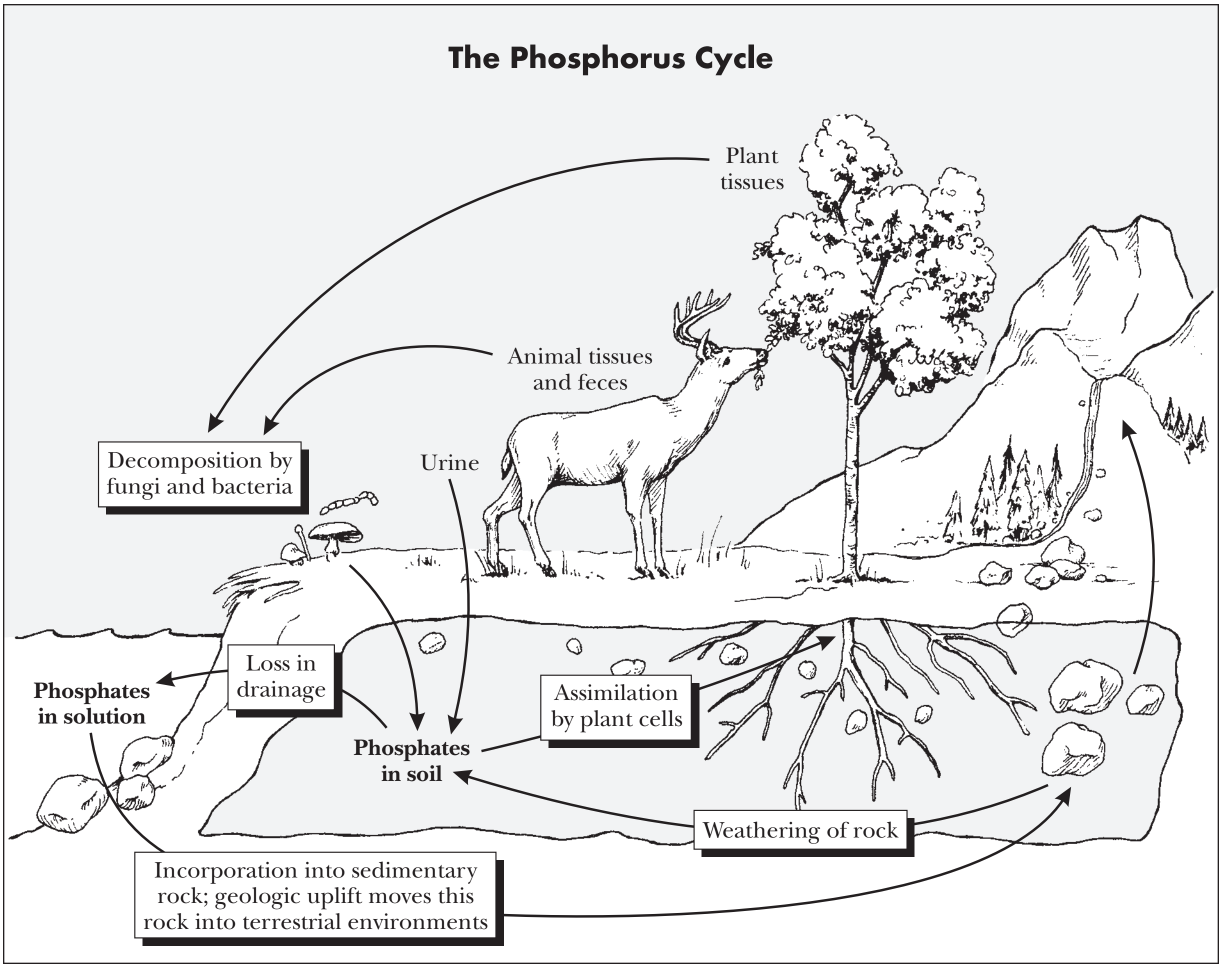
In the environment, phosphorus is found in combination with oxygen, and it forms ions such as phosphate (PO_4^{-3}), hydrogen phosphate (HPO_4^{-2}), dihydrogen phosphate ($H_2PO_4^{-1}$), and phosphoric acid (H_3PO_4). In rocks, phosphorus can also exist as metaphosphate (PO_3^{-1}), which is also known as phosphite.

Phosphorus is mined, largely, for the production of fertilizers. The use of phosphate minerals and their products as fertilizers has increased tremendously global food production. However, fertilizers have also increased phosphates in runoff waters.

Phosphorus moves quickly through plants and animals, but slowly through soils or oceans. Thus, the phosphorus cycle is one of the slowest of all biogeochemical cycles. Consequently, phosphorus is usually the limiting nutrient that controls biological productivity in many terrestrial and marine environments. Excess dissolved phosphorus leads to uncontrollable aquatic biological growth and water-quality problems. This process, called eutrophication, causes explosive algal growth or "algal blooms." Algal blooms rapidly utilize all the available nutrients, and after the algae die, thick pads of dead organisms fall to the bottom and oxidize. This reduces dissolved oxygen and creates an inhospitable environment for fish. Animals that depend upon fish as a food source or the water for reproduction are adversely affected by such events. Consequently, sharp increases in phosphorus influx tend to reduce animal populations.

Serious disruption of the phosphorus cycle occurs during cutting of tropical rain forests. Rainforest ecosystems are supported by highly efficient mineral recycling. Heavy rainfall leaches nutrients like phosphorus from the soil, but warm, moist conditions favor high decomposition rates. Fungi called mycorrhizae form special relationships with the roots of rain-forest trees, and this symbiotic association between the tree and the fungus allows the trees to absorb phosphorus before it enters the soil. This prevents phosphorus loss by leaching. Cutting down rain-forest trees leaves phosphorus in the soils and copious rain waters drive it into the lakes or oceans. Excess phosphorus kills sea creatures and also affects the predators that depend on these creatures for their survival. With the death of the large trees, there is not enough plant life to hold the soil in place and accelerated erosion ensues. Thus tree loss initiates a vicious cycle of erosion, nutrient loss, plant death, further erosion, more nutrient loss, and so on.

Rain forests play a major role in the regulation



The biogeochemical phosphorus cycle is the movement of the essential element phosphorus through the earth's ecosystems. Released largely from eroding rocks, as well as from dead plant and animal tissues by decomposers such as bacteria and fungi, phosphorus migrates into the soil, where it is picked up by plant cells and is assimilated into plant tissues. The plant tissues are then eaten by animals and released back into the soil via urination, defecation, and decomposition of dead animals. In marine and freshwater aquatic environments, phosphorus is a large component of shells, from which it sediments back into rock and can return to the land environment as a result of seismic uplift.

of global weather patterns and the balance of carbon dioxide (CO_2) in the atmosphere. Tropical rain-forest destruction puts large amounts of CO_2 into the air and concomitantly removes the trees that are responsible for removing CO_2, thus exacerbating atmospheric warming on a global scale.

Increased atmospheric CO_2 levels also increase ocean acidity. Acidification of the ocean decreases the ability of plankton to use dissolved phosphates. This would effectively starve plankton for phosphorus, and subsequently starve any organism that eats plankton and all organisms that depend on plankton eaters, thus causing a cascade of extinctions.

Photosynthesis

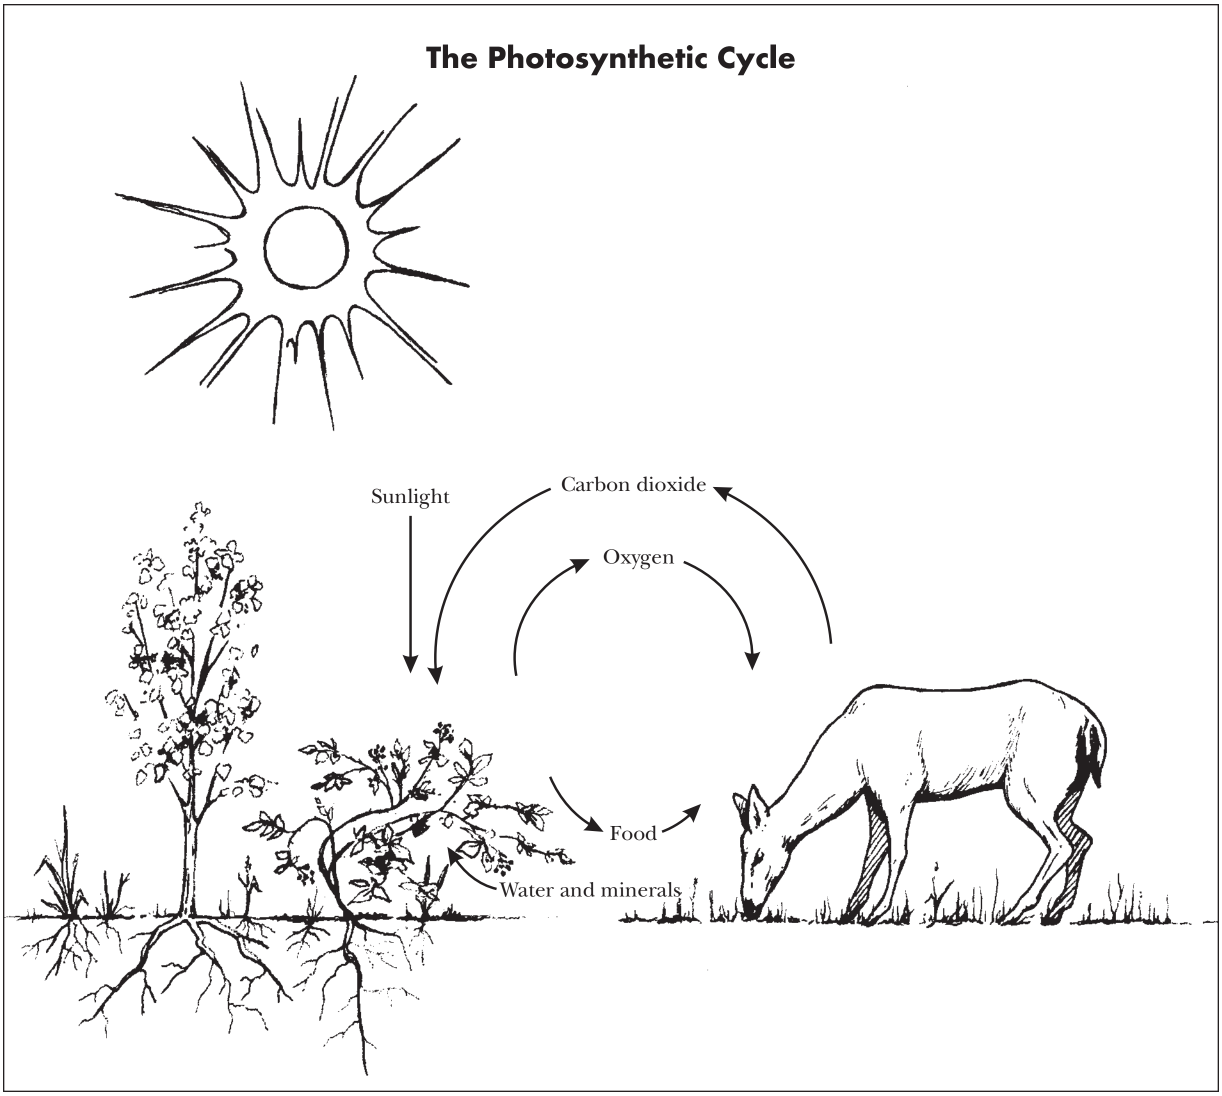
• **Categories:** Plants and vegetation; chemistry and geochemistry

• Definition

Photosynthesis is the process by which plants convert light energy from the Sun into chemical energy in the form of carbohydrates. The name carbohydrate literally means "carbon plus water," a vivid descriptive term for the sugar formed from combining carbon dioxide (CO_2) with water. The process of photosynthesis begins with the absorption of photons by plant pigments. As photons reach a reaction center made up of chlorophylls, light energy excites electrons from the splitting of water molecules. A portion of the energy released by the energized electrons is used to produce adenosine triphosphate (ATP). ATP is then used to produce carbohydrates from CO_2 and water. In the process, water acts as the source of both electrons and oxygen gas. Photosynthesis produces food for all living organisms, directly or indirectly, in all ecosystems. In addition, it releases oxygen and utilizes CO_2 and thus becomes an indispensable link in the carbon cycle.

Several pathways of photosynthesis are employed by different plants as a response to different climatic conditions, primarily temperature and water availability. In order to survive terrestrial environments, all land plants must cope with water deficits from time to time. When plants open their numerous microscopic pores, called stomata, to admit CO_2 for photosynthesis, they risk losing water through these openings by evaporation. Plants will thus at times close stomata in order to conserve water for survival. The delicate balance between conserving water and admitting CO_2 has led to the evolution of three major types of photosynthesis. The plants that employ each of these three different pathways not only display different anatomies but are adapted to different climates as well.

Some plants convert CO_2 into a three-carbon sugar and are thus called carbon 3 plants. Carbon 3 plants are typically well suited to temperate regions, where the weather is not very dry or hot and water is generally not a limiting factor. Examples of



The processes of photosynthesis and cellular respiration are complementary: Oxygen released into the atmosphere, a by-product of photosynthesis, is breathed in by animals, which in turn breathe out carbon dioxide, the gas that is essential for photosynthesis. (Kimberly L. Dawson Kurnizki)

carbon 3 plants include such crops as wheat, barley, and peas.

Other plants convert CO_2 into a four-carbon sugar and are thus called carbon 4 plants. Carbon 4 plants are equipped with a CO_2 pump that can concentrate CO_2 inside their leaves. This enables these plants to perform photosynthesis even when their stomata have to partially or temporarily close in order to conserve water on a hot and sunny day. Thus, carbon 4 plants are well adapted to high daytime temperatures and intense sunlight with periodic water deficits. This is the reason the carbon 4 crabgrass often outcompetes carbon 3 lawn grass when water becomes a limiting factor in the summertime. Other examples of carbon 4 plants include corn, sugarcane, and sorghum.

Carbon 4 plants generally do better than carbon 3 plants in hot and sunny habitats. Because operating their CO_2 pumps requires energy, however, in a cooler and moist habitat where water is not a limiting factor, carbon 3 plants possess an advantage over carbon 4 plants. When water is plentiful, there is no need to close the stomata to conserve water. Thus, the energy expenditure of pumping CO_2 by carbon 4 plants becomes a wasteful process.

Plants employing the third type of photosynthesis are uniquely adapted to desert habitats. Because of the scarcity of water, these plants cannot afford to open their stomata during the day at all lest they dehydrate. Desert plants thus engage in what is called crassulacean acid metabolism (CAM), in which they open their stomata to admit CO_2 at night, convert it into acids, and store them inside their vacuoles. They release the CO_2 stored inside the acids during the day for use in photosynthesis. CAM plants are well adapted to the high daytime temperatures, intense sunlight, and very low soil moisture of the desert biome. Some familiar CAM plants include cacti, pineapple, and sedums.

• Significance for Climate Change

Both water and CO_2 serve as essential raw materials in photosynthesis. Therefore, any climate change that affects the availability of either substance will affect photosynthesis. Given the various pathways different plants employ for photosynthesis, the same climate change will have different effects on different plants. Rising CO_2 concentrations in the atmosphere would in theory increase the photosynthetic rates of all plants. This phenomenon is described as CO_2 fertilization. However, the increase in photosynthesis from rising atmospheric CO_2 concentrations is short-lived: The response decreases under long-term exposure, because plants acclimate to elevated CO_2 concentrations through a process known as down regulation.

Plants' response to rising temperatures is complex, may be positive or negative, and is often compounded by other climatic factors. Moisture in the environment is particularly influential, as changes in temperature may correlate to changes in dew point and evaporation rate, significantly affecting the availability of water. Depending upon the degree of increase, warming temperatures may drive some plants out of their natural habitats, causing biodiversity declines or species extinction.

Carbon 3 plants tend to increase their photosynthetic rate as a result of CO_2 fertilization to a point where the associated temperature increase may offset the positive effect of rising CO_2. If the temperature increases above the level at which carbon 3 plants need to shut their stomata to conserve water, the positive effect of CO_2 fertilization diminishes or disappears entirely. In fact, facing the prospect of dehydration and drought as a result of climate change, some carbon 3 plants may no longer be able to even survive in their natural habitat.

On the other hand, carbon 4 plants may benefit from a warmer climate simply because they reach their maximum photosynthetic rate at a much higher temperature. Within certain range, the increases in both daily temperature and CO_2 concentration may have short-term benefits for carbon 4 plants. The increases in atmospheric CO_2 may have very little effect on CAM plants, because the leading constraints for their photosynthesis lies with the capacity to store acids inside their vacuoles. Since CAM plants are already adapted to the desert biome, however, an appreciable temperature rise that renders deserts even more hostile could be detrimental to the survival of CAM plants in general.

Pinchot, Gifford
American forester

Born: August 11, 1865; Simsbury, Connecticut
Died: October 4, 1946; Milford, Pennsylvania

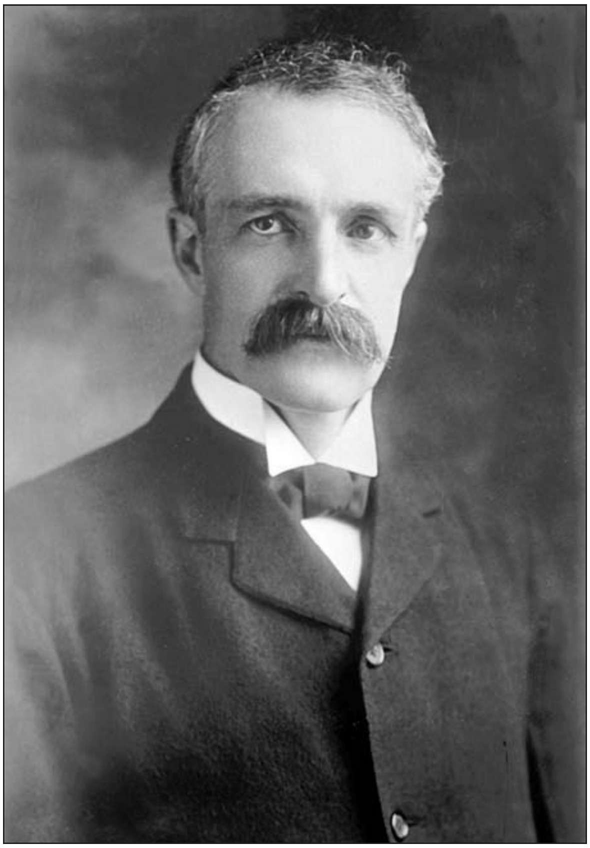
As first chief of the United States Forest Service, Pinchot set the example for modern forestry in general and U.S. forestry and forest management policy in particular.

• Life
Gifford Pinchot was the eldest child of James Pinchot, who obtained vast wealth from lumbering and land speculation. Disturbed by the damage that had been done to the land, James suggested that Gifford become a forester. Gifford graduated from Yale in 1889 and spent a year at the French National Forestry School. He was the resident forester for the Biltmore Estates for three years.

In 1896, Pinchot was appointed to the National Forest Commission by the National Academy of Sciences. In 1898, he was named head of the Division of Forestry. Later the Division of Forestry became the United States Forest Service, with Pinchot as its first chief. Fired by President William Howard Taft in 1910, Pinchot ran for the Senate in 1914 but was not elected. In 1920, he was appointed Pennsylvania state commissioner of forestry. He was elected governor of Pennsylvania in 1922 and in 1930, with unsuccessful Senate bids in between and again afterward. As a young man, Pinchot had fallen in love with a young lady who died after a long illness. Pinchot was so heartbroken that he did not marry until 1914, when he married Cornelia Bryce. They had one son, Gifford Bryce Pinchot. Pinchot died of leukemia at age eighty-one.

• Climate Work
Pinchot first saw how forests could be maintained by selective cutting while touring forests in Great Britain, France, Switzerland, and Germany during his year of study at the French National Forestry School. He had seen the devastation caused by clear-cutting of timber. Clear-cut forests do not quickly grow back, soil erodes, streams fill with silt, and animals cannot survive. Pinchot wanted to devise a way to maintain the forests of the United States. Thus, he adapted the European methods so that they would be useful in the United States.

Pinchot devised three tenets of a conservation ethic that proved successful for the National Forests of the United States. First, people should protect and preserve natural resources but also put those resources to use wisely and in a way that allows the resources to be renewed. He advocated selective cutting of forests and replanting after cut-



Gifford Pinchot. (Library of Congress) ting. He had seen that forests that were never cut at all gradually filled with dead trees. Second, natural resources were to be used for the good of all people and at a fair cost. Pinchot believed that only the government could keep large companies from monopolizing natural resources. He also thought that monopolies would drive up costs for the people. Third, conservationists should be willing to fight politically to protect the rights of the people against large companies.

Pinchot firmly believed that the Forest Service should not be politically based. He wanted a Forest Service of committed people, not political appointees. Political appointees, who owe someone else, may have to make decisions based on their appointment that are not in the best interests of the forests. Pinchot had to fight a two-front war during his time in the Forest Service. Some of the strict conservationists wanted the forests preserved as they were and wanted no cutting at all. Pinchot knew that no forest survives as is. Forests must be maintained, and Pinchot believed that selective cutting with replanting was the best way to do that.

On the other front, lumber companies had been clear-cutting and moving on for years. The forests seemed endless to them, so they saw no need to spend money replanting the cleared ground. Pinchot had seen the results of clear-cutting many times before. His idea to require a promise to replant before permission to cut was put into practice, angering many lumber companies.

Pinchot organized a Forest Service that was based on his conservation ethic. He arranged for the Forest Service to have authority and control of the National Forests and helped increase the National Forests from 22.7 million hectares to 69.7 million hectares. He contributed to the formation of the Society of American Foresters. He also was instrumental in establishing the Yale Forest School and served as a faculty member for many years. Pinchot's work for the Forest Service thus contributed directly to one of the United States' most important climatic resources, its forests.

Planetary atmospheres and evolution

• **Categories:** Astronomy; meteorology and atmospheric sciences

Comparisons of Earth's atmosphere with similar atmospheres such as those of Venus, Mars, and Titan provide insight into atmospheric evolution and physics.

• Key concepts

comparative planetology: scientific approach that tests theories by comparing data and observations of multiple planets

terrestrial atmosphere: a globally significant atmosphere covering a rocky planetary body

volatile: an element or compound with a low melting or boiling point

weathering: a chemical process in which atmospheric carbon dioxide is converted to carbonates through reactions with water and silicate minerals

• Background

The atmosphere of Earth defines the category of terrestrial atmospheres. Similar atmospheres are those of Venus, Mars, and Titan—the largest moon of Saturn. These atmospheres share the basic qualities of terrestrial atmospheres, yet they are quite different from one another. Using comparative planetology, the causes for these differences can be investigated, in turn providing further understanding of the atmosphere of Earth.

• The Current Atmospheres of Venus, Earth, and Mars

Earth and its two nearest planetary neighbors, Venus and Mars, possess atmospheres with different qualities. Earth's atmosphere has an average atmospheric pressure of 1.013 bars and an average surface temperature of around 15° Celsius. The chemical composition of the atmosphere is primarily nitrogen (N_2; 78.1 percent by volume) and oxygen (O_2; 21.0 percent). It also contains water vapor (H_2O; less than 3 percent) and a small amount of carbon dioxide (CO_2; about 380 parts per million). The atmosphere of Venus is thicker at 92 bars and has a surface temperature of 500° Celsius. Its composition is almost entirely CO_2 (96.5 percent), with a little N_2 (3.5 percent) and only trace amounts of H_2O (about 50 parts per million).

Mars has a much thinner atmosphere than Earth or Venus. Its atmospheric pressure is 0.006 bar and its surface temperature is –58° Celsius. As with the Venusian atmosphere, the Martian atmosphere is mostly CO_2 (95.3 percent) and N_2 (2.7 percent) with a trace amount of H_2O (less than 100 parts per million). Mars and Venus have no liquid water on the surface, although Mars possesses polar water ice caps. All three atmospheres experience greenhouse warming, about 500° Celsius for Venus, 35° Celsius for Earth, and 6° Celsius for Mars.

The differences between the three planets cannot be explained by current conditions alone. Rather, these differences arose as the planets evolved over the history of the solar system.

• Evolution of the Atmospheres of Venus, Earth, and Mars

The solar system formed 4.6 billion years ago; the planets' atmospheres formed in the first few hundred thousand years. Volcanic activity released CO_2, N_2, H_2O, and other volatiles previously trapped in molten mantles, with additional gases supplied by collisions with icy, volatile-rich small bodies. Some atmospheric gases were lost at the top of the atmospheres to space and at the planetary surfaces to liquid, ice, and incorporation into solids. All three planets probably had roughly comparable early reservoirs of volatiles in roughly the same proportions, meaning all three planets had the same materials to draw on, and each could have developed an atmosphere resembling that of either of the other two. Each atmosphere, however, evolved along a different path.

On Earth, early conditions allowed water in the atmosphere to condense into rain and create liquid water oceans. The rain, the oceans, and exposed regions of crust created conditions in which CO_2 could be trapped in solid carbonates through weathering. Weathering kept atmospheric temperatures within a range in which water remains liquid. As the solid Earth cooled further, volcanic activity decreased but weathering continued, removing CO_2 and leaving behind an atmosphere largely of N_2. The development of biological life also converted some CO_2 to O_2, with significant oxygen content appearing in the atmosphere around two billion years ago.

Being closer to the Sun, the early Venusian atmosphere was warmer than was Earth's. This warmth was enhanced by the greenhouse effect of an increasingly thick atmosphere of CO_2 and H_2O. As it grew warmer, virtually all the water on the planet vaporized, preventing weathering. This caused a runaway greenhouse effect, in which atmospheric CO_2 and greenhouse warming steadily increased while H_2 was preferentially lost at the top of the atmosphere, gradually reducing the water supply. This process created the thick, nearly waterless CO_2 atmosphere seen today. The runaway greenhouse effect may date from the origin of Venus's atmosphere, but another possibility is that a moist greenhouse phase preceded the later phase. The moist phase would have involved condensation, liquid

water, and weathering similar to those experienced on Earth at warmer temperatures. This period of moist greenhouse may have lasted for up to two billion years.

Evidence also exists for an earlier, moist or wet phase on Mars. This evidence is apparent in large fluvial erosion features, the detection of substantial subsurface ice, and similar observations. The early atmosphere was probably thicker and wetter than the contemporary Martian atmosphere, with significant rainfall. Debate is ongoing as to whether this rainfall resulted in large oceans or transient floods, relatively short-lived lakes, and more ice and glacial features.

Mars's wet period probably lasted for less than a billion years, with a substantial amount of liquid water lost to subsurface permafrost and the polar ice caps. Only one-half the radial size of Earth, solid Mars cooled more rapidly, so its volcanic activity ended earlier, ending the supply of volatiles. Volatiles continued to escape to space from a planet with a gravitational field 2.6 times weaker than that of Earth. Increasing this loss was a period of heightened asteroid bombardment around 3.9 billion years ago and solar-wind stripping after the disappearance of the Martian magnetic field around 4.0 billion years ago. These losses reduced the Martian atmosphere to its current thin veneer. Still, the variable obliquity and orbital eccentricity of Mars over geological time scales may have permitted occasional bursts of subsurface water to surface, creating more recent erosion features.

• Observations of Mars and Titan

The program of Mars exploration starting with Mars Pathfinder in 1996-1997 has been critical to reconstructing the past and current states of the Martian climate. These observations are also studied to determine if changes in solar output influence the climate on Mars (where human influences are nonexistent), contributing to the scientific understanding of Earth's climate and solar output as well. The Martian atmosphere also provides an additional testing ground for general circulation models, potentially improving models of Earth's atmosphere.

The Cassini-Huygens mission to Saturn and Titan explored another earthlike atmosphere in the solar system. Titan's atmospheric pressure is about 1.5 times that of Earth, and the moon has a surface temperature of around −179° Celsius with a largely N_2 atmosphere (more than 96 percent). Titan has a phase-change cycle, including rain and surface liquid lakes—but of methane (CH_4) rather than water. These similarities to Earth make Titan an inviting target for comparative planetology.

• Context

Comparative planetology has clarified the evolution of the terrestrial atmospheres. Venus is a planet where greenhouse warming occurred unabated; Mars was too small and too cold to maintain a thick, warm atmosphere. Both resulted in dry climates, likely inhospitable to life. The evolution of Earth struck a more hospitable balance, resulting in abundant liquid water and abundant life. Continuing to compare Earth's atmosphere and atmospheric history with those of Venus, Mars, and Titan will promote further understanding of the physics and chemistry that govern climate change.

Plankton

• **Categories:** Plants and vegetation; animals

• **Definition**

Plankton (from the Greek *planktos*, or wanderer) comprise a vast assortment of life-forms with limited or no swimming power that largely drift in the ocean. They are divided into the plantlike phytoplankton and the animal-like zooplankton.

Phytoplankton comprise at least four thousand species of plants that, as on land, use sunlight in the process of photosynthesis to generate sugars and other high-energy organic compounds. They live in the ocean's euphotic zone, the sunlit upper layer, which is only tens of meters deep. Phytoplankton range in size from microscopic to a millimeter in length and include single-celled organisms and tiny clumps of algae.

Because the ocean covers 71 percent of the Earth's surface, phytoplankton are a major driver of Earth's carbon cycle. Their photosynthesis extracts carbon dioxide (CO_2) from surrounding water and replaces it with oxygen. The resulting changes in oceanic gas levels change atmospheric gas levels as well. Some phytoplankton (such as coccolithophores) accrete calcium carbonate ($CaCO_3$) for shielding. If the carbon contained in their bodies reaches the ocean depths, it may be sequestered there for years, or even for millions of years.

Oceanic nutrient levels are major determinants of phytoplankton productivity. The most fertile areas are river estuaries, shallow waters, and upwelling areas in the deep ocean. Phytoplankton are eaten by zooplankton. Zooplankton range mostly from microscopic to the size of small snails, although jellyfish, some more than 2 meters in diameter, also swim weakly and can be classed as zooplankton.

Zooplankton slow the carbon cycle, because they consume phytoplankton and emit CO_2. Phytoplankton "blooms" of increased productivity are quickly followed by surging zooplankton populations. Conversely, zooplankton contribute to carbon cycling by accreting carbonate shells, dropping fecal pellets, and falling to the sea bottom upon death.

Together, phytoplankton and zooplankton directly or indirectly feed all the rest of the animals in the ocean, including human fisheries. Oceanic acidification may affect both planktonic food production and planktonic capture of CO_2. Increasing CO_2 levels in the atmosphere translate into higher levels in oceanic surface waters and favor increased photosynthesis. However, increased CO_2 levels also cause greater ocean acidity. Increased acidity in the waters may strongly hinder carbonate shell-building among plankton and other marine life-forms. If so, it would slow the marine carbon-capture process and contribute to even greater atmospheric CO_2 levels.

• **Significance for Climate Change**

In 1988, oceanographer John Martin declared, "Give me half a tanker of iron, and I can start a new ice age." Martin was referring to phytoplankton growth in the "bluewater desert" areas of the deep ocean. The creatures' growth rate is often limited by the availability of trace amounts of iron. It has been hypothesized that ice ages may result from large amounts of wind-blown dust enriching the oceans with iron. Such enrichment could have caused phytoplankton blooms that reduced atmospheric CO_2 levels, thus reducing the greenhouse effect and cooling the planet.

Similarly, Martin suggested that artificial iron fertilization in the oceans might reduce global warming. (A major campaign of oceanic fertilization would be a species of geoengineering.) Several limited experiments of a few hundred square kilometers and a few days duration have confirmed major iron fertilization in the Pacific Ocean and in the southern ocean around Antarctica.

Phytoplankton emit the sulfur-bearing gases dimethyl sulfide (DMS, CH_3SCH_3) and carbonyl sulfide (COS). Their breakdown product, sulfur dioxide (SO_2), produces airborne particles (aerosols) that reflect visible light but allow infrared light (heat waves) to pass through, thus causing more cooling. Ocean fertilization could be self-funding, because a part of the increased planktonic production could be harvested via increased fisheries production.

The major objections to oceanic fertilization are as follows: First, as noted, zooplankton populations grow to feed on phytoplankton blooms, and they quickly return much CO_2 to the atmosphere. Second, even if it is not eaten, much planktonic biomass decays and gives up captured carbon before it can sink to the bottom, so it is not an efficient carbon sink. Third, if fertilization were widely implemented, organic material reaching the deep ocean would vastly increase. In decaying, it could harm marine life by lowering oxygen levels in the deep waters. Fourth, plankton emit some greenhouse gases (GHGs), such as oxides of nitrogen, that might cancel some aerosol cooling. Finally, aerosols released by fertilization in sufficient amounts to cause noticeable cooling would also significantly decrease the sunlight available for photosynthesis. For these reasons, opponents of oceanic fertilization argue that it might result in some mitigation of global warming, but it could never represent a comprehensive solution to the problem.

Plate tectonics

• Category: Geology and geography

The Earth's lithosphere moves laterally, from regions in which it is being formed by igneous activity to regions where lithospheric plates are being subducted below other plates, forming more explosive volcanism. The volcanism can produce GHGs, and movement of the lithosphere can slowly move continents, affecting climate over time.

• Key concepts

crust: the upper part of the Earth's surface—about 7 to 10 kilometers thick in the oceans and about 25 to 70 kilometers thick on the continents

greenhouse gases (GHGs): atmospheric trace gases that trap heat rather than allowing it to escape into space

igneous rocks: rocks formed by the crystallization of magma or lava

lithosphere: the rigid part of the Earth, comprising Earth's crust and the rigid part of its upper mantle—about 100 kilometers thick in the ocean basins and about 150 kilometers thick on the continents

magma: molten rock and suspended crystals below the Earth's surface
mantle: the dense layer of the Earth below the crust
oceanic rise: linear mountain chains on the ocean floors in which lithosphere is formed by crystallization of magma or volcanism
subduction: the movement of one lithospheric plate below another

• Background

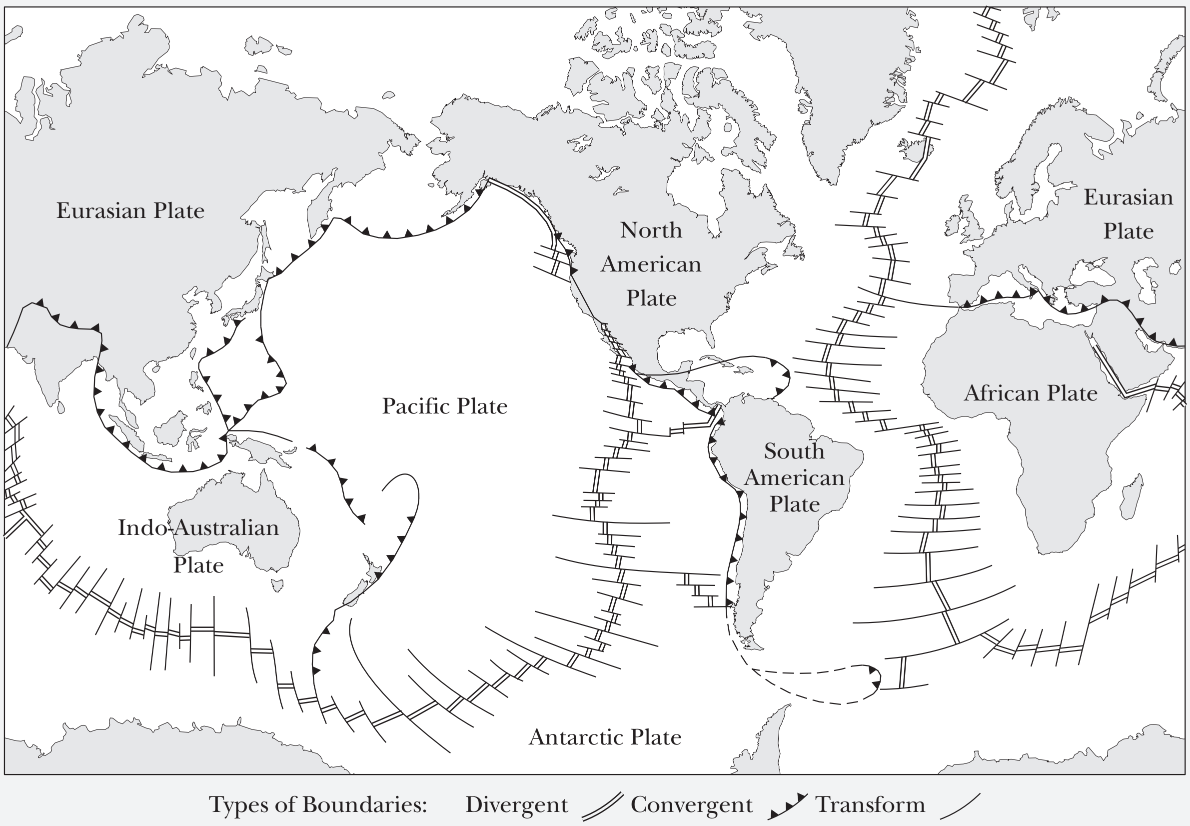
The atmosphere of the Earth has varied through geologic time, from times of global warming with no glaciers to times with abundant glaciers. For instance, there was significant cooling and glaciation from about 1 billion to 550 million years ago, from 300 to 260 million years ago, and from 35 million years ago to nearly the present. At other times, significant global warming occurred, especially in the interval from about 145 to 55 million years ago. Thus, global warming has occurred in the past and is not just a recent event. Reasons for these large global changes in temperature must be explained by natural processes such as plate tectonics.

• Earth's Tectonic Activity

The lithosphere of the Earth is composed of about twenty plates of varied sizes in which igneous rocks are being formed by volcanism or crystallization of magma along oceanic rises. In addition, volcanic gases are continually being evolved along the oceanic rises.

The oceanic lithosphere moves laterally away from oceanic rises, usually at a rate of less than 10 centimeters per year. A portion of the oceanic litho-

Earth's Tectonic Plates and Mid-Ocean Ridges



sphere eventually moves below another oceanic lithospheric plate or below continental lithosphere at a subduction zone. For instance, the portion of the lithosphere beneath the Pacific Ocean continuously moves below the portion of the lithosphere on which South America occurs. In addition, abundant volcanic activity, evolution of volcanic gases, and earthquakes occur above the subducted plate in South America. Also, continents resting on these lithospheric plates move laterally and vertically through geologic time.

• Greenhouse Gases

The amount of greenhouse gases (GHGs) in the atmosphere can affect the amount of energy given off from the Earth into space. Carbon dioxide (CO_2) is believed to be one of the most important of these gases that affect the atmospheric temperature. Most notable is the direct correlation of the amount of CO_2 in atmosphere trapped in ice cores in Antarctica over the last 400,000 years to that of the inferred temperature of the atmosphere.

Thus, understanding how and why the CO_2 content of the atmosphere changes is critical to understanding why the temperature of the atmosphere changes with time. Increased volcanic activity, for instance, will increase the rate of CO_2 production into the atmosphere, thus favoring temperature rise. Weathering of rocks uses up CO_2 and moves it as dissolved bicarbonate into the oceans, where it is used by organisms to create shells and skeletons of calcium carbonate, thereby sequestering the carbon from the atmosphere and favoring a decrease in atmospheric temperature. Movement of continents that allows for increased plant growth should also remove CO_2 from the atmosphere and favor a decrease in atmospheric temperature.

• Warming Climate

Global temperatures from about 250 million years to 55 million years ago were much warmer than those today. During this time, the temperatures at the equator are estimated to have been 2° to 6° Celsius warmer and those at the north and south poles on the order of 20° to 40° Celsius warmer than those today. Thus, there were no ice fields at the poles and many plants and animals could live further north and south than they can today. For example, dinosaurs could live at high latitudes until they disappeared about 65 million years ago.

The continents formed a supercontinent called Pangaea from 250 to 180 million years ago that extended from the north to the south poles. Then, the continental landmass began to rupture along an oceanic rise, so that what is now North and South America moved to the west and what is now Europe, Asia, and Africa moved to the east. Pangaea was likely dry in the interior, since rain near the coast would have dried the air before it reached the interior. This could have resulted in significant temperature variation in the interior of Pangaea from hot, moist summers to cold, dry winters. The lack of moisture could have kept glaciers from forming in the winter, and the hot summers could have melted most ice at the poles.

Spreading rates from the oceanic rift around 100 million years ago could have moved the continents at more rapid rates than do current plate tectonics. The rapid spreading could have generated much more magma at oceanic rises and subduction zones, producing large amounts of CO_2 and further warming the atmosphere. This process could explain the very high average temperature during this time. In addition, the ocean may have been more able to transport heat to warm the poles and cool the tropics.

• Cooling Climate

The climate began to cool about 55 million years ago. Large continental glaciers formed during some of this time that covered, for instance, what is now Canada and the northern United States. The reasons for this drastic cooling are a matter of debate, but there are several possibilities. Ocean spreading rates may have decreased slowly to the current spreading rates, reducing the amount of CO_2 emitted into the atmosphere and favoring cooling. Another possibility is that the continents may have been uplifted, making more moisture available to produce more rapid chemical weathering of the rocks. This increased weathering would have used more CO_2, as would the consequent increase in carbonate organisms in the oceans, sequestering carbon from the atmosphere and decreasing the greenhouse effect.

• **Context**

Plate tectonics are a function of geological and geothermal processes that bring heat to Earth's surface and that directly and indirectly influence the level of GHGs in the atmosphere. As such, they contribute to increases and decreases in global temperature, although they are not generally thought to be determining factors in climate change, either recent or on geologic timescales.

Pleistocene climate

• **Category:** Climatic events and epochs

During the Pleistocene epoch, major climatic fluctuations, including the advance and retreat of continental glaciers, were influenced by small variations in the amount of solar energy reaching high latitudes in the summer. Determining the details of this influence has major implications for scientists' ability to predict future climate change.

• **Key concepts**

climatic precession: cycle of variations in the Earth-Sun distance at summer solstice

loess: deposits of very fine grained, wind-blown material often associated with glacial deposits

marine isotope stage: half of a glacial cycle, as identified in the oxygen isotope data from ocean cores

orbital eccentricity: cyclically variant deformities in Earth's orbit

Pleistocene epoch: an epoch within the geologic timescale, ending at 11,700 years ago

Pliocene epoch: the epoch preceding the Pleistocene and beginning around 5.332 million years ago

• **Background**

Characterized by repeated cycles of glacial cold and interglacial warmth, Pleistocene climate was always changing. Scientists believe that the timing of these changes was controlled by periodic variations in the orbit of the Earth. They are still trying to figure out how the small changes produced by these variations were amplified into dramatic climatic shifts. Of particular interest is the question of if and when another glacial advance will occur.

• **Climate During the Pleistocene**

Geologists divide up the 4.6 billion years of Earth's history, usually based on the planet's fossil record. The planet's history is divided into eras, which are divided into periods, which are divided into epochs, which are divided into ages. Eras are neatly separated by major mass extinctions, and most of the other divisions are also reasonably clear. However, the division between two period/epoch pairs has proven to be more difficult: The base of the Quaternary period and the base of the Pleistocene epoch are either at the top or the bottom of the Gelasian age.

The ages within both the Pliocene and the Pleistocene epochs are determined by the marine fossils from those epochs, which are not difficult to date. A problem arises, however, from an attempt to put the beginning of the ice ages at the right age boundary. In 1948, at a meeting of the International Union of Geological Sciences, the top of the Gelasian age (1.81 milion years ago) was chosen as the advent of the ice ages. Since then, a tremendous amount of climate-related research has sug-

The unearthed tusks of a Pleistocene-epoch woolly mammoth—approximately twenty-three thousand years old—are tied to a reindeer sled for transport to Khatanga, Siberia. (AP/Wide World Photos)

gested that the bottom of the Gelasian, 2.59 million years ago, might have been a better choice. As often happens, both dates are used. The discrepancy is not signfiicant in the context of climate issues. Because the climate began to behave differently a little before 2.59 million years ago and it did not change much 1.81 million years ago, a description of Pleistocene climate will also apply to Gelasian climate, whether one considers the Gelasian age to be part of the Pleistocene or part of the Pliocene epoch.

Around 2.6 million years ago, the climate began to oscillate between glacial and interglacial states. When only land-based data on glacial advances were available, only a few advances were described, but as the ability to interpret isotope data from ocean cores developed, it was determined that there have been at least fifty advance/retreat cycles in the last 2.6 million years. The shift from continental rocks to ocean sediment cores as the source of definitive data was important in providing this additional data.

The surfaces of the continents, particularly when being scraped repeatedly by large glaciers, do not keep very good archives. In some places, glacial deposits lie on top of other glacial deposits, and those earlier deposits often have complete soil profiles. Geologists thus knew that there had been more than one glacial period, but they had little detailed knowledge about the succession of such periods. Each new advance usually removed any former glacial deposits, obscuring the record. In the deep oceans, however, remains of dead organisms accumulate, and there is little to remove them. As isotope geochemistry developed, it became apparent that the ratio of oxygen 18 (O^{18}) to oxygen 16 (O^{16}) preserved in these remains changed systematically in all of the world's oceans during the last three million years or so. Evaporation removes more O^{16}, and during glaciations will sequester much of this isotope in the ice sheets, thereby enriching the oceans in O^{18}. Fluctuations in the isotope ratio can indicate whether the Earth was in a glacial (high O^{18}/O^{16} level) or interglacial (low O^{18}/O^{16} level) state.

As cores of sediments were retrieved from the ocean floor, changes in the O^{18}/O^{16} ratio as a function of time were observed and analyzed. Shifts were numbered, starting with 1 for the present interglacial and using odd numbers for interglacials and even numbers for glacials. The time period represented by each number is called a marine isotope stage (MIS). Glacial cycles already known from continental evidence correlated with some of the MIS cycles, but there were many more MIS cycles, they were global in nature, and their dates were known more accurately. Terms such as "Illinoian" and "Moscovian Dnieper" were replaced by designations such as "MIS 6."

Using Fourier analysis and other methods, scientists found that some periods of time were very strongly represented in the marine isotope record. These peaks in information seemed to correspond to natural cycles. (Imagine recording the sounds from a neighborhood continuously for a decade and then analyzing them. One might expect to see information peaks at intervals corresponding to the cycles governing human activity: every twenty-four hours, every week, and possibly every year.) The peaks in the sediment cores occurred every forty-one thousand years, about every twenty-two thousand years, and every hundred thousand years.

• Causes

A glacier will grow if snow accumulates over periods of years, as snow that fell during the previous winter does not melt completely during the summer. Thus, summer temperatures are the limiting factor in glaciation. If summers are not warm enough to melt all of winter's ice accumulation, the glaciers will advance. Winter temperatures do not matter to this process, so long as they remain below freezing.

Temperatures on Earth are determined primarily by the Sun, and its influence is modulated by periodic changes in the tilt of the planet's rotational axis, the precession of that axis, and the eccentricity of Earth's orbit. These changes were known by the middle of the nineteenth century, and James Croll suggested in 1864 that they might be responsible for the advance and retreat of continental glaciers. Data, computations, and dating techniques were not yet sufficient to support the theory, however, and interest in it waned until Milutin Milanković resurrected the idea in 1913. He worked on the problem for decades, publishing his completed book in 1941; it was translated into English in 1969.

Milanković was able to calculate how much solar energy would reach a latitude of 65° north during the summer. He obtained this result by combining the effects of a 100,000-year cycle in the eccentricity of the Earth's orbit, a 41,000-year cycle in the inclination of the Earth's axis, and a roughly 22,000-year cycle in climatic precession. Thus, the peaks evident in ocean sediment cores matched precisely Milanković's cycles.

When the ocean core analyses were complete, there was no question that glacial advances and retreats followed the timing of the Milanković cycles. As a result, serious concerns were raised for a time about a coming glacial advance. Some papers written in the 1970's—as well as meetings, symposia, and water cooler discussions—concerned the global cooling that Milanković's work seemed to predict. In part, this was due to a decade-long cooling period in the Northern Hemisphere, but it also stemmed from the recognition that, according to Milanković, the current interglacial should end soon.

Trying to guess when it will end, scientists examined the record. Between 3 million and 0.8 million years ago, the cycles were dominated by the 41,000-year cycle. Afterward, however, a period began that is often called the Mid-Pleistocene Transition, and the cycles became dominated by the 100,000-year cycle. Although many theories have been put forward to explain this transition, it is still not well understood. In addition, it is unknown whether the current interglacial period has been extended by the effects of agriculture and other human activities over the last eight thousand years or whether it would have been longer than average regardless of human behavior.

• Pleistocene Weather

Estimates made from isostatic rebound studies suggest that the continental glaciers at their height during Pleistocene glaciations were 1-2 kilometers thick. The ice moved from north to south, reaching a latitude of 40° north, near the northern boundary of the state of Pennsylvania. Even when the glacier stopped advancing, the ice within it continued to move from north to south, grinding away at the material beneath it. At its southern edge, melting converted the ice to liquid water.

Where the glaciers terminated, the ice rose steeply, with large accumulations of ice adjacent to large lakes and hills. In the summer, this ice must have caused wind and precipitation patterns quite different from those experienced during interglacial periods. All year long, the presence of the glacier is likely to have altered global wind patterns. It was white, cold, and added considerably to the elevation. With so much water tied up in ice, sea level fell by about 100 meters, exposing huge expanses of the continental shelves to weathering and erosion.

• Context

If Earth's climate continues to behave cyclically, as it has for the past 2.6 million years, then another glacial advance will occur in the future, perhaps within a millenium or two. Alternatively, anthropogenic inputs of greenhouse gases may have warmed the planet so much that another glacial advance will only occur after humans stop burning fossil fuels and the resulting emissions have left the atmosphere. A third possibility is that anthropogenic outputs have altered the land so much that continental glaciations are no longer possible.

Clearly, these alternatives represent very different climate change scenarios. Although scientists are confident that Milanković cycles were the pacemakers for Pleistocene climate change, there is little agreement on the mechanisms connecting these pacemakers to the various drivers and amplifiers of the climate system. Nor is there agreement as to why the dominant cycle shifted from one of 41,000 years to one of 100,000 years in the middle of the Pleistocene epoch. As these and other issues become better understood, it may become possible to predict the future with greater confidence.

Otto H. Muller

Poland

- **Category:** Nations and peoples
- **Key facts**

Population: 38,500,696 (July, 2008, estimate)
Area: 312,679 square kilometers
Gross domestic product (GDP): $667.4 billion (purchasing power parity, 2008 estimate)

Greenhouse gas (GHG) emissions in millions of metric tons of carbon dioxide equivalent (CO_2e): 586.9 in 1992; 399.0 in 2005
Kyoto Protocol status: Ratified, December, 2002

• Historical and Political Context

Poland is a central European country located south of the Baltic Sea, between Germany and Ukraine. It has historically been the site of conflict among its neighbors, and has at times ceased to exist, when the entire area of the nation was annexed by other states. In 966, during the kingdom of Mieszko I, Poland accepted Christianity. In 1386, under the Jagiellon dynasty, Poland became an economic power, and that power increased in 1410. The decline of the Polish economy began in 1795 and resulted in the partition of Poland by Prussia, Russia, and Austria.

It took one hundred years for Poland to regain its independence, in 1918. On August 23, 1939, Germany and the Soviet Union signed the Ribbentrop-Molotov nonaggression pact; in this pact, Poland was secretly divided into Nazi- and Soviet-controlled zones. Germany invaded Poland on September 1, 1939, and the Soviets invaded on September 17. Poland became occupied by German troops after June, 1941, when Germany invaded the Soviet Union. The nation regained its independence in 1945, following the Yalta Conference; thereafter, the Polish Provisional Government of National Unity was formed. In January, 1947, elections were held that were controlled by the Communist Party, which established a communist regime.

Poland had became a Soviet satellite state; however, the Polish government was tolerant. In 1980, the independent trade union called Solidarity was formed. Solidarity became a political force, and in 1990 the country transformed its economy into one of the fastest growing in central Europe. Poland, however, was still underdeveloped and had high unemployment rates and poor infrastructure. Poland underwent significant political reorganization, becoming a democratic nation; it joined the North Atlantic Treaty Organization (NATO) in 1999 and the European Union in 2004.

• Impact of Polish Policies on Climate Change

International concerns for the environment and over greenhouse gas (GHG) emissions led environmental scientists—miners, coal processors, electrical and other engineers, economists, and others—to seek ways to save energy and decrease emissions during future development. This work, conducted under the auspices of the United Nations, gave rise to the Kyoto Protocol and new directions in the emission standards. The Kyoto Protocol to the U.N. Framework Convention on Climate Change (UNFCCC), adopted in December, 1997, entered into force in February, 2005. The objective of the protocol was to stabilize the GHG concentration in the atmosphere at a level that would minimize dangerous anthropogenic influence on the climate system. Poland ratified the Kyoto Protocol on December 2, 2002. The target reduction level of Polish GHG emissions is 6 percent in the period from 1988 to 2012.

Directive 2003/87/EC of the European Parliament and Council, issued October 13, 2003, established a scheme for GHG emission allowance trading within the European Community, amending Council Directive 96/61/EC. The directive was transposed into Polish law by the Act on Greenhouse Gas and Other Substances Emission Allowance Trading and eleven other regulations. Under this legislation, Poland is required to perform carbon dioxide (CO_2) monitoring for all installations that are covered by the European Union Emission Trading Scheme. The goal is for all countries to cut

GHG emissions and to find new energy sources to ensure clean, secure energy supplies.

In March, 2005, the European Commission issued a decision regarding Poland's national action plan for CO_2 emission allowances under the E.U. emissions trading scheme. The plan sought to reduce the nation's total CO_2 output by 141.3 million metric tons (16.5 percent) between 2005 and 2007. It was one of the four largest plans devised by European Union nations, covering more than eleven hundred installations.

Concerned to protect the environment, Poland became a member of the Party of Air Pollution, the Antarctic-Environmental Protocol, Antarctic-Marine Living Resources, the Antarctic Seals, and the Antarctic Treaty, as well as international agreements on biodiversity, climate change, desertification, endangered species, environmental modification, hazardous wastes, the United Nations Convention on the Law of the Sea, marine dumping, ozone-layer protection, ship pollution, and wetlands. Poland signed, but as of 2009 had not yet ratified, air pollution treaties governing nitrogen oxides, persistent organic pollutants, and sulfur.

• Poland as a GHG Emitter

Coal-powered plants are major GHG polluters in Poland. In the early twenty-first century, Poland has experienced significant economic growth, and electricity consumption is expected to rise by 80-93 percent by 2025. Therefore, GHG emissions are also expected to increase.

Poland's base-year emissions in 1992 were 586.9 million metric tons of CO_2 equivalent. In 2005, the nation emitted 399.0 million metric tons, and it is projected to emit 420.0 million metric tons in 2010. Under the Kyoto Protocol, Poland's target emissions are 551.7 million metric tons, or 6 percent below the base-year emissions. Poland's emissions were 32 percent below its base-year levels in 1988 and only 0.6 percent above that amount in 2004 and 2005. This decrease was a function of the decline of energy-inefficient heavy industry and of restructuring the economy in the late 1980's and early 1990's. Between 2004 and 2005, emissions from metal production and energy-related emissions from manufacturing and industrial processes decreased. However, the emissions from transportation, household energy use, and services increased.

Emission models predict that Poland will meet its Kyoto targets in almost all sectors, which will stabilize around their 2005 levels. The only major exception is in the transportation sector, where emissions are expected to increase beyond their target before 2012. After 2012, however, Polish GHG emissions will continue to increase. GDP growth in 2008-2012 is expected to be over 6 percent, and emissions between 2010 and 2020 will also increase. By 2020, Poland should emit about 81.6 percent of its base-year emissions.

Based on a United Nations 2004 report, Poland is the twentieth-largest GHG emitter on the world. Poland has reduced its GHG emissions by almost 18 percent since 1990. According to the European Commission, the March, 2007, requirements will cause Polish firms to reduce their emissions from 239 million metric tons to 208.5 million metric tons per year between 2008 and 2012. The cement industry, powered by coal, is one of the largest emitters of GHGs in Poland, accounting for 3 percent of total emissions (1.4 million metric tons of CO_2 equivalent). Poland attempts to trap some of these emissions in underground CO_2 depositional structures.

• Summary and Foresight

During World War II, Poland's economy lost 40 percent of its potential, and 66 percent of its industries were destroyed. Between 1949 and 1955, the People's Republic of Poland was able to begin realizing a six-year recovery plan. The plan changed the socioeconomic structure of Poland, transforming it from an agrarian-industrial country into an industrial-agrarian country. Under the Soviet Union, an economic transformation led to a planning-based economy, with an important focus on industries. Beginning in 1948, Poland started developing heavy industry, following the ideas of Joseph Stalin. Stalinist industrialization brought the acid-making plant Polchem to Torun, the Nowa Huta steelworks near Krakow, and the symbol of Soviet influence, the Palace of Culture, to Warsaw. Environmental protection was not of concern during postwar industrialization.

In 1980, the Ecology Club was established in Krakow, following the green movement in Western

Europe. The Ecology Club responded to environmental problems and abuses, blaming the Soviet Union for the state of Poland's rivers and its poor air quality. New industries emerged; the industrial basis of agriculture was changed, and the nation became increasingly urbanized. The six-year plan created a stable economy that formed the basis for further socialist transformation.

After the fall of communism, the government of Poland became concerned about the environment and sought to develop a responsible environmental policy. In the late 1990's, however, this attitude changed as a result of the relationship between central Europe and the European Union. After the Soviet Union's collapse, Poland found it needed to modernize and increase production to survive, while at the same time holding emissions below the Kyoto limits. After the breakdown of the Eastern Bloc, the country rapidly transformed to a market-based economy with strong growth rates, growing by 44.6 percent between 1990 and 2001. The transition to a well-developed, industrialized country was fostered by Poland's accession to the European Union. The country's main industries became machine building, iron and steel, coal mining, chemicals, shipbuilding, food processing, glass, beverages, and textiles.

Increasing production creates a higher demand for energy and causes an increase in GHG emissions. In 2007, GDP grew by an estimated 6.5 percent, driven by rising private consumption, increasing corporate investment, and the inflow of E.U. funds. Poland has ratified the Kyoto Protocol and must comply with its E.U. National Action Plan commitments. Poland has no nuclear power plants and relies mostly on coal to meet its energy needs. Many of the country's coal-fired power plants have been operated for over thirty years and need to be modernized or decommissioned.

In January, 2005, Poland's Council of Ministers approved a policy document entitled *Energy Policy to 2025*, which included a plan to build a nuclear power plant, to begin operation in 2021 or 2022. Since 1989, the Polish government has restructured the coal industry to make it more efficient, applying improved pollution prevention policies and technologies. In March, 2005, the European Union provisionally accepted Poland's National Allocation Plan, in which Poland reduced annual CO_2 emissions by 47 million metric tons. Poland has already met its Kyoto Protocol targets and reduced CO_2 emissions by 30 percent of their 1988 level.

Polar bears

• **Category:** Animals

• **Definition**

The polar bear has become an icon of global warming. In 1973, the five "polar bear nations" (the United States, Canada, Denmark, Norway, and the former Soviet Union) agreed to limit polar bear hunting to the Inuit and other native peoples. The bear population recovered, only to face a new threat: global climate change.

Changes in sea ice, permafrost, and prey species in the Arctic and subarctic are linked to reduced body condition and smaller litter size in polar bears. In western Hudson Bay, long-term studies conducted by wildlife biologist Ian Stirling of the Canadian Wildlife Service and his colleagues document climate warming and a significant reduction in the amount, location, and persistence of sea ice adjacent to the shore. The polar bear is heavily dependent on the ringed seal as a food source. Its usual hunting technique requires sea ice. A bear will locate the breathing hole of a seal and then ambush the animal when it comes up for air or will prey upon young seals in their dens. As sea ice diminishes, bears are less able to catch their prey.

A polar bear emerges from the Arctic sea among a group of ice floes. (©Dreamstime.com/Outdoorsman)

Hungry polar bears waiting on shore for sea ice to form have become a problem, invading northern villages and encountering native hunters. At one time, this increase in sightings was interpreted as evidence of increasing numbers and used to justify higher quotas for the taking of polar bears.

• Significance for Climate Change

A series of studies requested by U.S. secretary of the interior Dirk Kempthorne, coordinated by the United States Geological Survey, and released on September 7, 2007, predicted that two-thirds of polar bears would perish by the year 2050. All polar bears in Alaska would be gone. The studies—conducted by American and Canadian scientists—used conservative assumptions to project loss of sea ice due to global warming. At the time of the studies, there were an estimated twenty thousand to twenty-five thousand polar bears worldwide.

Because the polar bear, *Ursus maritimus,* is thought to have evolved from the brown bear, *Ursus arctos,* 200,000 years ago, some have suggested that the polar bear might reverse course and adapt to and live in the terrestrial ecological niche now occupied by the brown bear. Brown bears are primarily vegetarian, whereas polar bears are primarily carnivorous. Brown bear claws are adapted for digging, polar bear claws for grabbing and holding prey. Polar bears are slow to reproduce, and it is unlikely that they could change both their behavior and their physical characteristics quickly enough to cope with disappearing sea ice. Sea ice is central to the life of a polar bear. It provides habitat to prey animals and hunting, mating, and denning sites for the bears themselves. In western Hudson Bay, polar bears gather on the shore each year to wait for sea ice to form.

While polar bears and their response to global warming have been studied longer and in greater depth than has any other Arctic species, they are far from the only animal affected by a changing climate. Gray whales migrating south to their breeding grounds off the coast of Mexico have recently appeared to be emaciated, suggesting a shortage of their normal diet of tube worms and amphipods in their summer feeding grounds of the Bering and Chukchi Seas.

Other marine animals that are affected by the loss of sea ice and climate warming in the Arctic include ringed seals, bearded seals, ribbon seals, sea lions, walruses, narwhals, fish, and many sea birds. Biologists have only begun to study how these creatures will respond to the profound changes in their habitat. Polar bears—known to eat dead whales washed up on the shore as well as other carrion—might benefit temporarily from the die-off of marine animals, but will suffer eventually as their prey species are reduced.

On May 14, 2008, Secretary Kempthorne announced the listing of the polar bear as threatened under the provisions of the Endangered Species Act. This designation is one step down from that of endangered species and offers less protection from human activities. Kempthorne made clear that the Department of the Interior would not allow the polar bear's plight to be used to justify limits on greenhouse gases (GHGs) saying: "When the Endangered Species Act was adopted in 1973, I don't think terms like 'climate change' were part of our vernacular." The act, he said, "is not the instrument that's going to be effective" to deal with climate change.

Images of polar bears have been used by conservation groups to advocate reductions in GHGs in hopes of slowing and perhaps reversing global warming and also in fund-raising by these groups. Global warming skeptics complain that such images appeal to emotion and not to reason and demand further proof that a warming climate will result in great reduction and even extinction of polar bear populations by mid-century.

Polar climate

- **Category:** Arctic and Antarctic

- **Definition**

Polar climate is characterized by year-round cold conditions, tundra or ice cap, and permafrost. At Earth's south pole is Antarctica, 95 percent of which is covered in ice. Temperatures on the continent range from 0° Celsius to −70° Celsius. At Earth's north pole is the Arctic tundra, as well as treeless vegetation zones. The tundra is bordered on the south by forests and on the north by the Arctic lands and has a layer of permafrost. The Arctic is characterized by short, cool summers and long, cold winters. Arctic high temperatures range from 0° Celsius in Russia to 12.2° Celsius in Alaska; lows range from −16.3° Celsius in Canada to −28.1° Celsius at the highest point of Greenland's ice sheet.

Permafrost is a permanently frozen soil layer under the topsoil. The top layer, or active layer, melts and refreezes each year, while the lower level stays frozen year-round. The active layer provides water and a place for plants to grow. The temperature in the lower levels is at or below 0° Celsius, and usually ranges from −6° to −9° Celsius. One-fourth of the land in the Northern Hemisphere is in permafrost zones, and almost all of the permafrost areas in the Southern Hemisphere are in Antarctica.

At Law Dome Camp, in Antarctica, scientists study the polar climate and monitor any changes in it. (AFP/Getty Images)

• **Significance for Climate Change**

Although the ice sheet is not expected to melt completely in the near future, the Antarctic is warming ten times faster than the average anywhere else in the world. Since the mid-1940's, the average temperature is −16° Celsius warmer year-round and −13° to −14° Celsius warmer in early winter. The far western edges and ground are becoming warmer, and the ice sheet edge is rapidly eroding. The amount of sea ice was stable from 1840 to 1950, but has decreased since then by roughly 20 percent.

The icebergs are shrinking, glaciers are receding, and the immense Larsen Ice Shelf began disintegrating in 1995. Nearly 2,590 square kilometers of the ice shelf collapsed between 1998 and 2000. The breakups of ice chunks lead to the faster flow of ice from the glaciers upstream, which in turn can increase the sea level over time. With the edges of the ice sheet melting, the wildlife populations are fluctuating. Adelie penguins are dying off, because they cannot adjust to the changes in their environment. Meanwhile, other species are migrating south and establishing colonies. Scientists have observed the southern migration of elephant and fur seals, as well as other species of penguins. Additionally, low grasses, mosses, and tiny shrubs are thickening in several areas.

Climate changes are more dramatic in the Arctic. The Arctic is ringed by the lands of Canada, Denmark (through Greenland), Finland, Iceland, Norway, Russia, Sweden, and the United States. Sea ice remains over the entire Arctic Ocean and parts of nearby waters every winter. This sea ice provides a home for polar bears and transportation routes for people, and shields coastal towns and underwater creatures. Normally, the ice melts on land in the summer and breaks up some in the Arctic Ocean, but there was 80 percent less ice in 2005 than in the 1970's, with more rapid melting since 2003. Scientific data suggest that the Arctic Ocean may be ice-free in the summer as early as the 2030's, which has not happened in at least 800,000 years. A rise in ice sheet melting raises the sea level, and even a 1-2 millimeter rise increases flooding at the coastlines.

Summertime temperatures in parts of the Arctic are warmer than those recorded in the last four hundred years, and winter temperatures have increased by 2° to 4° Celsius since 1976. The Arctic cools the Earth, because it reflects more solar radiation than it absorbs, with ice and snow the most reflective, followed by tundra vegetation. The warmer temperatures have led to unpredictable weather patterns that threaten the delicate natural balance of the environment and endangered the plants and animals, as well as the humans who depend on them. The ice sheets near the coastline are smaller or nonexistent, which greatly affects subsistence whalers and seal hunters and subjects the coastline to damaging waves. Several coastal Alaskan villages have had to relocate inland and others are threatened because of coastal erosion.

When the lower layers of permafrost thaw, they can create an underground lake which may drain off, leaving a cavity. The surface will then slump inward, causing trees, roads, and buildings to slowly fall in. This melting has already happened in Siberia and Fairbanks, Alaska, where the permafrost is at the warmest levels since the last ice age. The sinkholes are patchy so far and usually occur where digging and construction opened up the landscape. Thawing permafrost can also cause the sea levels to rise slowly and, because it traps large amounts of carbon, melting permafrost releases the carbon back into the atmosphere as methane, a greenhouse gas.

Polar stratospheric clouds

• **Category:** Meteorology and atmospheric sciences

• Definition

Polar stratospheric clouds (referred to as "PSCs" by scientists and called nacreous clouds by the general public) form in the lower stratosphere between heights of 15 kilometers and 25 kilometers in the lee of high-latitude mountain ranges in winter. Ice crystals and particles composing the visible cloud are of uniform size, about 10 micrometers in diameter. After sunset, light from the Sun below the horizon continues to illuminate particles within PSCs, producing iridescent bright red and blue coloration zones in the clouds. Colorful PSC displays are most frequently photographed before dawn and after sunset when they appear in Oslo, Norway, but photographs and videotapes have also been taken in Scotland, England, Scandinavia, Iceland, Alaska, and Antarctica.

Atmospheric scientists have divided PSCs into two "Types" as defined by chemical and thermal differences. Type I PSCs have temperatures of about −78° Celsius. Type I(a) PSCs contain crystalline compounds of water and nitric acid; Type I(b) PSCs contain droplets of nitric (HNO_3) and sulfuric (H_2SO_4) acids; Type I(c) PSCs contain nonspherical particles of metastable nitric acid in water; and Type II PSCs are composed of water ice crystals at temperatures of −85° Celsius.

• Significance for Climate Change

Discovery of the formation of the ozone hole in the stratosphere above the Antarctic continent each spring focused scientific attention on chemical reactions depleting ozone. Scientists deduced that ultraviolet light from the rising Sun promoted chemical reactions leading to ozone destruction, and investigations linked chemical reactions going on within the PSCs to regional ozone depletion above the Antarctic.

Particles within Antarctic PSCs act as catalytic surfaces for reactions involving the destruction of relatively stable atmospheric chlorine compounds (including artificial chlorofluorocarbons sometimes called Freons). Through a series of reactions, these chlorine compounds are transformed into highly reactive molecular chlorine gas ($C1_2$) and hypochlorous acid (HCl) molecules, which rapidly form chlorine radicals, which in turn destroy ozone molecules. During winter and early spring, there is a strong easterly flow of air in the Antarctic stratosphere, the Antarctic Polar Vortex. Little air from lower latitudes mixes with the ozone-depleted air within the vortex, allowing greater depletion of ozone to occur, creating the ozone hole.

PSCs also catalyze other important chemical reactions, including denoxification, the conversion of oxides of nitrogen to nitric acid, which is found in all three Type I PSCs. Because decreasing the level of nitric oxide (NO_2) allows high levels of ozone-removing hypochlorite (ClO) to remain in the stratosphere, this denoxification promotes development of the ozone hole. Denoxification leaves the waste product nitric acid behind in the cloud particles, which eventually exits the stratosphere, a process called denitrification.

Polar vortex

- **Category:** Meteorology and atmospheric sciences

- **Definition**

When circulating, or spinning, liquids or gases occupy a region of space, scientists call that pattern of motion a vortex. A vortex can occur in a bathtub, in a kitchen sink, or in the atmosphere. When it takes place near the poles, it is called a polar vortex.

Polar vortices are so large that they surround the polar heights and often straddle the troposphere and the stratosphere. Their strength varies with the seasons; they are strongest in winter, reaching speeds of 100 meters per second, and they are weakest, or even nonexistent, in summer. Polar vortices have been observed on Jupiter, Mars, Saturn, and Venus.

pgas) that is inside them and prevent it from escaping through the sides. When the temperature drops below a certain critical value (about –80° Celsius), special clouds called polar stratospheric clouds (PSCs) form inside the vortex. Unlike ordinary clouds near the surface of the Earth, PSCs contain water-ice droplets mixed with a variety of other particles, and the chemical interactions among them are extremely sensitive to changes in temperature.

- **Significance for Climate Change**

Factories and homes produce chemicals known collectively as chlorofluorocarbons (CFCs). When CFCs are released into the atmosphere, they interact with sunlight and form chlorine compounds such as hydrochloric acid (HCl) and chlorine nitrate ($ClONO_2$). Ozone, which absorbs harmful ultraviolet radiation from the Sun, is found in a thin layer of the upper atmosphere called the ozone layer. Chlorine compounds in the atmosphere combine with each other, with water, and with other chemicals to create products that attack ozone. Scientists now know that the key chemical reactions that create these products only occur on the surface of PSCs. There is evidence that they cannot take place elsewhere in Earth's atmosphere.

Greenhouse gases (GHGs), which include CFCs, enhance the depletion of the ozone layer. While they cause atmospheric warming near the Earth's surface, GHGs actually cool the stratosphere, where ozone resides; since the chemistry of the ozone layer is very sensitive to temperature, even very small decreases in the temperature of the stratosphere increase the loss of ozone.

Scientists have observed a statistical correlation between the cycles of the polar vortex and the weather: Severe cold weather in the Northern Hemisphere correlates well with a weak polar vortex. Similarly, when that vortex is strong, weather in the Northern Hemisphere turns warm.

Pollen analysis

• **Categories:** Science and technology; plants and vegetation

• **Definition**

Pollen grains are produced by seed plants (gymnosperms and angiosperms), and they range in size from 10 to 100 microns. They contain undeveloped male gametophytes that are surrounded by a complex protective wall. Depending on the species that produces it, the pollen may or may not yet contain sperm. Most insect-pollinated plants produce small quantities of pollen because insects are efficient dispersers of pollen, so relatively little is wasted or released into the air. On the other hand, wind-pollinated plants produce large quantities of pollen because of the low probability that any given grain will land on another flower.

Many forest trees (including pines, oaks, and maples) and prairie plants (including grasses, ragweed, and sage) are wind pollinated, so most of their pollen is dispersed over some distances. In fact, much wind-blown pollen ends up in oceans, lakes, swamps, mangroves, or peat lands, and it accumulates with other deposits, layer by layer, year after year. As a result, the profile of pollen in sediments represents the types of vegetation in the surrounding areas at a given point in time and the proportion of each type of pollen is directly related to the relative abundance of its associated species.

• **Significance for Climate Change**

Pollen preserves best if its sedimentary environment lacks oxygen or is acidic, conditions that are unfavorable for decomposing organisms. If the sediments remain moist, pollen can be preserved for thousands or even millions of years. Using fossilized pollen, scientists can reconstruct changes in vegetation over thousands of years and determine when and how rapidly these changes occurred. Since vegetation is sensitive to climate change, a comparison of fossil pollen profiles with modern climate patterns has allowed scientists to reconstruct past climates. The term "pollen analysis" also includes the study of spores. Spores are produced by non-seed plants such as bryophytes and pteridophytes, but they have been included in the discipline of pollen analysis for the sake of convenience.

Pollen analysts concentrate on pollen walls, which are made up of two major layers. The outer layer, or exine, is subdivided into the ectexine and endexine, while the inner layer is referred to as the intine. The ectexine is composed primarily of sporopollenin, which is the most decay- and chemical-resistant biopolymer in nature. The endexine and intine are composed of proteins, callose, pectins, and cellulose and are easily degraded by microorganisms and chemicals. Since the structures of ectexines have not changed for thousands of years and they usually appear consistent within a genus or family, they are most useful in the identification of the plants that produced them. Some criteria used in identifying pollen include the presence or absence of apertures, type of apertures (pores or furrows), number of apertures, and surface ornamentations (spines, ridges, bumps, or striations).

To identify and analyze the sequences of fossilized pollen from lake sediments, most scientists obtain cores of sediments using a square-rod piston corer, a device that consists of a meter-long tube fitted with a piston. Several cores from various spots are obtained from a study area, and subsamples are taken at regular intervals along a core. The sediments of virtually any substrate will contain abundant fossil pollen. In fact, a cubic centimeter of lake sediment will typically contain tens or hundreds of thousands of pollen grains. However, since pollen is a very small portion of the sediments, these grains must be concentrated prior to analysis.

Pollen from peats and other substrates presents a particular problem, because contaminating organic materials from other sedementary materials are likely to be present. Therefore, core samples are passed through a series of sieves and washes designed to isolate the pollen. Humic materials are removed with potassium hydroxide. Carbonates are removed with hydrochloric acid. Silicates are dissolved with hydrofluoric acid. Cellulose is removed with a mixture of sulfuric acid and acetic anhydride. After this series of treatments, most of what remains is pollen. The ability of the pollen wall, specifically the ectexine, to resist strong organic acids and alkaline substances makes this concentration process possible.

The purified and concentrated pollen is mixed with immersion oil and mounted on a glass slide for microscopic analysis. Hundreds of pollen grains are counted from each subsample from a core. The variety of pollen types and quantity of each type are determined. Surface ornamentations and other pollen wall features are used to identify the associated plants. Fossilized pollen grains are also subjected to relative dating techniques to estimate their age. Radiocarbon dating is one such technique. It uses the naturally occurring radioisotope carbon 14 (C^{14}) to establish the age of organic remains up to about fifty thousand years. Plants and animals incorporate a quantity of C^{14} into their tissues in about the same proportion as that in the atmosphere. When these organisms die, the C^{14} decays at a fixed exponential rate. A comparison of the remaining C^{14} from a sample to that expected from atmospheric C^{14} allows scientists to determine the age of the sample.

Pollen analysis is used in Quaternary studies, such as paleoecology, paleoclimatology, paleogeography, and archaeology. By analyzing fossilized pollen from a broad geographic region, scientists can document changing patterns of vegetation over time and migration of individual taxa. At the largest spatial scale, pollen analysis has been used to reconstruct past climatic and environmental changes, as well as changes in biomes. These data have strengthened predictions of how vegetation is likely to respond to future climatic and environmental conditions. When taken together, all this information provides an indication of the future of agriculture and silviculture.

Polluter pays principle

• **Categories:** Pollution and waste; ethics, human rights, and social justice; laws, treaties, and protocols

• Definition

The polluter pays principle is a moral and sometimes legal principle in which the cost of curtailing and remediating environmental damages is assessed against those who have (knowingly or not) engaged in environmentally destructive actions. Legally, the polluter pays principle is an application of the doctrine of strict liability. This stands in contrast with remediation approaches in which a governmental entity remediates, or subsidizes remediation of, an environmental harm using tax revenues.

The polluter pays principle likely has ancient roots, as it is simply an aspect of personal responsibility applied to damages done to the environment and to others affected by environmental damage. Plato constructed one version of the principle involving water pollution in his *Nomoi* (*Laws*, 1804) codified from 428 to 348 B.C.E.:

> And let this be the law—if any one intentionally pollutes the water of another, whether the water of a spring, or collected in reservoirs, either by poisonous substances, or by digging or by theft, let the injured party bring the cause before the wardens of the city, and claim in writing the value of the loss; if the accused be found guilty of injuring the water by deleterious substances, let him not only pay damages, but purify the stream or the cistern which contains the water, in such manner as the laws of the interpreters order the purification to be made by the offender in each case.

Somewhat more recently, the Organization of Economic Cooperation and Development (OECD) enshrined the polluter pays principle in its 1972 Guiding Principles Concerning International Economic Aspects of Environmental Policies. In its original form, the modern polluter pays principle called only for polluters to bear the cost of instituting control measures, not of remediating existing damages. The principle gradually expanded after 1972 to place on polluters not only the costs of pollution controls but also the costs of remediating past pollution and of compensating those damaged by previous polluting behavior. This has led some to describe the current version as the "extended polluter pays principle."

• Significance for Climate Change

The polluter pays principle is either explicitly endorsed or referenced in a broad swath of international agreements, including the Convention on the Protection of the Marine Environment of the Baltic Sea Area; the International Convention on Oil Pollution Preparedness, Response, and Cooperation; the Agreement on the European Economic Area; the Protocol on Water and Health; the Declaration on Environment and Development (the Rio Declaration); and others. It is also considered an element of sustainable development, as that concept has evolved from its beginnings in the Brundtland Report. The polluter pays principle is also recognized in the preamble of the Canadian Environmental Protection Act.

The polluter pays principle is applied haphazardly in U.S. environmental regulations, and the principle is a far less widely recognized element of U.S. policy. The most prominent application of the polluter pays principle in the United States is as part of Superfund, a massive governmental effort to clean up hazardous waste sites. But even when, as in Superfund, the underlying law is strict, the polluter pays principle is more jargon than reality: Costs are not assessed based on a polluter's contribution to the problem, but on the ability of any polluter to pay, regardless of the damages they caused.

Several challenges have been raised with regard to the polluter pays principle. For example, it has been argued that those in lower economic brackets cannot always afford to remedy harms done in the course of fulfilling their basic needs. In places where older vehicle emissions contribute the majority of an air pollutant to a given region, applying the polluter pays principle would place the cost of avoidance and mitigation on those who cannot afford to pay. A related challenge is assessing the costs of pollution control and remediation on economically marginal (but socially beneficial) businesses that cannot pass on costs without losing economic competitiveness.

Still another challenge to the polluter pays principle is ensuring economic efficiency: Determinations of harm are often the result of judgments by juries, rather than hard forensic evidence. Subjective social values are also a part of this process that has often led to settlements in which the polluter pays substantially more than the true cost of damages inflicted by a polluting activity.

The involvement of the polluter pays principle in climate change policy debate is complex and inconsistent. At the global level, many governmental and nongovernmental organizations assert that the principle dictates that developed countries should pay to reduce their greenhouse gas (GHG) emissions and mitigate harms to developing countries before those countries should have to essay GHG controls of their own. Some governments, such as that of the United States, reject this application of the principle, asserting that the economic costs would be unsustainable. They argue from a long-term perspective that the principle would lead to an undue burden of controls falling on the countries that became significant polluters first, rather than on the countries that are the most significant polluters in the present.

Popular culture

• **Category:** Popular culture and society

Popular and scientific conceptions of global warming have often diverged. Popular portrayals of global warming have been shaped by political agendas, commercial interests of both fiction and nonfiction content producers (including the news media), and incomplete understandings based on fragmentary data. These popular potrayals and viewpoints have influenced political rhetoric and action, including some legislative initiatives.

• Key concepts

greenwashing: the exploitation and appropriation of environmental concerns and issues by corporations, government agencies, and political operatives to advance self-interested agendas

masscult: the dominant, mainstream culture as disseminated by the mass media

noble savage: an idea popularized during the eighteenth century Enlightenment that stressed the purity of early human beings and nature untainted by modern technology

• Background

A popular ecological mind-set was put into place by such pioneering 1960's best sellers as Rachel Carson's *Silent Spring* (1962), although the mind-set's ideological roots could be said to go back much further, to the Enlightenment and Romantic movements of the eighteenth and early nineteenth centuries. A tradition developed out of these movements that portrayed a split between nature and culture in which nature was seen as pure and benevolent, while human intervention was corrupting and destructive. This tradition was refined by the environmental movements of the late 1960's, blossoming into the green movements of the late twentieth century.

These movements entailed, among other things, alterations in attitudes toward and definitions of progress that called for people significantly to alter their lifestyles. The new valuations developed by the green movement were reminiscent of Enlightenment ideals relating to the figure of the noble savage and natural law. This image of an unsullied natural world jeopardized by misguided human intrusion proved to be a seductive vehicle, one with tremendous potential for commercial exploitation, not the least by the film industry. One avenue for its exploitation has been anxieties about global warming and climate change.

• Nightmare Scenarios

The popular concept that links global warming and climate change to potential worldwide disaster has played out most strongly in the film medium. In *Waterworld* (1995), a future Earth is depicted as covered almost entirely by ocean after a catastrophic melting of the polar ice caps. The film's protagonist struggles violently in his drearily boring aquatic environment to find a mythical thing called "land." The film ends with his success, as a colony is established on a piece of dry land (indicated, in some of the more complete versions of the film, to be the tip of Mount Everest), to begin civilization afresh.

Waterworld illustrates the nearly universal popular conception of global warming as a potentially disastrous problem, holding dire consequences for future generations. The scenario's likelihood is seriously questioned from scientific quarters. A total ice cap meltdown to the extent that all land is inundated except for part of Mount Everest surpasses all but the direst of environmental claims. Fiction films tend to modify fact based on their genre conventions and on the requirements of a visual medium. Narrative and spectacle are more important to film makers than is verifiable science.

It was the blockbuster film *The Day After Tomorrow* (2004) that fully defined the masscult image of the possible consequences of anthropogenic climate change. That film depicts a sudden worldwide disaster, brought on by abrupt melting of polar ice. Floods strike much of the world, as tidal waves are portrayed sweeping over downtown Manhattan. In addition, massive hurricanes and tornados are generated, and an ice age rapidly develops across the Northern Hemisphere. Here again, the film's scenario is extremely improbable, as it is generated by the requirements of blockbuster disaster films rather than scientific meteorological knowledge.

Kevin Costner waves to the German press while standing in front of a poster for his film Waterworld. *The film portrays an Earth completely covered in water after the melting of the polar ice caps.* (AP/Wide World Photos)

• Noncinematic Popular Culture

Commercials and advertisements have played upon environmental themes by advertising their products as being environmentally friendly. This is particularly true of automobile producers and dealers who market their motor vehicles as being fuel efficient and therefore ecologically responsible. Consumers are encouraged by marketing campaigns to "buy green," thereby limiting their impacts on the environment. Consumers who value environmentalism thus pay not only for the product but also for the feeling of socially constructive engagement that accompanies their purchases. So prevalent did commercial exploitation of conservationism become that in 1986 conservationist Jay Westerveld introduced the term "greenwashing" to denote this phenomenon.

Global warming is just one of many issues that the mass media has been accused of sensationalistically manipulating for profit. The media are too diverse to be encompassed by simple blanket statements, but one general assumption appears to be that scientific facts are sometimes moderated or overlooked for the sake of headlines. Media content is often driven by a cycle of crises, because such cycles have proven commercially desirable. As a result, newpapers and television news tend to convert stories into disaster stories whenever possible.

Popular interest is always maintained by a good, keen rivalry, especially when high-profile individuals pit themselves against one another over emotionally charged topics. Thus, when notables such as former vice president Al Gore—author of *An Inconvenient Truth* (2006) and *The Assault on Reason* (2007)—and celebrity author Michael Crichton—author of *State of Fear* (2004)—added their literary polemics to the debates on global warming, they increased the market for such polemics, causing many lesser-known authors to take sides as well.

• Myth and Half-Truths

Though most scientists accept the likelihood of some anthropogenic global warming associated with greenhouse gas emissions, they differ widely on both its extent and its probable results. The most glaring discrepancy between popular representations and the scientific consensus centers on the notion of sudden, cataclysmic change. The ecological armageddon exemplified in *The Day After Tomorrow* and other disaster films and novels is a lucrative scenario but one with very slight basis in scientific fact. Rapid global deterioration resulting from melting polar ice caps and sudden climatic shifts are considered unlikely. Theories of gradual climate change are far more widely embraced, as even "abrupt" changes in the context of Earth's climate usually take decades to occur. Such gradual changes, however, do not fit the conventions of disaster films.

Three popular suppositions have most frequently come under challenge. First, polar melting is unlikely to occasion a sudden and extreme rise in sea level causing massive inundation and loss of life. Far more likely is a rise in sea level of around 40 centimeters, impacting coastal areas and possibly forcing gradual relocation and resettlement. Second, temperature change is often portrayed as far more abrupt than it is likely to be. The most widely accepted scientific scenario views vast areas encompassing most of Africa, South America, the continental United States, southern Canada, southern Europe, and Asia from Siberia to the Himalayas becoming drier. At the same time, the Caribbean, Mexico, the southeastern United States, northern Europe, India, southern China, Japan, and Southeast Asia would become wetter. Neither change would result in the nearly instantaneous transformation of savanna to desert portrayed in some works of science fiction.

• Context

It remains to be seen how popular representations of global warming might meet and mesh with scientific consensus or whether the divide between the two will narrow. Looked upon from a more positive perspective, one might foresee that the differing views could continue to generate greater debate, maintain heightened interest, and in time lead to genuine efforts aimed at addressing real problems, while avoiding the extremes of either position.

Population growth

• **Category:** Environmentalism, conservation, and ecosystems

The world's human population is rapidly approaching seven billion. Human beings have increased the concentration of GHGs in Earth's atmosphere via many processes, including agricultural practices and the burning of fossil fuels. The sheer size and growth rate of the human population is a fundamental driver of global change, including global warming.

• Key concepts

agricultural revolution: the advent of human domestication and cultivation of plants and animals about ten thousand years ago

Green Revolution: a dramatic increase in global food production brought about by the development of new strains of wheat, rice, and corn around 1960

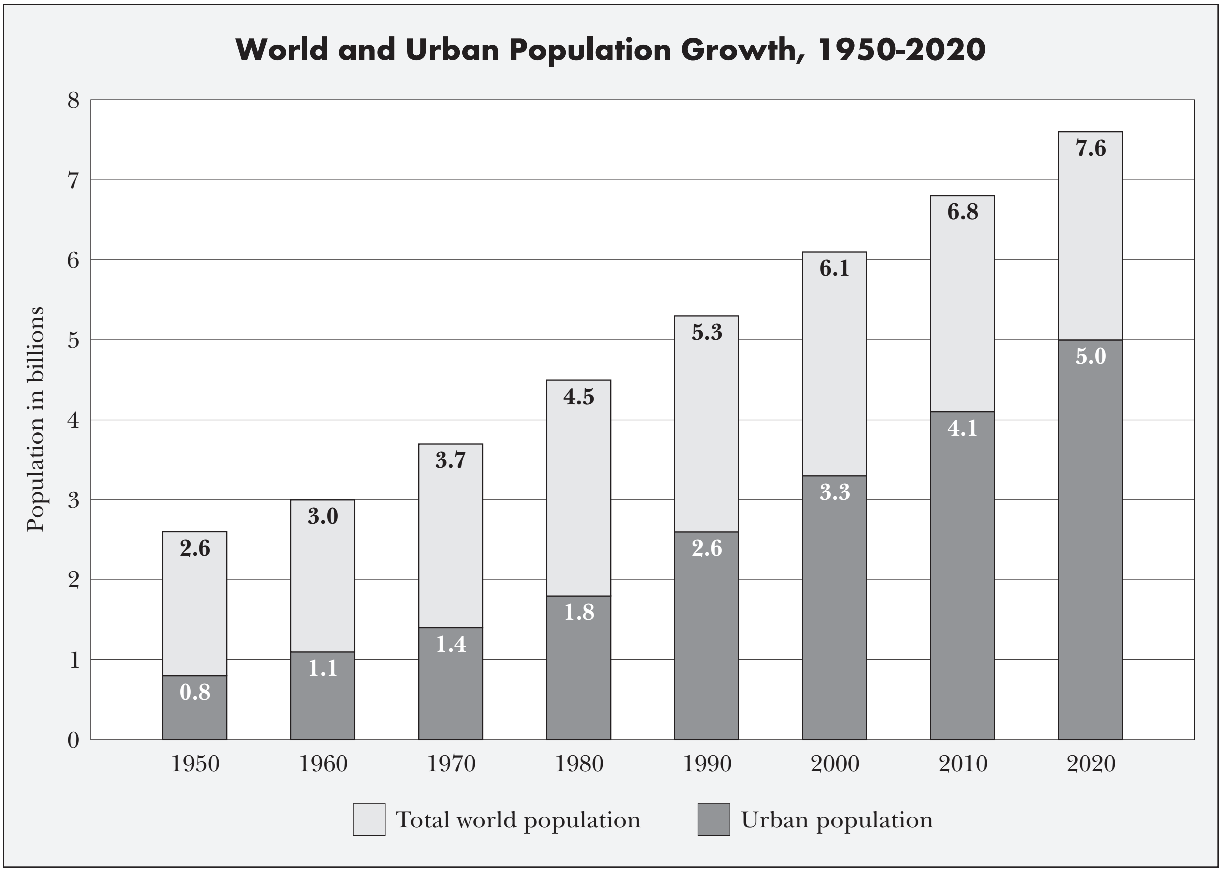
human population growth rate: the percentage by which a given population increases annually

Industrial Revolution: the eighteenth and nineteenth century mechanization of mining, manufacturing, and agriculture that transformed national economies

urbanization: the process of spatial concentration of the human population in cities

• Background

The human population is a fundamental driving force of climate change. Human activities ranging from agricultural practices to the burning of fossil fuels contribute greenhouse gases (GHGs) to the atmosphere. Both the number and the behavior of human beings are basic drivers of climate change.



In terms of numbers only, in the early twenty-first century, the global human population increased by about 200,000 people per day.

• History of Population Growth

Hominids that painted cave walls (*Homo erectus*) appeared almost one million years ago. By 8000 B.C.E., modern humans (*Homo sapiens*) numbered around 8 million. The first 990,000 years of human existence were characterized by a very low population growth rate (15 persons per million per year). The pro-natal fertility beliefs of early humans (whether conscious, unconscious, or instinctive) were undoubtedly necessary to maintain the tenuous presence of humanity on the face of the Earth. Pro-natal fertility beliefs served humanity well for 990,000 years, which perhaps explains why they continue.

Historical estimates of the Earth's total population are problematic. Nonetheless, there is little argument that human numbers have increased dramatically in the past three hundred years. The conventional wisdom regarding the dramatic changes in the growth rate of the human population typically attributes them to three significant epochs of human cultural evolution: the agricultural, industrial, and green revolutions.

• Agricultural, Industrial, and Green Revolutions

Prior to the agricultural revolution, the human population was probably less than ten million individuals, who survived primarily by hunting and gathering. With the domestication of plant and animal species about ten thousand years ago, the human population experienced an increase in its growth rate. Jared Diamond's book *Guns, Germs, and Steel* (1997) suggests that the geographic endowments of domesticable plants and animals, climate, and other environmental variables have had a profound influence on the fate of human societies, including their ability to engage in agricultural innovation. By about 5000 B.C.E., food production gains caused by the agricultural revolution enabled the planet to support about 50 million individuals.

For the next several thousand years, population continued to grow at a rate of about 0.03 percent per year. By the year 0, the population numbered about 300 million. Through the Roman Empire and the Middle Ages (0-1300 C.E.), the rate of population growth began to increase slightly because of colonization and agricultural expansion. However, there is evidence from this period to suggest that the size of the population was actively controlled by factors such as disease, famine, and war for short periods of time.

At the end of the Middle Ages, the human population numbered about 400 million. As people became more concentrated in denser urban environments, the effects of disease increased. Starting in 1348 and continuing to 1650, the human population was subjected to massive declines caused by the effects of the bubonic plague. At its peak in about 1400, the Black Death may have killed 25 percent of Europe's population in just over fifty years. However, by the end of the last great plague in 1650, the human population numbered 600 million, and this expansion may have been the outcome of the introduction of new species for agricultural cultivation. Agricultural cultivation expands with human population and produces climate change both by increasing GHG emissions and by deforesting and desertifying the surface of the Earth.

The Industrial Revolution began sometime between 1650 and 1750. In the period following 1700, the human population expanded at an accelerating rate. In just under three hundred years, the population of the Earth went from 500 million to well over 5 billion individuals, and the annual rate of increase went from 0.1 percent to 1.8 percent. It is believed the global population growth rate peaked at around 2.1 percent in the early 1970's.

A third revolution occurred sometime in the 1960's. The development of various vaccines and antibiotics in the twentieth century and the spread of their use to most of the world after World War II caused dramatic reductions in the crude death rate. This resulted in increased population growth rates. The third revolution is often called the Green Revolution because of the technology used to increase crop yields. The Green Revolution was really a combination of improvements in health care, medicine, and sanitation, in addition to an increase in the production of food.

• Context

The last few hundred years of human history was also a time of change in the human demographics. During this period, the concentration of industry in urban areas and the efficiency gains of modern agricultural machinery caused large numbers of individuals to move from rural areas to cities to find jobs. From 1900 to the present, the percentage of people living in cities went from 14 percent to about 50 percent. Demographers estimate that by the year 2025 more than 60 percent of the Earth's human population will be living in cities. Scientists estimate that the human population will continue to increase until the year 2050, at which time it will level out at between 8 and 15 billion. In this projection, it is assumed that 90 percent of this growth will take place in the developing world.

Every human being contributes GHGs to the atmosphere because of their food, shelter, and transportation needs. Increasing human numbers means increasing GHGs in the atmosphere. As the world's inhabitants have increased in wealth, GHG emissions have also increased. Increasing wealth historically has been related with increasing energy consumption per capita for housing, transportation, and agriculture. The significance of myriad environmental impacts associated with the size, growth, and spatial distribution of the human population should not be underestimated.

Portfolio analysis

• **Category:** Economics, industries, and products

• **Definition**

Around 2001, reports and publications about climate change began referring to a broad or diverse portfolio of policies, approaches, or technologies for coping with climate change. Working Group III of the Intergovernmental Panel on Climate Change (IPCC) issued a 2001 report listing portfolio theory as a potential tool of analysis. This report's description of portfolio theory highlighted the weighing of options by their risks and expected returns, consideration of budget, and arrival at a portfolio of options providing the highest anticipated returns for the lowest level of risk.

In the early 1970's, when large companies were acquiring unrelated businesses and becoming conglomerates, Barry Hedley and the Boston Consulting Group (BCG) developed the business portfolio concept as a planning framework. A parent company's managers could examine their various businesses, which might vary widely in performance and market share, in light of the company's overall resources. In portfolio analysis, managers view the company as a portfolio of businesses and select strategies for each business that fit the business's position in the growth-share matrix, as well as the overall needs of the company.

• **Significance for Climate Change**

The 2007 IPCC Working Group III report, "Mitigation of Climate Change," includes numerous references to both portfolio analysis and portfolios of policies. Gary Yohe, an economics professor at Wesleyan University and a lead author of the 2007 report, has written that his research strongly supports a portfolio approach. The portfolio's components should include adaptation measures (whose benefits would be immediate but would gradually decline); mitigation techniques (which would grow in importance as climate change has greater impact); and research and development (to create green technologies that will increase mitigation's efficiency).

This decision-making approach, unlike some others, takes market risk into consideration, weighing actions that will help businesses diversify their investments against risk. For example, it considers the interrelationships of the costs of different energy sources. This allows a diverse portfolio that contains large amounts of wind, solar, geothermal, and other nonfossil fuels. Though they cost more to generate than do fossil fuels, these alternative fuels do not fluctuate as much in cost. They decrease risk by increasing energy security and thus ultimately reduce costs.

The 2007 report recommends a broad portfolio for both mitigation and adaptation technologies—as well as a broad portfolio of research into such technologies—because it is doubtful that any single technology will solve the climate change problem. It also notes that many research studies show that certain adaptation measures affect mitigation, while other mitigation measures affect adaptation.

Poverty

• **Categories:** Ethics, human rights, and social justice; economics, industries, and products

Extreme or prolonged climate changes affect poor people's ability to secure a basic standard of living, reducing access to drinking water, threatening food security, and exacerbating health problems. Low crop yields, famines, and landmass erosion are expected to force millions of Earth's poorest people to leave their homes and seek better conditions elsewhere.

• Key concepts

developing countries: poor, primarily agricultural or island nations, many of which are located in the Southern Hemisphere

millennium development goals (MDGs): a set of objectives for economic development adopted by the United Nations in 2000

vulnerability to climate change: the risk that climate variability and extremes will cause a decline in the well-being of a given group or entity

• Background

Rises in average global temperatures will most adversely affect the world's poor and place at risk international efforts to eradicate poverty. Developing countries will bear the brunt of climate-related adversities that have already affected millions of people. The $6 billion spent annually on humanitarian responses to disasters would face sharp increases if global warming continues.

• What Is Known

Estimated deaths due to climate change are concentrated in the poorer regions of the globe. In 2000, mortality per million persons ranged from lows of 0-2 throughout countries in the more affluent Northern Hemisphere to highs of 70-100 in the poorest regions of the world such as sub-Saharan Africa. The area of the world stricken by drought doubled between 1970 and the early 2000's, turning even fertile land in Africa to desert.

Between 1900 and 2004, 73 percent of disasters were climate related; 94 percent of disasters and 97 percent of disaster-related deaths occurred in developing countries. In 1998, Hurricane Mitch affected more than 25 percent of households in Honduras, led to a 7 percent drop in agricultural output, and increased the nation's poverty rate significantly. The loss of livestock to Rift Valley disease from the 1997-1998 El Niño resulted in a billion-dollar ban by the Gulf States on trade from East Africa. Following the 2000 floods in Mozambique, the country's real annual growth rate fell by 7 percent. In 2002, flooding in Bangladesh damaged 20 percent of crops and left 1.4 million people food insecure.

Climate change brings the risk of increases in serious diseases. Subsequent Hurricane Mitch flooding increased the incidence of cholera fourfold in Guatemala and sixfold in Nicaragua. Since 1940, El Niño-related floods increased the severity of cholera in Bangladesh. Longer rainy seasons increased malaria in parts of Rwanda and Tanzania and diarrhea in young children in Gambia.

• Anticipated Consequences

By 2020, drought is expected to reduce African farming harvests by 50 percent. Between 75 and 250 million people in Africa may face water shortages, as may 3 billion people in the Middle East and on the Indian subcontinent.

By 2035, glaciers in the Himalayas are likely to melt to such an extent that the water supply of three-quarters of a billion people in Asia would be severely compromised. By 2050, rising sea levels, floods, and drought could render more than 200 million people homeless. The number of people at risk of annual flooding alone is expected to increase from 75 million to 206 million, with 90 percent of those at risk within Africa and Asia.

By 2070, rainfall in the wet season in Pakistan could increase by 5 to 50 percent, which would have significant impacts on the annual yield of cotton, the country's main cash crop, and thereby affect Pakistani prospects for economic growth, trade, and foreign investment. The world's percentage of people at risk from malaria is expected to increase from 40 percent to 80 percent by 2080, severely taxing many countries' and the international community's health care systems.

• Who Is Doing What to Help

The 1992 U.N. Conference on Environment and Development adopted the Framework Convention on Climate Change (UNFCCC). At the third conference of the UNFCCC in 1997, the Kyoto Protocol was adopted. Fearing that stabilizing its greenhouse gas (GHG) emissions would adversely affect its economy, the United States did not ratify the Kyoto Protocol.

In addition to the UNFCCC, over twenty-five other organizations constitute the United Nations Systems Work on Climate Change, including the Intergovernmental Panel on Climate Change (IPCC), the United Nations Environment Programme (UNEP), the United Nations Commission on Sustainable Development (CSD), the World Bank, the International Monetary Fund, and the World Health Organization (WHO).

Under United Nations auspices, the September 8, 2000, Millennium Declaration, signed by 189 countries, identified poverty eradication and environmental stability as two of eight interrelated millennium development goals (MDGs). The World Bank's *World Development Report, 2000/2001: Attacking Poverty* and the United Nations-commissioned *Human Development Report, 2007/2008* also linked poverty reduction goals to sustainable environmental strategies. International figures such as former U.S. vice president and 2007 Nobel Peace laureate Al Gore and rock singer Bono have taken up the cause of linking poverty reduction with sustainable development at world forum events.

This charcoal maker's child is one of hundreds of people who live and work in a garbage dump in Manila, Philippines, surrounded by the waste that they recycle to make their living. (Darren Whiteside/Reuters/Landov)

Linking poverty reduction with environmentally sustainable initiatives may work at cross purposes. Reducing trade barriers and promoting tourism to enhance economic growth increase the use of the transport sector, which accounts for about 20 percent of global carbon dioxide (CO_2) emissions. Neither international aviation nor shipping was included in the national emission-control targets set under the Kyoto Protocol.

The United Nations encourages nations to prepare themselves for extreme variations in climate. Many developing countries such as Bangladesh and Malawi, as well as more affluent countries such as Australia, use the U.N. National Adaptation Programmes of Action (NAPA) framework. About seventy low-income countries participate in the Poverty Reduction Strategy Papers (PRSP) process, which incorporates climate adaption strategies, as required for receiving debt relief under the Heavily Indebted Poor Countries (HIPC) Initiative and concessional assistance from the World Bank and International Monetary Fund (IMF).

• Context

Climate change may be the definitive human development issue of the twenty-first century, as Great Britain's 2006 Stern Review suggested and the *Human Development Report, 2007/2008* contended. Increased exposure to drought, more intense storms, floods, and environmental stress will dilute efforts of the world's poor to build a better life. Failure to meet climate-related challenges would consign the poorest 40 percent of the world's population, some 2.6 billion people, to a future of increased socioeconomic destitution and diminished opportunity. It would exacerbate socioeconomic disparities within countries, increasing the likelihood of civil conflicts and undermining efforts to build a more inclusive pattern of globalization, and it would raise the prospects of geopolitical confrontations between developed nations such as the United States and developing ones such as China as they compete for scare resources.

Precautionary approach

• **Categories:** Environmentalism, conservation, and ecosystems; laws, treaties, and protocols

• Definition

The precautionary approach, or precautionary principle, is a major principle of environmental policy in the presence of fundamental uncertainties. It can be traced to the early 1950's, when economist Sigfried von Ciriacy-Wantrup advocated a "safe minimum standard of conservation" as a policy goal. It can now be found in many international and national policy documents and conventions.

Uncertainties are the result of a lack of scientific knowledge or final proof of the consequences of human activities. Many of the effects of human consumption and production on both human and environmental health, including Earth's climate, are not yet known with certainty. Traditionally, science policy experts have argued that a final scientific proof should be reached prior to taking political actions such as mandating a reduction of greenhouse gas (GHG) emissions or banning chemicals. Some experts, however, have advocated taking action to protect the environment even if final proofs cannot be delivered or if scientists differ in their assessment of environmental risk.

The precautionary principle is a principle that tries to retain future development options and avoid irreversible effects. It is also a major element in policies pursuing sustainable development. Policy fields engaging with the precautionary approach include not only climate change policy but also policies regarding the release and admission of chemicals and genetically modified organisms.

• Significance for Climate Change

Referring to climate change, political decision makers have two alternatives. They can await final scientific proof that anthropogenic GHG emissions cause irreversible changes to the Earth's climate, or they can take immediate action. In the former case, no costs would be borne by today's generation, but there is a risk of tremendous cost to future generations if scientists are right and the Earth's mean temperature rises significantly. In the latter case, costs may be substantial to today's generation but future generations could be saved from bearing the enormous costs of climate change.

The United Nations Framework Convention on Climate Change (UNFCCC) has acknowledged the importance of the precautionary principle in climate change policies by aiming at a stabilization of "greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic (human-induced) interference with the climate system." The convention does not specify the target level of GHG concentrations in the absence of a final scientific proof determining that level. However, the precautionary principle realizes that decisions have to be made under conditions of uncertainty and that they may have irreversible effects. Therefore, the parties to the convention agreed to take

> precautionary measures to anticipate, prevent or minimize the causes of climate change and mitigate its adverse effects. Where there are threats of serious or irreversible damage, lack of full scientific certainty should not be used as a reason for postponing such measures. . . .

Scientific evidence suggests that costs of a precautionary policy today may be much less than future costs of climate change in the case that no action were taken today.

Preindustrial society

• Category: Economics, industries, and products

• Definition

Beginning about the second half of the eighteenth century, the Industrial Revolution ushered in the age of machine technology, driven by engines powered through steam and the combustion of wood, coal, and eventually oil. Social life, initially in Europe and ultimately throughout the world, was radically transformed. All aspects of human culture became increasingly mechanized and rationalized. The era of the factory, urban congestion, rapid transportation, and agricultural modification had begun. Patterns of employment and housing fell into line. It was no longer necessary to live so close to the source of food, and a gradual abandonment

Tribal leader Ashonko Alalaparoe of Kwamalasamutu, Suriname, has agreed to help American environmentalists protect the Amazon rain forest. Earth's remaining preindustrial societies are important allies in attempts to preserve natural resources from increasing industrialization. (Antonio Perez/MCT/Landov)

of agrarian customs for the higher energy consumption lifestyle of city and suburb began.

Preindustrial society came to be defined in retrospect in terms of its differences from industrialized society. In particular, it came to be seen as characterized by a slower lifestyle and one less rigorously rationalized by time clocks and assembly lines and cities planned to maximize traffic circulation. From a conservationist standpoint, the environmental footprint of preindustrial societies was radically smaller than that of a fully industrialized twenty-first century (or even nineteenth century) nation.

• Significance for Climate Change

Estimates indicate that the atmospheric concentration of carbon dioxide (CO_2) has roughly doubled since the last ice age, with half of that increase occurring in the two centuries since the Industrial Revolution. Many scientists would relate that change (and the global warming it arguably promotes) to the burning of wood, coal, and oil as fuels. Industrialization has meant a vast increase in the release of greenhouse gases (GHGs) into the atmosphere, as well as environmental pollution of soil and stream.

Some critics feel nostalgia for the world they see as having been lost to industrialization, and some foresee an inevitable recurrence of preindustrial circumstances in a "postindustrial" future. Still other critics emphasize that preindustrial societies did not necessarily engage in environmentally friendly practices, but were small enough, in terms of human population, that their impact on the environment was insignificant.

Preindustrial societies were nonetheless affected by sometimes abrupt climate change. They were extremely vulnerable in the event of sudden, extreme, or prolonged shifts in climatic conditions, which could affect the success of established agricultural practices, alter vectors of disease transmission, and encourage or obstruct population movement (with ensuing cultural and biological effects). As climate historian Hubert Horace Lamb soberly notes, for example, the

> drying up of the north African, Arabian, northwest Indian and central Asian deserts ended the human activities and cultures there and must have caused at first famines and ultimately . . . shift of populations.

The environmental habits of preindustrial societies may have been virtuous, or they may have been noxious but inconsequential in practice. In either case, their small scale guaranteed limited impact. The primary change in recent centuries has been increasingly rapid growth of human population. Whatever the initiating causes of that growth—improvements in nutrition and health are often mentioned, but the issue is complicated—there is little doubt that the lapse of key features of preindustrial life has helped produce high, expanding, and perhaps unsustainable levels of human population.

It may be difficult to address climate change effectively as long as human population continues to expand exponentially. On the other hand, if population in traditional societies was kept in check by high mortality because of disease, famine, and war, it would be hard to argue for the reinstatement of such factors.

Pseudoscience and junk science

• Categories: Popular culture and society; science and technology

Many ideas that are presented in popular media as science are actually false or very poorly supported by evidence. These pseudoscientific ideas can be used both as general disinformation and for specific practical purposes, such as winning a court case or influencing legislation.

• Key concepts

anecdotal evidence: isolated instances illegitimately used to establish a logical principle or general rule

conspiratorial outlook: a belief that others' behavior is caused by bias or ulterior motives

junk science: faulty science that attacks established scientific findings or advances poorly supported theories for a practical goal

pseudoscience: scientific-sounding claims that are either scientifically false or so poorly supported by evidence that they should not be taken seriously

• Background

Many people assume that any idea that claims to be science actually is science; they find the very existence of pseudoscience surprising. Pseudoscience is more than merely wrong or unsupported science. Merely being wrong or speculative does not make an idea pseudoscience. Speculation is a legitimate part of science, and many ideas in science that initially look promising turn out to be wrong (and vice versa). When ideas in legitimate science turn out to be wrong, supporters eventually admit it and abandon the ideas.

One example of such self-correction is cold fusion, the idea that nuclear fusion was possible using simple apparatus. After an initial flurry of interest in the 1980's, it turned out that the initial observations that seemed to support cold fusion were faulty. Most scientist supporters of cold fusion abandoned the idea. A few scientists continue to believe there was some basis for believing in cold fusion, but they also realize that they must supply adequate proof in order to convince other scientists.

In contrast, pseudoscience is not merely wrong, but its supporters also refuse to accept contrary evidence, often invent complex alternative explanations to support their ideas, and openly defy the consensus of the scientific community, often militantly. Frequently, they accuse the scientific community of bias or ulterior motives for refusing to accept unorthodox ideas.

There is no sharp boundary between science and pseudoscience. One useful simple classification is that of physicist James Trefil, who grouped scientific ideas into a center, where ideas are firmly supported and unlikely to be disproven, a frontier, where ideas are debatable, and a fringe, where ideas are very unlikely to be valid. Generally, frontier ideas move either into the center or out toward the fringe fairly quickly. For example, the idea that a meteor impact triggered the extinction of the dinosaurs was a frontier idea when it was first proposed but has moved toward the center. Cold fusion was also a frontier idea when it was first proposed but moved fairly rapidly to the fringe.

Rarely, even larger shifts occur. For example, continental drift was considered a fringe idea for decades before new evidence was discovered that caused it to move rapidly to the center in a modified form called plate tectonics. Not all fringe ideas necessarily deserve the label "pseudoscience." For example, although medical studies have not confirmed the idea that vitamin C in large doses helps prevent colds, the theory itself is harmless and does not violate any well-established scientific findings. Bigfoot and UFOs are fringe ideas that do not necessarily violate known scientific findings, but they count as pseudoscience because the evidence for these ideas is very poor. Finally, some ideas, such as the Earth being only a few thousand years old, are pseudoscience because they contradict well-demonstrated scientific findings.

Although some advocates of pseudoscience engage in deliberate deception, most sincerely believe the ideas they publish. They are often motivated by a desire for fame or to have their beliefs accepted as science, or for psychological reasons such as a need for mental or spiritual satisfaction. Usually, their ideas are supported by a combination of wishful thinking, faulty data, and logical fallacies.

• Identifying Pseudoscience

For scientists well trained in their fields, the distinction between science and pseudoscience is generally obvious. For nonscientists without specialized training, the distinction can be difficult. However, there are a number of clues that often are revealing and do not require much specialized training. If a new theory directly conflicts with established science, explicitly claims that existing science is wrong, or makes sweeping claims that most scientists reject, it is less likely to be legitimate science. If it merely reports a new discovery that seems improbable but does not contradict core scientific principles, it is more likely to follow accepted scientific practice, although it may still be incorrect.

The more strongly a theory opposes accepted science, the more likely it is to be pseudoscience—although almost all revolutionary scientific breakthroughs would also appear to be pseudoscience from the point of view of the prerevolutionary scientist. If a theory does radically oppose established science, one question to consider is whether its author makes obvious mistakes about simple matters. If so, the author is very unlikely to be correct in more complex matters that require more technical knowledge.

There are certain kinds of faulty data that crop up repeatedly in pseudoscience. Anecdotal data, for example, is data gathered from isolated cases and used to support a general conclusion. In order to be useful, anecdotal data must be both true and representative. If the anecdote is false, of course, then it cannot be used to prove anything, but even if it is true, it must still be representative and not just an isolated case. For example, it may be true that someone became ill after a vaccination, but if the event is just a rare case, it does not necessarily prove the vaccination is unsafe. To count as scientific evidence, the anecdote must be reproducible—that it, scientists must be able to reconstruct the situation described and obtain the same result.

Pseudoscience often also makes use of obsolete data. Often, the alleged facts were reported in newspapers or popular media or were early scientific findings that later either were found to be erroneous or were superseded by more accurate results. If a theory is based heavily on old data, especially from popular sources that are hard to check, it should be considered suspect.

Pseudoscientists often cite other authorities in support of their ideas. Important questions to ask about alleged supporting authorities include how well respected they are in their own fields, how well informed they are about the subject they are supposedly supporting, and whether they really do support the theory in question or whether they are being quoted out of context and without their consent.

• Logical Fallacies

One of the most widespread and conspicuous features of pseudoscience is a conspiratorial outlook. Pseudoscientists commonly claim that their theories are not being taken seriously by the scientific establishment because of ulterior motives, such as protecting research funding, refusal to admit that an outsider might have made an important discovery, pride, or ideology. Even if these claims are true, they have nothing at all to do with whether the scientific claims of the author are true.

A common tactic in pseudoscience, often termed the "Galileo fallacy," is to point to examples of scientists who were persecuted in the past only to be vindicated later on. Often, as in the case of Galileo, the examples are based on oversimplified stereotypes that are not historically valid. Even when it is true that an idea met opposition from other scientists only to be found true later, that does not mean that opposition makes an idea true. The vast majority of ideas that encounter opposition turn out to be false.

Disproving an idea does not prove its opposite. For example, in 2008 the method of lead analysis used to analyze the bullets that killed President John F. Kennedy was found to be faulty. The method could not be used to prove that all the bullets came from the same gun, as had been claimed. However, that does not prove that the bullets came from more than one gun; it only proves that the method was inconclusive. It is very common in pseudoscience for the author to attack some finding in science and then assert that his own idea must be correct. Even if the scientific concept really is incorrect, that does not prove that some contrary idea is true. Unanswered questions are merely unanswered; they are never proof for an idea. For example, although there are many unanswered questions about evolution, those unanswered questions do not disprove evolution.

• Junk Science

The term "junk science" came into widespread use in the 1980's. Perhaps the first significant example was the attempt by the tobacco industry to discredit the scientific evidence linking tobacco and lung cancer. Scientists and others working for the industry attacked minor and generally irrelevant flaws in the medical research, offered alternative explanations for the data, and questioned the validity of applying animal studies to humans. The intent of this strategy was to justify doubt in the minds of customers, legislators, judges, and juries. In fact, a common strategy in both pseudoscience and junk science is to exaggerate the degree of uncertainty about some scientific idea, and then assert that, since "the experts do not agree," people should decide for themselves whether or not an idea is valid.

• Context

Pseudoscience is a significant concept for many reasons. First, many people are unaware of its existence, and merely knowing that pseudoscience exists can help them understand that some claims that sound revolutionary are not worth serious consideration. Pseudoscience has often been used in support of extremist movements, and a historical understanding of its function will help to contextualize future pseudoscientific claims. Widespread popular acceptance of pseudoscience is an indication that public understanding of science and logic are poor. Considering that many public policy issues involve science and that scientific evidence is so widely used in court, poor public understanding of science and of the proper use of evidence are matters of grave concern. Finally, pseudoscience can illuminate the workings of science by contrasting real science with counterfeit science.

Both sides in the climate change controversy have accused the opposition of practicing pseudoscience and junk science. The most reliable way to determine which side is more correct is to become well informed about climatology. However, clues such as allegations of conspiracy or ulterior motive, strength and relevance of professional credentials, use of logical fallacies and questionable data, attempts to exaggerate doubt, and the weight of scientific opinion are all revealing.

Radiative damping

• **Categories:** Meteorology and atmospheric sciences; physics and geophysics

• **Definition**

When the temperatures of the lower atmosphere and surface of the Earth increase as a result of radiation-producing agents, such as the increase of greenhouse gas (GHG) emissions, the amount of infrared radiation emitted into space increases, producing a new energy balance for the Earth. The amount by which emissions of infrared radiation into space increases for a given increase of temperature is termed the radiative damping. The radiative damping coefficient equals the change in incoming radiation and outgoing radiation as a function of time (the radiative forcing) per change in global temperature.

• **Significance for Climate Change**

The radiation balance of the Earth is altered by the exchange of incoming solar radiation and the outgoing radiation emitted by the Earth or reflected by the Earth's surface, clouds, and aerosols. Changes in this balance produce changes in the Earth's temperature and climate. If the radiative damping coefficient, also referred to as the climate sensitivity coefficient, is large, the climate will change slowly. Radiative damping acts as a negative feedback mechanism to stabilize the Earth's climate against any major changes. If the atmospheric temperature rises, the amount of infrared energy radiated back into space increases, which in turn reduces the temperature rise. The sensitivity of global climate is essentially determined by the radiative damping of the global mean surface temperature anomaly through the outgoing radiation at the top of the atmosphere.

Predictions of values for radiative damping are based on computer algorithms known as general circulation models (GCMs). During the early twenty-first century, models have been improved to include not only radiative effects of the atmosphere but also simulations of the radiative effects of clouds, oceans, ice, and vegetation. Upwelling and diffusion within the oceans are included to account for their radiative damping effect. According to the Intergovernmental Panel on Climate Change (IPCC), GCMs indicate evidence for discernible human influence on the global climate via increased GHG emissions. Warmer temperatures cause ice to melt, which exposes more land and water, reducing radiative damping because more sunlight is absorbed than is reflected.

Controlling radiative damping is critical for reducing climate change. To maintain radiative damping at a level that negates global warming, radiative forcing needs to be stabilized, reduced to zero, and then sustained at or very near this newly established equilibrium level. Based on recent GCMs, achieving this would most likely involve reducing GHG emissions, stabilizing GHG concentrations, and reducing any of the agents that drive radiative forcing away from equilibrium. Adjusting radiative damping will help stabilize the Earth's climate and maintain an equitable habitat for life that depends on water.

Radiative forcing

• **Categories:** Meteorology and atmospheric sciences; physics and geophysics

• **Definition**

Earth's radiative forcing is the change over time of the net difference between the amount of the planet's incoming radiation energy and the amount of its outgoing radiation energy (the net irradiance). This differential is measured at the tropopause, the boundary in the atmosphere between the troposphere and the stratosphere. When there is more incoming than outgoing radiation energy, corresponding to positive radiative forcing, the average temperature of the Earth rises. When there is more outgoing than incoming radiation energy (negative radiative forcing), the average temperature decreases. Changes in radiation forcing can be produced by a variety of agents, most notably varying radiation outputs from the Sun or variations in the concentrations of greenhouse gases (GHGs) in the atmosphere.

• Significance for Climate Change

The Intergovernmental Panel on Climate Change (IPCC) requires that values of radiative forcing be reported relative to the year 1750, which is taken as the beginning of the industrial era. When the Earth's radiative balance strays away from its equilibrium state, global temperatures change. A linear relationship has been established between the amount of radiative forcing and the average global equilibrium surface temperature. The change in radiative forcing is equal to the change in global temperature multiplied by the climate sensitivity, or radiative damping, coefficient. Values of radiative forcing are reported in watts per square meter.

The Earth's radiation balance is directly influenced by changes in atmospheric composition, cloud properties, and surface and atmospheric temperatures. Since radiative forcing is rather easy to calculate, it provides a general estimate of climate changes due to variations in the radiation output of the Sun, changes in GHG concentrations, changes produced by emission of heat by various materials, and other agents that change the net amount of radiation energy. Since the majority of energy that affects the Earth's climate comes from the Sun, if radiative forcing were close to zero, the solar radiation energy coming to the Earth would be approximately equal to the infrared radiation emitted from the Earth.

Radiative forcing values are estimated by inputting available weather data into computer algorithms that are based on general circulation models (GCMs). Values are generated for contributions due to natural influences, particularly varying solar radiation, volcanic eruptions, and seasonal effects that alter cloud and ground cover, and for human contributions, particularly GHG emissions and aerosols. Some calculations indicate that the radiative forcing caused by human activities is more influential on climate change than is the radiative forcing caused by natural means. Other calculations indicate the opposite. In either scenario, reduction of GHG emissions is an important goal in regulating the Earth's climate.

Rainfall patterns

• **Categories:** Meteorology and atmospheric sciences; water resources

• Definition

Global rainfall patterns are produced by global scale atmospheric motions. In the tropics, warm air at the surface holds considerable moisture. As it is heated and rises, it cools, and the moisture condenses and falls out as rain. High in the atmosphere this air moves away from the equator to descend at latitudes near 30° north or south. As this dry, descending air approaches the surface, it warms, increasing its capacity to evaporate water. These latitudes contain many of the Earth's major deserts: the Sahara, Kalahari, Australian, and Saudi Arabian, for example. Air high in the atmosphere that reaches either pole also cools and descends. Most of Antarctica is a desert, and the dry valleys there are among the driest places on Earth.

Each of these convective systems has a return flow directed toward the equator, across the surface of the Earth. Between them is a third convective system, complicated by the jet stream and other factors. In this system the upper atmosphere moves toward the equator, and the return flow across the surface moves away from the equator.

The Coriolis effect, a result of the Earth's rotation, causes things in motion in the Northern Hemisphere to be deflected to the right and those moving in the Southern Hemisphere to be deflected to the left. Therefore, the return flows in the three cells described above, responsible for Earth's surface winds, come from the east between the equator and 30° latitude, from the west between 30° and 45° latitude, and again from the east at latitudes greater than 45°. As these winds move across the oceans, they evaporate water. If they are brought onto a continent and then are forced up over a mountain range, the air they are moving will cool and rain will fall out. Moving down the far side of the mountain range, the now dry air will warm and evaporate moisture again. In this way, mountain ranges typically have an excess of rain (orographic rainfall) on their windward sides and a deficiency of rain (rain shadows) on their leeward sides.

Other winds are produced by the variation in temperature between continents and oceans. In the summer, continents are warmer and air rises above them, bringing moisture-laden air in from the oceans, and monsoon rains occur. In the winter, this pattern reverses, and little rain falls.

• Significance for Climate Change

Humankind depends on patterns of rainfall—but not the total amount (most of which falls on the oceans) and not the amount that falls at a given location during a year (if it all comes in one torrential downpour, rain does more harm than good). What is important is the pattern, in both space and time, of the right amount of rainfall.

As climate changes, the geographically determined patterns of rainfall will probably change very little. The atmospheric convective cells will continue to operate, resulting in the variations in rainfall with latitude that are seen today and producing winds that will continue to blow in generally the same directions. On human timescales, mountains will stay the same, and hence orographic rainfall and rain shadows will persist.

Rainfall patterns, however, are also affected by the strength and locations of persistent high and low pressure regions, which control the particular paths taken by various air masses. In the temperate zone (between 30° and 45°), the generally west-to-east flow of air produced by the large-scale convective systems is actually rather wavy, wandering north and south as it interacts with topography and with the persistent pressure systems set up by the various modes, or pressure seesaws, that exist in the atmosphere. The degree of waviness and where the waves occur change with the seasons (the excursions of the jet stream are larger in the winter) and with these modes.

Some of these modes are the El Niño-Southern Oscillation cycle, the Pacific-North American (PNA) cycle, the Pacific Decadal Oscillation (PDO), and the Northern Annular Mode (NAM), which may include the North Atlantic Oscillation (NAO). Although what controls these oscillations is not well understood, their timing and intensity are probably more likely to change as the climate evolves than the larger, geographically determined, patterns.

Studies of proxies for rainfall and temperature have attributed variations in the monsoons to fluctuations in the strength of the ENSO. The Medieval Warm Period (MWP), from roughly 900 to 1300 C.E. when the North Atlantic and northern and western Europe experienced warmer conditions on average, is thought by some to have resulted from a very persistent phase of the NAO, causing the winds that blow from the west over much of Europe to be deflected far to the south prior to reaching that continent. In terms of human suffering, changing rainfall patterns may well turn out to be more significant than temperature changes or sea-level rise.

Ramsar Convention

- **Category:** Laws, treaties, and protocols
- **Date:** Adopted February 2, 1971; entered into force December 21, 1975

Signed by eighteen nations in 1971, the Ramsar Convention was the first international treaty on environmental conservation. Although its original mission was to conserve wetlands "as a contribution toward achieving sustainable development throughout the world," its efforts have expanded to consider the importance of wetlands in global climate change.

- **Participating nations:** *1971:* Belgium, Denmark, Finland, France, Germany (Federal Republic), India, Iran, Ireland, Jordan, Netherlands, Pakistan, South Africa, Soviet Union, Spain, Sweden, Switzerland, Turkey, and the United Kingdom. *Additional Parties as of December, 2008:* Albania, Algeria, Antigua and Barbuda, Argentina, Armenia, Australia, Austria, Azerbaijan, The Bahamas, Bahrain, Bangladesh, Belarus, Belize, Benin, Bermuda, Bolivia, Bosnia and Herzegovina, Botswana, Brazil, Bulgaria, Burkina Faso, Burundi, Cambodia, Canada, Cape Verde, Central African Republic, Chad, Chile, China, Colombia, Comoros, Republic of the Congo, Costa Rica, Côte d'Ivoire, Croatia, Cuba, Cyprus, Czech Republic, Democratic Republic of the Congo, Djibouti, Dominican Republic, Ecuador, Egypt, El Salvador, Equatorial Guinea, Estonia, Gabon, The Gambia, Georgia, Ghana, Greece, Guatemala, Guinea, Guinea-Bissau, Honduras, Hungary, Hong Kong, Iceland, Indonesia, Iraq, Israel, Italy, Jamaica, Japan, Kazakhstan, Kenya, Kyrgyz Republic, Latvia, Lebanon, Lesotho, Liberia, Libya, Liechtenstein, Lithuania, Luxembourg, Madagascar, Malawi, Malaysia, Mali, Malta, Marshall Islands, Mauritania, Mauritius, Mexico, Moldova, Monaco, Mongolia, Montenegro, Morocco, Mozambique, Myanmar, Namibia, Nepal, New Zealand, Nicaragua, Niger, Nigeria, Norway, Palau, Panama, Papua New Guinea, Paraguay, Peru, Philippines, Poland, Portugal, Republic of Macedonia, Romania, Russia, Rwanda, Saint Lucia, Samoa, Senegal, Serbia, Seychelles, Sierra Leone, Slovakia, Slovenia, South Korea, Sri Lanka, Sudan, Suriname, Syria, Tajikistan, Tanzania, Thailand, Togo, Trinidad and Tobago, Tunisia, Uganda, Ukraine, United Arab Emirates, United States of America, Uruguay, Uzbekistan, Venezuela, Vietnam, Yemen, Zambia

- **Background**

International organizations, including the International Union for Conservation of Nature, have worked to protect waterfowl since the beginning of the twentieth century. In 1962, Luc Hoffman and several international conservation groups called for an international convention on wetlands. The group later known as Wetlands International spent the next eight years conducting meetings and drafting treaty language, guided by G. V. T. Matthews. The agreement formally titled the Convention on Wetlands of International Importance, Especially as Waterfowl Habitat was signed in the town of Ramsar, Iran, in 1971, and came to be known informally as the Ramsar Convention.

- **Summary of Provisions**

The Ramsar Convention was the first environmental treaty to consider both conservation and the "wise use" of natural resources. Contracting nations have agreed to employ national land-use planning, law, management and public education to work toward the wise use of all their wetlands; to identify and manage appropriate wetland areas for inclusion on the Ramsar List, an official List of Wetlands of International Importance; and to cooperate internationally to protect wetlands and inhabit-

The List of Wetlands of International Importance

Article 2 of the Ramsar Convention, reproduced below, forms the heart of the convention. It establishes the List of Wetlands of International Importance, wherein the wetlands designated for conservation by the signatories are enumerated.

1. Each Contracting Party shall designate suitable wetlands within its territory for inclusion in a List of Wetlands of International Importance, hereinafter referred to as "the List" which is maintained by the bureau established under Article 8. The boundaries of each wetland shall be precisely described and also delimited on a map and they may incorporate riparian and coastal zones adjacent to the wetlands, and islands or bodies of marine water deeper than six metres at low tide lying within the wetlands, especially where these have importance as waterfowl habitat.

2. Wetlands should be selected for the List on account of their international significance in terms of ecology, botany, zoology, limnology or hydrology. In the first instance wetlands of international importance to waterfowl at any season should be included.

3. The inclusion of a wetland in the List does not prejudice the exclusive sovereign rights of the Contracting Party in whose territory the wetland is situated.

4. Each Contracting Party shall designate at least one wetland to be included in the List when signing this Convention or when depositing its instrument of ratification or accession, as provided in Article 9.

5. Any Contracting Party shall have the right to add to the List further wetlands situated within its territory, to extend the boundaries of those wetlands already included by it in the List, or, because of its urgent national interests, to delete or restrict the boundaries of wetlands already included by it in the List and shall, at the earliest possible time, inform the organization or government responsible for the continuing bureau duties specified in Article 8 of any such changes.

6. Each Contracting Party shall consider its international responsibilities for the conservation, management and wise use of migratory stocks of waterfowl, both when designating entries for the List and when exercising its right to change entries in the List relating to wetlands within its territory.

ing species that cross national boundaries. The Conference of the Contracting Parties (COP) meets every three years, and a smaller standing committee meets every year, to guide conservation efforts and measure progress. Contracting parties can make use of convention consultants, grant funds, and other assistance.

• Significance for Climate Change

The Convention on Wetlands and the United Nations Framework Convention on Climate Change (UNFCCC) are linked in several ways. The UNFCCC's Kyoto Protocol article on land use, land-use change, and forestry, as well as the article on development and transfer of technology, directly affects the conservation of wetlands. The convention has passed a series of resolutions calling for cooperation with the UNFCCC, especially in sharing information. Kyoto Protocol contracting parties invited advice from Ramsar scientists in drafting policies on peatland and carbon sequestration. Further, the convention has endorsed the development of a memorandum of cooperation between the Ramsar Convention Bureau and the UNFCCC to protect the interests of small island states, threatened by climate change and encroaching wetlands.

During the tenth meeting of the Ramsar Convention on Wetlands' COP, held in October, 2008, in the Republic of Korea, the Ramsar Convention entered into a new partnership with the International Union for Conservation of Nature (IUCN) and the Danon Group, producers of Evian bottled water. The initiative will attempt to control global warming through wetlands protection and restoration.

The convention has achieved great success in educating the general public about the importance of wetlands. By January, 2008, more than seventeen hundred wetland areas, covering more than 153 million hectares, had been included on the Ramsar List, ranging in size from less than one hectare to more than 6 million hectares.

Reason Public Policy Institute

- **Category:** Organizations and agencies
- **Date:** Established 1976
- **Web address:** http://www.reason.org

- **Mission**

The Reason Public Policy Institute works to apply marketplace principles to the issue of global warming, arguing against environmental regulations that might harm business. Many Web sites identify the Reason Public Policy Institute (RPPI) as a global warming skeptic organization funded by ExxonMobil, but it is much more than that. RPPI, the research division of the Reason Foundation, generates original research on issues including the environment, education, infrastructure, transportation, urban land use, local economic development, social services, privatization, and government reform.

According to a description in several RPPI reports, the Institute

> brings a political philosophy that supports rule of law, marketplace competition, economic and civil liberty, personal responsibility in social and economic interactions, and institutional arrangements that foster dynamism and innovation.

The Reason Foundation has been funded largely by corporations affected by these issues, including ExxonMobil, the Western States Petroleum Association, Shell Oil, the Edison Electric Institute, DaimlerChrysler, the Ford Motor Company, and other energy and transportation companies, as well as Microsoft, Bayer, Bank of America, and others.

RPPI research supports the views that anthropogenic causes are minimally responsible for global warming and argues against regulations proposed to combat global warming—especially those aimed at reducing greenhouse gas emissions. The 2001 report *Q and A About Forests and Global Climate Change* summarizes the organization's positions:

> Despite many remaining uncertainties in scientific understanding of climate change, most initiatives propose to slow or stop the buildup of greenhouse

gases by reducing fossil fuel use. Such policy options are likely to have little positive impact on climate, but could result in negative impacts on energy production, national economies, and personal autonomy.

• Significance for Climate Change

While the Reason Foundation continues to operate and to publish *Reason* magazine and research reports, documents issued after about 2005 have not carried the RPPI logo, and inquiries to the RPPI Web site are automatically redirected to the Reason Foundation's site. The Reason Foundation continues to work on climate and environmental issues and runs the Web site www.newenvironmentalism.org. For some years, Kenneth Green was director of the environmental program. Among his peer-reviewed studies published by RPPI are *A Plain English Guide to the Science of Climate Change*, *Climate Change Policy Options and Impacts*, *Evaluating the Kyoto Approach to Climate Change*, and *A Baker's Dozen: Thirteen Questions People Ask About the Science of Climate Change*. In 2004, RPPI published reports and op-eds challenging the Arctic Climate Impact Assessment report from the Arctic Council. Some time after 2005, ExxonMobil stopped supporting RPPI and other public policy think tanks, stating that these organizations had become a "distraction" from the real work of finding solutions.

Reefs

• **Categories:** Environmentalism, conservation, and ecosystems; oceanography

Reefs are sensitive, extremely biodiverse ecosystems that are strongly affected by climate change and play a vital role in ocean health. As global temperatures rise, the fragility and importance of the world's reefs simultaneously makes them a source of serious concern for environmentalists and provides early indications of the severity of climate change's future effects.

• Key concepts

ahermatypic corals: non-reef-forming corals

coral bleaching: loss of color in a coral colony due to stress-induced expulsion of zooxanthellae; often followed by death

corals: colonial cnidarians that excrete calcium carbonate exoskeletons

El Niño: weather phenomenon that sends an influx of nutrient-poor warm water into the normally cold, nutrient-rich surface waters off the coast of Ecuador and Peru

hermatypic corals: tropical corals that form reefs

reef: a marine feature lying below the water's surface; often formed by biological activity, as by corals

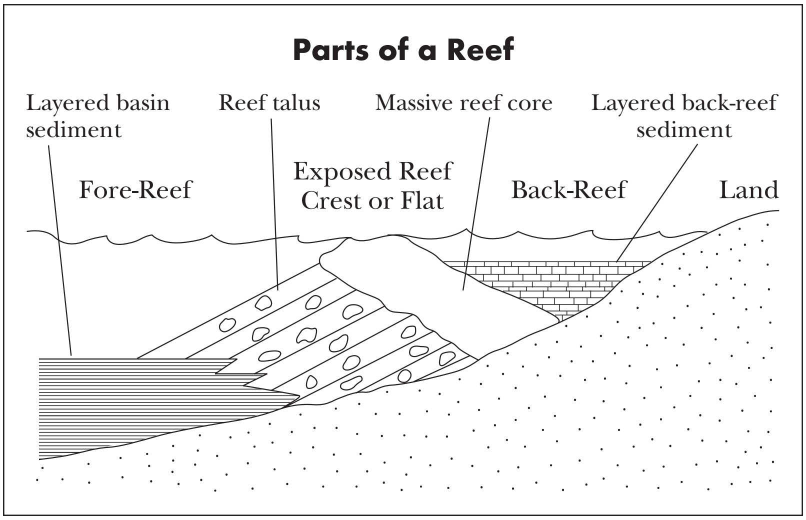
zooxanthellae: photosynthetic organisms that live in symbiosis with corals and other organisms, providing up to 90 percent of a coral's energy requirements

• Background

Coral reefs occupy thousands of square kilometers of shallow inshore waters in the tropics over a region of millions of square kilometers and are often used to define the tropical marine environment. Unlike other marine communities, reefs are built entirely by biological activity. They are composed of calcium carbonate produced by corals (phylum Cnidaria, class Anthozoa), with some contributions from calcareous algae and other organisms. Corals and the organisms that live with them are extremely sensitive to climate and are important indicators of ocean health.

• Reefs in Geological History

Reefs have a long history—reef-building organisms were some of the first marine life to develop hard skeletons. Reefs reached their periods of maximum development during the Middle Cambrian (513-501 million years ago), Devonian (416-359 million years ago), and Carboniferous (354-290 million years ago) periods, when they were dominated by a now extinct order, the rugose corals. During the Late Cretaceous (100-65 million years ago) and Neogene (23 million years ago to present) periods they have been dominated by scleractinian corals.



The fossil record shows that some reefs were formed by other organisms in the past. Calcareous algae and archaeocyathids (small, cone-shaped animals probably related to sponges) formed reefs in the Early Cambrian period (542-513 million years ago), as did rudist bivalves in the Late Cretaceous period (100-65 million years ago). However, corals have generally been the dominant reef formers through geologic history.

• Modern Reef Ecosystems

Although corals live throughout the world, even in polar and temperate regions, only tropical (hermatypic) corals form reefs. Most hermatypic corals have symbiotic unicellular organisms called zooxanthellae living in their tissues. Zooxanthellae are vital to coral reef health, providing up to 90 percent of a coral's energy requirements by photosynthesis. Reef distribution is also limited by temperature, water depth, light, salinity, sedimentation, and emergence into air.

Coral reefs are limited to shallow waters, typically less than 25 meters deep, which is why they are restricted to island and continent margins (with the exception of atolls). This limitation dervies from the symbiotic zooxanthellae, which require light for photosynthesis. Below 25 meters, there is insufficient sunlight to support photosynthesis. When the photosynthesis rate is reduced, corals produce calcium carbonate at a slower rate and are unable to form reefs. Hermatypic corals also require water with salinity close to normal seawater, or, in some cases, higher. Excessive sediment from runoff can smother corals and make it difficult for zooxanthellae to photosynthesize. Coral reefs thrive in areas with strong wave action, but are limited by low tide levels, as exposure to air can kill them relatively rapidly.

Reefs are typically divided into three categories: atolls, barrier reefs, and fringing reefs. Atolls are ring-shaped reefs that rise from very deep offshore waters and enclose a lagoon. They are found primarily in the Indo-Pacific area. Barrier and fringing reefs occur near a landmass, with a barrier reef being separated from land by a greater distance and deeper water. These two categories grade into each other and are sometimes considered one.

Although hard corals are the dominant organisms of reefs today, they are one of the most diverse, species-rich marine ecosystems as a result of efficient nutrient recycling. Some of the other important groups of organisms found in reefs are gorgonians or sea fans (order Gorgonacea), soft corals (order Alcyonacea), the fire coral *Millepora* (order Hydrocorallina), coralline algae such as Halimeda, mollusks, echinoderms, crustaceans, polychaete worms, sponges, and fish. Coral reefs may have hundreds or thousands of fish species, making them one of the richest environments for fish, which in turn contribute to the biological structure of the reefs. Finally, bacteria play a key role in decomposition and recycling of organic matter, as well as the biological productivity of reefs. Tropical marine waters are nutrient poor, while coral reefs are nutrient rich and extremely biodiverse. They provide crucial environments for many marine species.

• Reefs and Global Warming

Severe tropical storms, which may be increasing in frequency and severity due to global warming, are a major cause of reef mortality. Although hard corals are extremely sturdy and stand up to strong wave action, hurricanes and typhoons can destroy large areas of reef by uprooting coral colonies and carrying them off the reef. Storm deposits of broken coral are common in Caribbean fossil reefs.

The El Niño weather phenomenon, which sends an influx of nutrient-poor warm water into the normally cold, nutrient-rich surface waters off the coast of Ecuador and Peru, is also a periodic cause of catastrophic reef mortality. These changes in ocean patterns and climate can raise surface water temperatures for long periods of time, resulting in increased coral mortality rates, ranging from 50-98 percent overall.

The most puzzling cause of coral die-off is coral bleaching, which occurs when corals expel their zooxanthellae. If zooxanthellae do not recolonize quickly, the corals can die. Coral bleaching has been reported since the 1980's, sometimes associated with El Niño events. The causes are unclear, but it is likely associated with stress, particularly in warm water. Coral bleaching events have become more common, which some attribute to global warming. Reefs develop best in areas where the mean annual temperatures are between 23° and 25° Celsius, and only some can tolerate temperatures above 36° to 40° Celsius.

Coral reefs weakened by bleaching and storms are less resistant to diseases such as black band and white band disease, the latter of which has decimated Caribbean corals on a regional scale. Reefs can take over a hundred years to recover from some types of catastrophic mortality events.

• Context

Coral reefs are in increasing danger from the effects of global warming, from warmer waters to increasingly severe storms. Throughout history, reefs have completely disappeared for millions of years following mass extinction events, and there is evidence that reefs may soon disappear for the re-

A coral reef off the coast of Florida. (U.S. Fish and Wildlife Service) mainder of human history. Reefs act as an indicator of global warming and are crucial to marine biodiversity. It is also important to protect the health of coral reefs because they provide an important habitat for many food species, as well as protective barriers against storms for tropical islands.

Regional, local, and microclimates

• **Category:** Meteorology and atmospheric sciences

Climate change is not uniform across the world. Regional, local, and microscale processes often determine how the climate of a particular location will change in response to increasing concentrations of GHGs or other factors.

• Key concepts

aspect: the direction of slope, such as south-facing or north-facing

Gulf Stream: the warm current originating in the Gulf of Mexico that travels along the U.S. east coast before turning east to cross the Atlantic Ocean

monsoon: a seasonal shift in prevailing wind, often associated with significant rainfall

orographic process: any process triggered by topographic features

sea breeze: a sea-to-land wind developed as a result of land-water temperature gradients

trade winds: easterly surface winds in the tropics

urban heat island: an urban region that is significantly warmer than the surrounding rural areas

• Background

Climate is the long-term average of weather patterns. Due to the spherical shape of the Earth, the climate at any location is primarily determined by its latitude. However, the climates of certain regions can be significantly different from those at similar latitudes. Depending upon the spatial scale of interest, these climates are categorized as regional (covering hundreds or thousands of kilometers), local (covering tens of kilometers), and micro (covering few kilometers or even meters). Often, the climate in each of these cases is dominated by atmospheric processes operating only at those spatial scales.

• Regional Climates

Regional climates refer to climates of significantly large geographical area covering hundreds to thousands of kilometers with distinctive features distinguishing them from neighboring regions. The uniqueness of regional climates is driven by factors involving their locations, including distance from oceans and the proximity of large topographic features. Additionally, they are often characterized by specific large-scale atmospheric and oceanic processes such as the Atlantic and Pacific hurricanes, and the Asian and African monsoons that dominate other weather processes operating at smaller scales.

The oceanic influence is strongly evident in various regional climates of the United States. The cold water of the vast Pacific Ocean keeps the climate

Monsoon clouds pass over a beach in southern India. The Indian Ocean and the Asian monsoon are integral parts of the regional climate of South Asia. (Sivaram V/Reuters/Landov)

mild year-round in the western United States However, the relatively warm Atlantic helps generate massive hurricanes leading to hot and humid summers with lots of rain in the Southeast. The Atlantic Ocean strongly influences the regional climate of western Europe. In particular, the Gulf Stream, carrying warm tropical waters northward, keeps the western coast of Europe, especially the British Isles, unseasonably mild. Southern European and northern African climate is mild as a result of proximity to the Mediterranean Sea.

The Asian monsoon and the Indian Ocean play an important role in determining the distinctive climate of South Asia. The typical dry northeasterly trade winds reverse direction in the summer, bringing months of heavy and continuous rain to India and Southeast Asia. The influence of the Indian Ocean and the monsoon decreases, leading to drier climates, in the northern part of the Indian subcontinent.

Continental effects are evident in the climates of the midwestern United States, central and eastern Europe, midlatitudes of central Asia, and subtropical Africa. These regions experience hot summers, cold winters, and dryness throughout the year. As a consequence of this extreme climate, semiarid grasslands such as the prairie, savanna, and steppes are one of the most common vegetation in these regions.

• Local Climates

Local climates are climates of limited geographical areas covering only a few kilometers or tens of kilometers. Examples of local climates include land, sea, and lake breezes, orographic effects, and urban heat islands.

Sea/lake/land breezes are forced by the difference in thermal properties between land and water. Due to its high specific heat capacity, water heats up slower than land. Hence, on a warm summer day, the air over land gets warmer than the air over water. Since warm air is lighter, it rises, and cooler offshore air is drawn in to replace the rising air over land. Thus a cool sea/lake breeze develops. At night, the land cools down quickly, radiating heat to the atmosphere, but the sea remains relatively warm. Under these conditions the sea/lake breeze may reverse to form a land breeze.

Topographic features such as mountains/valleys can significantly influence the local climate. When moist air hits a mountain, it rises and cools, leading to orographic clouds and precipitation. Consequently, the windward side of a mountain is much cooler and wetter than the leeward side. Another important local climate process is mountain/valley winds. As the morning sun heats up the south- and east-facing slopes, air above the slopes warms and starts to rise, causing an upslope (anabatic) breeze. If the air is humid, it may lead to clouds and rain on mountain ridges. At night, the slopes cool radiatively and the cold air sinks back into the valley as downslope (katabatic) breeze. If there is a source of moisture in the valley, it may lead to extensive fog.

Another example of local climate is urban heat islands. They form in large developed metropolitan areas due to multiple reasons: increased heat absorption by concrete and asphalt structures, reduced evaporative cooling, trapping of outgoing radiation by buildings and waste heat from cars, air-conditioning, and industries. Consequently, cities tend to be several degrees hotter than surrounding regions.

• Microclimates

Microclimates are climates of very small areas with spatial scales ranging from a few meters to a few kilometers. The major factor behind the existence of a microclimate is the proximity to a heat sink or source. Microclimates exist near ponds, lakes, and wooded areas that generate a cooling effect or near factories and construction sites where the waste heat warms the ambient air.

Topographic aspect (direction of slope) has a profound effect on microclimate. South-facing slopes in the Northern Hemisphere and north-facing slopes in the Southern Hemisphere are exposed to more direct sunlight. Hence, they warm up quickly, reach higher temperatures, and stay warm for longer. Due to this effect the vegetation cover in opposing slopes of the same hill may be dramatically different. A similar effect is seen in areas that are shaded by natural or anthropogenic structures such as fences or tall buildings.

The city of San Francisco is a textbook example of microclimates. The city lies between the Pacific Ocean and the San Francisco Bay and the topography is complex, with 44 named hills. Due to these natural and anthropogenic reasons the city contains about 30 well-defined microclimate regions. The temperature within the city can vary by 5-10° Celsius, with similar range of variability in precipitation, wind speed, and incoming solar radiation.

• Context

It is well established that global warming is going to affect different regions differently. Local impacts will depend on how regional, local, and microscale processes respond to greenhouse gas forcing. Extracting regional climate information from global data sets or general circulation model simulations is very difficult. Simulations with regional climate models can provide this information but are computationally very expensive. Statistical methods can also be used to downscale information from global scales, but these are based on the assumption that the fundamental nature of interactions between different meteorological parameters remain the same across various climate regimes. Hence, regional climate change is one of the major challenges in climate change science.

Religious Right

- **Category:** Popular culture and society

The Religious Right is a loose, informal group of Christians and Jews who base political conservatism in religious doctrine. Americans classified as members of the Religious Right have split in their responses to reports of global warming, with some emphasizing the divine command to tend the Earth and others, while acknowledging their duty as caretakers, emphasizing the dominion God granted humans over other creatures.

• Key concepts

eschatological: pertaining to the end of this world

evangelical: pertaining to proselytizing Protestants who emphasize individual salvation through faith and place what they consider scriptural authority above church tradition

King James Bible: an English translation of the Bible authorized by King James I of England and originally published in 1611

prelapsarian: occurring before the fall of humanity into sin through the eating of the forbidden fruit in the Garden of Eden

• Background

Jews and Christians recognize Genesis as the first book of Scripture. It contains, according to many scholars, two consecutive accounts of Creation. In the older, a verse gives the prelapsarian intent of God for human beings: "And the LORD God took the man, and put him into the garden of Eden to dress it and to keep it." The other account of Creation provides for many readers a different picture of the place of men and women in what God has made, as the following verse indicates:

> And God blessed them, and God said unto them, Be fruitful, and multiply, and replenish the earth, and subdue it: and have dominion over the fish of the sea, and over the fowl of the air, and over every living thing that moveth upon the earth.

• Difficulty in Classifying Religious Americans

Classifying religious Americans according to whether they are members of the Religious Right is hard in some instances. American Catholics, for example, vary in their political beliefs and the importance they place on particular issues. Catholic opponents of abortion noted that, upon meeting Pope Benedict XVI on February 18, 2009, House Speaker Nancy Pelosi, a liberal Catholic, praised the Vatican's campaign against global warming but did not mention abortion, while the Vatican stressed that dignified human life begins at conception.

Southern Baptists, for their part, have disagreed about not only primarily theological issues but also superficially secular issues with religious implications, such as global warming. In response to prevailing Southern Baptist positions, the Nobel Laureate and climate activist Al Gore ended his long membership in the Southern Baptist Convention. Furthermore, among evangelicals in general there has been disagreement about public topics, with some evangelicals, such as Ron Sider, being far from right-wing and others, such as Joel Hunter, registering as Republicans but working closely with Democrats. With respect to global warming, at least one prominent, politically conservative evangelical, Pat Robertson, has shifted from skepticism to cautious support of Gore.

• Emphasis on Caretaking

Seeing human beings as caretakers of the Earth even after humanity's first sin, the National Religious Partnership for the Environment, founded in 1993, comprises the Coalition on the Environment and Jewish Life, the United States Conference of Catholic Bishops, the National Council of Churches USA, and the Evangelical Environmental Network. Among the founders of the Jewish group in 1992 was Sheldon Rudoff, the president of the Union of Orthodox Jewish Congregations of America. Among the members of the National Council of Churches, besides such left-leaning denominations as the United Church of Christ, are various Orthodox communions.

As for the Evangelical Environmental Network, in 1994 it issued its Evangelical Declaration on the Care of Creation, the signers of which included David Neff, the editor of *Christianity Today*, usually thought of as a conservative magazine. Led by Jim Ball, the network explicitly opposes nature worship but applauded the Evangelical Climate Initiative, which became public with a statement released in February, 2006, and signed by many prominent evangelicals, including Joel Hunter and Rick Warren. Ironically, Richard Cizik, who was instrumental in obtaining signatures, had to withdraw his own because he worked for the National Association of Evangelicals, which declined to support the initiative. The statement spoke of the great harm that global warming would bring, especially to the poor, and advocated laws to reduce emissions of carbon dioxide (CO_2).

• Emphasis on Ruling

An environmental document differing notably from the 2006 statement of the Evangelical Climate Initiative was the Cornwall Declaration on Environmental Stewardship, issued in 2000, which eventually included as signatories Jacob Neusner, an eminent scholar of Judaism; Richard John Neuhaus, the Catholic priest who edited *First Things*; and the famous evangelicals R. C. Sproul, D. James Kennedy, James Dobson, and Charles Colson. The declaration recognizes the moral obligations that humans have to care for their natural environment, but it claims that they serve as stewards and producers (as well as polluters and consumers), that untouched nature does not mean paradise, and that some environmental matters receive so much concern in rich countries that serious environmental problems in poor countries receive little concern.

In the same vein, the Interfaith Stewardship Alliance was formed in late 2005 and included among its members not only Dobson and Colson but also the global warming skeptic E. Calvin Beisner of Knox Theological Seminary and Richard Land of the Ethics and Religious Liberty Commission of the Southern Baptist Convention. In "A Call to Truth, Prudence, and Protection of the Poor: An Evangelical Response to Global Warming," the Alliance advocated efforts to lessen poverty and help all peoples adjust to whatever climates may come instead of efforts to try to stop global warming at the cost of big increases in energy prices. The Cornwall Alliance, the successor in 2007 to the Interfaith Stewardship Alliance, continued the previous program to respect individual productivity and freedom while following God's law for His Creation.

• Context

Despite differences, all members of the vaguely defined Religious Right believe that God owns the Earth, whether they consider humans as gardeners or viceroys. Neither group rejects the idea of caretaking, however much they disagree about how that care is to be taken. Furthermore, neither group totally rejects the idea of human dominion, because to be ruled by nonhuman creatures and never to harm any of them at all is to die. A charitable examination of each side should reveal good intentions, whether or not they are misdirected. The examination should also reveal that those persons who reject extensive governmental intervention to reduce global warming are, in that respect, to the political right of those who otherwise may be members in good standing of the Religious Right.

Renewable energy

• **Categories:** Energy; environmentalism, conservation, and ecosystems

• Definition

Renewable energy is derived from inexhaustible sources, such as solar energy, wind, biomass, geothermal energy, and the ocean's tides. Solar energy is captured through passive or active means and can be used as heat or electricity. Passive solar energy can be captured by constructing buildings and houses, so heat radiating from the Sun can be used to heat interiors through the strategic placement of windows. Active solar energy comes from the use of photovoltaic (PV) technology, concentrating systems, solar water heaters, and solar cookers.

Only PV technology and concentrating systems can produce electricity from the Sun's heat. PV technology consists of solar cells made of silicon or thin films made from semiconductor materials. Concentrating systems, also known as central solar power (CSP), use mirrors to concentrate sunlight onto a liquid to produce steam, which can then be used to power a turbine and generate electricity.

Wind power is created through the use of wind turbines, which create electricity when the blades are turned by blowing wind. Biomass includes all living or dead plant material and organic waste from humans. Biomass, such as wood and other plants, can be burned in heat and electricity operations, or it can be converted into biofuel to be used in an internal combustion engine. Geothermal energy is the internal heat energy of the Earth. It can be taken directly from vents in the Earth's crust, where it can be used to heat homes or greenhouses. It can also be used to create electricity by injecting water into hot spots so that steam is produced, which can then be used to run a turbine.

Ocean energy includes the energy from waves, tides, and changes in water temperatures. Waves and tides can produce electricity by turning turbines, similar to wind. Changes in sea temperatures at various depths can create energy through a process called ocean thermal energy conversion (OTEC). OTEC can be used in certain areas of the ocean where the water is warm enough to create steam from a special low-boiling-point fluid, which is then used to power a turbine and produce electricity.

• Significance for Climate Change

Many experts and world leaders view renewable energy as a major solution for mitigating climate change. The use of fossil fuels to satisfy human energy needs is one of the major contributors to greenhouse gas (GHG) accumulation in the atmosphere. Renewable energy, with the exception of biomass, does not create GHGs in the process of creating heat or electricity as fossil fuels do, because nothing has to be burned. Although biomass must be combusted, it has the potential to emit less GHGs than do fossil fuels, though how much less is heavily debated.

If renewable energy sources are used as substitutes for fossil fuels, the amount of GHG emissions would be reduced and presumably so would climate change. Renewable energy is also seen as a solution to the worldwide growth in energy demand that has the potential to contribute even more GHG emissions. As more developing countries seek electrification for household and industrial uses and find needs for motorized transportation, their demand for energy will increase their use of fossil fuels and their GHG emissions. Renewable energy is thus a potential solution to allow for development to continue while reducing its impact on the climate.

A geothermal drilling rig in Paris, France, participates in an initiative to provide clean heat for the entire nineteenth arondissement. (Benoit Tessier/Reuters/Landov)

Although political agreements such as the Kyoto Protocol do not require that renewable energy be used to reduce GHG emissions, it is expected that renewable sources will have to become part of the energy mix to achieve the goals of such agreements. From transnational organizations like the European Union to the cities that are a party to the U.S. Conference of Mayors Climate Protection Agreement, governments are passing laws that require utilities to produce electricity from renewable energy. Renewable energy has had difficulty competing in an open market with fossil fuels, a seemingly inexpensive energy source, creating a need for government intervention. It is expected that once renewable energy is economically competitive with fossil fuels, demand for it will soar. Energy experts such as Jeremy Leggett and U.S. representative Jay Inslee argue that efforts similar to those that put humans into space, developed nuclear energy, and won World War II will be needed to make renewable energy a viable solution for global warming.

Reservoirs, pools, and stocks

• **Categories:** Meteorology and atmospheric sciences; environmentalism, conservation, and ecosystems

• Definition

Reservoirs, pools, and stocks are designations used in box models. A box model is a simplified version of a complex system, in which various parts of that system are reduced to boxes that are linked by fluxes. A reservoir is any box within that system that can accumulate, store, or release the substance of interest. In box models of the global carbon system, the oceans, terrestrial plants, soil, and rocks are examples of reservoirs. The atmosphere is typically not considered to be a reservoir. "Pool" is a term that is synonymous with "reservoir" but can include the atmosphere.

Stocks are the actual accumulations of the substance of interest. Thus, in a box model of the global carbon cycle, the stock is the mass or amount of carbon in various forms—including carbon dioxide (CO_2) gas and dissolved species or solids, such as organic matter or inorganic minerals—in each reservoir. The stock in each reservoir is assumed to be well mixed, so that regardless of the size of the reservoir, the concentration of stock throughout the reservoir is uniform. The stock present in each reservoir can change over time, as the rate of input or output from each reservoir varies. In simple box models, reservoirs or pools are held to constant volumes. In more complicated models, the size of a reservoir can change. Numerical methods and computer programs are utilized with box models to solve equations to determine parameters such as the amount of stock in a given reservoir over time or the time needed for the amount of stock in a reservoir to change.

• Significance for Climate Change

Box models, as simplified conceptual models of complex systems and processes, are of fundamental importance for predicting future climate conditions. Results from such models underlie the predictions that are published by the Intergovernmental Panel on Climate Change and other scientific and policy-making bodies. Such models can be applied to any complex system, regardless of scale, such as the global carbon cycle or the biochemical processes in a single cell. With regard to future global warming scenarios, variations in the global carbon cycle are among the fundamental drivers of climate change. Other topics of interest include the global cycles of water, nitrogen, oxygen, and sulfur.

In the development of a box model, the reservoirs and stocks of the species of interest are fundamental properties that must be defined in order to perform the necessary calculations. One of the largest sources of error in box models involves defining the size of reservoirs and pools and determining the amount of stock in each. For example, within the global carbon cycle, the stock of carbon present as gas hydrates in the seafloor is presently not well known. This value must be estimated from a relatively low number of measurements in specific regions and extrapolated to all other places on Earth where these compounds might be present. Gas hydrates have been a source of discussion in the scientific community as a trigger for rapid warming in the recent geologic past (as in the clathrate gun hypothesis of James Kennett).

A key question that is often addressed using box models is how the stock within a given reservoir might change in response to certain events. For example, to estimate the amount of global warming that has been caused by anthropogenic production of CO_2, scientists must use box models to determine how the stock of CO_2 in various pools (such as the atmosphere and oceans) has changed in response to the increased input of CO_2 to the environment. Predictions of the length of time needed for atmospheric CO_2 stocks to decline in response to future CO_2 emissions are also based upon box models of the global carbon cycle.

Residence time

- **Category:** Chemistry and geochemistry

- **Definition**

Residence time measures how long an individual atom or molecule spends in a system from entrance to exit. For example, the residence time of a carbon dioxide (CO_2) molecule in the atmosphere is the duration spent by the molecule from its entrance via emission from fossil fuel combustion to its exit via uptake by ocean or land ecosystems. The residence time of a carbon atom in a land ecosystem is the length of time spent by the atom from photosynthetic fixation to the respiratory release of the carbon.

An average residence time of an element (molecule or atom) in a system can be calculated from division of pool size by flux of the element when the system is in equilibrium. For example, residence time of CO_2 in the atmosphere is approximately equal to

$$750 \text{ Gigatons} \div 200 \text{ Gigaton years}^{-1} = 3.75 \text{ years}$$

The residence time of the carbon atom in the land ecosystem is approximately

$$2{,}000 \text{ Gigatons} \div 120 \text{ Gigaton years}^{-1} = 16.67 \text{ years}$$

However, when a system is not in equilibrium, the influx of an element into a system is no longer equal to the efflux. For example, CO_2 concentration is building up in the atmosphere. Thus, influx of CO_2 into the atmopshere is larger than the efflux. In this case, the residence time calculated by pool/influx is smaller than pool/efflux.

• **Significance for Climate Change**

Residence time is a critical parameter to characterize element cycling in a system. In studies of carbon sequestration in terrestrial ecosystems, residence time is a key parameter to quantify the potential capacity of an ecosystem to sequester carbon. All carbon atoms that enter an ecosystem from the atmosphere via photosynthesis will eventually be released back to the atmosphere via respiration. Carbon sequestration occurs in a land ecosystem when a fraction of influxing carbon stays in the ecosystem for a long time. Thus, the longer the residence time, the larger the carbon sequestration capacity. Carbon incorporated into the wood of trees has a longer residence time than that in leaves or fine roots. Carbon incorporated into soil organic matter in general has an even longer residence time than that in wood. That is the reason why stimulating carbon sequestration in forests and soils is potentially effective at mitigating greenhouse emissions.

The residence time can describe the average time for a molecule to stay in the atmosphere before being removed by mixing into the ocean and land ecosystems. To evaluate the impacts of greenhouse gases (GHGs) on enhanced greenhouse effects, a concept, atmospheric lifetime, has been introduced to represent the net concentration changes of the various GHGs by all sources and sinks instead of just the removal processes as described by residence time. Although the residence time of CO_2 in the atmosphere is only a few years, its atmospheric lifetime to indicate recovery from a large input of atmospheric CO_2 from burning fossil fuels is tens of thousands of years. The atmospheric lifetime is estimated to be 12 ± 3 years for methane, 120 years for nitrous oxide, and 3,200 years for sulfur hexafluoride. The longer the atmospheric lifetime is, the greater the total impact of a GHG on global warming. That means the impacts of these GHGs on global warming will last long after emission is cut back.

Response time

• **Categories:** Chemistry and geochemistry; meteorology and atmospheric sciences

• **Definition**

The response time of a natural system is the amount of time it takes for the system to respond to a change in the forcing mechanisms. In the case of the climate system, the forcing mechanism of most importance is radiative forcing, which is defined as the net irradiance at the top of the tropopause (boundary between the troposphere and the stratosphere). There are many processes that can affect radiative forcing, including natural phenomena such as variations in the Earth's orbit or in the output of solar radiation, or anthropogenic (human-induced) effects such as the addition of greenhouse gases to the atmosphere. Different components of the Earth system, such as the troposphere, stratosphere, or ocean, have different response times. These differences are largely controlled by heat capacity, which is the amount of heat required to change the temperature of a specific mass of the substance by 1° Celsius.

Heat capacity acts like a shock absorber, slowing the response rate of a system to a temperature change. The heat capacity of the ocean is approximately four times greater than that of the atmosphere, so that the response time of the ocean is much slower than that of the atmosphere. Response times of the atmosphere are typically on the scale of days to weeks, while that of the deepest parts of the ocean can exceed one thousand years. Variations in response time are also observed within each reservoir. For example, because the troposphere is coupled to the ocean—which acts as a brake for changes in the troposphere—its response time is typically on the order of weeks to a few months. In contrast, the response time of the stratosphere is shorter, ranging from a few days to weeks.

• Significance for Climate Change

The response time of different reservoirs is a critical aspect in attempts to predict future climate change. For example, the Intergovernmental Panel on Climate Change (IPCC) uses coupled ocean-atmosphere models to determine the effects of anthropogenic carbon dioxide (CO_2) emissions on climate change. Even in a scenario where CO_2 emissions would be fixed at a level equal to that of the year 2000, global temperature in 2100 is predicted to be 0.6° Celsius higher than today. This continued rise in temperature is due to the slow response time of the oceans. Regional variations in global temperature changes are also observed in models, because the response time of the individual ocean basins vary. The National Oceanic and Atmospheric Administration's Geophysical Fluid Dynamics Laboratory has shown that the response time of the ocean varies with the direction of the change in radiative forcing. If the change was cooling (for example, decreased amounts of atmospheric CO_2), the ocean responded approximately twice as fast as if the change was in a warming direction.

Because the slow response time of the oceans means that global temperatures are predicted to rise even if CO_2 emissions were instantly held at year 2000 levels, many scientists and policy makers are calling for research into geoengineering solutions to global warming. Geoengineering refers to any attempt by humans to control global climate. A variety of possible mechanisms have been proposed, which are designed to achieve one of two outcomes: decrease the amount of incoming solar radiation or reduce the amount of CO_2 in the atmosphere. Proposed projects include chemical approaches such as adding iron to the ocean to reduce atmospheric concentrations of CO_2 ("iron fertilization") and pumping sulfur dioxide into the stratosphere to cause a higher rate of cloud formation.

Other proposals include the installation of a "sunshade" made from stacks of very thin silicon nitride ceramic in space to block incoming solar radiation. Currently, most climate scientists and geoengineering advocates are in agreement that not enough is known about the negative consequences of any of the proposed geoengineering projects. Therefore, these scientists advocate conducting research to determine the potential consequences, such as regional variations in drought cycles or a decrease in atmospheric ozone. Finally, projects aimed at reducing the amount of incoming solar radiation may eventually lead to a decrease in global temperature, but may not directly affect other effects of increased concentrations of atmospheric CO_2 that will remain a concern, such as ocean acidification.

Revelle, Roger
American oceanographer

Born: March 7, 1909; Seattle, Washington
Died: July 15, 1991; San Diego, California

In an article coauthored with Hans Seuss in 1957, Revelle proposed the idea of the greenhouse effect, indicating that this phenomenon would lead eventually to global warming. Later in his career, Revelle served on the faculty of Harvard University, where he taught Al Gore, among others.

• Life
Roger Revelle was born in Seattle, Washington, on March 7, 1909. He received a bachelor's degree in geology in 1929 from Pomona College and then attended the University of California at Berkeley, receiving a Ph.D. in oceanography in 1936. After completing his studies, Revelle went to work at the Scripps Institution of Oceanography in San Diego, leaving briefly to serve as an oceanographer for the U.S. Navy during World War II. During this time, he was quite influential in the Navy's oceanographic research program. He returned to Scripps, remaining there until 1964 and serving as director of the institution from 1950 until 1964. Thus, Revelle was a major contributor to the field of oceanography in both the public and the private sector. He also served as a science adviser to the John F. Kennedy administration.

Upon leaving Scripps, Revelle went to Harvard University, where he founded the Center for Population Studies and served as a professor for Al Gore, sparking his interest in climate change and global warming. Gore later cited Revelle as his mentor in his crusade against global warming, for which Gore won the Nobel Peace Prize. While at Harvard University, Revelle focused his interest and his research on the problems of world hunger. Revelle was hopeful that by increasing knowledge of biology and of the environment, science could improve agricultural production. In 1976, he returned to California as a professor of science, technology, and public affairs at the University of California in San Diego. In 1974, he served as president of the American Association for the Advancement of Science. Shortly before his death in 1991, he was awarded the National Medal of Science for his work on the greenhouse effect.

• Climate Work
Revelle and Hans Seuss wrote the seminal paper in the field of global warming. In this paper, Revelle and Seuss suggested that the burning of fossil fuels was dramatically increasing the amount of carbon dioxide (CO_2) in the atmosphere. They then went on to indicate that this CO_2 was very slowly absorbed by the surface of the ocean. They attributed the slowness of this process to the buffer effect, which has become known as the Revelle effect. Revelle and Seuss also believed that the CO_2 unleashed by the burning of fossil fuels would result in a greenhouse effect, with the CO_2 absorbing infrared radiation and trapping heat over the Earth's surface. This process in the long run would lead to global warming.

Revelle hoped that the International Geophysical Year (July, 1957-December, 1958), which he helped create, would provide an opportunity to investigate the impact of increasing CO_2 levels on the temperature of the planet. In 1984, Revelle became the first chair of the Committee on Climate Change and the Ocean under the auspices of the Scientific Committee on Ocean Research. Since that time, this organization has been concerned with the ocean's role in global warming. Work that Revelle pioneered in the mid-twentieth century served as the precursor to the concern over global warming and climate change as it existed in the early twenty-first century.

Rowland, F. Sherwood

American chemist

Born: June 28, 1927; Delaware, Ohio

The award of the 1995 Nobel Prize in Chemistry to Rowland, his coworker Mario J. Molina, and Paul J. Crutzen "for their work in atmospheric chemistry, particularly concerning the formation and decomposition of ozone" was considered a vindication of environmental science, thitherto belittled by the mainstream scientific community.

• Life

F. Sherwood Rowland was the second of three sons born to Sidney Rowland and Margaret Lois Rowland (née Drake). His father was a professor of mathematics and chair of the Department of Mathematics at Ohio Wesleyan University in Delaware. Frank received his elementary and high school education in the Delaware public school system. Accelerated promotion policy allowed him to enter first grade at age five, skip fourth grade, enter high school at age twelve, and graduate at age fifteen. During summers in high school, he operated the local volunteer weather station, his first exposure to experimentation and data collection. He also played varsity tennis and basketball.

After graduating in 1943, Rowland attended Ohio Wesleyan University and enlisted in a U.S. Navy program, attaining the rank of specialist (athletics) third class. After his discharge, he returned to Ohio Wesleyan, receiving a bachelor's degree in 1948. He enrolled in his parents' alma mater, the University of Chicago, where he continued to participate in basketball and baseball and worked on radiochemistry under future (1960) Nobel chemistry laureate Willard Frank Libby, receiving a master's degree in 1951 and a Ph.D. in 1952. On June 7, 1952, he married Joan Evelyn Lundberg, with whom he had two children, Ingrid Drake (b. 1953) and Jeffrey Sherwood (b. 1955).

Rowland became an instructor in chemistry at Princeton University (1952-1956), spending summers (1953-1955) at the Brookhaven National Laboratory. In 1956, he became assistant professor of chemistry at the University of Kansas, where he headed a research group studying the chemistry of energetic tritium atoms and rising to the rank of full professor. In 1964, he became professor of chemistry and department chair (1964-1970) at the newly established University of California, Irvine, where he was later named Donald Bren Research Professsor of Chemistry.

• Climate Work

Rowland has deliberately changed his research subject every few years, turning to the environment, a significant topic to the general public and his family. He learned that in 1971 British atmospheric scientist James E. Lovelock used his new electron capture detector to demonstrate that the inert synthetic chlorofluorocarbon (CFC or Freon) trichlorofluoromethane ($CC1_3F$) had spread throughout the troposphere (the 10-kilometer layer of the atmosphere below the stratosphere) over the north and south Atlantic Ocean. As a photochemist and kineticist, Rowland was aware that the molecule could not remain inert in the troposphere indefinitely.

In 1973, together with postdoctoral research associate Mario J. Molina, who had just received a Ph.D. from the University of California, Berkeley, Rowland began to search for a sink—a source of reactions by which CFCs are decomposed. The researchers concluded that the CFCs would rise into the stratosphere, where ultraviolet rays would break them down into chlorine atoms, which would react with the ozone layer by catalytic chain reactions. Based on their measurements of the relevant reaction rates, Molina and Rowland calculated within three months that continued usage of CFCs for several decades would deplete the ozone layer by several percentage points.

Among the deleterious environmental consequences of the depletion of the ozone layer is the increase in the number of cases of skin cancer. Molina and Rowland predicted an additional forty thousand cases in the United States alone by 2050. Also, the increased ultraviolet radiation could kill the phytoplankton that form the bottom of the ocean's food chain, as well as affecting global climate. The Environmental Protection Agency (EPA) banned the use of CFCs in aerosols in 1974. The United Nations' 1987 Montreal Protocol and later provisions further restricted their release into the atmosphere. Although there has been an anti-environmental backlash because of political considerations, additional work by Rowland, Molina, and numerous other scientists have confirmed the reality of the anthropogenic depletion of the ozone layer.

Rural air quality

• **Category:** Pollution and waste

• **Definition**

Pollutants affecting the quality of rural air include particulate matter, ozone, and emissions from industries, power plants, and vehicles. Air in rural areas is also polluted with dust from unpaved roads, livestock gases, and agricultural products containing ammonia, nitrogen oxide, sulfur dioxide, and other toxic chemicals. Urban emissions transported by wind currents also pollute rural air.

Medical professionals identify health risks associated with rural residents' contact with harmful pollutants in air they breathe. Local, state, and national governments worldwide consider strategies to control rural air pollution and restrict emissions. The U.S. Environmental Protection Agency (EPA) developed the National Ambient Air Quality Standards (NAAQS), which is frequently used to measure pollution levels in rural areas.

• Significance for Climate Change

During the 1990's, temperature increases associated with global warming exacerbated pollution in rural locations, resulting in the EPA issuing stricter emission standards. This federal regulation alerted the public that rural areas experienced severe air pollution, contrary to many people's perception of the countryside as having cleaner air than do urban sites. Many agricultural organizations, including the American Farm Bureau Federation, stated that emission standards would impede farming and resisted compliance. At that time, most pollution control agencies did not enforce attainment, and rural air quality declined.

By the early twenty-first century, ozone, particulate matter, and smog represented significant pollution hazards to rural residents. Vehicle exhaust and other emissions chemically react with sunlight to produce ozone. Officials recognized that ozone pollution was created both by rural emissions and by urban industries releasing greenhouse gases (GHGs) that drifted into rural areas and contributed to raising temperatures conducive to generating ozone. As smog accumulated in rural areas, the EPA adjusted prior NAAQSs, considering air safe if 1 cubic meter did not exceed a maximum of 15 micrograms of particulates and 75 parts per billion of ozone.

The San Joaquin Valley, an agricultural region in central California, suffers poor rural air quality. Mountains in that area restrict pollutants' movement. Smog fills the valley. In 1999, a coalition consisting of such groups as Medical Advocates for Healthy Air had focused on poor air quality, as global warming conditions heated the San Joaquin Valley. That alliance estimated that particulates caused thirteen hundred deaths annually in the valley. Citing provisions of the Clean Air Acts (1963-1990), the coalition legally pressured officials in the San Joaquin Valley Unified Air Pollution Control District to devise programs to protect rural air quality and seek attainment of federal standards.

The San Joaquin Valley Unified Air Pollution Control District monitors wineries' boilers, verifying that they do not discharge excess carbon and other pollutants while burning. Approximately 2.5 million dairy cattle in the valley contribute to smog by expelling gas containing volatile organic compounds created by microorganisms during digestion. These compounds convert into ozone in the atmosphere. The San Joaquin Valley Unified Air Pollution Control District's Rule 4570 requires dairies stocking one thousand or more cattle to comply with air quality regulations in order to secure permits.

Costs of Rural and Urban Air Quality Degradation by Motor Vehicles, 2000

Pollutant	*Impact*	*Rural Emissions ($)*	*Urban Emissions ($)*
Particulate matter	Mortality	12,695	21,558
Particulate matter	Nonfatal illness	3,683	6,232
Sulfur dioxide, nitrogen dioxide, carbon monoxide	Nonfatal illness	0	51
Ozone	Nonfatal illness	28	16
Total		16,406	27,857

Source: Federal Highway Administration, United States Department of Transportation.
*Costs of human illnesses, in millions of 1990 dollars. Costs of crop damage, reduced visibility, and other physical effects on the environment are not included.

Increased ozone associated with climate change harms tomato cultivation in the San Joaquin and Sacramento Valleys; tomatoes generate several hundred million dollars yearly for the region. Rural air pollution affects crop yields globally. Despite these damages, nonattainment of EPA standards often prevails. Exemptions allow commercial agriculturists to use machinery and diesel fuels that emit pollutants that are harmful to air quality and also intensify global warming. Livestock confinements produce methane, hydrogen sulfide, and other pollutants that contribute to climate change while lowering air quality.

Industries often select sparsely populated rural locations for their factories. Many rural residents represent lower socioeconomic classes and lack the influence and resources to prevent industrial intrusion. Factories generate heat that traps GHGs and smog above rural areas. Industrial particulates damage fields and forests. Commuters' vehicles, moving between rural and urban areas, worsen air quality in the countryside. The San Joaquin Valley Unified Air Pollution Control District utilizes the Indirect Source Rule to reduce rural development pollutants, charging fees for construction of subdivisions and buildings with substantial square footage. Officials invest those funds in alternative fuels and air quality and climate control projects.

Wildfires and domestic fires for cooking or waste removal add smoke and ozone to rural air. Fires set to clear rural land destroy carbon-absorbing plants. In 2007, as temperatures warmed, a combination of GHGs and air pollution referred to as the Asian Brown Cloud contributed to melting approximately forty-six thousand glaciers, causing flooding and depleting long-term water sources in rural areas. This pollution traveled to other continents. The California Air Resources Board and the National Aeronautics and Space Administration (NASA) deployed aircraft in 2008 for scientists to evaluate air pollution movement and how it affects the atmosphere and climate changes.

Russian Federation

- **Category:** Nations and peoples
- **Key facts**

Population: 141,377,752 (July, 2007, estimate); population of former Soviet Union: 293,047,571 (July, 1991)

Area: 17,075,200 square kilometers; area of former Soviet Union: 22,402,200 square kilometers

Gross domestic product (GDP): $2.225 trillion (purchasing power parity, 2008 estimate)

Greenhouse gas (GHG) emissions in millions of metric tons of carbon dioxide equivalent (CO_2e): 2,763 in 1990; 1,699 in 1999; 1,932 in 2005

Kyoto Protocol status: Ratified, 2004

• Historical and Political Context

Several major themes in Russia's history influence the nation's political, military, and economic actions to the present day. Among them are its geographic and cultural isolation from the rest of Europe and repeated invasions from both Europe and Asia. The hardships endured by Russians throughout their history have created a deep sense of tragedy that is readily apparent in Russian literature and music and that has led to a pervasive political culture of suspicion against external and internal threats.

During the nineteenth century, Russia alternated between periods of reform and repression, as some rulers (czars) attempted to enact long-overdue reforms and others resorted to repression to control the mounting pressures for change. Following Russia's catastrophic losses during World War I (1914-1918), a revolution deposed the last czar, only to be followed by the overthrow of the new government during the Bolshevik Revolution of October, 1917. The Bolsheviks (from the Russian word *bolshe*, meaning "more") were so called because they became the majority faction of the Marxist Russian Social Democratic Labor Party. The system of government imposed by the Bolsheviks, called communism, was an attempt to implement the economic theories of Karl Marx. Under communism, the state owned and ran all businesses. The former Russian Empire was renamed the Union of Soviet Socialist Republics (or Soviet Union).

In theory, communism was supposed to act on behalf of the people. In practice, it was inefficient and repressive. The worst repression came under the rule of Joseph Stalin, from 1922 to 1953. Stalin's attempt rapidly to industrialize the Soviet Union resulted in famines in which millions died, and in the 1930's he launched a vast campaign of terror, called the Great Purge, during which millions of alleged enemies of the state were killed or exiled to prison camps. During World War II (1939-1945), the armies of Nazi Germany drove deep into Russia before being driven out, and more than 20 million Russians died.

After World War II, the Soviet Union succeeded in imposing communist governments in much of Eastern Europe and emerged as the main geopolitical rival of the United States and its allies. The rivalry was expressed in a long period of tension called the Cold War (1947-1991), which saw no direct warfare but many "proxy wars" in which the United States and Soviet Union supported opposing sides. After Stalin's death in 1953, the Soviet Union moderated its internal repression somewhat, although it remained highly authoritarian, and it advanced rapidly in military and space technology. Having acquired nuclear weapons by 1949, the Soviets launched the first artificial satellite in 1957 and the first human in space in 1961. By the late 1980's, Soviet leaders, aware of growing problems in the Soviet system, began inaugurating reforms, but the reforms failed to prevent the dissolution of the Soviet Union in 1991. Roughly one-quarter of the area of the Soviet Union and half of its population—former satellite states, or soviets—seceded from Russia to form fourteen independent countries.

• Impact of Russian Policies on Climate Change

Under communism, many of the important themes of Russian history reasserted themselves. The cult of suspicion that long pervaded Russian thinking produced a vast secret police and prison camp system, tight controls on dissent and access to information, and tight controls on outside access. The Soviet Union vigorously disseminated propaganda, displaying its greatest successes in an effort to persuade others of the superiority of its system, while simultaneously making it difficult or impossible to learn about failures. Furthermore, the Soviet Union focused its efforts on heavy industry, military power, and spectacular achievements in technology, to the detriment of the consumer sector and the environment.

In one respect, the Soviet Union was a victim of its own success. It succeeded in portraying itself as far more militarily powerful than it actually was,

and the resulting arms race with the United States was a principal factor in finally bankrupting the Soviet Union. The Soviet Union also succeeded in portraying itself as having far better social services and concern for the environment than it really did, and the limited access to much of the Soviet Union made it difficult for outsiders to learn the real extent of the nation's environmental disasters. The secret police system stifled even constructive dissent, so foreigners and Russians alike remained uninformed about even grave environmental problems. The reality was that in remote industrial areas of the Soviet Union there were appalling toxic chemical accidents, oil spills, and pollution.

Two environmental disasters are emblematic of the environmental problems Russia has inherited from the former Soviet Union. The 1986 disaster at the Chernobyl Nuclear Power Plant (located in the present Ukraine) was the worst nuclear reactor accident in history. The cause of the Chernobyl disaster has been attributed both to operator errors and to poor reactor design, but it is clear from all accounts that the accident was the result of conducting a crucial test when only a skeleton crew was on duty, that many of the workers were inexperienced and familiar only with conventional power plants, that monitoring devices did not adequately reflect the developing crisis, and that neither the reactor crew nor first responders were aware of the radiation danger (and many died as a result). The meltdown of the Chernobyl nuclear reactor released radioactive fallout into the atmosphere that eventually extended across the western Soviet Union, Europe, and eastern North America; more than 300,000 people had to be evacuated and resettled, and parts of Ukraine, Belarus, and Russia were severely contaminated.

The drying up of the Aral Sea (actually a large lake shared by present Kazakhstan and Uzbekistan) has been called the greatest environmental disaster of modern times. Because of water diversion for agriculture, the lake shrank in area by three quarters between 1960 and 2008. A plan to divert water from Siberia to the Aral Sea was abandoned in the 1980's but may be revived in the future.

Both the Chernobyl and the Aral Sea disasters typify the Soviet-era tendency to ignore future risks and environmental dangers in favor of immediate practical results, coupled with poor planning and lack of accountability to the society. Although Russia reformed many features of its government and economy after the dissolution of the Soviet Union, many of its regulatory agencies remained inefficient or corrupt. In such an environment, there are many opportunities to ignore greenhouse gas (GHG) emissions standards or divert funds meant for modernization.

• Russia as a GHG Emitter

According to the United Nations Environment Programme, in 1990 Russia emitted 2.763 billion metric tons of GHGs measured in carbon dioxide (CO_2) equivalent, the amount of CO_2 that would have the same effect as the gas in question. (For example, 1 metric ton of methane is measured as about 20 metric tons of CO_2 equivalent.) These 1990 emissions account for about one-sixth of total global GHG emissions for 1990, the year before the Soviet Union dissolved. By 1999, thanks to Russia's economic collapse and the shutdown of many industries, emissions fell to 1.699 billion metric tons of CO_2 equivalent. By 2005, Russia's emissions had risen to 1.932 billion metric tons of CO_2 equivalent, still 28.7 percent below their 1990 levels.

In 2004, Russia ratified the Kyoto Protocol. Thanks to its economic decline, Russia was already below its Kyoto emissions target. The Kyoto Protocol called for a 5 percent reduction in GHG emissions from 1990 levels by 2008, but Russia's emissions in 2005 were 28.7 percent below 1990 levels. As analyst John Carey pointed out, Russia's low emissions were a "valuable commodity" that it could trade under emissions-trading rules. The trading is advantageous to other European nations, because it is cheaper for them to buy emissions credits from Russia than to remodel their own industries. Russia's ratification pushed the protocol over the threshold for entry into legal force. The ratification was opposed by the United States, which was left as the only leading industrial nation not to have ratified the protocol.

Russia is also one of the world's largest petroleum producers, fourth in the world after Saudi Arabia, Kuwait, and Iraq, with an estimated 70 to 130 billion barrels of proven oil reserves and 47 trillion cubic meters of natural gas. Sale of petroleum and natural gas can furnish Russia with much-needed funds for modernization. More than half of Russia's own energy comes from natural gas. By selling its petroleum and natural gas abroad, Russia effectively exports its emissions while receiving additional money for emissions credits. As Russia recovers economically, its own domestic emissions are certain to increase.

Russia is among the world's largest producers of oil. This pumping station is one of many driving the nation's Eastern Siberia-Pacific Ocean oil pipeline. (Kolbasov Alexander/ITAR-TASS/Landov)

• Summary and Foresight

For more than a decade following the collapse of the Soviet Union, Russia struggled to maintain its stability and economic survival. By 2008, Russia had begun to recover and began rebuilding militarily and asserting its interests more vigorously. For example, it resumed its practice of long-range flights over neutral waters and held joint military exercises with other nations, including China. In 2005, Russian president Vladimir Putin said, "the demise of the Soviet Union was the greatest geopolitical catastrophe of the century," a clear sign of Russia's hope to regain its global influence.

Despite its problems, Russia in the early twenty-first century was a far more open and free society than the Soviet Union. However, Russia continued to suffer the Soviet legacy of inefficient production, widespread corruption, and poorly designed and outdated equipment. Although Russia's economic decline made it easy to meet its Kyoto obligations, in order to improve the quality of life of its people, Russia will have to increase its industrial output, and to do that it will need to modernize its antiquated industries. In turn, the nation's GHG emissions will inevitably increase. The challenge facing Russia in the first half of the twenty-first century is to modernize and increase output while simultaneously holding emissions below the Kyoto limits.

A major obstacle facing Russia in rebuilding its economy is widespread corruption and organized crime. According to many accounts, a substantial amount of the cost of any business venture is bribes to the bureaucrats responsible for approving the project. Organized crime existed under communism as a widespread black market, and, after the collapse of the Soviet Union, organized crime quickly gained control of many sectors of the Russian economy. Numerous journalists and business leaders who threatened to expose corruption or refused to pay bribes to organized crime gangs have been assassinated. Russian organized crime has also emerged as a world leader in cybercrime, such as online identity theft and distribution of computer malware.

Sahara Desert

• **Categories:** Environmentalism, conservation, and ecosystems; geology and geography

• **Definition**

The Sahara Desert is the world's largest warm desert region and covers an area of approximately 9 million square kilometers, from the Atlantic coast of Africa to the Red Sea and from the Mediterranean Sea to the Niger River and the margins of the Ethiopian highlands. Most of the Sahara Desert experiences an arid or hyperarid climate, with scant precipitation. Rainfall is mainly from winter cyclonic storms on its northern margins, whereas the southern Sahara receives summer monsoonal rainfall.

• **Significance for Climate Change**

The history of climate change and variability in the Sahara is a clear indication of the sensitivity of a major desert region to climate change on all timescales. Changes in Saharan climates also affected global biophysical systems via variations in the flux of windblown dust, for which the Sahara is the major global source. The major past climate changes in the Sahara Desert were the result of cyclic changes in the Earth's orbit and are therefore not good analogues for future climates in the region, although some authors have suggested that the early-to-mid Holocene humid period may be an appropriate model for the response of the Sahara region to future climate change and global warming.

Information on the history of climate in the Sahara comes from deposits of lake basins, fossil rivers, springs, and sand dunes, supplemented by the record of marine sediments offshore of the western Sahara. Desert conditions appear to have prevailed in the Sahara for at least 7 million years, evidenced by pollen in ocean cores and sand dune deposits in Mali dating back that far, but these conditions were interrupted on many occasions by periods of increased rainfall.

The present extent of the Sahara Desert dates to a period lasting from six thousand to four thousand years ago, when the region was desiccated following an interval of much increased rainfall that lasted for several thousand years—the African Humid Period. Reconstructions of past environments from the region show that savanna vegetation covered most of the region in the early-to-mid Holocene, with perennial or intermittent streams occupying now dry wadis and large lakes in topographic basins, such as the Bodelé Depression. Human and animal populations greatly increased at this time. These lakes gradually dried out starting about six thousand years ago, resulting in increased dust flux. Increased rainfall throughout the Sahara was the result of the insolation maximum in Northern Hemisphere low latitudes caused by cyclical changes in Earth's orbit. This phenomenon promoted a much stronger West African monsoon circulation. The African Humid Period in the Sahara was, however, not uniformly wetter: A significant dry spell occurred around eight thousand years ago.

A nomad and his camel survey the Sahara Desert. (©iStockphoto/Graeme Purdy)

Prior to the Last Glacial Maximum (LGM), the northern Sahara experienced increased and more effective precipitation from winter storms, giving rise to groundwater recharge in the period from 45,000 to 23,500 years ago. Studies of noble gases in groundwater indicate temperatures were 2°-3° Celsius lower at that time than they are today in the northern parts of Sahara. They were at least 5°-6° Celsius lower in the southern Sahara. Other periods of wetter climate in the Sahara are poorly dated but appear to have occurred during several interglacial periods.

At the time of the LGM, the Sahara experienced intense aridity and sand dune formation that extended to areas far to the south of the modern limits of the Sahara, including Mauritania, Mali, and Niger, where linear dunes formed between twenty-five thousand and twelve thousand years ago. Dust flux to ocean sediments also increased at this time. Glacial age aridity in the Sahara was accompanied by an intensified trade wind circulation and the virtual absence of monsoon circulations.

Analysis of climatic data and historical records show the sensitivity of the southern Sahara and its margins to climate variability, with major droughts occurring at regular intervals. In recent decades, such climate variability has been linked to Atlantic Ocean surface temperatures. Warmer waters off Africa result in convection over the ocean rather than the land and reduced monsoon rainfall in a wide area from Senegal to Ethiopia.

Global climate models differ in their predictions of the direction and magnitude of future change in the Sahara, as in many other arid regions, in large part because prediction of precipitation in global climate models is less reliable than are estimates of future temperatures. In the Sahara, there is support in many climate model predictions for increased rainfall in southern and southeastern areas (including the Sahel) but strong drying in the northern and western areas. Some models, however, suggest that strong drying will occur throughout the region. The differences between model predictions for the Sahara show the complexity of forcing factors for this region, as well as the possible influence of feedbacks between land surface conditions and the atmosphere, which may affect rainfall total, effectiveness, and spatial distribution.

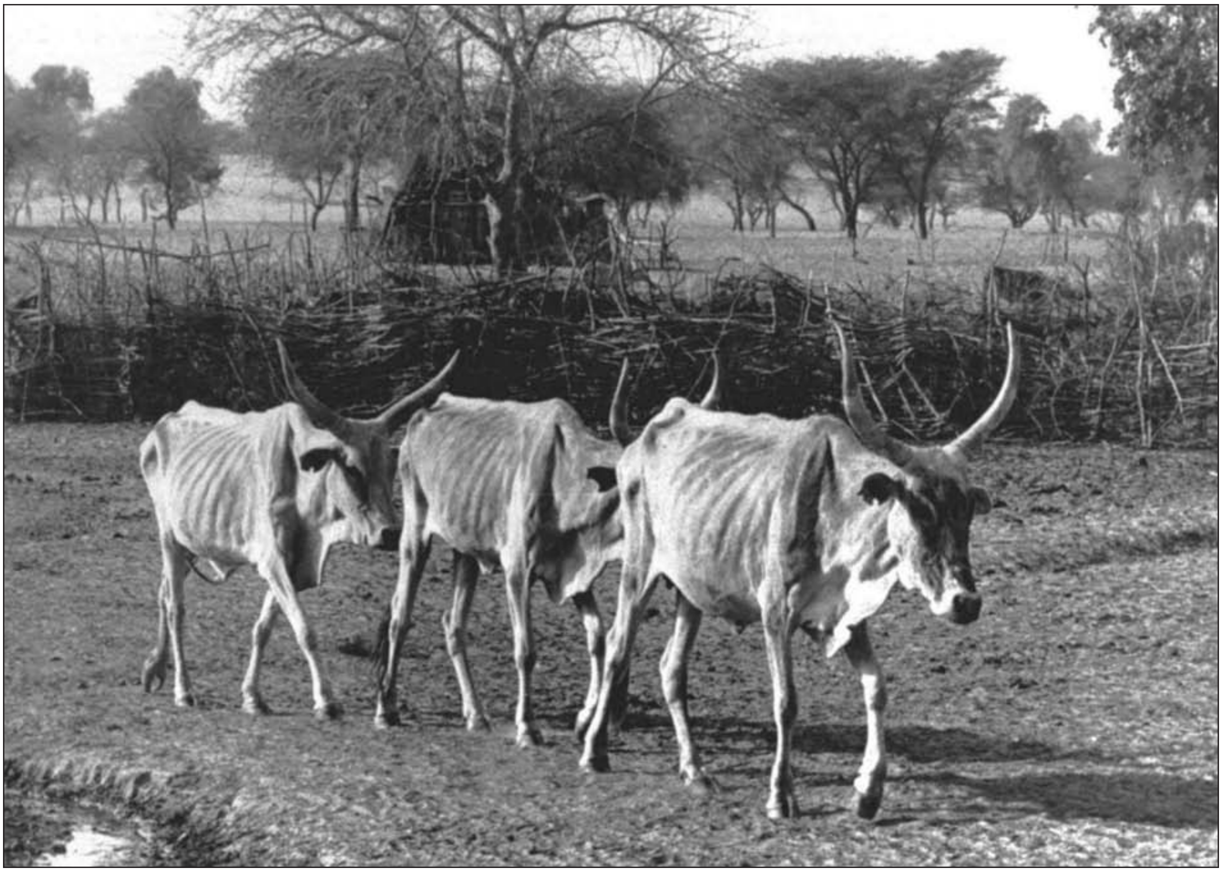
Sahel drought

- **Category:** Meteorology and atmospheric sciences

- **Definition**

The Sahel (meaning "shore" or "edge" in Arabic) is the region in Africa between the Sahara Desert and the savanna and stretches from the Atlantic Ocean to the Red Sea and Indian Ocean. The area covers all or part of twenty-three countries, the majority of which are in West Africa. Sahel in West Africa is also a geopolitical group made up of nine countries.

The Sahel experienced droughts in 1968, 1973, 1983, 1985, and the late 1980's and 1990's that brought untold hardships to several millions inhab-



Emaciated cattle wander through the drought-ridden Sahel district of Senegal. (AP/Wide World Photos)

iting the region. The memory of these droughts still commands the world's attention, as their effects contribute to human suffering and ecological degradation in the region. During this period, more than one million people died of starvation because of crop failures resulting from low rainfall. Goats and other livestock ate everything in sight, including clothes spread outside to dry.

Initially, the droughts of the 1970's and 1980's were blamed on anthropogenic sources, but these do not appear to have been the cause, as the sharp decline in annual precipitation in the Sahel correlates with the difference in temperatures between northern and southern Atlantic Oceans and the Indian Ocean. The slight warming of these oceans may have led to the formation of a deep convective current that is believed to weaken the convergence of the air mass systems that produce precipitation in the Sahel region. The warming of the Indian Ocean is thought to have minimal effect on the Sahel droughts.

On a geologic timescale, the Sahel has experienced wet seasons, as evidenced by buried river valleys seen in radar images of the region and by animal drawings (petroglyphs) on the desert rocks. In addition, geologic records show that the region does experience droughts from time to time. The presence of sand dunes in Lake Chad suggests that the lake was once dry. Multidecadel- to centennial-scale droughts have occurred in the Sahel, and the region's climate has changed over several millennia as it has experienced desertification.

• Significance for Climate Change

Desertification is the process by which marginal lands, such as in semiarid regions, lose natural vegetation cover; it can be anthropogenic or natural. Desertification in turn affects climate. Desertification is widespread in the Sahel, and it appears to be moving southward.

Few surface waters exist in the Sahel; the Niger River and Lake Chad are the two dominant surface-water bodies in the region. The vast majority of inhabitants are pastoral farmers. Overgrazing occurs in the region, especially during drought. Overgrazing leads to the decimation of vegetation, and this leads to decrease of the land surface albedo—that is, the surface absorbs more incident radiation from the Sun, increasing the temperature at the land surface. This is one of the reasons semiarid and arid regions are hot. In addition, because of the felling of trees for fuel and overgrazing, the land surface becomes exposed to severe wind and water erosion. The wind removes the topsoil as dust, typical of the Sahara Desert to the north. Most African dust comes from the semiarid Sahel region south of the Sahara. As rainfall decreases, more dust is produced. The presence of the dust may reduce daytime temperature by 3° Celsius and increase nighttime temperature by the same amount. Currently, there is an upswing in rainfall.

Drought and conflict are of concern in the Sahel. The increase in population of both humans and animals places a greater demand on resources that may further exacerbate the drought conditions in the region. There is no consensus as to whether the Sahel will experience increased rainfall due to global warming. Although conflicting models make it difficult to predict the outcome of climate change in the area, a higher temperature would lead to higher rates of water evaporation and a greater demand for water.

The pastoral system, land tenure, politics, and climate change would lead to change in land use and land cover (LU/LC). Animals move southward during drought, denuding the land of vegetation. Lack of vegetation would result in severe soil erosion from flash floods and wind erosion, as observed around Lake Chad. The change in LU/LC affects the climate of the region, including the production of dust, and contributes to a positive feedback loop leading to greater desertification and climate change. Although human activities adversely affect the Sahel, the people of the region plant trees and drought-tolerant crops, and they collaborate internationally to minimize adverse effects and to adapt to climate-related changes in the Sahel.

Saltwater intrusion

• **Category:** Water resources

• **Definition**

Under normal conditions, freshwater prevents salt water from encroaching on coastal aquifers. Along coastlines, freshwater and salt water are in equilibrium, such that less dense freshwater floats on more dense salt water. The interface between freshwater and salt water is maintained near the coast and below land surface. Saltwater intrusion happens when seawater flows into coastal freshwater as a result of changes in the elevation of groundwater near the coasts. Hydraulically connected groundwater and seawater may change their elevation gradient direction as a result of changes in water storage due to pumping and droughts or due to sea-level rise caused by melting ice. These changes create a diffusive zone, or a zone of dispersion—a brackish region of transition between freshwater and salt water. A hydrostatic equilibrium is achieved by the weight of a unit column of freshwater extending from the water table to the saltwater-freshwater interface stabilized by a unit column of salt water extending from sea level to the same point on the interface, which is roughly 40 meters of freshwater below sea level for every meter of groundwater.

Freshwater resources in coastal regions are threatened by salinization. Salinization is the increase of chloride ion concentrations in freshwater aquifers along coastlines and in some instances inland. Saltwater intrusion, caused by both natural and human activities, occurs by lateral inflow from coastal waters and vertical influx to discharging wells. Groundwater pumping can reduce freshwater flow toward coastal discharge areas, causing salt water to be drawn toward the freshwater zones of the aquifer. Saltwater intrusion decreases freshwater storage in the aquifers, which can result in the abandonment of supply wells.

Once saltwater intrusion has occurred, it is almost impossible to reverse, making it a significant threat to freshwater resources. Many coastal areas are arid, increasing the magnitude of the threat. Indeed, in many such areas, including California, the Middle East, and the Mediterranean, the future sustainability of groundwater resources is at risk from overuse and from contamination, increasing the urgency of managing and protecting water resources in a sustainable manner.

A numerical ranking system known as the GALDIT index exists to assess the potential for saltwater intrusion. Developed by the EU-India INCO-DEV COASTIN project, this index rates coastal aquifers' vulnerability to saltwater intrusion based on a combination of factors, including aquifer hydraulic conductivity, depth to groundwater, level above the sea, distance from the shore, impact of existing seawater intrusions in the area, and thickness of the aquifer. The index also considers the stability of groundwater in the vicinity, categorizing it as unconfined, confined, or leaky.

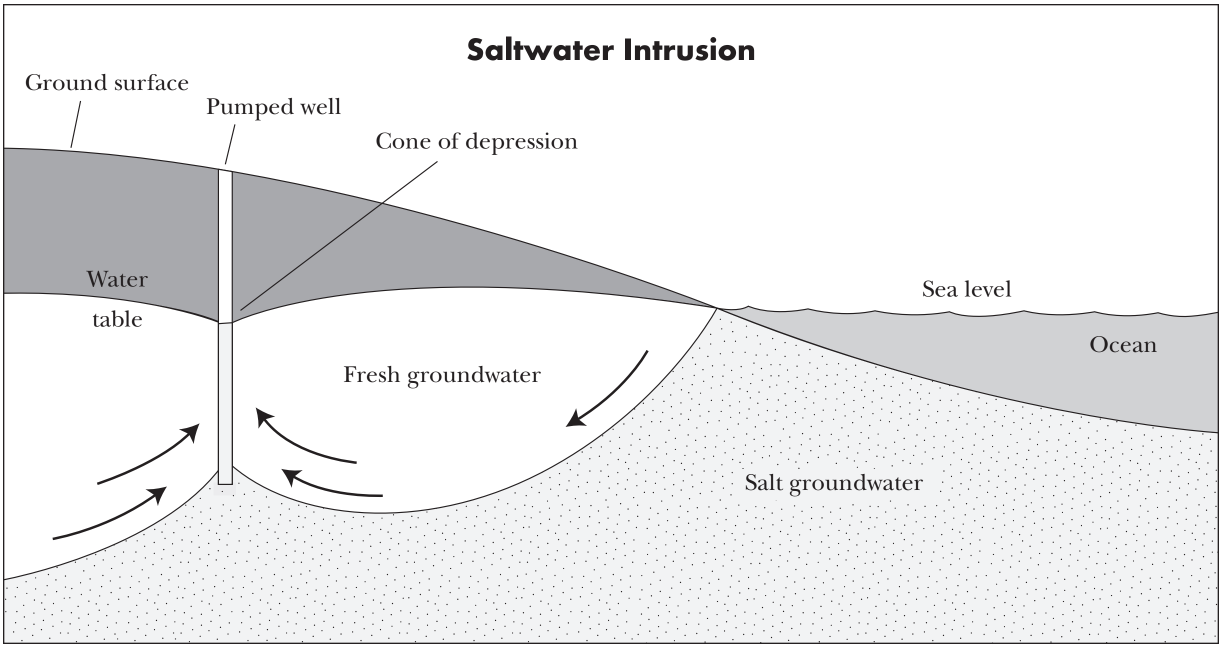
• Significance for Climate Change

Saltwater intrusion can be related to climate change and global warming. Increasing temperatures at the Earth's surface cause droughts, higher evaporation, increases in surface runoff, decreases in precipitation and infiltration, and ice melt. These changes affect groundwater storage and therefore groundwater elevation and gradient. Natural causes of saltwater intrusion include storm surges caused by hurricanes and other tropical systems and rises in sea level. The rise of sea levels pushes seawater further inland, threatening freshwater aquifers.

Anthropogenic saltwater intrusion can result from dredging canals in coastal zones that allow salt water to migrate farther inland. Louisiana, moreover, has experienced this type of saltwater intrusion as a result of overpumping the freshwater aquifer for potable water and irrigation needs, which reduces the head difference at the saltwater-freshwater interface and induces the flow of salt water into the freshwater system when that system is not capable of recharging completely, such as during drought conditions.

Freshwater systems benefit from mechanisms capable of restoring equilibrium after potentially damaging events. After Hurricanes Katrina and Rita, for example, salinity that had been introduced into the freshwater marshes was naturally removed by tidal flushing before substantial damage was done. Damage to freshwater systems was observed in areas not affected by tidal and precipitation flushing of salt water from the water table.

Coastal communities are taking into account the impact of rising sea level on water resources. The Florida Aquifer is endangered by saltwater intrusion, motivating Floridians to reduce groundwater pumping and find alternative water resources. This saltwater intrusion cannot be stopped, but the rate of its progression can be slowed down.



In southwest Florida, the Southwest Florida Water Management District established the Southern Water Use Caution Area to mitigate saltwater intrusion, among other hazards due to overpumping the Florida Aquifer. Another form of mitigation used in California is to use treated wastewater to recharge the aquifer.

Since 1850, the Los Angeles area has used an injection-well barrier to push freshwater into the aquifer near the coast. The State of New Jersey constructed sea walls, bulkheads, and jetties to protect the freshwater aquifer from the rising sea level. Overall, in coastal communities exposed to storm surge, a sustainability plan for saltwater intrusion proposes to construct coastal barriers slowing storm surge to prevent the loss of wetland habitat. This project requires coordination by state and federal agencies, such as the United States Geological Survey, the Environmental Protection Agency, and the Army Corps of Engineers.

The sustainability of freshwater resources is associated with the sustainability of life in coastal communities. Sustainability plans to protect these resources are costly, but if such plans are not executed, freshwater may become unavailable in many heavily populated coastal areas. The threat of global and coastal climate change simply increases the vulnerability of these freshwater resources.

Saudi Arabia

- **Category:** Nations and peoples
- **Key facts**

Population: 28,146,656 (July, 2008; includes 5,576,076 non-nationals)

Area: 2,149,690 square kilometers

Gross domestic product (GDP): $582.8 billion (purchasing power parity, 2008 estimate)

Greenhouse gas (GHG) emissions in millions of metric tons of carbon dioxide equivalent (CO_2e): 341 in 2000

Kyoto Protocol status: Ratified, 2005

• Historical and Political Context

Saudi Arabia is located in the Middle East and borders the Persian Gulf, the Red Sea, Yemen, the United Arab Emirates, Iraq, Qatar, Oman, Jordan, and Kuwait. Riyadh is its capital city, with a population of 4,193,000. Saudi Arabia is a monarchy led by King Abdullah, who has been head of state since 2005, and an appointed 150-member consultative council. Saudi Arabia is the historical home of Islam, its official religion, and Arabic is its official language. Like most of its Gulf State neighbors, Saudi Arabia is a founding member of the Organization of Petroleum Exporting Countries (OPEC) and is the world's largest producer and exporter of total petroleum liquids. It was the world's largest producer of crude oil in 2008, producing 3.9 million barrels per day.

As of 2009, Saudi Arabia held the world's greatest proven oil reserves—264.2 billion barrel—and the fourth greatest proven natural gas reserves—7,306 cubic kilometers. With approximately one-fifth of the global proven oil reserves and minimal production costs, Saudi Arabia is expected to remain the world's largest oil exporter over the short and long term. As a result of its role in energy production, Saudi Arabia, with 0.4 percent of the world's population, accounts for 1.1 percent of global greenhouse gas (GHG) emissions, the highest level of GHGs on average among the oil-producing Gulf States. Since World War II, Saudi Arabia has been closely aligned with the United States as a major trading partner. It is the second-largest exporter of oil to the United States after Canada.

• Impact of Saudi Policies on Climate Change

On January 31, 2005, Saudi Arabia ratified the Kyoto Protocol and was classified as a developing, non-Annex I nation, meaning that it was not required by the protocol to reduce its GHG emissions. Because of its relatively high GHG emissions, however, Saudi Arabia expressed interest in the protocol's clean development mechanism (CDM), which allows industrialized, Annex I countries to satisfy their Kyoto commitments in part by funding environmentally friendly development projects in non-Annex I countries.

In 2006, Saudi Oil Minister Ali al-Nuaimi hosted an international CDM conference in Riyadh, where attendees reviewed investment opportunities in Saudi Arabia and other oil-rich Gulf States for new CDM projects, including some that employed high-technology carbon capture-and-storage technology. In such technology, carbon dioxide (CO_2) is removed from petroleum processing plants and sequestered in mature oil fields. CDM programs have assumed greater significance for the Gulf States that fear their oil exports might be restricted should the United Nations raise environmental standards in 2012, when the Kyoto Protocol is to be replaced. Industrial diversification is an alternative to CDM programs.

The World Trade Organization (WTO) has encouraged Saudi Arabia to lessen its economic dependence on its oil and petroleum industries by diversifying its industrial sector so as to include more environmentally friendly endeavors. Paradoxically, since 2000, the wealth garnered from the GHG-emitting energy industry has driven such diversification, enabling Saudi Arabia and other Gulf States to achieve significant economic development both with their own domestic capital and through some 750 American business ventures. This activity has resulted in a diverse range of new business opportunities for the Saudi government and employment opportunities for the country's workforce. As part of an effort to attract foreign investment and diversify the economy, Saudi Arabia has substantially increased spending on job training and education, infrastructure development, and salaries for government employees. Saudi Arabia acceded to the wishes of the WTO in 2005 and announced plans to establish six "economic cities" in different regions of the country to promote development and diversification.

• Saudi Arabia as a GHG Emitter

According to the United Nations Development Programme (UNDP), if all the countries in the world were to emit CO_2 at levels comparable to that of Saudi Arabia, the world would exceed its sustainable carbon budget by approximately 511 percent. Reuters in 2008 ranked Saudi Arabia twenty-third out of the twenty-five highest GHG emitters in the world. The top-twenty-five GHG emitters are a diverse group comprising thirteen Annex I nations, eleven non-Annex I nations, and one regional party, the European Union.

One unifying metric among the top GHG emitters is the significant association between GHG emissions, population size, and gross domestic product (GDP) ranking; most of the top GHG emitters have either large populations, large GDPs, or both: Seventeen of the top twenty-five emitters are among the twenty-five most populated countries, and twenty-two of the top twenty-five emitters have the largest economies, some because of large populations and others because of high wealth per capita. For example, from 1990-2002, the growth rate of CO_2 emissions for affluent oil exporters Indonesia, Iran, and Saudi Arabia was 97 percent, 93 percent, and 91 percent, respectively.

Saudi Arabia's non-CO_2 emissions grew by 50 percent from 1990-2000, the highest percentage among the top-twenty-five GHG emitters. Population growth in Saudi Arabia was 46 percent from 1990-2002, the highest percentage of the top-twenty-five GHG emitters, three times greater than that of China, and almost twice that of Iran. Energy intensity (energy consumption per unit of GDP) increased in Saudi Arabia by 52 percent from 1990-2002, the highest percentage among the top-twenty-five GHG emitters.

As regards per capita ranking, while the OPEC Gulf States have high per capita GHG emissions, data show that of the top-twenty GHG emitters, generally, the highest emitters per capita were the Annex I countries (Australia, the United States, and Canada, ranked fifth, seventh, and eighth, respectively, with per capita GHG emissions of 25.6 metric tons, 24.3 metric tons, and 22.2 metric tons, respectively). Annex I countries' per capita emissions are approximately double those of the highest-

ranked developing country in the top twenty (South Korea, at 11.0 metric tons per capita), and they are six times that of China (3.9 metric tons per capita). Saudi Arabia was ranked fifteenth in per capita GHG emissions, producing 16.5 metric tons per person.

The population density of Saudi Arabia in 2007 was 11.3 persons per square kilometer, in a country a little more than one-fifth the size of the United States. Economic growth in the top GHG emitters is sometimes measured in terms of GDP per capita, and this measurement has been shown to bear a significant relationship to a country's GHG emissions. Usually, significant GDP growth per capita results from energy-intensive activities, which significantly increase GHG emissions. In 2008, the Saudi GDP was ranked twenty-third in the world by the International Monetary Fund (IMF); the Saudi petroleum sector accounted for roughly 45 percent of the nation's GDP, 80 percent of its budget revenues, and 90 percent of its export earnings. Some 40 percent of the GDP came from the private sector.

High oil prices through mid-2008 enhanced economic growth, government revenues, and Saudi ownership of foreign assets, enabling Saudi Arabia to pay down its domestic debt. In March, 2009, Saudi Arabia, along with other OPEC member nations, cut production of oil to support falling oil prices on the world market, and crude oil futures rose to $51.55 per barrel in New York. OPEC lowered Saudi Arabia's production quota for oil, although it was reported that the Saudi government privately promised to satisfy the energy needs of their export partners. However, liquid fuel demands in the United States are expected to increase by only one million barrels per day from 2007 to 2030, as domestic biofuels and other renewable energy sources, along with increasing domestic oil production, reduce U.S. dependence on the foreign oil market. As a result, the United States is projected to import less than 40 percent of liquid fuels it consumes in 2025. This decrease will likely decrease Saudi oil revenues, either directly by lowering volume of sales or indirectly by lowering prices.

• Summary and Foresight

At the April, 2009, Group of 20 (G-20) summit in London, French President Nicholas Sarkozy declared that global leaders were moving to create a new world order, less centered on U.S. and Anglo-Saxon models, with increased regulation of the global financial sector and a greater role for international institutions and emerging markets. In addition, the G-20 pledged to triple the resources of the IMF, enabling developing countries to more fully participate in the global economy; the United States and the European Community need the monetary and energy resources of rising powers such as Brazil, China, and Saudi Arabia to help restore the global economy and tackle the ongoing challenge of climate change.

While the United States remains the preeminent military and economic power in the world, its ability to manage its financial markets and banking system will be significant factors in overcoming the global economic and climate crises. Also important is how emerging nations such as Saudi Arabia, the only Arab country and OPEC member invited to the G-20 summit, present themselves to the world. Saudi Arabia's handling of its currency reserves, trade policies, and energy exports will influence global climate policy and affect the efficacy of that policy. Saudi energy policy and development will also affect the rights of indigenous populations, farmers, youth, and women, who, according to the U.N. Stockholm Declaration of 1972, enjoy a human right to a healthy environment.

When the U.N. Conference of the Parties to the Framework Convention on Climate Change (COP) meets in Copenhagen, Denmark, in December of 2009 to address climate change and to plan the treaty that will replace the Kyoto Protocol in 2012, Saudi Arabia will provide input as both a developing, non-Annex I country and a wealthy, OPEC-member oil exporter and a significant emitter of GHGs. At a pre-COP meeting in March, 2009, U.S. president Barack Obama called for an increase in the amount of corn-based ethanol for use in U.S. gasoline. An advisor to the Saudi oil minister, Mohammad al-Sabban, indicated that while his country does not support subsidies for biofuels, citing environmental and economical concerns, it would cooperate, demonstrating a willingness to consider alternative energy sources.

Al-Sabban also declared that Saudi Arabia would invest heavily in renewable, especially solar, energy and build a carbon-neutral city, stating that Saudi Arabia has abundant sunshine and land and is able to export solar power to its neighbors on a large scale. Saudi Arabia's aim is to diversify its economy and become environmentally friendly at the same time, but it needs the assistance of the industrialized countries, in the form of direct investment and transfer of technologies, to ease the burden of the new climate regimen likely to be set forth by the successor treaty to the Kyoto Protocol. Thus, the Saudi government, which controls the petroleum and crude oil sector, is encouraging increased growth of the private sector—especially in power generation, telecommunications, alternative energy, natural gas exploration, and production of petrochemicals—in order to lessen the domestic economy's dependence on oil exports and to increase employment and educational opportunities for the burgeoning Saudi population. Saudi unemployment is rampant, and the large youth population generally lacks the education and technical skills required by private-sector employers.

Cultural and economic change go hand in hand in Saudi Arabia. In 2009, Saudi king Abdullah appointed Nour Fayez as the first female cabinet minister of the country as part of major cabinet reorganization, producing a cabinet with a more liberal bent. Nour Fayez became the deputy minister for women's education, a milestone for a country where women gained the right to vote in 2004. In Saudi Arabia, women are 5 percent of the country's workforce, the lowest percentage worldwide. The appointment of Nour Fayez will not only empower Saudi women but will also enhance the recognition of the importance of women's contribution to the workforce and their role in Saudi development.

King Abdullah also appointed a moderate, Prince Faisal bin Abdullah bin Muhammad, to be minister of education. These recent events reflect some of the aspirations of the Green Party of Saudi Arabia (GPSA), a political organization established in 2001 in a semi-clandestine fashion, because political parties are officially banned in Saudi Arabia. Both Saudi citizens and expatriates are known members of GPSA, which fosters the values of the worldwide green movement and its aims to protect the evironment by supporting biodiversity, sustainability, and personal and global responsibility, while opposing the use of nuclear energy as harmful to the environment. In addition, the GSPA supports the creation of a constitutional monarchy that balances economic development with sustainability, along with promotion of environmentally friendly education, industry, and public policy, as well as gender equality in the political sector. The GPSA supports the Saudi government's efforts gradually to reform political and social life, but it does not advocate the violent overthrow of the kingdom's current institutions.

Sauer, Carl
American geographer

Born: December 24, 1889; Warrenton, Missouri
Died: July 18, 1975; Berkeley, California

Sauer's "The Morphology of Landscape" was a seminal work in geography, establishing the idea of cultural landscapes. For this work, he is known as the founder of American cultural geography.

• Life
Carl Sauer was born in Warrenton, Missouri, on December 24, 1889. He received a bachelor's degree in 1908 from Central Wesleyan College, where his father was on the faculty. He then attended Northwestern University and in 1915 received a Ph.D. in geography from the University of Chicago. While he was attending graduate school, he served as a map editor for Rand McNally Publishers (1912-1913). Upon his graduation from the University of Chicago, he was hired by the University of Michigan as an instructor in the Geography Department.

By 1922, Sauer had become a full professor at the University of Michigan, but he chose to leave in 1923. At that time, he moved to the University of California, Berkeley, as a full professor and chair of the Department of Geography. In large part as a result of Sauer's efforts, the graduate program in geography at the University of California, Berkeley, came into being and became world renowned. Sauer remained at Berkeley until 1957, when he retired and was appointed professor emeritus. He worked closely with the Department of Geography at Berkeley as an emeritus professor until his death in 1975.

• Climate Work
The notion of a cultural landscape was developed by Sauer in 1925 in his paper "The Morphology of Landscape," which appeared in the *University of California Publications in Geography*. Cultural landscape quickly became a central concept in the field of geography. Today, the United Nations Educational, Scientific, and Cultural Organization (UNESCO) defines cultural landscapes as specific geographical locations that in some unique ways represent the interactions of people and nature. When Sauer developed this concept in his 1925 article, he indicated that culture is a major force in determining the visible features of the planet within specific areas. He therefore was the first person who indicated that humankind (culture) and the environment have a mutual impact on each other.

Sauer indicated that the natural landscape is a medium upon which culture can act, resulting in the notion of cultural landscape. He indicated that while both culture and society develop

"Foreword to Historical Geography"

In an address given to the Association of American Geographers in 1940, excerpted below, Carl Sauer set out his ideas about the nature and function of a discipline of historical geography.

Every human landscape, every habitation, at any moment is an accumulation of practical experience and of what Pareto was pleased to call residues. The geographer cannot study houses and towns, fields and factories, as to their where and why without asking himself about their origins. He cannot treat the localization of activities without knowing the functioning of the culture, the process of living together of the group, and he cannot do this except by historical reconstruction. If the object is to define and understand human associations as areal growths, we must find out how they and their distributions (settlements) and their activities (land use) came to be what they are. Modes of living and winning a livelihood from their land involve knowing both the ways (culture traits) they discovered for themselves, and those they acquired from other groups. Such study of culture areas is historical geography. The quality of understanding sought is that of analysis of origins and processes. The all-inclusive objective is spatial differentiation of culture. Dealing with man and being genetic in its analysis, the subject is of necessity concerned with sequences in time.

out of their landscape, they also work together to shape that landscape. This notion of the cultural landscape forms the basis for the field of cultural geography. It is often discussed in relation to global warming. Over the past century, human interaction with the landscape (environment) of the planet has involved many changes in agricultural practices, as society has emerged from the family-run farm to much more technologically advanced farming communities. Old land-use practices have been pushed aside to make way for technology.

These changes in culture result in changes in the landscape. Technology, along with the demands and challenges of the modern world, may gradually cause loss of biodiversity. This use of technology along with a lack of concern for the land may be at least partly responsible for major changes in the climate, including the warming of ocean temperatures and the melting of glacial and polar ice. If people continue to expose their natural resources to the demands of advancing technology, they may accelerate the changes occurring within the environment, which in turn may produce potentially harmful situations for humankind. Should this continue to occur, climatic events such as tsunamis and increased global warming will become ever more problematic for human societies. While Sauer did not highlight these specific ways in which culture and the environment might mutually affect one another, his notion of the cultural landscape did indirectly predict and does account for these climate-related changes today.

Schumacher, E. F.

German English economist

Born: August 16, 1911; Bonn, Germany
Died: September 4, 1977; On a train en route to Zurich, Switzerland

Schumacher foresaw the problems that would be caused by societies that embraced the exploitation of resources for immediate gain without considering the long-term effects of such exploitation.

• Life

E. F. Schumacher was the third of five children born to Edith Zitelmann and Hermann Albert Schumacher, a professor of economics at Bonn and Berlin Universities. Schumacher matriculated from Ardnt Gymnasium and moved to New College, Oxford, and then to Columbia University, New York, to study economics and politics as a Rhodes Scholar

Solving the Problem of Production

In Small Is Beautiful, *his seminal work, Ernst Friedrich Schumacher begins by declaring that modern people have made a fundamental error: They believe that the "problem of production" has been solved and that any current micro problems are easily overcome coincidences. Schumacher argues that production is still an inherent problem for humanity, and he examines the consequences of overlooking this problem by erroneously declaring it solved.*

Modern man does not experience himself as a part of nature but as an outside force destined to dominate and conquer it. He even talks of a battle with nature, forgetting that, if he won the battle, he would find himself on the losing side. Until quite recently, the battle seemed to go well enough to give him the illusion of unlimited powers, but not so well as to bring the possibility of total victory into view. This has now come into view, and many people, albeit only a minority, are beginning to realise what this means for the continued existence of humanity.

The illusion of unlimited powers, nourished by astonishing scientific and technological achievements, has produced the concurrent illusion of having solved the problem of production. The latter illusion is based on the failure to distinguish between income and capital where this distinction matters most. Every economist and businessman is familiar with the distinction, and applies it conscientiously and with considerable subtlety to all economic affairs—except where it really matters; namely, the irreplaceable capital which man has not made, but simply found, and without which he can do nothing.

from 1930 to 1933. He was not comfortable with the Nazi government, and, after marrying Anna Maria (Muschi) Petersen on October 10, 1936, he and Muschi moved to London, where Schumacher took a job in a financial firm. The couple would have four children.

During World War II, Schumacher was interned as an enemy alien. An article that he wrote attracted the notice of John Maynard Keynes, who arranged for his release from internment. Soon afterward, Schumacher took a job at Oxford's Institute of Statistics. Toward the end of the war, the institute's work changed from war economics to planning a reconstruction and recovery program. Schumacher's advice greatly aided Great Britain's recovery after the war.

In 1946, Schumacher became a British citizen in order to become economic adviser to the Allied Control Commission in the British zone of western Germany. By 1950, he felt that his influence was declining. He returned to England to be the economic adviser to the National Coal Board. This position entailed less travel, so he and Muschi bought a home in Caterham, Surrey, where he lived until his death. He worked for the coal board for twenty years, although he did take some leaves of absence to travel to Burma and India. Muschi developed cancer and died at her family's home in Germany in 1960.

On January 29, 1962, Schumacher married Verena (Vreni) Rosenberger, a Swiss woman who had been hired originally as an au pair. She and Schumacher would have four children together. In 1971, Schumacher began to work full time in intermediate technology and resigned from the coal board. He also became a Roman Catholic. In 1973, he published his ground-breaking book, *Small Is Beautiful: Economics as if People Mattered.* It was a great success and led him to publish *A Guide for the Perplexed* (1977). He was in much demand as a speaker. While on a train in Switzerland, during a speaking tour, he had a fatal heart attack; he was buried at Caterham.

• Climate Work

Schumacher believed that if one accepts that there is a god who made humanity, then one's responsibility is to work toward the good of humankind. He saw the scientific, technological materialism of the Western world as a problem for the future of the world. While in Burma, Schumacher developed the principles that he called "Buddhist economics." He made the claim that he could have called it "Christian economics" but no one would have listened.

The four principles were based on the idea that doing good work was essential for people and that using local labor and resources for a locale was the logical ideal.

Schumacher's four principles were as follows: first, that work to an employer is the cost of an item and needs to be as small as possible. Work to the worker is made in place of leisure and wages are the compensation for the discomfort. Second, it is wrong to consider products as more important than people from a Buddhist (or Christian) view. Third, work has three values to a person: it provides a chance to grow in ability, to give of one's person to a common cause, and to produce products that are needed to exist. Fourth, work should not be designed to be so mundane that the worker is bored. That is valuing the product more than the person.

Along with his Buddhist economics, Schumacher proposed the principles of intermediate size and intermediate technology. He believed that a large concentration of industry using the maximum in technology would put people out of work. If an industry's size were controlled, its technology would be simpler and it would employ more workers. In this way, more people would work and the standard of living would stay high for everyone, not just the privileged who had jobs. Schumacher was also a strong proponent of renewable resources and protecting the environment.

Science and Public Policy Institute

- **Category:** Organizations and agencies
- **Date:** Established February, 1995
- **Web address:** http://scienceand publicpolicy.org

• Mission

The Science and Public Policy Institute (SPPI) is a global warming skeptic organization that focuses its efforts on research and education surrounding advancement of public policies for energy and the environment. The SPPI was formerly known as the Center for Science and Public Policy for the Frontiers of Freedom, which was founded by former Republican senator and directing member of the El Paso Natural Gas Company Malcolm Wallop in February of 1995.

As of 2008, the organization's executive director was Robert Ferguson, former chief of staff to several Republican members of Congress. The SPPI's membership includes prominent climate change skeptics. Its chief policy advisor is Christopher Monckton, a former advisor to British prime minister Margaret Thatcher. Its chief scientific advisor is Willie Soon, who is an astrophysicist and geoscientist by training and a proponent of the theory that climate change is caused by solar variation and not by human activities. The activities of the SPPI are supported by money from tobacco and oil companies, including Philip Morris, RJ Reynolds Tobacco, and ExxonMobil. Since 1998, the SPPI has received $467,000 from ExxonMobil.

• **Significance for Climate Change**

The SPPI funded a film titled *Apocalypse? No!* (2008), created to refute the theories highlighted in the Al Gore film *An Inconvenient Truth* (2006) The SPPI's other projects and publications also center on environmentalist skeptism. In July, 2008, SPPI policy advisor Monckton published in the journal *Physics and Society* an article arguing that computer models used by the United Nations Intergovernmental Panel on Climate Change were preprogrammed with erroneous values. These values, according to Monckton, effectively resulted in a 500 to 2000 percent overestimate of carbon-dioxide-induced effects on temperature that was reported in the 2007 U.N. climate assessment report. The SPPI is closely affiliated with other notable global warming skeptic organizations such as the Heartland Institute and the Center for the Study of Carbon Dioxide and Global Change.

The SPPI has programs to continually monitor and review publications and projects centered on climate change. For example, SPPI's ScareWatch program provides annotated bibliographies of publications that cover the negative implications of global warming and attempts to rebut and discredit organizations and individuals affiliated with such publications.

Scientific Alliance

• **Category:** Organizations and agencies
• **Date:** Established 2001
• **Web address:** http://www.scientific-alliance.org/

• **Mission**

The Scientific Alliance is a nonprofit organization that was formed in 2001 in the United Kingdom in order to deal with issues facing the environment. Businessman Robert Durward started it in conjunction with political consultant Mark Adams. The organization's membership consists of individuals interested in the field of biotechnology and environmental change; some are scientists and others are nonscientists. Its present director is Martin Livermore, the author of *Climate Change: A Guide to the Scientific Uncertainties* (2007), published by the Centre for Policy Studies. The Scientific Alliance tries to foster discussion about issues dealing with the environment, but it is generally felt to be pro-business.

• **Significance for Climate Change**

The Scientific Alliance is an activist group that contends that it deals logically with issues of the environment, trying to calm the panic caused by extremist groups who use scare tactics to frighten the public. The organization currently consists of many individuals in the field of biotechnology and people skeptical about the issues of climate change. It maintains an active Web site that it contends is dedicated to discussion of present-day environmental challenges. It has sponsored several conferences dedicated to exploration of environmental challenges. Its first conference was held in November, 2002, and was entitled Fields of the Future. This conference highlighted the importance of genetically modified foods for the future of the world while indicating that organic farming would lead to ecological collapse and mass starvation.

A second conference held in November of 2004 was entitled Cautionary Tales: Rethinking Environmental Decision Making and Risk Assessment. This conference warned of the risks of organic farming as well as the risks that would be associated with wind power. In 2005, the organization's conference was titled "Apocalypse No: Assessing Catastrophic Climate Change." This conference featured many speakers who indicated that individuals such as Al Gore (author of *An Inconvenient Truth*) and other pro-environmentalists were attempting to determine the direction of the future of the world by falsely creating a panic based on environmental change.

In December of 2004, the Scientific Alliance published a paper criticizing the Kyoto Protocol and minimizing the risks of global warming. The Kyoto Protocol was adopted in the late 1990's in an attempt to reduce greenhouse gases and minimize global warming. The Scientific Alliance as an organization has worked and continues to work to convince society that climate change is unlikely to occur, unimportant, and proposed by radicals trying to influence the course of society.

Scientific credentials

- **Category:** Science and technology

- **Definition**

Scientific credentials include academic degrees, institutional affiliations, scholarly publications, grants, and awards. They are used to establish expertise, entitling one's opinions on scientific issues to special attention from professional colleagues, policy makers, and the public.

- **Significance for Climate Change**

In light of disagreements about the existence, causes, and importance of global warming, there has been debate over whose opinions should be taken seriously. Scientists are frequently invited to speak outside their field, especially by journalists who may see little difference (for their purposes) between one expert and another. As citizens, scientists of course have views about various subjects on which they are not experts, but they (or others) may exaggerate the weight of these opinions.

The only earned degree of Freeman Dyson, known by some as the best physicist never to have received a Nobel prize, was an undergraduate bachelor's degree in mathematics (he has been awarded numerous honorary degrees). Despite his many accomplishments, including early recognition of the possibilities for offsetting carbon emissions through forest management, Dyson has complained that

> they say, I have no degree in meteorology and I am therefore not qualified to speak. But I have studied the climate models and I know what they can do. The models . . . do a very good job of describing the fluid motions of the atmosphere and the oceans. They do a very poor job of describing the clouds, the dust, the chemistry and the biology of fields and farms and forests.

Danish political scientist Bjørn Lomborg complained that when he wrote *Verdens sande tilstand* (1998; *The Skeptical Environmentalist,* 2001) his book was reviewed in *Scientific American* by four scientists

The 2009 appointment of Nobel laureate Stephen Chu, foreground, as U.S. secretary of energy was hailed by some as a sign that the Obama administration would take seriously the scientific credentials of those whose advice it sought on climate policy. (AP/Wide World Photos) without his having an opportunity to reply. He responded online. In April, 2002, the journal's editor, John Rennie, replied to the critique, emphasizing that

> Lomborg's lack of credentials as an environmental scientist does not disqualify him from making an environmental argument, but it does legitimately bear on whether his knowledge of the field and his paraphrasing of its findings can be trusted.

To his critics, Lomborg was a scientific neophyte who drew misleading conclusions because he failed to consider the full range of facts a professionally qualified environmental scientist would know. In Rennie's view, Lomborg's book was "not really a scientific work so much as a polemic." Lomborg's supporters saw *Scientific American*'s dismissal of his work as motivated by rejection of his "politically incorrect" views. The controversy made Lomborg famous, and in 2004 *Time* magazine named him one of the world's hundred most influential people.

Prominence in the media—including radio, television, movies, publishing, journalism, and the Internet—can create the appearance of scientific authority. Popularity, influenced by criteria such as plausibility and likableness, supports political influence. Popular misconceptions about scientific credentials have been exploited by all sides of the culture wars. Scientists such as Lomborg and Dyson are alternately seen as experts or interlopers. Former NASA climatologist Roy Spencer, also out of sympathy with the Kyoto consensus, wrote,

> Contrary to popular accounts, very few scientists in the world—possibly none—have a sufficiently thorough, "big picture" understanding of the climate system to be relied upon for a prediction of the magnitude of global warming. To the public, we all might seem like experts, but the vast majority of us work on only a small portion of the problem.

Some experts believe people must radically change their lives to deal with global warming, while others think little change is required. Some advocate adopting a precautionary principle and acting in light of worst-case scenarios, while others say an excess of caution is unfair to the disadvantaged. Those who dislike business as usual, for independent reasons, may find a lower level of confidence (about the probability and results of global warming) a satisfactory basis for change. Those who support business as usual will demand more justification before abandoning accustomed ways. With global warming, as with other large issues, it is easy to see the glass as now half full, now half empty—when, in fact, it is both.

Scientific proof

- **Category:** Science and technology

- **Definition**

Scientific proof is the means by which a question comes to be considered sufficiently settled, on the basis of scientific argument and evidence. What makes a theory, method, or result count as scientific has been controversial, both among philosophers of science and as a practical issue in courts of law. The term "proof" is also problematic. To prove originally meant to test (the word stems from the same Latin root as "probe"): Thus, something successfully tested has been "proven," but such proof is, contrary to popular expectation, no guarantee of truth.

Scientific theories create confidence by their ability to explain and predict events. In an experiment, investigators test their theory about how the world works: If certain forces are in play, then specific results should be observed. Hard sciences (such as physics and chemistry) often allow for such simple testing. Social sciences (such as economics and sociology) do not permit this, though there is dispute as to whether this is because they cannot offer good theories or because they deal with more complicated aspects of the world. Confidence in claims is increased if they are supported by evidence from distinct and various sources. Confidence is diminished if those who discover, test, or report facts seem to lack objectivity.

- **Significance for Climate Change**

While climates cannot as yet be created in a test tube, it is possible to compare the theoretical expectations of a given theory or model with what is known about the past. When the available climatological evidence consists, for example, of tree rings or ice cores, scientists hypothesize earlier events that would explain that evidence. When a climate model correctly "predicts" facts (such as temperature) known to be correct for the data available from the past, there is some reason to take its future predictions seriously. On the other hand, if a theory gets the past wrong, that is reason for suspicion (though, in some cases, it might be reason for a correction of the historical record).

Climate systems are so complex that there is room for much disagreement about what constitutes the facts of Earth's climate, about the history of those facts, and about the causal relationships determining them. Consider, for instance, the gradual disappearance of the snows of Kilimanjaro. Coastal protection activist Mike Tidwell reported in 2006 that Kilimanjaro would be free of ice within a decade as a result of warming climate. Skeptical environmentalist Bjørn Lomborg, on the other hand, claimed in 2007 that Kilimanjaro's ice loss is attributable not to temperature changes but rather to a drying climate.

Both arguments relied on the reports of others, and with regard to such reports there is controversy about what is, or is not, scientific proof. Tidwell has characterized the leading climatological reporting agency, the Intergovernmental Panel on Climate Change (IPCC), as "the largest scientific collaboration in human history," but skeptic Roy Spencer claims that "most of those 2,000 'scientists' are actually bureaucrats and governmental representatives; very few of them are climate scientists." He believes that these representatives promote policy for ulterior reasons and find the science after the fact to justify their positions.

There is an important asymmetry between alarmists and deniers. For those who believe climate change to be occurring through processes over which human beings may be able to exert some control, waiting until all the evidence is in risks fatal delay in reversing causes and mitigating effects. They think it prudent to emphasize the scope of the risks, while avoiding the endless qualifications that are part of normal scientific practice. Those who minimize the idea of anthropogenic global warming, on the other hand, see no need for a rush to judgment. They view alarmists as overstating troubling results and understating qualifications and uncertainties, using oversimplified science to achieve policy objectives.

Sea ice

- **Categories:** Cryology and glaciology; oceanography

- **Definition**

Sea ice is formed when the surface layer of the ocean reaches the freezing point. For salt water, this occurs at a temperature of –1.8 Celsius, slightly colder than the freezing point of freshwater. Because water is more buoyant in its solid state, the newly formed ice floats on top of the ocean, forming a barrier between the cool air and the warm water.

There are two types of sea ice. Fast ice (also known as land fast ice) is seawater that has frozen along the shore line, or, in shallow areas, has frozen to the ocean floor. These formations are, by their very nature, stationary. Drift ice is frozen salt water that floats and is affected by winds and currents. First-year ice sheets, or floes, are typically thin and subject to shattering and refreezing, forming rafts and ridges.

A cluster of drift ice is called pack ice, and this is what covers both the Arctic and the Antarctic regions of the planet. The amount of pack ice in the polar regions varies with the season. During winter, sea ice usually covers between 14 and 16 million square kilometers in the Arctic and between 17 and 20 million square kilometers in the Antarctic. In the Antarctic, the sea ice melts during the summer and is therefore considered seasonal ice, but in the Arctic it remains year around.

The German vessel Polarstern *makes its way through sea ice.* (AFP/Getty Images)

Sea ice poses a hazard for shipping and has been noted in sailors' logs going back to the fourth century B.C.E. Sea ice is commonly confused with icebergs. Although both represent significant shipping hazards, icebergs are made of freshwater, usually from precipitation or snow melt, and break off from glaciers.

• Significance for Climate Change

Sea ice, especially Arctic sea ice, plays a significant role in the overall global climate by regulating the exchange of heat, moisture, and salinity in the ocean. As seawater freezes, its salt content is reduced in a process called brine rejection. The salt rejected from the frozen water increases the salinity of the surrounding ocean and can affect ocean currents. Sea ice insulates the warm ocean water and keeps it from losing heat to the much colder arctic or subarctic air. It also, however, reflects more sunlight than the surrounding ocean, preventing the sunlight from warming the ocean. When more sunlight reaches the water, the heat is absorbed, raising the temperature. Fissures or cracks in the ice release the trapped heat from the warmer ocean water, which can affect precipitation and cloud cover.

Greenhouse gases (GHGs) emitted through human activities and the resulting increase in global mean temperatures are the most likely underlying cause of sea ice decline, but the direct cause is a complicated combination of factors resulting from the warming and from climate variability.

Passive microwave satellite data show that, as of 2006, the Arctic sea ice decreased by 3.6 percent during each of the previous three decades. In 2007, Arctic sea ice was at a record low. Despite a recovery to near average levels during the following winter, 2008 summer sea ice coverage was nearly as low as the previous year. As a result, the remaining ice pack is thinner than in previous years and is less able to withstand the varying temperatures brought about by global warming.

As the global climate changes, the quantity of polar sea ice is diminishing, affecting regional ecosystems. Animals such as polar bears, walruses, and seals rely on ice floes for breeding, shelter, and especially hunting. As the summer ice diminishes, the summer hunting season—crucial for animals that hibernate—grows shorter. The large mammals have to travel farther to find food, and more time passes between kills. A 1980 study found that the average female polar bear in the Hudson Bay region of Canada weighed 300 kilograms. By 2004, that average weight had dropped to 230 kilograms. This decline has led to an overall 15 percent drop in polar bear birth rate. Scientists at the United States National Snow and Ice Data Center have predicted that, if current trends persist, by the year 2030, the Arctic Ocean will be without ice for the first time in over one million years.

Sea-level change

• Category: Oceanography

Rising sea levels associated with global warming pose a threat to beaches and coastlines, coastal communities, and aquifers, directly or indirectly affecting the lives of hundreds of millions of people.

• Key concepts

aquifer: a layer of sand, gravel, or permeable rock containing water

glacier: a flowing body of land ice

ice cap: a domed body of ice covering a highland; smaller than an ice sheet

ice sheet: a deep body of ice covering and dominating a land mass

ice shelf: a floating body of ice extending from a coast and often attached to an ice sheet

post-glacial rebound: a rise in elevation of a land mass after a glacier on top of it melts

sea level: the theoretical level of the surface of the ocean, halfway between high and low tide

sea-level equivalent (SLE): the change in global average sea level that would occur if a given amount of water or ice were added to or removed from the oceans

thermosteric sea-level change: variability in sea level due to changes in water temperature

water table: the upper level of groundwater

• Background

Sea level can change, both globally and locally, as a result of changes in the shape and size of the ocean basins, changes in the total mass of seawater, and variations in water temperature and salinity. It is estimated that the global sea level rose by 10 to 25 centimeters in the twentieth century, and forecasts made in 2007 predicted an increase of 20 to 60 centimeters during the twenty-first century. However, these forecasts were subsequently revised upward.

• Dynamics of Sea-Level Change and Rise

The forecasts made by the Intergovernmental Panel on Climate Change (IPCC) in 2007 took some account of runoff from melting mountain glaciers and melting ice sheets in Antarctica and Greenland. For the most part, however, they were estimates of thermosteric sea-level change. Water increases in volume as it grows warmer, although it is difficult to establish a timescale for such expansion, delayed as it is by the thermal inertia of oceans (especially at their greatest depths). Thus, at least some of the observed changes in sea level in the recent past are undoubtedly due to earlier changes in air and sea temperature, while sea levels will probably rise over a period of several hundred years even if temperatures are brought under control. Regional and local sea levels are and will continue to be affected by such factors as salinity, atmospheric pressure, river runoff, currents, storms, tides, and wave patterns.

• Consequences of Sea-Level Rise

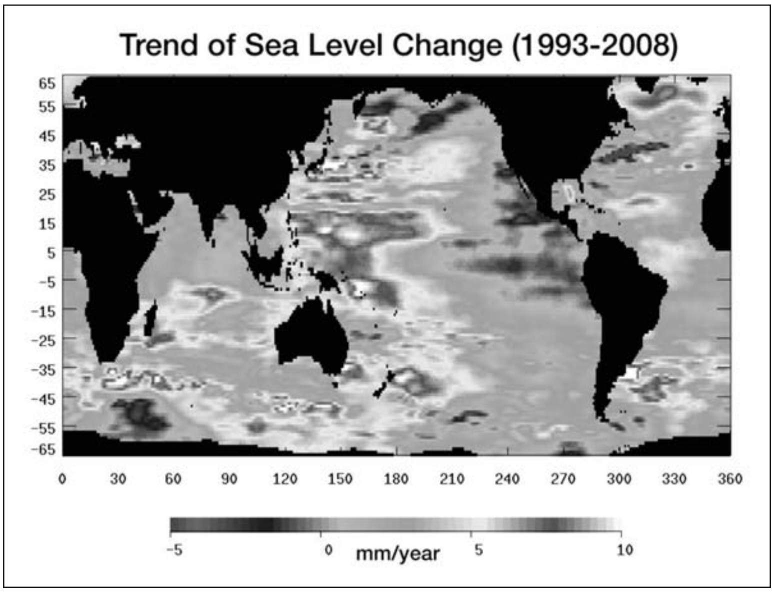
Although the dynamics of sea-level change are complex and not completely understood, there is less uncertainty about the consequences of sea-level rise, which poses severe dangers to coastlines by eroding beaches and flooding adjacent low-lying areas. There is no indication that rising sea levels (as opposed to warmer seas) contribute to the intensity of storms, but they do leave coastal areas more vulnerable to their effects by overwhelming estuaries and covering barrier islands. In particular, rising sea levels threaten the developing countries of Asia and Africa, where major population centers are often situated in or near low-lying deltas. Island nations such as Maldives and Kiribati will in time disappear below the sea, necessitating the mass relocation of their entire populations. Rising sea levels also pose the danger of saline pollution to aquifers, which in turn will lead to shortages of freshwater needed for agriculture and human consumption. Because of growing populations, such shortages are already a serious problem in many parts of the world.

• Increased Danger

The IPCC acknowledged that limited understanding of the processes involved in melting ice sheets meant that their effects were underestimated in its 2007 report. Soon afterward, however, more thorough studies of the Greenland and Antarctic ice sheets revealed that they were melting more rapidly than expected. This melting was due not only to increases in temperature but also to disintegration caused by water seepage in crevasses. Coupled with other findings, this evidence suggested that sea levels would increase by 50 to 100 centimeters in the twenty-first century. A rise of the latter dimension would flood over 33,670 square kilometers in the United States alone and create over 100 million refugees worldwide.

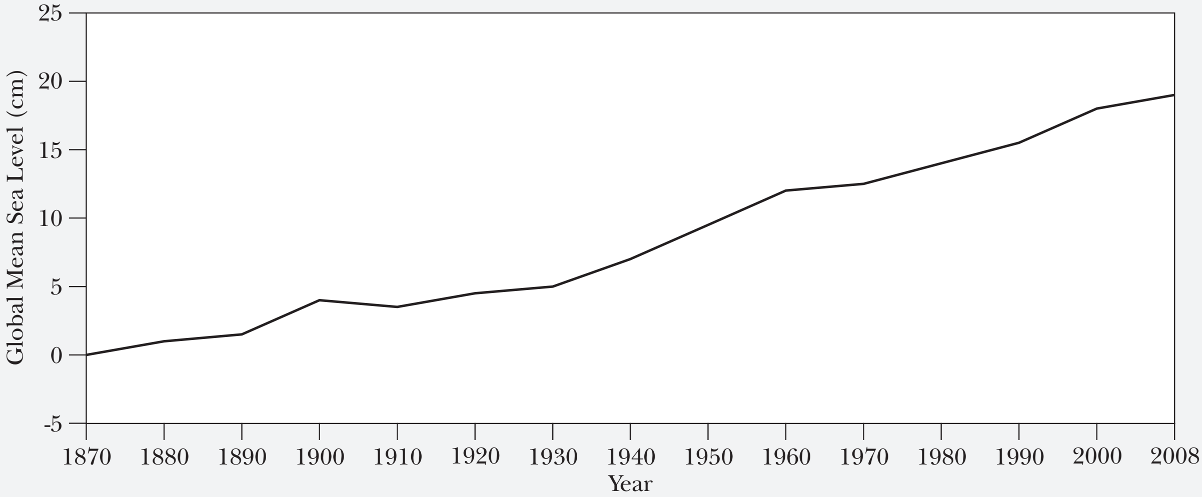
Concerns about rising sea levels heightened in April, 2009, with the collapse of an ice bridge linking the Wilkins Ice Shelf, which once covered some 16,000 square kilometers of the Antarctic Ocean, to Charcot Island. It was one of nearly a dozen such formations in the region to have collapsed in the preceding fifty years. Because ice shelves float, their disintegration does not raise water levels, but in their absence, the glacier ice accumulated behind them enters the sea more readily—a process that does raise water levels.

Forecasts of sea-level rise created by melting ice



This chart of sea-level changes from 1993 to 2008 shows that such changes are very different in different regions of the globe. (NASA/JPL)

Estimated Global Mean Sea-Level Rise, 1870-2008



Data from World Climate Research Programme.

sheets are complicated by two other factors. Postglacial rebound would decrease the size of the ocean basins, while small but significant changes in the Earth's rotation are also likely to follow the disappearance of the enormously heavy ice sheets in Antarctica, resulting in higher sea levels in the Indian Ocean.

• Context

Fragmentary evidence suggests that sea level began to rise in the middle of the nineteenth century, while more compelling evidence shows that this rate began to increase toward the end of the twentieth century. A number of factors enter into this increase, but because so many people live in coastal areas around the world, the immediate consequences of what appears to be an increasingly rapid rate of sea-level rise are grave.

The long-term consequences of melting ice sheets are even more profound. For instance, the West Antarctic Ice Sheet, a formation that scientists believe is particularly vulnerable to disintegration as world temperatures increase, contains the sea-level equivalent of 5 meters. The Earth's glaciers, ice caps, and ice sheets combined contain an extraordinary sea-level equivalent of 68.5 meters. While no one predicts that the ice sheets are in immediate danger of wholesale melting, the momentum of such a change, should it begin, would be virtually impossible to counter by any technology currently available to humankind.

Sea sediments

• **Categories:** Oceanography; geology and geography

• Definition

Sea sediments collect on the sea bottom, constituting the upper layer of the ocean floor. They consist of materials weathered from the continents, the remains of planktonic organisms, and minerals that are deposited by hydrothermal vents. Marine sediments are generally classified according to their source as terrigenous, metalliferous, or biogenic.

Terrigenous sediments are derived from the weathering of continental material, and are transported to the oceans by rivers, wind, and even glaciers. Terrigenous sediments are found most often near the continental margins, where rivers deposit much of their load. Very fine grained terrigenous sediments (clays) are transported to the central abyssal plains by wind and are the dominant sediment type under surface waters characterized by low levels of plankton productivity. Local accumulations of terrigenous sediments deposited by calved icebergs after they melt are known as "ice-rafted debris." These terrigenous sediments are typically larger than are sediments transported by rivers or winds and accumulate near the polar regions.

Biogenic sediments, which dominate most regions of the seafloor, are the skeletal remains of microscopic plankton. Biogenic sediments are classified as either calcareous or siliceous depending on their chemical composition. Coccolithophores, foramaniferans, and pteropods produce calcareous skeletons composed of carbonate minerals, while diatoms and radiolarians produce siliceous skeletons composed of opaline silica.

Metalliferous sediments are found near the crests of mid-ocean ridges, where mixing of hot hydrothermal vent fluids with deep ocean waters causes the precipitation of metal (iron, zinc, copper) sulfide and oxide minerals. Sea sediments accumulate on the seafloor at very different rates. Accumulation of sediments near the continental margins can be as rapid as 1-10 centimeters every thousand years, while wind-blown terrigenous dust accumulates on the abyssal plains at rates of 1-2 millimeters per thousand years.

• Significance for Climate Change

The distribution of marine sediments is a function of the location of the sediment source, the chemical reactions that occur in the water column and on the seafloor as the sediments accumulate, and the input rate of terrigenous sediments. Biogenic sediments are produced in surface waters in regions that contain sufficient concentrations of nutrients such as nitrogen, phosphorus, and silica. Production of siliceous plankton dominates in surface waters of the southern ocean, the Arctic Ocean, along continental margins where upwelling occurs, and along the Equatorial Divergence. Production of calcareous plankton dominates in the remaining regions.

When both calcareous and siliceous plankton settle through the water column, they are subject to chemical dissolution. Calcareous sediments are preserved where the ocean floor is generally less than approximately 4,000 meters deep and large inputs of terrigenous material are absent. Below 4,000 meters, the carbonate minerals that make up calcareous sediments are dissolved before they can be preserved, because there are low concentrations of dissolved carbonate ions in deep waters.

While the ocean is everywhere undersaturated with respect to silica, the rate of dissolution decreases with temperature, and thus with depth, in the ocean. Siliceous sediments are therefore preserved in deep regions of the ocean, under areas of high radiolarian or diatom productivity. The preservation of large amounts of terrigenous sediments in the deep abyssal plains, far removed from the continents, reflects the low levels of productivity found in the central gyres: There are no biogenic sediments produced in these waters to dilute the amount of terrigenous sediments delivered by the wind.

Changes in sea sediments preserved over geologic time reflect climate change in a variety of ways. For example, along a transect from a mid-ocean ridge toward a continental margin, the expected distribution of sediments will be as follows: metalferous sediments near the ridge crest, calcareous sediments, siliceous sediments as the ocean floor deepens below 4,000 meters, and then terrigenous clay. During times of colder climate, when sea level drops in response to glacier formation, a larger region of the ocean floor will be shallow enough to preserve calcareous sediments. When the climate is colder, the atmospheric concentration of carbon dioxide (CO_2) decreases. This, in turn, leads to an increase in the concentration of carbonate ions in the deep ocean and a deepening of the depth at which calcareous sediments can be preserved. Thus, a wider swath of seafloor on either side of a mid-ocean ridge will preserve calcareous sediments.

Because siliceous oozes accumulate under highly productive surface waters in generally cool regions, colder climates can favor the expansion of areas on the seafloor where these sediments are found. Generally drier conditions during glacial times, moreover, contribute to an increase in the flux of terrigenous sediments to the deep abyssal plains. Warmer, wetter climates can be recorded in sea sediments by an increase in the deposition of terrigenous sediments near the continental margins. Finally, global temperature changes are recorded in the isotopic composition of oxygen preserved in calcareous or siliceous sediments, and of carbon found in calcareous sediments. Changes in the pH of the ocean—which reflect atmospheric concentrations of CO_2 and temperature—are recorded in the isotopic composition of boron that is preserved in some biogenic sediments.

Sea surface temperatures

- **Category:** Oceanography

- **Definition**

Sea surface temperature (SST) is a bulk measurement of the temperature of the surface of the ocean. Average SST ranges from approximately –3° Celsius in the Arctic Ocean to 28° Celsius in equatorial waters. SST is one of the parameters recorded by ships as part of their standard atmospheric and oceanic observation practices, which are governed by international codes first established in the late nineteenth century.

The earliest sea surface temperature measurements were taken using a simple bucket and thermometer. Such measurements reported the average value for the upper 1-2 meters of the ocean. Since the 1940's, it has been standard practice to record the temperature of water coming through a ship's intake ports. This measurement, however, can record a temperature of any depth up to 20 meters, depending on the ship's buoyancy, and can be affected by heat from the ship's engines. Today, temperature data are still recorded in this manner on research vessels, weather ships, and many commercial and military vessels, with the result that many of the data are concentrated along shipping routes.

SST data are transmitted to the World Meteorological Commission and then transferred to weather services around the globe. SST readings are also recorded using moored and drifting buoys. With buoy readings, temperature probes are placed at a standard depth of 1 meter below the surface. Data from buoys are often transmitted by satellite to a data center, such as the National Data Buoy Center. As part of the World Ocean Circulation Experiment (WOCE), over forty-eight hundred drifting buoys were released to record SST among other data. Since the 1980's, SSTs have increasingly been obtained using satellite-borne radiometers. These instruments indirectly measure the temperature of the ocean's "skin" (the top 10 microns) based on the radiation intensity of select wavelengths, typically in the infrared spectrum.

• Significance for Climate Change

Sea surface temperature is a critical parameter used in general circulation models (GCMs), as well as meteorological models, to predict future climate and weather, respectively. While air surface temperatures have increased since the 1900's, global SST records are more complicated. In fact, an examination of historical records of SSTs showed a warming in the Atlantic Ocean by up to 0.4° Celsius, while equatorial Pacific SSTs cooled by approximately 0.2° Celsius.

Because of the slow response time of the oceans, as compared to the atmosphere, most scientists consider that, in most cases, observed seasonal changes in SST reflect changes in atmospheric conditions. However, there are exceptions to this assumption, most notably El Niño-Southern Oscillation (ENSO) events. ENSO events are coupled atmosphere-ocean phenomena that occur when warmer SSTs feed back into changes in atmospheric circulation patterns. El Niño phenomena are marked by warmer SSTs in the eastern equatorial Pacific Ocean, centered near the coasts of Peru and Ecuador, and they lead to a shift in the strength and direction of atmospheric circulation across the equatorial Pacific. This shift is known as the Southern Oscillation. ENSO events appear to have a periodicity of approximately three to eight years, in a highly irregular pattern.

On seasonal timescales, SSTs are important factors in the development of storms and hurricanes (tropical cyclones). A threshold SST of approximately 27°-29° Celsius is required for a hurricane to develop. The reasons for this threshold remain unknown, but, generally, higher SSTs appear to be correlated with the development of stronger hurricanes. According to observations correlated by the Intergovernmental Panel on Climate Change (IPCC), there has been an increase in intense hur-

Deviations in Mean Global Sea Surface Temperature

The following table lists deviations in average global sea surface temperature from the baseline temperature average set during the period between 1951 and 1980.

Year	*Deviation (in 0.1° Celsius)*
1880	–2
1890	–2
1900	–1
1910	–3
1920	–2
1930	–1
1940	+1
1950	0
1960	+1
1970	0
1980	+1
1990	+3
2000	+4

Data from Goddard Institute for Space Studies, National Aeronautics and Space Administration.

ricane activity in the North Atlantic since 1970. The available data do not show a clear trend in the annual number of tropical cyclones, however, and data integrity prior to 1970 remains questionable. Climate models used by the IPCC, which are based on projections of global temperature to the year 2100, indicate that an increase in hurricane activity is likely.

SST measurements are crucial to the coupled atmosphere-ocean models used to predict weather and climate, but obtaining long-term and reliable data sets that cover a wide geographic region remains a challenge. Because satellite-based SST measurements and ship- or buoy-based measurements are taken at different depths in the water, these data sets cannot be directly compared. This complication arises because satellite-based measurements are strongly affected by daytime heating of the thin layer they are able to measure, as well as by surface evaporation and reflected radiation. Also, because radiometers often cannot obtain readings through cloud cover, satellite SST data contain a fair-weather bias: SST readings are not obtained from these instruments on cloudy days, so short-term variations related to these meteorological conditions are not recorded. Ships, meanwhile, retain their own problems, because any craft powered by a motor will necessarily alter the temperature of the water through which it travels.

Seasonal changes

• Category: Meteorology and atmospheric sciences

• Definition

Weather and climate are variable phenomena in all regions of the world. Thus, irrespective of whether climate is undergoing a linear change to a new climate regime, climate is in some sense always changing. For example, an arid region in Peru may well have several years without any appreciable rain, followed by one or two weeks of relatively wet conditions. This might in turn be followed by another long period with no appreciable rain. Such climatic changes are quite normal. To determine whether climate change is of the type generally referred to by such phrases as “global warming,” one would look at a relatively significant change in the overall weather pattern. For example, long periods of dry years may become less lengthy or more lengthy, and periods of appreciable rain may also become more or less lengthy.

Another example would be snowfalls in the winter in much of northeastern North America, where snowfall varies considerably from one year to the next, and one decade to the next. Thus, the 1940’s was a period of relatively low snowfalls in some places, while the 1950's was a period of relatively high snowfalls in the same places. Such variations are quite common and are simply part of the total climate package of any particular area.

- **Significance for Climate Change**

Seasonal climates in all regions of the world have varied over all timescales, and the last one hundred to two hundred years is, in most cases and most areas, not significantly different than any other period of similar length. During the last millennium, for example, there have been long periods with warm and dry conditions (especially during the Viking explorations of northern Europe in the eleventh century), as well as long periods of cold conditions (especially during the Maunder Minimum from 1645 to 1715, which was a period when very low sunspot activity coincided closely with the coldest part of the Little Ice Age).

Global warming may cause the seasons to become generally warmer in most cases, but they may become cooler in some places. There may also be greater variation or greater change in daytime or nighttime temperatures than in overall average temperatures. In addition, the average temperatures during winter months may change in a given area in a direction opposite that of the change in the average temperatures of the summer months. Rainfall patterns and frequencies of heavy rainfalls and droughts may be affected, as well as the frequency, path, and intensities of tropical storms such as hurricanes, tropical cyclones, and typhoons.

The climate predictions from the 2008 report of the Intergovernmental Panel on Climate Change (IPCC) suggest an overall warming in the winter in North America by 2°-3° Celsius by the year 2050 and drier conditions during the summer in the Mediterranean. However, given the complexities of global, regional, and local climate systems, it is not at all easy to translate such broad-scale predictions into more focused predictions. Thus, even if the report is accurate, it is extremely difficult to know how those changes will affect winters in the American Midwest or tourism and agricultural water supplies in southern Europe, for example.

Thus, in the 2040's, Chicago could experience fewer days with snow but a greater intensity of snowfall. A 3°-4° Celsius increase in summertime temperatures may well translate into a nighttime temperature increase of 1°-2° Celsius, a daytime increase of 4° Celsius, and an overall increase of 10 percent in the number of days with a maximum temperature of 38° Celsius or more. While the climate models from the IPCC reports appear on the surface to be relatively specific for an area such as the western United States, the specific translation of such forecasts into, say, the Rocky Mountain area poses considerable difficulties, especially if one is interested in what will happen in the wintertime or the summertime in a place such as Denver during a specific decade.

Second Assessment Report

- **Category:** Laws, treaties, and protocols
- **Date:** Published 1995

- **Definition**

The United Nations Intergovernmental Panel on Climate Change (IPCC) was established by the World Meteorological Organization and the United Nations Environment Programme

> . . . to assess on a comprehensive, objective, open and transparent basis the latest scientific, technical and socio-economic literature produced worldwide relevant to the understanding of the risk of human-induced climate change, its observed and projected impacts and options for adaptation and mitigation.

The IPCC publishes a set of assessment reports at approximately five-year intervals. The IPCC's Second Assessment Report (SAR), published in 1995, consisted of three volumes, each assembled by a separate "working group." The three volumes of the SAR were:

- *WG I: The Science of Climate Change*
- *WG II: Impacts, Adaptations, and Mitigation of Climate Change: Scientific-Technical Analyses*
- *WG III: Economic and Social Dimensions of Climate Change*

Together, the technical volumes were nearly two thousand pages long. Each of the volumes was summarized in a short "summary for policy makers." The SAR was accompanied by a synthesis report that summarized information specifically relevant to Article 2 of the United Nations Framework Convention on Climate Change.

The SAR is a highly technical document that few, if any, individuals are qualified to understand in its entirety. Most discussion of the SAR is actually based on the summaries for policy makers, which were published considerably earlier than the underlying technical materials. Unlike the technical reports, the summaries for policy makers are drafted by governmental representatives to the IPCC and are formally approved by a panel comprising only a small selection of lead authors.

The SAR itself was written by a team of approximately 1,200 authors, with approximately 476 lead authors and 748 contributing authors. Authors and contributors could contribute to more than one section, so this tally is not of "unique" authors. The SAR lists 1,417 expert reviewers.

- **Significance for Climate Change**

Publication of the SAR marked a sharp turning point in the understanding of and public debate regarding climate change, as well as the need to reduce greenhouse gas emissions. While the First Assessment Report (FAR) of the IPCC (1990) had concluded only that "[t]he unequivocal detection of the enhanced greenhouse effect is not likely for a decade or more," the SAR concluded that "[t]he balance of evidence suggests a discernible human influence on global climate." This attribution marked a shift in the debate from a speculative linkage to human activity to an authoritative one.

The conclusions of the SAR in the Summary for Policymakers were:

(1) Greenhouse gas concentrations have continued to increase.
(2) Anthropogenic aerosols tend to produce negative radiative forcings.
(3) Climate has changed over the past century.
(4) The balance of evidence suggests a discernible human influence on global climate.
(5) Climate is expected to continue to change in the future.
(6) There are still many uncertainties.

The conclusions of the SAR were accepted as definitive by world governments and served as the knowledge base used in negotiation of the Kyoto Protocol in 1997.

Perhaps because of its import in public policy development, the SAR was a source of more controversy than earlier reports. Several contributing authors to the SAR, physicists Frederick Seitz, William Nirenberg, and S. Fred Singer, accused physicist Benjamin D. Santer (lead author of a key chapter on the attribution of climate change to human activity) of making unauthorized changes to the text of the chapter after peer reviews had been concluded and final wording agreed upon by contributing authors. Santer asserted that his changes were made as a normal part of the peer review process.

Santer's claim was supported by the chairman of the IPCC as well as the other authors of the chapter, but the claims against Santer were never retracted and continue to circulate on the Internet and in publications critical of the IPCC assessment report process.

In a separate controversy, the economic analysis conducted in volume 3 of the SAR was attacked for improperly using statistical values of human life that assigned more or less value to human life based on country of origin. This was the only assessment report that conducted such economic assessments of climate damage that included valuation of human mortality.

Security

• **Category:** Nations and peoples

• **Definition**

Security refers to the general stability of a nation; it includes military defense against other nations and threats, as well as defenses against lower-level threats to stability, including civil unrest, political instability, disruptions of resources, and terrorism. Climate change has the potential to affect many of the resources that industrialized nations take for granted. Those resources are necessary to protect the land, air, and sea, as well as nations' military capabilities. Provisions for food, shelter, health, longevity, space, and transportation may suffer, as may the general level of emotional security that helps maintain civil order in any nation where the populace vastly outnumbers the military and civil peacekeepers.

Governments must adapt to altering climates to maintain their security, so they must search for preventive and collaborative ways to pursue both military and health security that respond both to actual threats and to potential future threats. All societies need to conserve vital resources, while maintaining the ability to protect themselves. Even within the realm of military defense alone, competing interests must be taken into account. For example, testing nuclear weapons may make nuclear powers better able to defend themselves from other nuclear powers, but it could just as easily prove significantly counterproductive by destabilizing the relations among such powers. On a broader level, the military-industrial complex of the United States and other developed nations accounts for extremely high greenhouse gas (GHG) emissions, as it is an energy-intensive manufacturing sector. Thus, traditional military security activities may contribute significantly to the decrease in national and international climate security.

- **Significance for Climate Change**

Food availability is just one immediate example of a security concern raised by climate change. Such change can affect land fertility, and traditional methods of increasing fertility depend heavily on fossil fuels and GHG emissions, which may increase global warming and exacerbate the problem. Global warming may also lead to an increase in the number and spread of infectious diseases: Malnutrition and other disruptions in food quality can contribute to disease, as can changes in temperature and humidity that increase such disease vectors as mosquitoes and water contamination.

As food quality suffers, this in turn can lead to a decline in labor productivity, both for those who own and run farms and for those who cannot obtain the necessary nutrition to function effectively at work. The decline in productivity could specifically hinder military workers. New diseases can also weaken military capabilities, making nations more vulnerable and placing them at higher risk of security threats. Microbial changes in the environment can affect the very young and the very old, potentially increasing mortality rates. In nature, bees and other pollinators could become extinct, further endangering food supplies.

Firefighters battle a blaze set by members of the ecoterrorist Earth Liberation Front in Woodinville, Washington. Ecoterrorism is one climate-change-related threat to security. (Marcus R. Donner/Reuters/Landov)

The most vulnerable nations, like the most vulnerable individuals, are those with the least power and resources. Thus, climate change is widely expected to have the greatest immediate security impacts on the nations that are already the least secure. In Darfur, for example, a scarcity of natural resources has led to conflict among the local populations. There has been competition for water between groups that, in the past, were able to coexist. In the Palestinian territories, Israeli settlers receive more water per capita than do Palestinians, greatly exacerbating political and social tensions between the two groups. These conflicts may serve as canaries in the coal mine, revealing to more stable nations the dangers of severe climate change. However, they are also of immediate concern, because the world's major economic powers depend upon the availability of the world's markets, so any significant global instability, even in the developing world, represents a threat to the industrialized nations' economic security.

Global transportation could be significantly affected by the need to reduce GHG emissions, as it is a major source of such emissions. Business travel in particular could be significantly curtailed, as telecommuting and teleconferencing technologies replace in-person meetings. At the same time, the potential collapse of some national resource chains and infrastructure increases the likelihood of significant international migration, as climate refugees seek new homes in which to support themselves. Such large potential influxes of immigrants threaten the social and economic stability of their new homes, especially if resources in those new homes are already under pressure from climate change.

At the extreme end of climate-related security concerns lies the threat of significant and sustained violence in the service of resource competition, both within and among nations. Such violence could escalate to warfare. This danger makes it all the more necessary for nations to collaborate and succeed at finding a solution to projected climate changes. In order for national governments and their people to be protected from the risk of political unrest and terrorism, this goal is key.

Sequestration

• **Categories:** Pollution and waste; meteorology and atmospheric sciences

Sequestering CO_2 and other GHGs from the atmosphere by geological, biological, or chemical processes and storing them in forms that will not affect Earth's climate is a primary mechanism for reducing atmospheric GHG concentrations and limiting global warming.

• Key concepts

carbon neutral: the quality of neither subtracting nor adding a net amount of carbon to the atmosphere

photosynthesis: process whereby carbon is taken from the atmosphere and incorporated into organic compounds by plants in order to store solar energy by converting it into chemical energy

sink: a source of storage of a substance that removes it from environmental circulation

• Background

Since the Industrial Revolution began, atmospheric levels of carbon dioxide (CO_2) have risen from 275 parts per million to the present level of 380 parts per million. Evidence suggests that this observed rise in atmospheric CO_2 levels is due primarily to the use of fossil fuels. There is a worldwide awareness that global warming is a result of the rising levels of CO_2 and other greenhouse gases (GHGs). Earth's atmospheric CO_2 level could easily exceed 550 parts per million by the middle of the twenty-first century if no corrective actions are taken. A variety of methods of CO_2 sequestration has been suggested, including the use of oceans, underground caves, chemical reactions, or living organisms for CO_2 removal. Several pilot projects for CO_2 sequestration are under way in different countries.

• Ocean Sequestration

Oceans serve as Earth's largest CO_2 sink—and a natural one as well. CO_2 simply dissolves in the ocean or is taken up by resident microscopic algae (phytoplankton). Based on these ocean features, scientists are considering two approaches for CO_2 sequestration. One option envisions direct injection of a stream of CO_2 waste into the ocean depths. An immediate problem with this approach is that direct injection may create acidic water that would kill a majority of oceanic life forms.

A second idea is to enhance photosynthesis by algae. Algae are the most important carbon sink on Earth, consuming CO_2 as they photosynthesize and converting it into organic matter, a process known as carbon fixation. For instance, oceanic algae annually sequester 2 gigatons of CO_2, compared to the 1.5 gigatons sequestered by all terrestrial ecosystems together. Some of this CO_2 permanently remains in the ocean in the form of calcium carbonate or silicates. One proposal for algal sequestration suggests fertilizing the ocean with iron in order to stimulate photosynthesis by algae. However, because water circulates very slowly throughout the oceans, this method might require hundreds of years before significant amounts of CO_2 are sequestered.

• Underground Sequestration

CO_2 can also be pumped into depleted underground oil and gas reservoirs. There is enough underground capacity to store the gigatons of excess atmospheric CO_2 accumulated over hundreds years. These reservoirs would be sealed and capped to avoid the escape of CO_2. Safety is a concern for CO_2 underground storage, as the CO_2 may escape, suffocating people and animals in its path. This happened in Cameroon in 1986, when 1 million cubic meters of CO_2 erupted from the Lake Nyos crater, killing eighteen hundred people. This CO_2, however, was not placed underground by humans. Another possibility is to inject CO_2 into saline aquifers, geological formations that contain salt water in their pore spaces. These aquifers have the capacity to store up to 10,000 gigatons of CO_2.

• Microalgal Sequestration

One proposed solution for carbon sequestration would be to use microalgae (microscopic algae) to capture CO_2 that is discharged into the atmosphere by power stations and other industrial plants. Several U.S. start-up companies (GreenFuel Technologies, GreenShift, Solix, and Valcent Products) are pursuing this idea by using pilot-scale algal photobioreactors to remove CO_2 from power plant waste gases. Microalgae are photosynthetic microorganisms similar to plants, but they grow quickly and can greatly increase their total biomass within hours. Photobioreactors are various types of closed systems made of an array of transparent tubes in which microalgae are cultivated and monitored.

The design of a photobioreactor is an important factor governing algal productivity for CO_2 sequestration. Photobioreactors should be simple, inexpensive, and energy efficient and should allow a high-cell density of algal growth. For the efficient removal of CO_2 from power plant effluent gases, it would also be advantageous to use algal species that can tolerate and assimilate high concentrations of CO_2 (more than one hundred times atmospheric levels).

Large-scale cultivation of microalgae in photobioreactors as a technology for CO_2 sequestration will have an impact on global climate only if the algal biomass is used to substitute for fossil fuel. Algae in photobioreactors, for example, can be used to generate environmentally friendly biofuels such as biodiesel and hydrogen. Although the use of algal biomass as an energy source releases CO_2, the process as a whole can be considered carbon neutral in that the CO_2 released during conversion to fuel or through the use of fuels had been assimilated during the original growth of microalgae and can be recycled again through uptake by microalgae.

U.S. GHG Sequestration, 1990-2007 (in millions of metric tons of CO_2 equivalent)

Year	*U.S. GHG Emissions*	*Reduction by Sinks*	*Net Emissions*
1990	6,098.7	841.4	5,257.3
1995	6,463.3	851.0	5,612.3
2000	7,008.2	717.5	6,290.7
2005	7,108.6	1,122.7	5,985.9
2006	7,051.1	1,050.5	6,000.6
2007	7,150.1	1,062.6	6,087.5

Data from U.S. Environmental Protection Agency.

• Other Biological Sequestration

Other biological methods of CO_2 sequestration have also been investigated. One is the conversion of CO_2 into methane by microbes called archaea. The resulting methane could be used as fuel. Another biological method of carbon sequestration would be to enhance natural terrestrial ecosystems. Terrestrial ecosystems absorb CO_2 mainly through plant photosynthesis. These ecosystems can help remove CO_2 from the atmosphere by storing it in plant biomass and soils. Certain woody plants, such as poplars, are being considered for CO_2 sequestration. These plants consume CO_2 during vegetative growth and convert it into lignin, a biological compound that is very resistant to decomposition. However, even when woody plants are used, the CO_2 will ultimately return to the atmosphere by fermentation or through respiration by microbes and animals. A potential solution would be similar to microalgal sequestration technologies, involving the use of plant biomass to generate biofuels.

• Chemical Sequestration

In addition to the geological and biological methods mentioned above, there are also chemical methods for CO_2 sequestration. These methods use chemicals such as magnesium silicate, amines, or ammonia to capture CO_2. All known CO_2 sequestration technologies are very expensive. It may therefore be more cost effective to adopt alternative fuels and avoid CO_2 emissions to the extent possible, rather than continuing to emit CO_2 and relying on sequestration to mitigate its greenhouse effect.

Siberian river diversion proposal

- **Category:** Water resources

- **Definition**

Until the 1960's, the Aral Sea in Central Asia was the fifth-largest freshwater sea in the world. At 66,900 square kilometers, it was roughly the size of Belgium and the Netherlands combined. It had a major fishery, and seaside resorts were located on its shores in the Soviet Union. Irrigation from the sea's main tributaries, the Amu Dar'ya and the smaller Syra Dar'ya, supported varied agriculture, including some cotton.

Then, the Soviets massively expanded cotton production. The desert of the Aral Sea Basin was the only Soviet region warm enough to grow cotton. The nation increased cotton production and suppressed other crops. It became the world's greatest cotton producer for a number of years.

Cotton is a water-intensive crop, and the necessary irrigation infrastructure installed by the Soviets caused much water to evaporate away rather than flowing to the Aral Sea. Furthermore, inefficient irrigation methods leached salts from the soil to the surface. Farmers fought this salinization by annually "washing" their fields with more water. Finally, the Karakum Canal sent water to an area outside the Aral Sea Basin.

The result of all these factors in combination has been possibly the world's worst ecological disaster. The Aral Sea shrank to three saline lakes with one-tenth the water it once held. Most of its dry seabed became a salty, pesticide-laced desert. Meanwhile, the breakup of the Soviet Union in the early 1990's left five independent countries in the basin: Kazakhstan, Krgystan, Uzbekistan, Tajikistan, and Turkmenistan. Coordinating water policy became an international endeavor and was therefore much more difficult. The five countries have been too poor to be able to switch from cotton, and their decaying irrigation systems are even less efficient than they were in the Soviet days. One initiative has brought increased freshwater to a portion of the original Aral Sea, and this area is diked off from the saline areas. However, this program is only regenerating a small part of the original sea.

One desperate response to this disaster would be massive water diversion from major rivers that flow north into the Arctic Ocean. The Soviets designed such a project and began construction on it from 1976 until 1986, when cost and environmental concerns killed the project. However, the project was revived as a possibility in the early twenty-first century.

- **Significance for Climate Change**

Critics of the Siberian rivers diversion scheme called it fixing one disaster with another. Dams would back up reservoirs, and pumps would take headwaters from these reservoirs into other basins. The Arctic river diversions would actually have started in European Russia, involving 19 cubic kilometers per year, mostly from the Pechora and Sakona Rivers. These waters would have been diverted to the Volga River for drainage to the Caspian. (The small gradient eastward from the Volga would have allowed easy diversion to the Aral Basin.)

Diversion from the Ob and Irtysh Rivers, discharging roughly 385 cubic kilometers of water to the Arctic Ocean each year, might yield as much as 60 cubic kilometers. However, those waters would come at the cost of 3 gigawatts of pumping power to get over the 113-meter Turgay Divide from Western Siberia to the Aral Basin. Then, a 2,200-kilometer Siberal canal would need to be constructed to reach the Aral Sea.

The greatest complaint about these potential diversions has been that better irrigation practices would be more cost effective. Water leakage from the Siberal canal would vastly increase the water demand from the rivers and the cost of the project.

Most important for world climate, these diversions would decrease freshwater flow to the Arctic Ocean. This decrease would be important, because the Arctic is not temperature stratified as tropical and temperate ocean waters are. The Arctic Ocean is salinity stratified. Warmer, saltier water flows northward from the Gulf Stream in the Atlantic (which has become the Norwegian Current) and flows under the frozen freshwater at the surface. These salty waters are as much as 1° Celsius above freezing, while the surface waters are at freezing or below during winter. Moreover, saline water freezes at lower temperatures than does freshwater.

The Siberian river diversions could radically change the Arctic and, consequently, the world's climate. If freshwater inflow were significantly decreased, as from the Aral Sea diversions, the Arctic pack ice might melt in the summer. This would probably contribute to global warming. However, open water could provide more evaporated water to generate snow that could cause global cooling. It would be a global experiment.

That experiment could happen for two reasons. First, the countries around the Aral Sea may go from poverty to oil and gas riches. Second, Russia's government may continue "the Great Game" of the last two centuries by trading water for the allegiance of the countries around the Aral Sea. Third, Russia could also use water moving toward the Aral Basin for its own irrigation.

Sierra Club

- **Category:** Organizations and agencies
- **Date:** Established 1892
- **Web address:** http://www.sierraclub.com

• Mission

The Sierra Club was one of the first major environmental organizations to address climate change. In 2005, the organization took its efforts even further by making climate change the centerpiece of its campaign for environmental protection for the next several years.

Founded in California by renowned environmentalist John Muir, the Sierra Club has grown from a club that promoted outdoor excursions to foster an appreciation for the natural environment, to a grassroots political organization under David Brower, to a political powerhouse with state chapters and national offices in Washington, D.C. Historically, state chapters have focused on issues pertinent to their areas, while the national chapter campaigns for federal solutions to more widespread problems. With the national chapter's commitment to the issue of global climate change, all chapters have converged on the issue, promoting local, regional, and national solutions. The club's mission, while promoting the enjoyment of nature through outings, also includes educating and involving people in the protection of natural resources through all lawful means possible. Their efforts to combat global warming directly relate to their mission.

• Significance for Climate Change

The Sierra Club first put global warming on its agenda in the late 1980's, after scientific reports indicated that humans may be responsible for warming and that the effects could be detrimental. During the 1990's, the Sierra Club focused on pressuring the federal government to take action. In 1992, the group funded a television advertising campaign aimed at President George H. W. Bush and his lack of attention to global warming at the 1992 Earth Summit. The club collaborated with other groups and held the unofficial Global Forum concurrently with the Rio Earth Summit. At the forum, strategies for influencing government that focused on influencing policies at the national level were discussed.

With Democrats in Congress, the Sierra Club maintained a dominant strategy of campaigning for federal action on global warming. This strategy was perpetuated by the election of President Bill Clinton and Vice President Al Gore, who was seen as a sympathizer to the group's cause. Under President Clinton and Vice President Gore, representatives of the Sierra Club and other members of the environmental movement were allowed to the table during policy formulations on global warming. Having open access to this level of policy making facilitated a continuing strategy to focus their efforts on encouraging federal action on the issue. However, the club's efforts did not result in passage of federal legislation, and although Gore signed the Kyoto Protocol, it was seen as a largely symbolic gesture, as the Clinton administration failed to send the document to the Senate for ratification. The federal government had basically refused to make a commitment to greenhouse gas emissions reductions.

The Sierra Club's strategy broadened, and it began a campaign to target automobile manufacturers in the mid-1990's. This campaign initially critiqued the use of cars and sports utility vehicles (SUVs) that have low gas mileage and thus contribute more carbon emissions to the atmosphere. It expanded to target companies making SUVs, and the club launched a full-scale attack on Ford's Excursion in late 1998. In 2000, the Sierra Club presented Toyota with an environmental excellence award for the release of the Prius hybrid. It was the first time in the club's 108-year history that it had honored a product. It continued its disparagement of SUVs into the new millennium.

In 2003, the Sierra Club joined forces with other environmental groups in lobbying the Environmental Protection Agency (EPA) to regulate carbon emissions under the Clean Air Acts (1963-1990), but the agency refused. As a result, the Sierra Club joined other groups, states, cities, and petitioners in a suit against the EPA for not properly enforcing the Clean Air Acts. In 2007, the Supreme Court sided with the Sierra Club in *Massachusetts v. EPA*, agreeing that greenhouse gases (GHGs) could be regulated under the Clean Air Acts.

In 2005, the Sierra Club changed the focus of its conservation efforts. The main goal of its efforts became to move the United States beyond fossil fuel reliance as a solution for reducing carbon emissions. As part of this focus, the organization encourages states and cities to adopt legislation to move beyond fossil fuels. This strategy represented a direct response to a lack of federal action on global warming, although the club continued its traditional efforts to lobby for federal legislation on global warming as well. A cornerstone of this effort was the Sierra Club's Smart Energy Solutions initiative. Within this initiative is the Clean Car Campaign, a continuing effort by the Sierra Club to encourage the federal government and automakers to raise the CAFE standards and allow states to do the same. The club sees improved fuel economy as the most important solution for reducing GHG emissions in the United States.

Another campaign within the Smart Energy Solutions initiative is Cool Cities Campaign. Cool Cities encourages and supports local communities that sign on to the U.S. Conference of Mayors Climate Protection Agreement, an effort started by Seattle mayor Greg Nickels to adopt the Kyoto Protocol at the local level. The campaign encourages new cities to join and provides a network of support for participating cities to share their success stories and learn from the efforts of other cities throughout the country. The campaign also provides support for grassroots organizers wishing to convince their home cities to sign the agreement. The club also encourages legislation at the state level to improve

David Brower stands in his office at the Sierra Club in 1968. (Joe Munroe/Landov) energy efficiency and investment in renewable energy. Furthermore, the club opposes every new coal power plant through litigation and lobbying in an effort to move the country away from fossil fuel dependency.

The Sierra Club educates and encourages individuals to join its campaigns through a variety of outreach methods, including the Two Percent Solution campaign to reduce people's carbon footprints through changes in lifestyle and personal consumption choices. The Two Percent Solution campaign is an effort to reduce carbon emissions by 2 percent per year, the amount needed to reduce emissions by 80 percent by 2050. The club has utilized the Internet to promote the Smart Energy Solutions initiative through the use of mass e-mailings and the Hotline E-newsletter, a bimonthly publication that consolidates news and information about global warming.

Sinks

• **Categories:** Meteorology and atmospheric sciences; pollution and waste

• Definition

A sink is a process or mechanism that removes or absorbs carbon dioxide (CO_2) and other greenhouse gases (GHGs) from the atmosphere. The 1992 U.N. Framework Convention on Climate Change (UNFCCC) defines a sink as any process, activity, or mechanism that removes or absorbs a GHG, aerosol, or precursor of a GHG from the atmosphere.

Sinks, to be so called, must be net sinks—that is, if they also release GHGs into the atmosphere, they must remove more GHGs than they emit. Otherwise, they would count as sources of GHG emissions. The most common sinks are carbon sinks, which include oceans and terrestrial ecosystems such as forestry and soil. Carbon sinks remove carbon from the atmosphere and store them; in the latter respect, they are also referred to as reservoirs.

Forests act as carbon sinks through the process of photosynthesis. Oceans act as sinks when atmospheric CO_2 dissolves in ocean surface waters and is stored there. This continues until the surface waters are saturated, at which point the rate of CO_2 uptake declines. The CO_2 remains in the surface until the oceans turn over, which happens in cycles of about one thousand years. During this overturning, the surface waters move downward, carrying with them the dissolved carbon. This enables the oceans to continue to absorb carbon from the atmosphere.

• Significance for Climate Change

CO_2 is the most important anthropogenic GHG, and the amount of CO_2 in the atmosphere has increased by about 35 percent in the industrial era, mainly by human activities. However, the increase in CO_2 in the atmosphere is less than the increase in CO_2 emissions. This is because, of approximately 400 billion metric tons of carbon released into the atmosphere by human activity in the past two hundred years, only about 40 percent has remained in the atmosphere. The rest has been absorbed by carbon sinks, especially land and oceans. Without these carbon sinks, the amount of CO_2 in the atmosphere, one of the major causes of anthropogenic climate change, would be considerably higher than it currently is.

Terrestrial ecosystems—land and vegetation—currently act as a net global sink for carbon. They are, however, also potentially major sources of GHG emissions. Over the years, deforestation has contributed an estimated 30 percent to GHG concentration. When trees are cut down, the atmosphere is affected in two ways: The trees, which also act as reservoirs of CO_2, release carbon into the atmosphere, and the CO_2 that would otherwise have been removed from the atmosphere by these trees remains in the atmosphere. These two effects of deforestation on the whole make the warming of the climate worse.

Modifying carbon sinks to enhance their carbon uptake would have the effect of slowing the rate of climate change. By reducing the rate of deforestation or by planting more trees (afforestation or reforestation), Earth's carbon sinks can be expanded. Under the Kyoto Protocol's clean development mechanism (CDM), afforestation and reforestation projects are eligible to earn carbon credits. This provides an incentive to increase the planting of trees and hence to enhance Earth's reserve of carbon sinks.

Skeptics

• **Category:** Meteorology and atmospheric sciences

• **Definition**

In the climate change controversy, the term "skeptic" is a generic term widely used to denote people who question some or all notions of anthropogenic climate change. The term "denier" was used earlier in the controversy but is unsatisfactory for several reasons. First, many skeptics accept some aspects of anthropogenic climate change. Also, the term "denier" implies arbitrary or unreasonable doubt about anthropogenic climate change, whereas many doubters believe they have sound reason for being skeptical. The term "skeptic" has emerged as a general label used by both sides in the debate, because it is reasonably neutral. There remain people on both sides who use more polemic and less neutral terms to describe the opposition.

The range of skeptical opinion on anthropogenic climate change spans a spectrum from relatively mild and reasonable concerns about data gathering or interpretation, on one hand, to outright denial that climate is changing at all on the other hand. In roughly increasing order of dissent, skeptical positions include:

(1) Concerns about features not adequately modeled by climate studies, such as cloud cover
(2) Concerns about the need to program many assumptions into climate models
(3) Doubts about the validity of computer modeling of climate in general
(4) Doubts about how data are measured
(5) Doubts about how to link recent quantitative measurements with older historical and prehistoric climate indicators
(6) Doubts about whether present climate changes are anthropogenic or are merely part of long-term natural climate changes
(7) Claims that warming of the climate might actually be beneficial
(8) Claims that climate change is too far along to reverse or mitigate
(9) Claims that attempts to halt or reverse climate change would impose unacceptable economic or political costs
(10) Claims that human activities have no effect
(11) Claims that no long-term climate changes are occurring at all
(12) Claims that the Earth is actually cooling, or has begun to cool after a warming period

The first five of these positions are not skeptical per se. All scientists engaged in climate studies are well aware of the problems and uncertainties in climate modeling, and in many cases, scientists who are described in the media as skeptics are merely describing problems that are common knowledge in the scientific community. The polarity of the debate and the desire of the media to maintain that polarity leads many scientists to be described as skeptics who are not skeptics at all: They may be fully convinced of the reality of anthropogenic climate change in general but critical of a particular study or hypothesis regarding that change.

Defenders of the sixth position argue that long-term climate cycles and solar variability are more important than anthropogenic changes. They are not necessarily skeptical of the existence of minor anthropogenic factors, but they doubt that such factors are the primary cause or that changes to those factors are capable of preventing global warming.

The seventh through ninth positions are policy positions rather than scientific ideas. Some people who take those positions agree that humans have modified the climate but believe the costs of trying to reverse the effects outweigh the benefits. They are not necessarily skeptics, but strong advocates of these policy positions very often either are skeptics or are categorized as such within the context of climate policy debates. The last three positions amount to outright denial of anthropogenic climate change.

• Significance for Climate Change

Confirming anthropogenic climate change involves collecting and interpreting vast amounts of data on a global scale and correctly understanding the physical mechanisms that store heat on the Earth. Also, attempting to predict what climate will do in the future requires the use of extremely complex computer models that are still imperfect. Climate change is not merely a scientific question but also one that has enormous implications for economics, public policy, and national security. If governments act to reduce climate change and the predictions of danger are wrong, trillions of dollars may be wasted and enormous harm done to freedom and the economy. If governments do not act and climate change does occur, then the consequences may include coastal flooding, droughts, famine, and vast refugee movements. Anthropogenic climate change presents the frightening prospect of unavoidable risk where every course of action, including doing nothing at all, poses danger.

Some aspects of anthropogenic climate change are settled beyond debate. There is virtually no argument that carbon dioxide (CO_2) has increased in the atmosphere since the start of the Industrial Revolution (roughly since 1750), there is little debate over whether the increase is due to human activity, and it is well established that CO_2 absorbs infrared radiation. Although there are dissenters, more and more people on both sides of the debate agree that Earth's climate is getting warmer. The debate over anthropogenic climate change revolves mostly around how much of the warming is due to human activity, how certain scientists can be of a human role, and whether it is possible or desirable to intervene.

Unfortunately, in addition to people who question anthropogenic climate change for responsible scientific reasons or who debate whether attempts to affect climate change will be useful, there are people in the skeptic camp who exploit legitimate questions as a pretext for outright denial of climate change. For example, many prominent skeptics have ties to front organizations run by business and political interests opposed to attempts to reduce greenhouse gas emissions. Some skeptics distort or misinterpret credentials. A common example is for media weather reporters to comment on climate change, even though many do not have scientific credentials relevant to climate research. In another example, U.S. senator James Inhofe of Oklahoma published a Web page in 2007 claiming that 650 prominent scientists rejected climate change, but detailed examination of the list shows that over half of those listed have no qualifications at all to comment on climate change.

Skin cancer

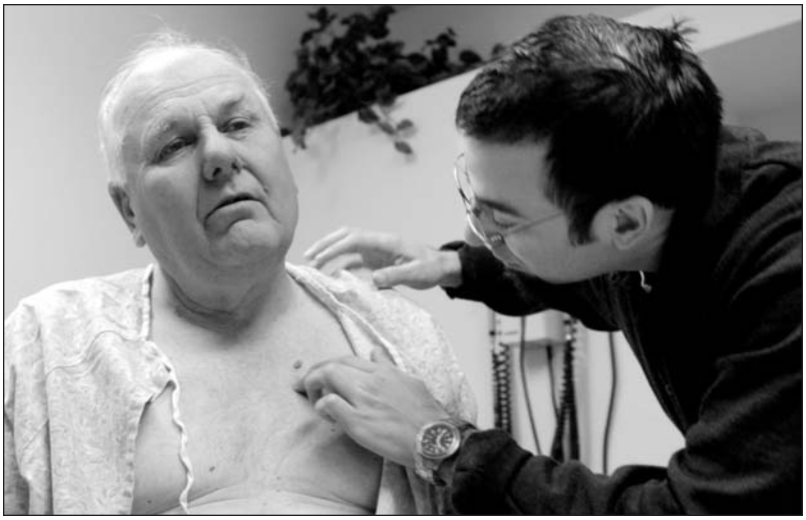
• **Category:** Diseases and health effects

• Definition

Skin cancer is the most common type of cancer in the United States, with about one million Americans developing skin cancer each year. The two most common types of skin cancer are basal cell and squamous cell cancers. These nonmelanoma skin cancers are less serious than melanoma. Most basal cell and squamous cell skin cancers can be cured if found and treated early. Left untreated, however, they can spread and cause more serious health problems.

Although skin cancer can occur anywhere, these cancers usually occur on parts of the skin frequently exposed to the Sun, such as the face, head, neck, hands, and arms. Basal cell carcinoma, the most common type of skin cancer, grows slowly and rarely spreads to other parts of the body. Squamous cell carcinomas are more aggressive, sometimes spreading to lymph nodes and body organs. Another skin disorder related to Sun exposure is actinic keratoses, premalignant skin growths that develop on body areas exposed to the Sun and are considered a risk factor for developing squamous cell carcinoma. Although much less prevalent than other types, melanoma is the most serious type of skin cancer and is also one of the fastest-growing cancers. Melanoma occurs in skin pigment cells called melanocytes, which produce melanin and give skin its natural color. Melanoma can occur on any skin surface and can become invasive and spread to other parts of the body.

Most skin cancers are caused by exposure to sunlight or ultraviolet (UV) radiation. Although the chance of developing skin cancer increases with



A dermatologist examines cherry orchard owner Gary Honald for possible skin cancer. (Benjamin Brink/The Oregonian/Landov)

age, especially after age fifty, skin damage from the Sun can occur at an early age, and skin cancer can affect people of all ages. Skin cancer risk is associated with exposure to UV radiation over a person's lifetime. Skin cancers are more common in individuals with fair skin that burns or freckles easily and in people who have red or blond hair and light-colored eyes. Although it is less common in darker-skinned individuals, they also are susceptible to skin cancer.

• Significance for Climate Change

The incidence of skin cancers is likely to increase with global warming. Ultraviolet radiation comes from the Sun; two types of rays, UVA and UVB, reach the Earth's surface. Although UVB rays are more likely than UVA rays to cause sunburn, UVA rays penetrate further into the skin. Many studies have demonstrated that exposure to UV radiation has contributed to the worldwide increase in skin cancers, including malignant melanoma. People who live in areas that get large amounts of UV radiation have a higher risk of skin cancer.

In the United States, areas in the south, such as Texas and Florida, receive more UV radiation than areas in the north, such as Minnesota. Skin cancers occur more commonly per capita in Australia and in other parts of the Southern Hemisphere. People who live in the mountains are also exposed to higher levels of UV radiation. In Santiago, Chile, the incidence of melanoma increased by 105 percent between 1992 and 1998. In some parts of the world, especially Western countries, melanoma is becoming more common every year, with the percentage of people developing melanoma more than doubling in a thirty-year period; this increase is expected to continue.

One of the major environmental changes associated with global warming is depletion of the ozone layer. The ozone layer forms a physical barrier in the stratosphere and protects living organisms from harmful UV radiation coming from the Sun. Scientists have documented a decrease in the ozone layer during the latter part of the twentieth century, and this decrease is expected to continue into the twenty-first century. The decrease in ozone levels permits more UV radiation to pass through the atmosphere and reach Earth's surface. Although the amount of UV radiation produced by the Sun does not change, the ozone layer provides less protection as it gets smaller. The amount of UVB radiation measured at the Earth's surface doubles during the annual formation of an ozone hole over the Antarctic. A relationship between reduced ozone and increased UVB levels was also confirmed in a study conducted in Canada.

Ozone depletion and the resulting increase in UV radiation have significant human health effects. Since more UV radiation reaches the Earth, human exposure to these harmful rays is increasing. Among other potential effects on human health, this situation may entail increases in the incidence of skin cancers, including melanoma. People having lightly pigmented skin will be most susceptible. Changes in the immune system may also occur, and although such alterations do not directly cause skin cancer, they may impair the body's ability to defend against cancer.

Slab-ocean model

- **Category:** Oceanography

- **Definition**

A slab-ocean model is a simple, nondynamic, computer-generated ocean model used in coupled simulations between ocean and atmosphere where the ocean is represented as a motionless layer of water with a depth of 50-100 meters. "Slab" refers to the layer of nominal thickness of water chosen to represent simple upper-ocean seasonal heat capacity. In slab models, sea surface temperatures (SSTs) are computed from surface energy balance and heat storage, appearing as a fixed-depth, homogeneous, mixed layer of water with no ocean currents. Because of their general nature, slab-ocean models are also referred to as "simple mixed-layer models" or "bulk models." Standardized equations are used to define the momentum, temperature, and salinity of the model's mixed layer, implying that these parameters are constant over the depth of the model's mixed layer.

When run coupled with atmospheric data, a slab-ocean model can simulate seasonal cycles of upper-ocean heat storage, permitting a simplified understanding of the seasonal cycle and its effects on climate sensitivity: Shifts in climate are reflected as changes to the seasonal heat capacity of the upper ocean. Changing input values can cause the defined slab-ocean layer to act as a heat source or sink for a larger model, and to some extent it can simulate the effect of moving currents. However, there is no true current or upwelling (vertical motion) in a slab-ocean model, so it can only simulate the climate effects of a steady ocean current. As a result, a slab-ocean model cannot simulate a dynamic change in an ocean current, upwelling, or overturning of circulation due to atmospheric climatic changes. Since ocean currents are a major portion of real ocean morphology and they are not represented in slab-ocean models, the models cannot simulate all aspects of SST distributions.

Ocean currents work to move heat horizontally from the tropics poleward, and excluding currents from slab models tends to produce simulations in which SSTs are higher in modeled tropical environments and colder in modeled high latitudes than they are in actuality. Slab models also exclude the contributions of upwelling, which produces temperature changes in upper ocean layers. As a result, areas rich in upwelling regimes require input corrections.

In an effort to correct such temperature errors in slab-ocean models, simulations often include a heat flux value called the *Q*-flux. The heat flux correction simulates a source of heat transport producing effects similar to those generated by real ocean currents, but, when running slab-ocean models, the same *Q*-flux corrections must be run in both the control and forced simulations to maintain experimental integrity. Changes to upper-ocean temperatures due to increased atmospheric temperatures, melting ice, or increased radiation can be simulated simplistically and run to equilibrium with *Q*-flux corrections.

Equilibrium for a slab-ocean model is the point at which the atmosphere and the ocean reach a balanced state, such that the climate variables being measured do not drift toward another state. Taken as a representation of thermodynamic equilibrium, slab models may reflect changes to the climate system, assuming the observed ocean heat transport is the same in both controlled and forced experiments. Forcing parameters in slab-ocean models include energetic effects of surface fluxes, such as solar radiation; work from waves; buoyancy dissipation; and frictional effects of wind.

• Significance for Climate Change

In climate studies, slab-ocean models are used to estimate the equilibrium response of climate to a given forcing, not the transient evolution of climate. Also, as the model's layer is considered motionless, the model cannot reflect ocean circulation changes resulting from environmental changes. In spite of their simplistic nature and problems with SST errors due to known ocean currents and upwelling, slab-ocean models are useful in researching global climate sensitivity and have helped establish data for the assessment of global response to such forcing mechanisms as increased atmospheric carbon dioxide and melting ice. In practice, their sensitivity to upper-ocean-layer temperature changes causes slab-ocean models to be affected by data reflecting changes in sea ice and glacial melt waters.

The Earth's oceans and atmosphere have different response times to changes: ocean depths may take centuries to react to a change in forcing, whereas the atmosphere may respond in days. Because of their limited thickness parameters, slab models do not take a long time to adjust to forcings applied to the model. Where complex models reflecting the slow response time of deep-ocean circulation may require changes to develop over hundreds or thousands of model years to reach equilibrium, slab models reach equilibrium in twenty to thirty model years for a 50-meter-thick slab. As a result of a slab model's simplified parameters, researchers can get reasonable results for the overall effect of a forcing as a percent increase or decrease using less computing time than would be consumed by a more complex model.

Coupling slab-ocean models with atmospheric models allows for a quick comparison of differences in the timescales over which ocean and atmospheric phenomena form and react to changes. When coupled ocean and atmospheric models are further coupled with additional models, such as carbon or nitrogen models, they produce increasingly accurate simulations of the Earth's climate. These coupled models, however, retain all errors introduced in each individual simulation, and this fact imposes an important constraint on the models' collective findings.

Soil erosion

• **Category:** Environmentalism, conservation, and ecosystems

Soil is one of Earth's most vital natural resources. Erosion removes topsoil, reduces soil fertility, lowers the primary productivity of plants, and thus diminishes the land's capacity to hold CO_2 and other GHGs. Climate change, especially in precipitation and temperature, can exacerbate soil erosion, which in turn may help drive climate change.

• Key concepts

conservation tillage: practices designed to leave stubble and other crop residues on the land surface to reduce soil erosion and surface runoff

cover crops: plants grown to cover the land surface for the purpose of managing soil fertility, soil quality, water, weeds, pests, diseases, diversity, or wildlife

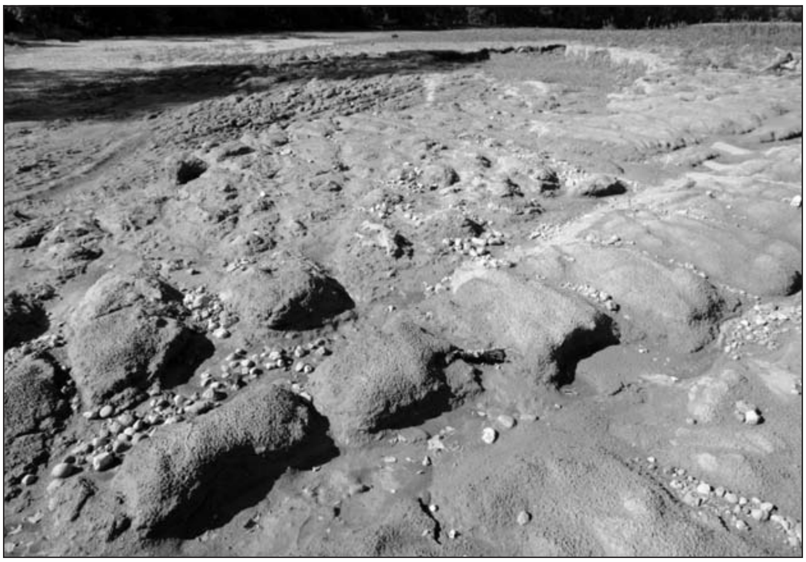
intercropping: the cultivation of two or more crops simultaneously on the same field

land management: the oversight and planning of land use and development

runoff: precipitated water flowing over land toward water bodies, including the land surface material dislodged and carried by it

• Background

Soil is the material formed from weathering rocks and decaying plants and animals. It is considered a nonrenewable resource on a human timescale, because it takes thousands of years to form fertile soil. The degradation of soil quality is thus considered permanent and irreversible. President Franklin D. Roosevelt once wrote, "A nation that destroys its soils, destroys itself." Soil is the foundation on which agriculture produces all goods that sustain human society. Thus, it is paramount to preserve this resource in order to maintain agricultural productivity and environmental quality. A changing climate, especially in terms of temperature and precipitation, affects soil quality through heightened erosion and accelerated runoff.



The soil of this Indiana cornfield was badly eroded by flooding in July, 2008. (AP/Wide World Photos)

• Agricultural Practices

About 80 percent of the world's agricultural land is affected by soil erosion. Intensive agriculture practices have resulted in changes in soil structure and its microbial community and made the land more prone to erosion and surface runoff. Because topsoil supplies plant roots with much of the nutrients required for growth, the loss of topsoil necessitates the application of chemical fertilizers to replenish the lost nutrients. The short-term solution of using fertilizers and other chemicals, however, has led to several long-term detrimental effects. First, the resulting structural changes reduce the porosity and infiltration rate of soil and lower the land's capacity to hold water. These in turn increase surface runoff and soil erosion. Second, both topsoil loss and applied chemicals act to reduce microbial diversity and population levels in the soil. As a result, even a very limited amount of organic residue cannot be readily converted to useful soil ingredients.

The overuse of chemical fertilizers also creates other environmental problems. For example, there exists a progressively diminished return from fertilizer applications. As a result, higher doses of fertilizers are needed to maintain the same level of crop yields. The hiked application of agro-chemicals further damages the soil structure and microbial community, creating a vicious cycle of soil erosion. Historically, natural erosion rates varied from 38 to 161 grams per square meter per year. Erosion from present-day farmland reaches an average of 577 to 966 grams per square meter per year. In addition, excess fertilizers are washed off to streams and lakes, causing eutrophication. The most potent greenhouse gas (GHG), nitrous oxide, is also released from excess fertilizers. Other agricultural practices that are known to intensify soil erosions include row-cropping, tillage, and monocropping.

• Impact of Climate Change

Several major climate factors contribute significantly to soil erosion, including temperature, precipitation, carbon dioxide (CO_2) concentration, and wind. Increasing temperatures contribute to soil erosion indirectly in several ways. First, warmer temperatures can increase biomass production rates as a result of a faster accumulation of the required growing degree-days for crop maturity. Second, temperature affects microbial activity levels and subsequently the decomposition rates of plant residues in the soil. Higher temperatures mean faster decomposition, which may lead to more soil erosion due to a low level of ground cover by residues. Third, temperature has major impacts on evapotranspiration rates, which affect soil moisture, which in turn influences water infiltration rates and runoff amounts. Finally, extended periods of high temperatures may lead to drought and make soil prone to wind erosion or water erosion when storms do fall.

Soil erosion and runoff patterns often follow those of annual precipitation. Predictions from various modeling systems all seem to suggest that, where precipitation increases significantly, erosion also increases significantly. A 7 percent increase in precipitation in Great Britain could lead to a 26 percent increase in erosion. A 10 percent rainfall increase in South Africa could lead to a 20-40 percent increase in runoff. For the U.S. Corn Belt, a 20 percent precipitation hike was predicted to result in a 37 percent increase in erosion and a 40 percent increase in runoff. Wetter soil from precipitation entails lower infiltration rates and increased surface sealing, both of which may increase runoff rates. Increased runoff leads to heightened shear stress, which in turn increases the detachment force of the flow and thus increases erosion.

Atmospheric CO_2 concentrations affect soil erosion directly through the amount of biomass accumulation and transpiration by plants and indirectly as a GHG. Higher CO_2 levels may increase photosynthetic rates, which lead to higher biomass accumulation, which in turn affects ground residue cover. Increased plant residue results in reduced soil erosion and runoff. At the same time, increased CO_2 may suppress transpiration through stomatal resistance, which leads to wetter soil, conducive to higher runoff-induced erosion. Increased air CO_2 levels may warm the climate and exert their effects through higher temperatures as well. Increased wind erosion is often associated with rising air temperatures, excessively dry soil due to drought, lack of ground cover or wind breaker, and high wind speed.

• Context

Despite the known damaging effects of soil erosion, there is little reliable information regarding its global impacts, nor is there a comprehensive monitoring system to gather data. There is little doubt, however, that soil erosion has been accelerated during the past century. Studies using various modeling systems have all demonstrated that climate changes contribute to soil erosion. Up to 68 billion metric tons of topsoil are eroded annually, an equivalent of 90,000 square kilometers of productive land lost.

Erosion results directly in the loss of topsoil and reduction of soil fertility, both of which lead to lower crop yields and higher production costs. Indirectly, erosion causes sediment movement and deposits that create problems downstream, including the clogging of water ways, increased potential for floods, decreased reservoir capacity, and poorer water quality resulting from agro-chemical contamination. Minimizing erosion is important not only for the present but also for generations to come. Soil erosion should be monitored through a comprehensive network that is fully equipped and standardized across the globe. Sustainable agricultural practices will make significant differences in erosion control: Conservation tillage, crop rotations, intercropping, and cover crops will all help reduce soil erosion.

Solar cycle

- **Category:** Astronomy

- **Definition**

Temporary dark markings on the surface of the Sun, known as sunspots, have been observed since ancient times. As seen from Earth, though, most sunspots are too small to be observed with the naked eye. It was not until the invention of the telescope that sunspots could be observed with regularity. Sunspots were a regular feature on the face of the Sun in the early seventeenth century; however, sunspots all but disappeared later in that century for a period of time lasting into the eighteenth century. This period with almost no sunspots is called the Maunder Minimum.

By the beginning of the nineteenth century, astronomers had recognized that the number of sunspots increased and decreased according to a pattern. A peak number of sunspots, called the solar maximum, occurs about every eleven years. The cycle of sunspot activity does not have an exact period, however, with some cycles lasting closer to ten years and others lasting close to twelve years. Furthermore, each sunspot cycle does not result in the same average number of sunspots at its maximum. Every sunspot cycle is a little different from the other cycles.

Sunspots are visible signs of magnetic activity on the Sun. Sunspots form in regions of intense magnetic field activity. These active regions are also the locations of huge explosive releases of magnetic energy called solar flares. The more active the Sun's magnetic field becomes, the more sunspots will appear on its surface. Astronomers have also found that, during each sunspot cycle, the Sun's magnetic field is reversed from that of the cycle before. Thus, the magnetic field follows a twenty-two-year cycle, composed of two eleven-year sunspot cycles.

- **Significance for Climate Change**

Since the advent of space-based observations of the Sun, astronomers have found that the Sun's energy output varies slightly with the sunspot cycle. The more active the Sun is, the more active the sunspot cycle, and the greater the solar irradiance. Since solar energy is the driving force behind Earth's climate, variations in the Sun's energy output could potentially result in climate change. The variation in solar energy is very small, typically less than 0.1 percent. Small changes of that magnitude, averaged out over a solar cycle, should not have a long-term effect on the climate. However, not all sunspot cycles are equal in activity. Some are more active than average and some are less active than average. Historical data indicate that sunspot cycles sometimes exhibit trends in activity over long periods of time. An extended period of unusually active or unusually inactive sunspot cycles could have a cumulative effect on the climate.

During the Maunder Minimum in the seventeenth century, a significant shift toward a cooler climate was observed in many locations. This period of cooling is called the Little Ice Age. (The term "Little Ice Age" is used differently by different writers. Many use it to refer to the climate cooling from about 1300 to 1850, while others use it for the latter half of that interval, when cooling was greatest, beginning around 1550 or 1600.) There is no proof that there was a causal relationship between the two events, but most solar astronomers believe that the Maunder Minimum and the Little Ice Age are connected. Furthermore, there has been a general trend of increasing activity since the Maunder Minimum. Detailed measurements of solar irradiation go back only about a half century. During that time, there has been an observed correlation between solar energy output and the average number of sunspots. Thus, it makes sense that during the Maunder Minimum, the Sun was less active and was providing less solar energy to Earth than normal, resulting in a general cooling of the climate.

If the correlation between sunspot numbers and solar irradiation is consistent, the general increase in average solar activity since the Maunder Minimum would be expected to correspond with a period of increased solar heating of the Earth. Some researchers believe that much of the global warming observed during this time period may be the result of natural solar energy increases. Other researchers, though, dispute the degree of change in solar energy output, suggesting instead that the increase in solar energy reaching Earth may only partially explain the observed temperature increases on Earth during the same period of time. If it is true that current global warming trends are the result of increased solar activity rather than human activity, it is unclear whether any human actions could reverse those trends, since they may not be a function of greenhouse gas (GHG) levels. On the other hand, a correlation between solar activity and global warming does not in and of itself establish that atmospheric GHG concentrations are unrelated to warming. Both factors could be contributors to climate change.

The Sun emits more charged particles when it is more active. These charged particles interfere with galactic cosmic rays, changing the amount of carbon 14 produced on Earth. Increased activity results in less carbon 14. These changes can be monitored by measuring the carbon 14 content of artifacts of known age. Such studies seem to support the hypothesis that increases in solar activity correlate with warmer periods in Earth's climate history and periods of reduced solar activity correlate with cooler periods in history.

Solar energy

- **Category:** Energy

- **Definition**

Solar energy includes all human-derived means of collecting and utilizing energy from the Sun, for such applications as heat, air conditioning, or electric power generation. Two primary classes of solar energy are photovoltaics, converting radiant energy into electricity, and thermal solar, using radiant energy for heat or directly to power air-conditioning units. Thermal solar energy may be subdivided into active systems and passive systems.

Active systems require another source of energy, typically electricity, to power pumps or fans. These systems may be used to provide domestic hot water, to heat the interior of a building, or in some cases to provide steam. Active systems include flat-panel, exterior, stationary collectors and systems that concentrate solar rays in order to produce higher temperatures. Arrays of mirrors have also been used to concentrate diffuse sunlight in a small region, where extremely high temperatures may be achieved. Other focusing systems use troughs of parabolic mirrors to reflect light to a central axis, where a contained moving fluid transports the heat.

Passive systems require no input energy beyond that of the Sun itself; they convert sunlight directly into space heat for buildings. Three types of passive systems are direct gain, indirect gain, and attached gain. Direct gain systems utilize large expanses of glass facing toward the equator to admit sunlight, as well as substantial amounts of interior mass to avoid overheating. Indirect gain systems place a dark-colored, massive wall close to sunward-facing glass. The wall converts sunlight into heat, which then radiates into the room. The third passive system, attached gain, is essentially a greenhouse attached to the sunward wall of a building and accessible through insulated doors. When the greenhouse is warm, the doors are opened to provide heat to the rest of the building; when the greenhouse is cold, the doors remain closed.

A fourth type of passive system, used for domestic hot-water production, is the thermo-siphon. It utilizes flat-plate collectors, with a water storage tank placed at a higher elevation than the top of the collectors. When water in a collector is heated by the Sun, it naturally rises and enters the storage tank, where a heat exchanger transfers the heat to a hot-water line. The rising collector fluid creates a siphon effect, which maintains the circulation.

- **Significance for Climate Change**

Global warming is likely caused in part by the anthropogenic release of carbon dioxide (CO_2) from the combustion of fossil fuels. Moreover, fossil fuels, as a nonrenewable resource, are being depleted by energy-intensive nations such as the United States. Enough solar energy reaches Earth to provide virtually all of humanity's energy needs if it can be collected and used efficiently. Solar technology is not yet capable of exploiting solar energy to such an extent, but research is ongoing. Meanwhile, fossil fuels still provide the vast majority of the energy

A bank of photovoltaic cells in Spain collects solar energy and converts it to electricity. (©Milacroft/Dreamstime.com) consumed in the production, delivery, and utilization of consumer goods.

Crude oil is the most important raw material for industrial manufacturing, but it is a nonrenewable resource that may reach peak production in the near future. Ecological destruction is also associated with resource recovery and manufacturing. Thus, it is in the best interests of contemporary industrialized societies to engage in a concerted effort to transition to renewable energy and environmentally sustainable resource use by terminating the dependence on fossil fuels.

Solar energy is a dilute source of energy that lends itself to small-scale applications. In almost any location in the United States, homeowners can reduce their dependence on fossil-fuel-derived energy by passive solar design or retrofitting an existing structure for passive solar gain. Although even a good solar design will not usually eliminate the need for a backup system in locations where winters tend to be overcast, it can substantially reduce energy consumption. Active systems for domestic water heating can provide 100 percent of a family's needs, since, unlike space-heating systems, they can be used throughout the summer.

Passive solar energy uses few nonrenewable resources and creates no pollution; active systems require collectors that necessitate using nonrenewable resources, such as copper and aluminum, but these are recyclable. Furthermore, well-constructed collectors will function for decades. Photovoltaic systems are still relatively expensive, but the price is expected to decline in the near future. Although it may not yet be cost effective to derive all of one's electrical energy needs from photovoltaics, the systems will reduce dependence on the electrical grid, and if more energy is generated than is required, the excess can be sold back to the utility company.

SourceWatch

- **Category:** Organizations and agencies
- **Date:** Established 2003
- **Web address:** http://www.sourcewatch.org

• Mission

SourceWatch has a general mission of monitoring and reporting on efforts by propagandists and public relations organizations to shape public opinion. Although climate change is not its sole mission, the large number of front organizations active in the controversy make climate change a major area of concern, and SourceWatch has a portal dedicated to climate change.

SourceWatch is a Web site run by the Center for Media and Democracy. It began as Disinfopedia in March, 2003. The name was a conscious play on Wikipedia, and, like Wikipedia, Disinfopedia was a wiki-based (user-written and -edited) reference site. The name was changed to the present SourceWatch in January, 2005. The site has a strong resemblance in format and appearance to Wikipedia, but it uses different logos and color schemes to distinguish itself. Also, in an effort to regulate editing, the site adopted a policy in 2006 of requiring users to register before being allowed to edit content. In addition to SourceWatch, the Center for Media and Democracy hosts numerous sites such as Congresspedia, which reports on Congress, and wikis devoted to the tobacco industry, nuclear issues, election protection, and climate change. All of these sites are cross-linked.

SourceWatch

SourceWatch describes itself in these terms:

SourceWatch is a collaborative project of the Center for Media and Democracy to produce a directory of the people, organizations and issues shaping the public agenda. A primary purpose of SourceWatch is documenting the PR and propaganda activities of public relations firms and public relations professionals engaged in managing and manipulating public perception, opinion and policy. SourceWatch also includes profiles on think tanks, industry-funded organizations and industry-friendly experts that work to influence public opinion and public policy on behalf of corporations, governments and special interests. Over time, SourceWatch has broadened to include others involved in public debates including media outlets, journalists, government agencies, activists and nongovernmental organizations. Unlike some other wikis, SourceWatch has a policy of strict referencing, and is overseen by a paid editor. SourceWatch has 43,353 articles [as of April 8, 2009].

• Significance for Climate Change

It is important to realize that being funded by industry, being supportive of industry, and working to influence public opinion do not automatically make someone's ideas wrong. Knowing that an organization has a secret purpose or source of funding can be useful, because it demonstrates the need to beware of distorted facts and arguments and the need to cross-check information against other sources. However, the simple fact that someone has connections to industry does not prove anything about the truth or falsity of that person's statements.

Although SourceWatch has a political stance that can be described as liberal, environmentalist, and critical of corporations, it generally avoids a polemic tone, although a somewhat sarcastic tone is evident on some of its portal pages and lead articles. Most of the articles are quite short, with longer commentary and analysis found on the other sites linked to SourceWatch. The political orientation of SourceWatch is evident not so much in the content of its articles as in the selection of topics it chooses to include, as well as the other sites it links to.

SourceWatch's portal on front groups includes many references to organizations secretly working on behalf of industry, but none to groups opposed to tort reform and secretly supported by the legal profession or to groups with hidden ties to radical leftist movements. SourceWatch does have the virtue that its articles have extensive references. SourceWatch can provide a quick overview of an author's stance on political or environmental issues, as well as information about groups that sponsor the author's work. It is also a useful starting point for finding links to additional information on people, organizations, and issues related to politics and the environment.

South Africa

- **Category:** Nations and peoples
- **Key facts**

Population: 48,687,000 (July, 2008, estimate)
Area: 1,219,912 square kilometers
Gross domestic product (GDP): $489.7 billion (purchasing power parity, 2008 estimate)
Greenhouse gas (GHG) emissions in millions of metric tons of carbon dioxide equivalent (CO_2e): 303.2 in 1990; 348.0 in 2000; 383.6 in 2005
Kyoto Protocol status: Accessed 2002

• Historical and Political Context

Native South Africans were immigrants from other parts of Africa. Since 1652, South Africa was occupied by Europeans for over 300 years. The power shifted between the Dutch and the British through all these years and sometime was shared by the two parties. In 1652, the Dutch East India Company founded Cape Town. In 1806, the British took over Cape Town. The Boers, descendants of the Dutch settlers, founded their own republics in the South African interior. In 1899-1902, the Boers and the British fought the Anglo-Boer War for the control of South Africa's diamonds and gold. The British won the war. In 1910, South Africa became a British dominion. The Boers later negotiated with the British and gained hegemony.

Under Europeans' control, racial discrimination and racial segregation were generally practiced. The infamous policies of apartheid were officially made into laws in 1948 and were enforced for nearly forty years. Laws divided South African residents into racial groups including black, colored, Asian, and white. The whites lived in the white area, which covered more than 80 percent of South African land. Nonwhites had to carry permits when entering white areas. Laws also segregated educational standards, job categories, and public facilities. Through the "homeland" system established in 1959, blacks were deprived of their citizenship and forced to live in the so-called tribal homelands, which occupied small and economically unproductive areas of the country. Uprisings and protests against apartheid were ruthlessly repressed. The anti-apartheid leader Nelson Mandela was arrested and jailed. He was released from the jail in 1990 after serving 28 years. In 1994, South Africa held the first election in which blacks had the right to vote. Nelson Mandela, representing the African National Congress (ANC), won the election and became the first black president of South Africa. Since then, the ANC has become the governing party of South Africa.

• Impact of South African Policies on Climate Change

In the last four decades, South Africa has lost a large area of natural habitat mainly due to extensive economic development and deforestation during the nineteenth century. The early European settlers exploited South Africa's forest brutally. Nowadays forest only covers approximately 1 percent of South Africa. Coal is the major energy resource in South Africa. In the past, South Africa had limited access to foreign oil due to anti-apartheid sanctions. Sasol Ltd., a partly state-owned company, built several coal-to-liquids (CTL) plants. These CTL plants became big greenhouse (GHG) emitters. Sasol's Secunda CTL plant is one of the largest single emitters of CO_2 on Earth.

After 1994's democratic election, the South African government implemented the Reconstruction and Development Programme (RDP). RDP intended to meet people's basic needs and create jobs

through public works. In 1996, a new economic policy called Growth, Employment and Redistribution (GEAR) was adopted. At the beginning of the twenty-first century, the South African government started to promote independent power producers (IPPs) in the South African electricity market. However, the government did not make much progress on these policies due to the lack of investment in infrastructure.

• South Africa as a GHG Emitter

According to the Climate Analysis Indicators Tool (CAIT), in 1990, South Africa emitted 303.2 million metric tons of carbon dioxide (CO_2) equivalent in GHGs. Annual GHG emission increased to 348.0 million metric tons CO_2 equivalent and 383.6 million metric tons CO_2 equivalent in 2000 and 2005, respectively. GHG emissions ranked 17, 19, and 20 among the twenty top GHG emitters worldwide in 1990, 2000, and 2005, respectively. In the past two decades, South Africa's annual GHG emission contributed about 1.1-1.2 percent of total GHG emissions worldwide. In the past decade, GHG emission has increased nearly 2 percent annually. Mining and the energy industry contributed most of the GHG emissions in South Africa. The state-owned utility, Eskom, contributed to about 50 percent of the nation's GHG emissions. Eskom provides 95 percent of the country's electricity.

The international community agreed to address global climate change and drafted the United Nations Framework Convention on Climate Change (UNFCC) and the subsequent Kyoto Protocol. South Africa ratified the Convention in 1997. In 2001, the Seventh Conference of the Parties (COP-7) to the UNFCCC reached agreement to facilitate the accession of the Kyoto Protocol, and South Africa acceded to the Kyoto Protocol in 2002. South Africa is classified as a non-Annex I (or developing) country and is not obliged to adhere to a commitment to reduce GHG emissions.

• Summary and Foresight

South Africa is the most economically advanced country in Africa. Its economy has heavily depended on energy-intensive industries. Although its government has often been commended for taking active roles in controlling climate change, GHG emissions still increased significantly in the past decade. The government made many ambitious plans to reduce GHG emissions, such as generating 15 percent of electricity from renewable resources by 2020; conducting a National Greening Strategy through forestry development; promoting energy-efficient lighting; and reducing the use of coal for energy. For example, South Africa is committed to "greening" the 2010 World Cup by conserving water and energy and reducing GHG emissions.

Although apartheid has been replaced by multiracial democracy, consequences of apartheid still influence South Africa's politics and society. Recent elections still show a major racial divide in the country. The income imparity between white and black remains significant. The governing party has stressed its commitment to economic development and environmental protection. However, the nation is still facing serious challenges such as poverty, unemployment, environmental degradation, and the HIV/AIDS epidemic.

South Korea

- **Category:** Nations and peoples
- **Key facts**

Population: 48,508,972 (July, 2009 estimate)
Area: 98,477 square kilometers
Gross domestic product (GDP): $1.278 trillion (purchasing power parity, 2008 estimate)
Greenhouse gas (GHG) emissions in millions of metric tons of carbon dioxide equivalent (CO_2e): 410 in 1995; 532.5 in 2004; 536 in 2005
Kyoto Protocol status: Ratified 2002

• Historical and Political Context

Korea's history dates from 2333 B.C.E. In its earlier dynasties, Buddhism greatly influenced the nation's politics and culture. The last regime, the Joseon Dynasty, formed in the fourteenth century, and Confucianism exerted a massive influence over the whole of the society. From the seventeenth century on, practical and liberal ideologies began to be adopted, leading to agricultural improvements and social reforms.

Korea has suffered many foreign invasions. In 1910, Japan colonized the peninsula. Korea was librated from Japanese colonial rule at the end of World War II, when Japan surrendered unconditionally to Allied forces in August, 1945. After the war, the new global geopolitics and ideology of the Cold War led to the division of the peninsula into two nations, South Korea and North Korea, with utterly opposed political and economic systems.

In August, 1948, the legitimate, democratic South Korean government was formally established. South Korea developed full democracy and a market economy. In June, 1950, the Korean War broke out, as North Korea invaded South Korea. The war lasted until July, 1953. Since the 1960's, South Korea's growth-oriented, export-led economic development has seen remarkable growth. In 2006, South Korea's economy was the twelfth largest in the world, and the nation became a global economic leader. Meanwhile, South Korea successfully hosted the twenty-fourth Olympic Games in 1988 and cohosted the 2002 FIFA World Cup with Japan. Since the 1990's, Korean popular culture has become popular throughout Asia, in a phenomenon known as the

Korean wave. Through these occasions, Korea has demonstrated to the world not only its advanced economy and modern technologies but also its rich cultural heritage.

• Impact of South Korean Policies on Climate Change

South Korea's development strategy since 1960 achieved extraordinary economic growth rates. The unprecedented growth was achieved by massive production and an energy-concentrated industrial structure, focusing on the steel, petrochemical, and cement industries. After thirty years of rapid economic development, Korea transformed itself from an agricultural economy into a highly industrialized economy. This development strategy required a seemingly infinite supply of energy and natural resources and entailed considerable consumption of fossil fuels and emission of greenhouse gases (GHGs). Furthermore, low oil prices for industrial use and very low investment in energy-saving equipment were responsible for inefficient energy consumption that contributed to rapid increases in carbon dioxide (CO_2) emissions.

Since the late 1990's, South Korea has changed its traditional energy paradigm of mass production and mass consumption in response to international climate change agreements. This effort has resulted in significant decreases in GHG emissions per capita. The skyrocketing price of oil and increasing dependence on imported energy, moreover, forced the government to adapt sustainable economic growth strategies. In 2008, South Korea launched a green energy development strategy, Green Korea, focused on changing the national energy structure to fight global climate change by cutting GHG emissions and to reduce energy dependency. This strategy includes devising various initiatives to develop new and renewable energy resources, promoting energy conservation, and improving energy efficiency. To accomplish these goals, the government will emphasize investment in solar and wind energies, hydrogen fuel cells, carbon capture and storage, and energy storage technologies. By 2030, fossil fuel and renewable energy are projected to account for 61 percent and 11 percent of energy consumption, down from 82.7 percent and 2.4 percent, respectively, in 2008.

• South Korea as a GHG Emitter

As a result of South Korea's rapid economic growth from the 1960's to the late 1990's, energy consumption and CO_2 emissions also grew rapidly. Energy consumption, however, grew much more rapidly than did economic growth. This was primarily because of the poor energy efficiency of each sector of industry and governmental heavy-industry-oriented development strategies. During the period of economic development, CO_2 emissions increased significantly. The average annual growth rate of CO_2 emissions was 7.4 percent between 1981 and 1997. Over this period, total CO_2 emissions increased 3.3 times. In addition, the growth rate of the transportation sector was greater than that of other sectors because of significant increases in the number of automobiles in the nation. This trend slowed after the late 1990's.

CO_2 emissions doubled again between 1990 and 2004. These emissions grew faster than those of any other member nation of the Organization for Economic Cooperation and Development (OECD) over the same period. South Korea's total emissions continue to increase, although the ratio of GHG emission to gross domestic product (GDP) has de-

creased. In 2004, South Korea was the world's thirteenth-largest economy but ranked as the ninth-greatest GHG emitter, and it contributed about 1.7 percent of global CO_2 emissions. It was on track to become the sixth-greatest GHG emitter by 2010.

- **Summary and Foresight**

South Korean GHG emissions have grown significantly along with rapid economic growth. Because Korea's industrial structure is biased to the resource- and energy-intensive industries, South Korea consumes more energy than do other leading industrial countries to make the same products. This energy-intensivity results from South Korea's heavy and chemical industry drives in the 1970's and 1980's and the poor energy efficiency of those industries. In the early twenty-first century, South Korea undertook rapid restructuring of its industrial sector, transitioning from conventional heavy industry to new high-technology industries.

In 2008, South Korea adapted a new energy plan for sustainable development, focusing on clean energy industrial initiatives, introducing highly energy efficient technologies and products, and promoting the use of non-polluting, alternative, renewable energy sources. Particular emphasis was placed on the government's initiatives to restructure the electricity industry, which contributes one-third of South Korea's total CO_2 emissions, and to significantly increase the share of renewable energy sources from 2.4 percent in 2008 to 11 percent in 2030. According to this plan, the government seeks to maintain the level of CO_2 emissions of 2005 (536 million metric tons) until 2012 and then reduce the emission by an average 2.2 percent annually.

South Korea also takes responsibility for matching global efforts for global climate change. South Korea was the first developing country to express its intent to reduce GHGs voluntarily from 2018. Developed countries that are party to the Kyoto Protocol are required to reduce GHG emissions by an average of 5.2 percent from their 1990 levels between 2008 and 2012.

Speculative fiction

- **Category:** Popular culture and society

Speculative fiction portrays alternate realities, often in order to comment on present-day reality. Either through analogy or through literal use of contemporary science, speculative-fiction authors have commented upon issues involving climate change and have introduced some readers to the central concepts used in its scientific study and policy discussion.

- **Key concepts**

dystopia: a fictional world in which living conditions are extremely bad; the opposite of a utopia *science fiction:* the branch of speculative fiction that attempts to be scientifically plausible

speculative fiction: the branch of fiction that deals with unproven entities and occurrences, including science fiction, fantasy, alternative history, and supernatural horror

• Background

Climate change has been used by the science-fiction branch of speculative fiction since the late nineteenth century. In *The War of the Worlds* (1898) by H. G. Wells, Mars has undergone climate change to the point where it is dying. The Martians then invade the Earth so that they can live here instead. Science fiction involving climate change is usually dystopian. In Philip K. Dick's *The Three Stigmata of Palmer Eldritch* (1965), global warming is one of several background details that inform the reader that the setting is a future much worse than the present.

• Natural Climate Change

Traditionally, science-fiction novels have assumed that climate change happens naturally. One example is J. G. Ballard's 1962 novel *The Drowned World*, whose premise is that solar flares destroy the ionosphere. This raises global temperatures, causing the polar ice caps to melt. Even at the time, the premise was considered dubious. Subsequent research has shown that the relationship between the Sun's output and the Earth's climate is more complicated than Ballard assumed. Critics generally approach this and Ballard's other ecological disaster novels as metaphorical rather than as possible futures.

In Larry Niven and Jerry Pournelle's *Lucifer's Hammer* (1977), a comet strikes the Earth, initially causing an outbreak of volcanoes, tsunamis, and earthquakes, then widespread flooding, and eventually a new ice age. This premise has become more plausible in the twenty-first century than at the time the book was written, because the theory that a similar event caused the demise of the dinosaurs has gained widespread acceptance.

• Anthropogenic Climate Change

Beginning in the late twentieth century, speculative fiction that used climate change as a premise usually also assumed that the change had human origins. One challenge of writing fiction involving climate change is that the science behind the stories can become obsolete after only a few years. Examples are David Brin's *Earth* (1990) and Bruce Sterling's *Heavy Weather* (1994), which were current with climate science at the time they were written but are now somewhat dated.

One example, Kim Stanley Robinson's *Science in the Capital* trilogy (*Forty Signs of Rain*, 2004; *Fifty Degrees Below*, 2005; and *Sixty Days and Counting*, 2007), received critical acclaim both for the quality of the writing and for the author's knowledge of climate science. The action takes place mostly in Washington, D.C., and most of the main characters are scientists. A rise in the average global temperature caused by human emission of greenhouse gases (GHGs) generates an unfortunate chain of events. The Arctic ice cap melts, and the infusion of freshwater into the North Atlantic causes the Gulf Stream to stall, in turn causing winters in North America and Europe to become much colder, longer, and drier. The characters undergo food scarcities, housing shortages, power outages, and reduced medical services.

Other examples include *Global Warming Aftermaths* (2008), edited by Eric Reynolds, an original short story anthology in which all the stories are set in a future after global warming has occurred, *Hotter than Hell* (2005) by Canadian environmental scientist Mark Tushingham, in which war breaks out between the United States and Canada over freshwater, and Tushingham's sequel *Hell on Earth* (2008).

• Denial of Climate Change

There are also works of speculative fiction that assume that climate change is not taking place. The premise of Michael Crichton's novel *State of Fear* (2004), for instance, is that the theory of global warming caused by the human emission of GHGs is not only false, but a deliberate hoax. Most global warming advocates are mistaken, according to the book, but some intentionally misrepresent the data in their quest for power. Crichton inserts graphs, charts, and footnotes into the text and provides twenty pages of references at the end of the book. At the time the book was published, Crichton was criticized in scientific circles for citing only the books and papers that supported his premise and for misrepresenting the ones he did cite.

• Context

In literature, there is a type of story known as the cautionary tale. This kind of story has a message along the lines of "if you do x (or fail to do x), then y will happen." "Y" is always an avoidable negative consequence. (Robert Heinlein used the prototypical title "If This Goes On—" for a 1940 science-fiction cautionary tale, although it was about religious fundamentalism rather than climate change.) The very best cautionary tales are the ones for which the readers do not realize there is a message until after they have finished reading and think about what they have just read. The ones that are too overt in their message either alienate or bore the reader. If they are published at all, they usually do not stay in print for long. Speculative fiction is full of such stories, good, bad, and indifferent, and many of the recent ones concern climate change.

Stockholm Declaration

- **Category:** Conferences and meetings
- **Date:** Issued June 16, 1972

Presented by the U.N. Conference on the Human Environment, the Stockholm Declaration put forth principles that might guide the world's nations to preserve and enhance the human environment, while recognizing that a healthy environment is a human right.

• Definition

In 1968, the notion of holding an international conference on the environment was brought to the fore by the United Nations Economic and Social Council at its forty-fifth session. A council resolution underscored the immediate need for intensified action at the national and the international levels to contain and, if possible, halt the continuous deterioration of the human environment. The U.N. General Assembly, at its twenty-third session, endorsed the council's recommendations. As a result, the Stockholm Conference on the Human Environment was convened on June 5-16, 1972, in Stockholm, Sweden. The importance of the Stockholm conference was threefold: It was the first global conference on the human environment; it was the predecessor of the first U.N. Conference on Environment and Development (UNCED) in 1992; and it acknowledged the need to articulate "third generation human rights," those that go beyond the merely civil and social. Such rights are legally difficult to enact, but the conference endorsed them in the Stockholm Declaration, which recognized a human right to a "healthy environment."

• Summary of Provisions

The framers of the Stockholm Declararios considered the need for a common outlook and shared principles for various international environmental issues, including human rights as proclaimed in the first article, "[b]oth aspects of man's environment, the natural and the man-made, are essential to his well-being and to the enjoyment of basic human rights, the right to life itself." The first Principle of the Declaration echoes this sentiment:

> Man has the fundamental right to freedom, equality and adequate conditions of life, in an environment that permits a life of dignity and well-being, and he bears a solemn responsibility to protect and improve the environment for present and future generations.

Principle 8 focuses on economic and social development as being "essential for a favorable working environment . . . necessary for the improvement of the quality of life." Principle 9 declares

> Environmental deficiencies generated by the conditions of underdevelopment and natural disasters . . . can best be remedied by accelerated development through the transfer of financial and technical assistance as a supplement to the . . . developing countries and such timely assistance as may be required.

The twenty-first of the Declaration Principles is the best known, and it is believed by many international legal scholars to be the foundation for much of the environmental diplomacy that has occurred since Stockholm because it acknowledges that states have,

> . . . in accordance with the Charter of the UN and the principles of international law . . . the sovereign right to exploit their own resources pursuant to their own environmental policies, and the responsibility to ensure that activities within their own jurisdiction or control do not cause damage to the environment of other States . . . .

Other principles stress the need for scientific research and technology, education for youth and adults alike, rational planning, and international cooperation to protect the global environment.

The Stockholm Delcaration

The Stockholm Declaration, excerpted below, begins with a statement regarding the fundamental nature of humanity and of the human-nature relationship. This ontological statement forms the philosophical underpinning for the declaration.

The United Nations Conference on the Human Environment, having met at Stockholm from 5 to 16 June 1972, having considered the need for a common outlook and for common principles to inspire and guide the peoples of the world in the preservation and enhancement of the human environment,

Proclaims that:

1. Man is both creature and moulder of his environment, which gives him physical sustenance and affords him the opportunity for intellectual, moral, social and spiritual growth. In the long and tortuous evolution of the human race on this planet a stage has been reached when, through the rapid acceleration of science and technology, man has acquired the power to transform his environment in countless ways and on an unprecedented scale. Both aspects of man's environment, the natural and the man-made, are essential to his well-being and to the enjoyment of basic human rights the right to life itself. . . .

3. Man has constantly to sum up experience and go on discovering, inventing, creating and advancing. In our time, man's capability to transform his surroundings, if used wisely, can bring to all peoples the benefits of development and the opportunity to enhance the quality of life. Wrongly or heedlessly applied, the same power can do incalculable harm to human beings and the human environment. We see around us growing evidence of man-made harm in many regions of the earth: dangerous levels of pollution in water, air, earth and living beings; major and undesirable disturbances to the ecological balance of the biosphere; destruction and depletion of irreplaceable resources; and gross deficiencies, harmful to the physical, mental and social health of man, in the man-made environment, particularly in the living and working environment.

In addition to the declaration, an action plan comprising 109 recommendations was put forth at Stockholm. The plan encompassed six general topics, including educational, informational, and sociocultural aspects of the environment. For example, recommendation 95 called for

> providing countries with . . . technical and financial assistance in preparing national reports on the environment, in setting up machinery for monitoring environmental development . . . and drawing up national social, educational and cultural programmes.

Recommendation 96 called for the secretary-general and the U.N. Educational, Scientific, and Cultural Organization (UNESCO) "to establish an international programme in environmental education . . . directed toward the general public." Other recommendations addressed the need for financial support, as well as management of "global pollution, natural resources, and human settlements." However, while development was included as a Stockholm conference agenda issue, it was not dealt with until UNCED in 1992.

• Significance for Climate Change

The first international conference of its kind, the U.N. Conference on the Human Environment focused attention on the need for global collaboration to decrease general and marine pollution, and created environmental monitoring networks both regional and global, providing the framework for future environmental collaboration that led to the establishment of the U.N. Environment Programme (UNEP) for which Canadian Maurice F. Strong served as the first executive director. UNEP continues to coordinate U.N. environmental activities, helping developing countries implement environmentally sound policies by encouraging sustainable environmental practices. Importantly, the Stockholm Conference and the scientific conferences on the environment that it preceded significantly influenced the environmental policies of the European Community, later the European Union.

As an example, in 1973, the European Union established the Environmental and Consumer Protection Directorate and the first Environmental Action Program. The Stockholm Conference was the predecessor of the first U.N. Earth Summit, which specifically focused on the environment alongside development, and put forth the notion of sustainability as a necessary component of climate change. Importantly, UNCED produced the U.N. Framework Convention on Climate Change (UNFCCC), a most significant treaty with a mission of stabilizing greenhouse gas (GHG) emissions at a level that might prevent anthropogenic disruption of the Earth's climate, such as global warming. Originally a legally nonbinding document, the treaty included provisions for updates called "protocols," the best known being the legally binding Kyoto Protocol, which established specific limitations for GHG emissions for developed nations.

Storm surges

- **Category:** Meteorology and atmospheric sciences

- **Definition**

A storm surge, or tidal surge, is water pushed toward the shore by the winds of a storm. The combination of high winds, low pressure, and wave action is what makes a storm surge. The rush of water, combined with the regular action of the tide, causes water to rise significantly higher. This influx of water can cause significant flooding, especially in low-lying coastal areas.

Storm surges occur when a tropical storm or hurricane makes landfall. The pressure in the center, or eye, of a storm is low enough that surface water is drawn upward in a dome, just as beverages may be drawn up through a drinking straw. As the storm reaches land, this dome of water piles up against the shoreline, and the area within the right front quadrant of the storm's forward motion is in particular danger.

Storm surges are sometimes confused with tsunamis. A tsunami (from the Japanese word for "harbor wave") is generated by an undersea earthquake or volcanic eruption that creates a set of waves that can grow in intensity as they reach shallow coastal regions. Storm surges only occur in the presence of tropical storms, hurricanes, or cyclones.

The amount of surge is related to the size of the storm, as well as the slope of the Continental Shelf. A shallow slope allows more water to travel inland, while a steeper slope limits the surge but poses a greater danger of generating a breaking wave. The effects of a storm surge are multiplied in confined areas such as harbors and can also be felt in inland rivers and lakes.

The National Hurricane Center (NHC) uses the

A storm surge slams into the beach in central Bombay, India, in May, 2001, destroying the stalls in its path. (AP/Wide World Photos) sea, lake, and overland surges from hurricanes (SLOSH) model to determine which areas should be evacuated in the event of a storm surge. Storm factors taken into consideration by this model include forward speed, pressure, size, track, and wind speed. These factors are weighed against the timing of the tide and the topological configuration of the projected landfall.

• Significance for Climate Change

The inland reach of a storm surge is dependent on the slope of the Continental Shelf and the height of the land above sea level. In the United States, most of the population on the Gulf of Mexico and the Atlantic coastline is a little more than 3 meters above sea level, making those areas particularly vulnerable. If the sea level were to rise as a result of climate change, the population's vulnerability would increase significantly.

Waves and the action of the current during a storm surge can cause additional damage. Water weighs 1,000 kilograms per cubic meter, and the erosion of beaches and coastal highways is a particular problem. Moreover, the influx of salt water on freshwater bodies disrupts local ecosystems. Salt water that travels far inland may not dissipate for weeks.

The storm surge associated with Hurricane Katrina in August, 2005, was one of the most massive in U.S. history, spanning an area between Grand Isle, Louisiana, and Mobile Bay, Alabama. The storm surge drove water from the Gulf of Mexico up into Lake Pontchartrain and the Mississippi River, which in turn breached the levees in the city of New Orleans and the surrounding areas. Lake Pontchartrain, normally about 0.3 meter above sea level, peaked at 2.62 meters above sea level. According to the U.S. Geological Survey, more than 560 square kilometers of land were eroded into the ocean. The Chandeleur Islands, which formed the easternmost point of Louisiana, were completely destroyed.

The human and financial impact of the Katrina storm surge on the northern Gulf Coast is well documented, but there was a significant ecological price as well. Retreating flood waters carried raw sewage, pesticides, toxic chemicals, and other waste products into the surrounding wetlands. Overall, sixty national wildlife refuges were damaged as a result of Hurricanes Rita and Katrina. A contributing factor to the damage from the 2005 storm season was the ongoing loss of wetlands and barrier islands, which had previously protected the low-lying areas from the worst of the earlier hurricanes.

Stratigraphy Commission of the Geological Society of London

- **Category:** Organizations and agencies
- **Date:** Geological Society established 1807
- **Web address:** http://www.geolsoc.org.uk

- **Mission**

The Stratigraphy Commission of the Geological Society of London is a body within the society that operates independently from any industrial or academic organization and apart from the Geological Survey of Britain. The Stratigraphy Commission represents the interests of geological scientists in all aspects of stratigraphic studies (mainly the study of sediments and sedimentary rocks) and helps provide a forum for discussion of issues related to stratigraphy. The commission contributes to selected topical debates within the geological community, one of which is global warming.

- **Significance for Climate Change**

The commission has prepared a global warming essay, or position paper, that lays out the consensus of scientific opinion on this matter for the public and political leaders. The essay commences its discussion by delving into a review of climate change as rooted in geological history, which entails discussing the stratigraphic record of climate change.

The global warming essay of the Stratigraphy Commission minces no words in saying at the outset that global climate change is recognized as a key threat to the continued development and even the continued survival of human society. The essay goes on to say that the commission finds the evidence compelling that anthropogenic climate change is now pervasive and that the need for immediate action is compelling.

Drawing on the stratigraphic record, the commission noted that ice age climate change has historically been pervasive, rapid, and frequent. The essay notes that during the last 2.6 million years, there have been at least 104 major fluctuations from global cold to global warmth. Each fluctuation, the report notes, was complex within itself and typically involved global temperature changes spanning 5° Celsius and sea-level changes averaging 130 meters. The report notes that animal populations of the past avoided mass death by migration; however, human populations do not have the available space to which to migrate. The essay says that human population growth and development have coincided with one of the few and infrequent episodes of climate stability (over about ten thousand years) in recent Earth history.

The essay discusses ice core records, global greenhouse gases, and the geological record of climate change in calling for a plan of action on anthropogenic climate change. The essay goes so far as to suggest a program of massive human sequestration of carbon dioxide in human-made reservoirs and a switch to alternative fuel sources, including conversion to nuclear power generation as much as possible.

Stratosphere

- **Category:** Meteorology and atmospheric sciences

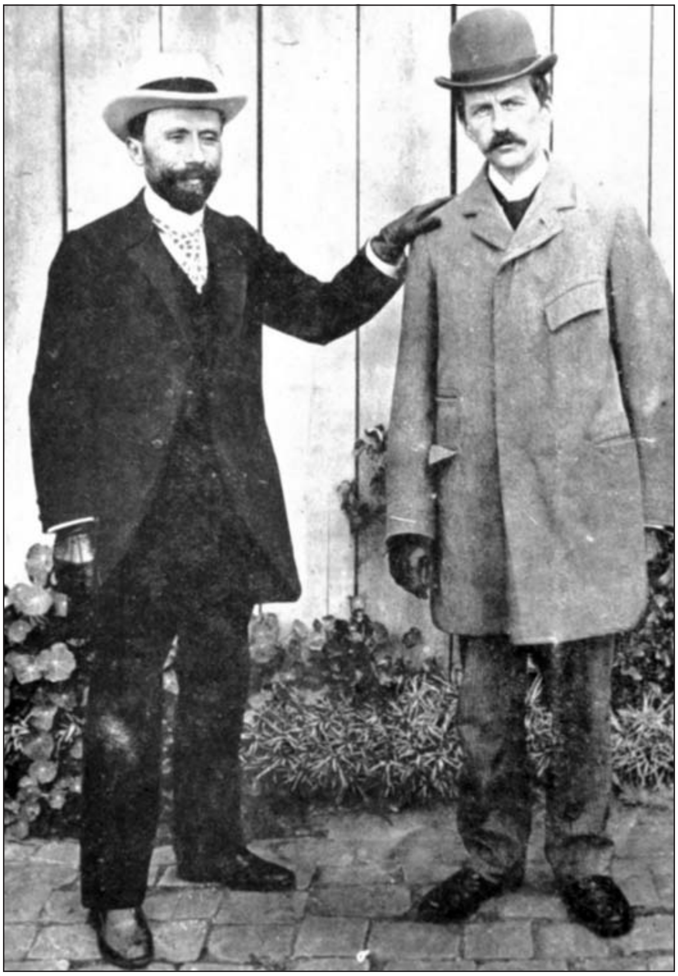
- **Definition**

The stratosphere is a highly stratified region of the atmosphere that is bounded below by the troposphere and above by the mesosphere. The stratosphere ranges from about 15 kilometers above the Earth's surface at its lower boundary to about 50 kilometers at its upper boundary. The stratosphere contains about 90 percent of the ozone in the atmosphere. Because of the ozone layer in the stratosphere, which absorbs much of the ultraviolet radiation reaching Earth from the Sun, the temperature increases with increasing height throughout the stratosphere. This ozone-induced increase in temperature with height corresponds to stable stratification, which has a strong impact on the stratospheric circulation.

• Significance for Climate Change

Since scientists Richard Assmann (1845-1918) and Léon Philippe Teisserenc de Bort (1855-1913) independently launched balloons and discovered the stratosphere more than a century ago, the stratosphere continues to be probed and measured by a wide variety of scientific instruments, including radiosondes, lidars, rocketsondes, and satellite sensors. These measurements have revealed a region containing a number of prominent circulation features. These features include the midlatitude westerlies in the wintertime hemisphere, the corresponding easterlies in the summertime hemisphere, the Brewer-Dobson circulation, and the equatorial quasi-biennial oscillation (QBO).

The midlatitude westerlies and easterlies affect the planetary wave energy that propagates vertically from the troposphere into the stratosphere, while the Brewer-Dobson circulation, which is characterized by ascent in the equatorial region of the stratosphere and descent in the polar regions, transports ozone from its production region in the tropics to the polar regions. The QBO, which is characterized by an oscillation in zonal winds in the equatorial lower stratosphere, can extend its influence far beyond its seat of origin to affect, for example, Northern Hemisphere surface temperatures. These features, as well as the space-time evolution of the stratosphere, depend vitally on the interactions between radiation, chemistry, and dynamics. Perturbations to these interactions are caused by both anthropogenic and natural forcing and occur over a wide range of timescales.



Léon Philippe Teisserenc de Bort, who helped discover the stratosphere, places his hand on the shoulder of Abbott Lawrence Rotch, who founded the Blue Hill Meteorological Observatory. (NOAA)

Changes in stratospheric temperature, which are intimately connected to the radiative, chemical, and dynamical interactions in the stratosphere, have undergone episodic, quasi-periodic, and secular changes over the past several decades. These changes have been attributed to volcanic events, the eleven-year solar cycle, and anthropogenic forcing. Studies have shown that volcanic events can eject aerosols into the lower stratosphere that alter the radiation balance there, resulting in elevated temperatures that can last for a couple of years.

The eleven-year solar cycle has been shown to modulate the temperature and ozone in the stratosphere, which modulate the stratospheric westerlies. The modulation of the westerlies in turn affects the energy propagation of the planetary waves, which through refraction and reflection can impart a downward influence on the troposphere. Anthropogenic forcing has caused ozone depletion and increases in well-mixed greenhouse gases (WMGGs) such as carbon dioxide (CO_2), which together have produced a cooling trend in the stratosphere that began most noticeably in the early to mid-1980's. Stratospheric ozone is expected to recover in the coming decades, but not enough to offset the cooling due to the projected increases in WMGGs.

The significance of the stratosphere to climate change hinges on the fact that as the composition of the stratosphere changes, so too will the dynamical circulation. Climate models show, for example, that anthropogenic forcing agents such as WMGGs cause the Brewer-Dobson circulation to strengthen. A strengthening of the Brewer-Dobson circulation will cause the westerly winds to weaken and the temperatures to increase in the extratropical stratosphere. The changes in the winds and temperature in the stratosphere are expected to couple downward to affect the weather and climate of the troposphere.

Subsidiary Body for Scientific and Technological Advice

- **Category:** Organizations and agencies
- **Date:** Established 1994
- **Web address:** http://unfccc.int

- **Mission**

Established by Article 9 of the United Nations Framework Convention on Climate Change (UNFCCC), the Subsidiary Body for Scientific and Technological Advice (SBSTA) provides the UNFCCC Conference of the Parties (COP) with information and advice on scientific and technological issues relating to the convention.

The SBSTA serves as the link between the scientific, technical, and technological assessments and the information provided by competent international bodies, and the policy-oriented needs of the COP. The SBSTA is open to participation to all parties to the UNFCCC and comprises government representatives competent in the relevant fields of expertise. With the entry into force of the Kyoto Protocol to the UNFCCC in 2005 the SBSTA also began to serve as the Subsidiary Body for Scientific and Technological Advice to the Protocol. As in the COP, parties to the convention who are not parties to the protocol may participate as observers when the SBSTA serves as a subsidiary body to the Protocol. The SBSTA generally meets twice per year and reports to the COP and the Conference of the Parties serving as the meeting of the Parties to the Kyoto Protocol (CMP) on all aspects of its work.

- **Significance for Climate Change**

The SBSTA responds to scientific, technological and methodological questions asked by the COP/CMP and their subsidiary bodies, and assesses both the scientific knowledge relating to climate change and the effects of measures taken in the implementation of the Convention. It also works to identify technologies and promote technology development and transfer, to provide advice on scientific programs and international cooperation in research and development related to climate change, and to support capacity-building in developing countries.

The SBSTA considers a wide variety of issues. As of 2008, specific examples include consideration of the reports of the Intergovernmental Panel on Climate Change (IPCC); provision of information and advice on the scientific, technical and socioeconomic aspects of impacts, vulnerability, and adaptation to climate change; consideration of scientific, technical and socioeconomic aspects of mitigation of climate change; consideration of methodological issues, including reporting and accounting procedures, under the Convention and the Protocol; and consideration of methodological issues related to reducing emissions from deforestation in developing countries.

Sulfate aerosols

- **Category:** Chemistry and geochemistry

- **Definition**

Sulfate aerosols are tiny (submicron) liquid or solid particles suspended in the atmosphere. Anthropogenic emissions are probably the leading source of sulfate aerosols in the atmosphere. The global dimming from sulfates and certain other aerosols may partly counterbalance global warming, masking the greenhouse effect. The most important anthropogenic sources of sulfate aerosols are sulfur impurities in coal, petroleum products, and natural gas. Health and environmental concerns have caused Western countries to sharply curtail these emissions, but rapidly industrializing developing nations are more than compensating for this reduction in the developed world.

In addition to anthropogenic emissions of sulfur into the environment, the world has a natural sulfur cycle analogous to the carbon cycle. Sulfur compounds, especially, hydrogen sulfide (H_2S) and sulfur dioxide (SO_2), escape from volcanoes and eroding rocks. These and other sulfur compounds eventually redeposit. However, some of this sulfur flux passes through the atmosphere, with significant climatic effects. Non-SO_2 sulfur compounds entering the atmosphere are oxidized into SO_2. The SO_2 combines with hydrogen in water to form sulfuric acid (H_2SO_4) or with ammonium ions to form ammonium sulfate $(NH_3)_2SO_4$. These form liquid or gas aerosols that eventually fall to the ground or are washed down in rain.

Before returning to the ground, sulfate aerosols influence climate by reflecting visible light back up into space while allowing infrared light (heat waves) to pass through and by providing nucleation sites for water condensation into clouds. The clouds also reflect visible light and allow infrared to pass. The resulting cooling is the opposite of the warming greenhouse effect.

Sulfur is also a small but significant fraction of the mass in organic matter. The most significant terrestrial source of sulfur-compound emissions is organic decay, particularly in marshlands, but all organisms emit some by-product sulfur compounds. At sea, plankton metabolism dominates sulfur emissions, with dimethyl sulfide (DMS or CH_3SCH_3) and carbonyl sulfide (COS) being the most common.

Volcanic sulfur emissions average significantly less than anthropogenic emissions. However, major explosive volcanic eruptions insert large pulses of sulfate aerosols into the stratosphere. Reaching the greater altitude and drier air of the stratosphere allows these aerosols to remain aloft longer. These pulses have been associated with significant cooling, including the 1816 "year without a summer" after the 1815 eruption of Mount Tambora and the milder cooling after the smaller 1883 Krakatoa eruption. The much smaller (but better documented) 1991 eruption of Mount Pinatubo put roughly 18 million metric tons of sulfates into the stratosphere and caused cooling for several months.

• Significance for Climate Change

Although aerosol analyses are even hazier than are most climate science, humanity may be balancing a significant fraction of greenhouse-gas-related warming with sulfate-aerosol-related cooling. Increased industrialization in areas without pollution controls could tip the balance into cooling. Conversely, humanity may opt to attempt planetary climate change or geoengineering if global warming is seen as a major threat. Two methods have been seriously proposed, direct sulfate injection into the stratosphere and ocean fertilization. The arguments for both are that they could be stopped at any time. The arguments against them are that they might have only limited effects and might have unexpected side effects.

In 1974, Russian geologist Mikhail I. Budyko suggested that, if global warming became a problem, humanity could burn sulfur in the stratosphere to create a haze similar to that arising from volcanic eruptions. Recent calculations suggest that such an "artificial volcano" could offset the warming of twofold or even threefold increased atmospheric carbon dioxide (CO_2), and the price might be as low as one billion dollars annually. The sulfates would also stop some ultraviolet radiation. This ability might prove important, because sulfates attack ozone, and the need to preserve the ozone layer may be a limitation. Continued sulfate injections might be needed to compensate for the lost ozone.

In 1988, California oceanographer John Martin said "Give me a half tanker of iron, and I will give you an ice age." Less ambitious fertilization of nutrient-limited areas in the ocean would cause plankton blooms emitting sulfate aerosols for greater albedo and capturing CO_2 from the atmosphere. The plan could even be self-funding through increased fishery yields.

However, ocean fertilization has potential limitations. The effects may be less efficient because of predator activity on the plankton, and some plankton emissions may be greenhouse agents rather than cooling agents. Most worrisome, an attempt to compensate for a major fraction of yearly greenhouse warming might cause so much organic material to rain into deeper waters that they could become toxic from excess CO_2.

Sulfur cycle

- **Category:** Chemistry and geochemistry

- **Definition**

The ancients referred to hell as a place of fire and burning brimstone. Brimstone was their term for the rotten-egg-smelling gas of sulfur dioxide (SO_2). Sulfur is also present in other, less odious forms owing to a series of transforming oxidation-reduction reactions, and in one form or another it is in constant flux between Earth and sky and back again to Earth. This is the sulfur cycle. Technically, the sulfur cycle describes the mineralization of organic sulfur to sulfide, its oxidation to sulfate, and the reduction of sulfate to sulfide, followed by microbial conversion into organic compounds.

Oxidation is most simply defined as the addition of oxygen, while reduction is the removal of oxygen from a compound. However, chemists more narrowly define oxidation-reduction reactions as the transfer of electrons between compounds. The term organic refers to chemical compounds having a carbon basis, which implies having come from living organisms. During its cycle, electrons recombine to move sulfur in and out of organic and inorganic compounds.

From the Earth's crust, sulfur finds its way into the atmosphere in the form of hydrogen sulfide (H_2S). It does this in a variety of ways: It comes from volcanic eruptions, decomposition of organic material, fossil fuel combustion, and gas exchange from the ocean. Once it is in the atmosphere, H_2S is oxidized to SO_2. SO_2 then combines with water vapor to become sulfuric acid, allowing sulfur to return to Earth in drops of rain. Because living things require low levels of sulfur, plants then take up the sulfur and incorporate it into protein, and it becomes part of the food chain. These organic sulfur compounds are returned to the land or water after the plants die or are consumed by animals. Ultimately, decomposition returns sulfur to its H_2S form, and the cycle begins again. The source of sulfur is the Earth's crust. Rocks and salts contain most of the planet's sulfur, but it is also found in ocean sediments and in an organic form in protein.

- **Significance for Climate Change**

SO_2 when dissolved in the moisture of clouds transforms into weak sulfuric acid. These acid-laden clouds reflect more of the Sun's radiant energy than do uncontaminated clouds, in a process called cloud brightening. The result is climate cooling.

Another form of sulfur of environmental concern is dimethyl sulfide (DMS). Marine life in the form of phytoplankton produces DMS in great quantities. When DMS escapes into the troposphere, it oxidizes into sulfate particles. Scientists have found that these particles play a role in forming condensation nuclei, which promote cloud growth and increased rainfall. This suggests that elevated ultraviolet radiation from large-scale climate change might damage phytoplankton to the extent that DMS levels are reduced, thereby lowering rainfall amounts.

Highly populated and industrial areas of the United States, Eastern Europe, and—increasingly—Asia have the highest levels of sulfur emissions. The associated problems are likely to increase, as areas such as industrialized China continue to grow. One specific problem is that of acid rain. These rain droplets containing sulfuric acid have caused great damage to freshwater ecosystems.

The issue of climate impact from sulfur is not in doubt, but authorities debate whether carbon dioxide (CO_2) discharged from burning fossil fuels raises climate temperatures beyond the cooling effects of the sulfur dioxide that is also discharged. Millions of metric tons of SO_2 gas can reach the stratosphere from a major volcanic eruption. The year 1816 witnessed the great Mount Tambora eruption. Because of the lingering ash cloud that had spewed into the atmosphere, thereby lowering temperatures around the world, the following year became known as the year without a summer. Crops failed in the United States, and food shortages became commonplace around the globe. More recently, environmentalists think it likely that greenhouse warming was delayed for a few years by the eruption of Mount Pinatubo in 1991. Research reveals that volcanic ash clouds together with sulfur dioxide emissions can force dramatic temperature changes.

A certain type of bacteria known as *Thiobacillus ferroxidans* is capable of harvesting energy for its growth and reproduction through the oxidation of sulfides into sulfates, leaving large amounts of caustic acid in its wake. In heavy metal or coal mining, large amounts of acid are produced in this way that are often referred to as acid mine drainage. Many treatment systems are coming on line to treat coal-mine drainage in order to raise the pH of contaminated water and control the precipitation of dissolved metals.

Sulfur hexafluoride

• **Category:** Chemistry and geochemistry

• Definition

Sulfur hexafluoride, also called sulfur (VI) fluoride, is a gas that is about five times as dense as air, tasteless, odorless, nonflammable, nontoxic, and with very little chemical reactivity. Thus, it will not corrode metals with which it is in contact at ordinary temperatures. In 1937, it was discovered to have a higher dielectric strength than air and was suggested for use as an insulating material in electrical equipment—a use that continues to the present. About 80 percent of the sulfur hexafluoride used is in the electric power industry. Other than its electrical uses, sulfur hexafluoride has found application in etching silicon films for liquid crystal display panels, as a filling in double-paned windows, and as an inert atmosphere in magnesium metal casting.

• Significance for Climate Change

Sulfur hexafluoride strongly absorbs infrared radiation in the wavelength region 8-12 microns. The solar heating of the Earth causes the planet to emit infrared radiation. In the absence of an atmosphere, the Earth would stay relatively cool. Greenhouse gases (GHGs) in the atmosphere, such as water vapor, carbon dioxide (CO_2), and methane, absorb infrared radiation, ultimately raising the temperature of the Earth.

The Intergovernmental Panel on Climate Change (IPCC) has evaluated various gases for their global warming potential (GWP) and found that sulfur hexafluoride is the most potent greenhouse gas tested. Sulfur hexafluoride is 22,200 times as potent a greenhouse gas as is CO_2 under comparable conditions. In addition, the compound has an estimated atmospheric lifetime of thirty-two hundred years, guaranteeing that any emissions will accumulate over time. Emissions are estimated at 1,000-1,500 metric tons per year, leading to an atmospheric concentration in 1990 of 4 parts per trillion. This is a considerably lower level than CO_2 (around 380 parts per million), but because of the great GWP of sulfur hexafluoride, it is still a serious consideration.

Sulfur hexafluoride has been named in the Kyoto Protocol (1997) as a GHG that must be phased out as much as possible. The electric power industry has responded by putting better seals on circuit breakers to prevent leaking and by reducing the amount of the gas in each unit. Substitutes have been found for the inert atmosphere in magnesium casting, but in electrical applications, substitutes such as perfluorocarbons are not as effective in the application and are also serious GHGs.

Sun

- **Category:** Astronomy

Solar radiation is the fuel that drives Earth's climate engine. Global average temperatures respond to variations in both the amount of energy emitted by the Sun and the amount of that energy absorbed and retained by the Earth.

• Key concepts

albedo: the fraction of incident light reflected from a body such as Earth

greenhouse effect: the tendency of Earth's atmosphere to transmit visible radiation from the Sun to the ground, where it is absorbed and reemitted as infrared radiation that cannot readily escape to space

insolation: the amount of radiant energy per square meter per second received by the Earth from the Sun

• Background

The Sun is a typical yellow dwarf star. It is a mixture of incandescent gases, primarily hydrogen (80 percent by mass) and helium (20 percent by mass) with trace amounts of heavier elements. The Sun has a total mass of 1.99×10^{30} kilograms and a radius of 6.96×10^{8} meters. The Earth orbits the Sun at an average distance of 1.5×10^{11} meters.

The surface of the Sun has a temperature of 5,800 Kelvins, the temperature at which thermal radiation peaks at yellow in the visible section of the electromagnetic spectrum. Radiation emitted by the Sun totals 3.93×10^{26} watts. This tremendous amount of energy emitted each second is replenished by nuclear reactions occurring in the core of the Sun. Hydrogen is converted into helium (four atoms of hydrogen fuse to form one atom of helium), with the excess mass converted to energy.

• Structure

At the center of the Sun, the pressure is approximately 3.16 quadrillion kilograms per square meter, 300 billion times Earth's atmospheric pressure. The temperature is 15 billion Kelvins. These conditions permit the fusion of four hydrogen nuclei (protons) into one helium nucleus with the net loss of 7 percent of the original mass. This mass is converted into energy in accordance with Albert Einstein's special theory of relativity. The Sun converts 4.5 million metric tons of matter into energy each second.

The core of the Sun is the region where nuclear fusion takes place. It contains 40 percent of the mass of the Sun and produces 90 percent of the energy radiated by the Sun. The core extends outward to one-quarter of the distance to the surface. At this radius, the temperature falls to 13 million Kelvins, which is too cool to sustain the fusion reaction.

The energy escaping the core is predominantly in the form of X rays, an extremely energetic type of electromagnetic radiation. The material of the Sun from the top of the core out to three-quarters of the distance to the surface is a hot, dense plasma that is opaque to X-ray radiation. This layer slows the transport of energy from the core outward to such an extent that it may take millions of years for the energy from the core to reach the Sun's surface and escape into interplanetary space.

At the three-quarters mark, the temperature of the Sun is about 1.5 million Kelvins. The X-radiation has been replaced by ultraviolet radiation. The plasma in this region undergoes convection, in which hot, buoyant plasma rises to be replaced by cooler and denser plasma from above. This drastically increases the rate at which energy moves outward toward the surface, with the result that the temperature begins to drop precipitously. Three tiers of ever-smaller convection cells fill the Sun from the three-quarters mark out to the surface. The temperature drops steeply in this region to the relatively cool 5,800 Kelvins at the surface.

The outermost shell of the Sun is called the photosphere. The appearance that the Sun has a definite physical surface is an illusion. The density, pressure, and temperature of the photosphere drop continuously and smoothly with increasing distance from the center, but at a certain point the gas composing the photosphere abruptly changes from opaque to visible to transparent and becomes invisible from that point outward.

The region outside the photosphere is regarded as the atmosphere of the Sun. It is divided into two layers. The chromosphere reaches out to 10,000 kilometers above the photosphere, where the temperature rises abruptly to 1 million Kelvins. This new region of the solar atmosphere is called the corona.

The photosphere is an intensely active region. The tops of the third-tier convection cells are visible and give the surface a granular appearance. Sunspots are large, relatively cool regions that appear dark in contrast to the surrounding hotter material. They are associated with intense localized magnetic fields. About 1 percent of the solar surface is covered by spicules, jets of superheated plasma visually resembling flames. Prominences are loops of plasma trapped by the magnetic field lines associated with sunspots. Prominences may extend thousands of kilometers out into the chromosphere and occasionally erupt, flinging solar material out into interplanetary space.

Facts About the Sun

	Sun	*Earth*
Mass (10^{24} kg)	1,989,100	5.9736
Volume (10^{12} km^3)	1,412,000	1.083
Volumetric mean radius (km)	696,000	6,371
Mean density (kg/m^3)	1,408	5,520
Surface gravity at equator (m/s^2)	274.0	9.78

• Capacity to Effect Climate Change

The Earth receives 1,350 watts per square meter of radiation from the Sun at the top of the atmosphere. This is referred to as the average insolation. The insolation varies over the course of the year due to the eccentricity of the Earth's orbit. The insolation also varies as the number of sunspots waxes and wanes over an eleven-year cycle. Long period variations in insolation associated with recurrent ice ages are due to minute variations in the shape of the Earth's orbit traceable to interplanetary gravitational influences.

Approximately 36 percent of the radiation received from the Sun is reflected back into space, with most of this reflection coming from clouds and ocean water. The ratio of radiation reflected to radiation received is called albedo.

The ultraviolet portion of the solar spectrum ionizes virtually all of the atoms at altitudes above 160 kilometers to form the ionosphere; more is absorbed in the stratosphere. Only a small fraction of solar ultraviolet radiation reaches the surface of the Earth. Virtually all of the visible and near-visible infrared radiation reaches the surface. With limited exceptions, all of the rest of the solar radiation, in the form of infrared radiation and radio waves, is absorbed in the atmosphere. The portion of solar radiation absorbed by the ground is reemitted as infrared radiation to which the atmosphere is opaque. The atmosphere thus acts as a gate that lets the energy of the visible radiation in but does not permit the reemitted infrared radiation to escape. This phenomenon is called the greenhouse effect; it keeps the Earth warmer than it would otherwise be.

Sun protection

- **Category:** Diseases and health effects

• Definition

Sun protection refers to methods of preventing damage or injury to the skin from ultraviolet radiation (UVR) emitted by the Sun. Such methods often involve physical or chemical barriers, Sun exposure reduction, or both. Physical barriers act to physically block UVR and include sunscreens, fabrics, and glass. Chemical barriers act by absorbing UVR and primarily include the chemicals incorporated in some sunscreens and in certain fabrics.

Sunscreens, usually applied as creams, lotions, or sprays, are composed of chemical substances that prevent UVR penetration of the skin. Sunscreens that act as a physical barrier to UVR include zinc oxide and titanium dioxide. Sunscreens that act as a chemical barrier to UVR include para-aminobenzoic acid (PABA), cinnamates, camphor derivatives, oxybenzone, avobenzone, octocrylene, and salicylates. The effectiveness of sunscreens in protecting skin against UVR is measured by a number called the Sun protection factor (SPF); a higher number indicates a greater degree of protection.

Fabrics act as physical barriers to UVR and include those that make up clothing, umbrellas, and hats (especially wide-brimmed hats to protect the face, eyes, and neck). The effectiveness of fabrics to block out UVR is indicated with a number called the ultraviolet protection factor (UPF); the higher the number, the greater the ability to protect against UVR. Fabrics that have a greater ability to block UVR are darker in color, heavy-weight, and tightly woven. Fabrics may also act as chemical barriers when they are made from fibers having such an ability or when the fabric is impregnated with a chemical sunscreen.

Limiting Sun exposure, especially between 10:00 A.M. and 4:00 P.M., when the Sun's ultraviolet rays are the strongest, and seeking shade when appropriate are effective in protecting against UVR. These precautions must be observed even on cloudy days, because UVR can penetrate clouds. Although a certain amount of protection is afforded by a hat or umbrella, the ground can reflect UVR. Therefore, sunscreens should also be applied.

Glass also acts as a physical barrier to block the three main types of UVR (UVA, UVB, and UVC). Some glass (such as the side and rear windows of many automobiles) block only UVB and transmit a considerable amount of UVA. Other types of glass used in automobile windshields, such as laminated glass (two pieces of glass bonded together with a plastic), are much more effective in blocking UVA and UVB. The effectiveness of glass to block UVR can also be increased by the application of UVR-blocking substances to the glass. Sunglasses, which may be made of glass, polycarbonate, or other materials, are particularly effective in protecting the eyes from UVR. Sunglasses designed with side panels or that wrap around afford better protection against UVR reaching the eyes from the sides.

Sun protection is particularly important for beach visitors. (©iStockphoto.com/Sieto Verver)

• Significance for Climate Change

The ozone layer is a layer of gas present in the stratosphere (the middle portion of the Earth's atmosphere) that plays a significant role in the regulation of UVR transmission to the Earth. Of the three main types of UV radiation that reach the Earth from the Sun, UVC is extremely hazardous, but it is completely absorbed by the ozone layer, as is most of UVB; UVA is completely transmitted through the ozone layer.

Substances that contribute to global warming can deplete the ozone layer, thereby allowing increased amounts of dangerous UVR to reach the Earth. Ozone-depleting substances include chlorofluorocarbons (CFCs), hydrochlorofluorocarbons (HCFCs), halons, methyl bromide, carbon tetrachloride, and methyl chloroform. These chemical compounds are unstable in the stratosphere when subjected to UVR. As these compounds undergo reactions in the stratosphere, they are broken down into halogens such as chlorine, fluorine, or bromine. These halogens play a role in converting ozone into oxygen and other related by-products, thereby depleting the ozone layer. The continued depletion of the ozone layer leads to higher levels of UVB transmitted to the Earth, which in turn can lead to an increase in various medical problems.

All forms of UVR are harmful to biological organisms. UVA is responsible for damaging the deeper layers of the skin and producing harmful skin effects, including accelerated skin aging, tanning, and other conditions, such as drug-induced sunlight sensitivities. UVB affects the top layer of the skin and can produce skin cancers, especially basal cell carcinoma and melanoma. Skin cancer is the most common form of cancer in the United States, and more than 90 percent of the cases are due to Sun exposure. Significantly, Australia has the highest incidence of skin cancer in the world; associated risk factors are the great number of fair-skinned individuals in the country and the amount of Sun exposure.

UVB also causes tanning, sunburns, actinic keratosis (benign skin lesions that may develop into invasive squamous cell cancer), and formation of senile cataracts. UVB has been associated with other effects on the eyes, including the development of pterygium (benign tissue growth of the conjunctiva) and acute inflammation of the eyes, specifically the inside lining of the eyelids, cornea, and iris.

UVB has also been linked with decreased ability of the immune system to elicit a protective response.

This immunosuppression has been observed in a number of rodent and human studies; in fact, rodents exposed to UVB have shown increased susceptibility to certain infectious diseases. Solar UVR and exposure to sunlamps and sunbeds were classified by the United States Department of Health and Human Services in 2000 as known human carcinogens. Therefore, as the continued depletion of the ozone layer will lead to higher levels of UVR and a concomitant increase in the various medical conditions discussed above, Sun protection is essential for everyone exposed to UVR and should begin even in infancy.

Sunspots

- **Category:** Astronomy

- **Definition**

Sunspots are concentrated areas of magnetic activity on the surface of the Sun. They are both cooler and darker than the areas that surround them. The difference in temperature is caused by the fluctuation of the Sun's intense magnetic field, which in turn affects the convection zone on the surface. The convection zone is the outer 20 to 30 percent of the Sun, in which hot gases rise from the star's core and cool gases sink toward that core. Sunspots appear as dark blotches on the surface of the Sun and can have a diameter as great as 80,000 kilometers. The surface area varies as they travel over the Sun's surface, but the average sunspot is the same size as the planet Earth.

Sunspots are divided into two areas: the darker umbra and the lighter penumbra. Plasma on the surface of the Sun reacts with a sunspot's magnetic field, exploding from the surface in what is called a solar flare. Similar spots have been identified on other stars and are known as starspots. Sunspots vary in intensity over recurring cycles of roughly eleven years. These cycles form part of a longer, twenty-two-year cycle, in which sunspots appear in the northern hemisphere of the Sun for the first eleven years and the southern hemisphere for the second eleven years.

The ancient Aztecs had a myth of a Sun god with a pockmarked face, which may indicate that they were aware of sunspots. The first recorded observation of sunspots was made by ancient Chinese astronomers. The first Western reference occurs in Greece during the fourth century B.C.E.

While it is possible, albeit very dangerous, to observe sunspots with the naked eye, the invention of the telescope in 1608 changed the way astronomers looked at the Sun. It is unknown who was the first European to measure and record information about sunspots; the discovery is variously attributed to the Italian Galileo, Johannes Fabricius of Holland, Englishman Thomas Herriot, and Christopher Scheiner of Germany. While these men all noted the appearance and activity of sunspots, however, they lacked the detailed instruments needed to identify the nature of the phenomenon correctly. Scheiner, a priest who believed that the heavens were perfect, identified them as small moons and planets orbiting the Sun. It was Galileo who correctly observed that the appearance of the sunspots changed as reached the edge of the Sun's surface, which meant they had to be a feature of the

Sun, not something orbiting the Sun. He posited that they might be clouds.

• Significance for Climate Change

Throughout history, sunspots have been blamed for everything from earthquakes to economic fluctuations, but their effect on the Earth is far subtler. Early astronomers noted the correlation between heavy sunspot activity and Earth's magnetic activity. European astronomers noted a long-term decrease in sunspot activity from 1645 to 1715, called the Maunder Minimum for E. W. Maunder, who did much of the research. This era of low sunspot activity corresponds with what is called the Little Ice Age, a particularly cold era for much of the Earth.

Using historic records of sunspots and the aurora borealis (also known as the northern lights), as well as geological evidence of atmospheric deposits, scientists have determined that the Sun was very active prior to the Little Ice Age. Similar occurrences have been noted during the Oort Minimum (1010-1050), the Wolf Minimum (1280-1340), and the Spoerer Minimum (1420-1530). The pattern seems to be a cycle of seventy years of abnormal cold, followed by two hundred to three hundred years of warming.

Modern telescopes operate in many different wavelengths, and modern sunspot measurements include ultraviolet and infrared light, as well as gamma rays and X rays. The problem with identifying a definitive connection between solar activity and climate change on Earth is that scientists have only been able to accurately measure solar radiation since the satellite age. Measurements taken since the late 1970's have confirmed the existence of an eleven-year cycle, but also found that solar radiation only fluctuated by 0.1 percent.

When solar radiation output is at its peak, the level of high-energy radiation in Earth's upper atmosphere increases. This increase causes an increase of ozone, which can double the temperature in the thin upper atmosphere. This in turn affects the stratosphere, specifically the wind patterns, and has an impact on climate around the world. Increased solar radiation is also tied to increased cloud cover.

Scientists base their findings on total solar irradiance (TSI), a measurement of all wavelengths of solar energy outside the Earth's atmosphere. This measurement confirms the 0.1 percent fluctuation over time, but it also reveals that solar radiation can vary by 0.2 percent over the course of just a few days and that such variation is tied to sunspot activity. While this appears to be an insignificant figure and plays only one small part in the overall climate picture, it is equivalent to the total energy used by the human race over the course of one year.

Sustainable development

• **Categories:** Economics, industries, and products; environmentalism, conservation, and ecosystems

In the face of climate change and dwindling environmental resources, sustainable development is key to maintaining the ways of life and standards of living to which industrialized nations have become accustomed, while protecting Earth's environment and the interests of future generations.

• Key concepts

biofuels: energy sources derived from recently dead organisms, most commonly plants

carrying capacity: the maximum population that can be supported indefinitely with the available resources and services of a given ecosystem

community: a group of people who live and interact within a specific geographic or social sphere

ecosystem services: all the interdependent organisms and nonbiological factors that combine to provide the conditions necessary to the sustainable existence of life within a given ecosystem

sustainability: the ability of an environmental or environmentally dependent system to continue indefinitely without exhausting the means of its reproduction

• Background

Sustainable development aims to address a number of interrelated global issues, such as poverty, inequality, hunger, and environmental degradation. The concept emerged out of numerous environmental movements begun in the 1970's and 1980's. The 1992 Earth Summit in Rio de Janeiro, Brazil, was one of the major international events to bring sustainable development into the mainstream. However, the progress in sustainable development has been quite slow across the globe. Many challenges and a lack of political will are responsible for this less-than-satisfactory progress.

• Progress and History

The term "sustainability" was first officially defined by the World Commission on Environment and Development as entailing "development that meets the needs of the present without compromising the ability of future generations to meet their own needs." Although it means many different things to different people, sustainable development generally refers to sustainability in terms of environmental, economic, and social progress and equity, all interconnected and operating within the limits of natural resources. At the heart of such development is the goal of a healthy and harmonious relationship between humans and natural resources, such that the latter can continue to provide for future generations of the former.

Sustainable development has been an urgent global issue for many years, although the record on moving toward achieving the goal has been quite poor. For instance, the world has failed not only to protect the interests of future generations but also to meet the needs of present generations. Currently, 1.3 billion people live without access to clean water, and nearly 50 percent of Earth's population survives on less than two dollars a day and lacks access to basic sanitation. A further 2 billion people are without electricity. These alarming statistics come in an age of immense wealth that is increasingly concentrated in fewer hands.

In the years since the Rio Earth Summit, sustainable development has ranked very low on international agendas. As a result, poverty has deepened, global inequality has widened, and environmental degradation has heightened. According to the

United Nations Human Development Report, 20 percent of the world's population in the richest countries accounts for 86 percent of total consumption expenditures, while the poorest 20 percent accounts for a minuscule 1.3 percent of expenditures. Given the tremendous inequality of wealth and resource partitioning in the world, it is no wonder the term "sustainability" bears quite different meanings to different people.

• Sustainable Agriculture and Forestry

Beginning in the second half of the twentieth century, agricultural productivity increased dramatically. This increase has helped improve the lives of billions, but at the same time it has weakened nature's ability to deliver other key services. These range from clean air and water to protection from disasters to preservation of biodiversity to prevention of soil erosion. Environmentally damaging industrial agriculture threatens future sustainability. Sustainable development seems to be the best option to halt or even reverse environmental degradation and grow food now without jeopardizing key services later.

Sustainable development must begin with a transformation of fundamental philosophies on agriculture. Many current agricultural systems are operated on business models that are geared solely to make money and profit. In other words, crops are not grown for people to eat but are produced for consumers to buy. This practice leads to a major diversion of land use from food production to profit generation. It also makes food less nutritious and less tasty, as crops are bred for shelf life and uniform appearance (qualities that are evident to shoppers in supermarkets and that facilitate lucrative high-volume models of production) rather than nutritional content or taste (qualities that are invisible until after one makes a purchase).

Much of the best agricultural land in the world is used to grow cash crops such as cocoa, cotton, tea, tobacco, and sugarcane or is converted to rangelands for high-demand livestock. Profit-driven operations have also led to overexploitation of natural resources. Mathematical ecologist Dick Levins comments about the necessity of changing attitudes on farming, saying,

> . . . farmers in sustainable agriculture are concerned about feeding their families and paying their bills, but those are not their only goals in life. They set out to protect the land, improve their quality of life, and enhance the communities in which they live. Their day-to-day decisions are not guided by a single minded search for profit, but by a delicate balancing act among many goals.

Because people rely upon trees and plants to build houses, produce paper, make furniture, and provide medicines, pressures on forests are staggering. Sustainable forest management is the only way to maintain the long-term health of the world's forests. According to the United Nations Food and Agriculture Organization (FAO), sustainable forest management is

> the stewardship and use of forests and forest lands in a way, and at a rate, that maintains their biodiversity, productivity, regeneration capacity, vitality and their potential to fulfill, now and in the future, relevant ecological, economic and social functions, at local, national, and global levels, and that does not cause damage to other ecosystems.

Without preserving any of these vital components, forests will eventually cease to provide society's members with the goods and benefits to which they have grown accustomed, including many valuable species that provide medicines. This loss of these species will be irreversible and permanent.

• Sustainable Energy Sources

Among the most important resources that must be sustained are energy resources. Alternative and renewable energy sources, particularly clean energy sources, are necessary components of any plan of sustainable development. Such sources include biofuels, geothermal power, solar power, wind power, and wave power. In the short term, any technology that improves energy efficiency may be considered a component of the transition to sustainable energy practices.

Biofuels in particular can be produced from almost any organic carbon source. However, most biofuels are produced using plants and plant-derived materials. The first generation of biofuels includes vegetable oils, biodiesel, bioalcohols, and solid biofuels such as wood, grass cuttings, domestic refuse, and dried manure. The most common use of these substances is as liquid fuel for transportation. Two common strategies are employed to produce biofuels: Sugar and starchy crops are used to produce ethanol through yeast fermentation, while natural plant oils, such as canola, soybean, and palm oils, are extracted and processed for use as biodiesel.

Production of first-generation biofuels is highly controversial, because it requires direct use of grains and takes away land from growing food crops, exacerbating world hunger. Moreover, biofuel crops, particularly corn, are extremely hard on soil, making them among the least sustainable crops in the world. The low energy efficiency of such crops is also cause for concern. As a result of these factors and related debates, technologies are being developed for second- and third-generation biofuels. Second-generation biofuels will be produced using cellulosic biomass, which is theoretically capable of much greater energy efficiency than is corn, as well as a variety of nonfood crops. Third-generation biofuel is also called algae fuel or oilgae, and it will be derived from low input/high yield algae (which produces thirty times more energy per unit of area than do land crops).

In general, sustainable economic development improves the economy without undermining society or the environment. There are various definitions of sustainable business or economic development from different sources, most of which share many common characteristics. According to the Lowell Center for Sustainable Development,

> Sustainable Production is the creation of goods and services using processes and systems that are: nonpolluting; conserving of energy and natural resources; economically efficient; safe and healthful for workers, communities, and consumers; and, socially and creatively rewarding for all working people.

• Context

By and large, current societies and socioeconomic practices are unsustainable. As a result, future generations will have a poorer, more polluted world to live in. Everyone depends on nature and ecosystem services for the resources necessary to live decent, healthy, and sustainable lives, including clean air, drinkable water, nutritious food, clothing, shelter, and so forth. Human activities in recent decades have pushed the Earth to the brink of massive species extinctions, threatening humanity's well-being. While the Industrial Revolution and technological advancement have served to improve the living standards of millions, the associated environmental degradation remains a heavy price.

Anthropogenic scourges of the planet have become significant barriers to sustainable development. Better protection and more efficient uses of various natural assets are vital if humans expect to inhabit the Earth in harmony with the planet's many other species and their ecosystems. Real sustainable development must recognize the interconnectedness between human beings and the environment if true environmental and social justice is to be obtained. Measures must be taken and technology must be developed to conserve natural resources, to secure alternative forms of energy, to develop an economy friendly to the environment, and to preserve cultural diversity and heritages. These goals can be achieved only through coordinated global efforts, across all sections of government, business, and local communities.

Technological change

- **Category:** Science and technology

The growth and continued evolution of technological systems and artifacts pose significant challenges and opportunities relating to global climate change. New technologies may damage the environment, but technologies may also be created to protect or restore that environment. In either case, technology is the driving force behind anthropogenic climate change.

• Key concepts

product life cycle: the complete history of a product, from the process of its creation to its ultimate disposal or reconstitution

tradeoffs: the balanced benefits and harms attributable to a given action or entity

unanticipated consequences: effects not foreseen

• Background

Human beings have an inherent capacity to create and re-create their environments. Human technological prowess far outstrips that of any other species. The ability of human beings to reshape landscapes, for example, can be easily observed from orbit. With the advent of industrialization and mass production and distribution, the pace and intensity of technological change accelerated.

Humans have created more devices and achieved more wholesale reshaping of the Earth during the past few hundred years than the previous several millennia. Perhaps the most outstanding exemplar of this reshaping has been the widespread creation and growth of cities, many of which contain populations of over ten million persons. Over one-half of the world's population lives in these densely packed urban environments, and collectively their inhabitants or those who service their needs from afar generate the bulk of the pollutants that affect the soils, water, other species, and air of the Earth.

• Measuring Technological Change

The extent of technological change is difficult to characterize precisely. One could catalog the patents granted in a certain time frame, but that information is just a small part of the overall picture. Many patents, which globally number in the millions, are never commercialized. Many patents that do result in actual products, goods, or services do not achieve large-scale success or dissemination. A significant number of patents, however, achieve extraordinary levels of influence, affecting human beings and the entire planet in profound ways. For example, the automobile and the many patents associated with it over time have arguably transformed both the human-made and the natural world.

Technological change itself can be thought of as a set of interrelated processes whereby a particular new artifact, system, or innovation is introduced on a scale sufficient to alter in some measurable manner the various environments in which that artifact, system, or innovation functions. All technological change involves a complex interaction among a host of actors, including inventors, government officials, sponsors, producers or manufacturers, distributors, users, and beneficiaries.

Each technology or technological system embodies within itself a set of implicit or explicit values, constraints, limitations, and problems that either are readily discernible or become discernible over time. For example, automobiles are designed to transport human beings and cargo from one location to another, but they also embody a set of values involving comfort, speed, agility, safety, efficiency, aesthetics, and so forth. They are designed and built within a set of constraints that minimally includes statutes and regulations that govern the sector, cost, marketability, and life cycle of each product, as well as the condition of the larger environment within which it will be embedded. For example, a nation that has few roads in good condition may require a significantly different type of automobile from one in which there are many paved highways.

• Technological Change and Global Climate

Modern technological systems have forever altered the relationship between users of technology and the natural world. Many technological devices exhibit a "black box" character for their users, who cannot discern or understand the fundamental principles upon which the devices operate or the ways in which they interact with larger technological systems to achieve their intended results. Because they do not understand the technologies they use, few people reflect on the consequences associated with personal technological choices. Human beings are thus separated from the natural world in ways that they were not in earlier centuries, when individuals could easily trace a set of relationships between, say, the food on their table or the artifacts in their local environments and the sources from which those foodstuffs and artifacts were derived. This disconnection from the natural world and the technology underlying everyday objects makes it difficult for consumers to think of their daily choices as affecting the environment.

Rampant consumerism is a second feature of the contemporary technological world, in which the average person accumulates multitudes of devices and technological systems over the course of his or her lifetime. The sheer amount of consumer products found within the home of an average American family would elicit envy from a wealthy ancient Roman nobleman. Average American families have traveled and personally experienced more of the sights and sounds of the world than ancient counterparts who were kings, queens, or emperors. All of these accumulated devices and the larger technological systems within which they are embedded directly or indirectly contribute to pollution and global climate change. The sheer weight of these devices is thus more important to climate change than any particular technology. Because virtually all industrial technologies are energy intensive and because so many aspects of life in a highly technological society contribute to environmental degradation, consumers may feel that calls to act environmentally responsible represent direct attacks upon their way of life.

• Technological Solutions to Global Climate Issues

Just as humans have created technologies to meet their needs and serve their desires across millennia, there is emerging evidence that this same capability is increasingly being employed by the private and public sectors to address problems related to global climate change. The state of California, which is home to 10 percent of the U.S. population, is just one encouraging example among many around the globe. During the early twenty-first century, it has decreased its ratio of carbon dioxide (CO_2) emissions to each dollar of gross domestic product (GDP), reaching a level that is 20 percent less than that of Germany. California generates 24 percent of its electrical power from renewable fuels and has the world's largest solar-power plant, largest wind farm, and most powerful geothermal facility. The Energy Efficiency Center at the University of California at Davis is pioneering new ways to take the best ideas from research and rapidly commercialize them.

Actions undertaken by President Barack Obama and the U.S. Congress to provide billions of dollars in economic stimulus monies for green technologies represent another encouraging sign that change is possible. However, technological change is an unpredictable process, and there is no clear relationship between monetary investments and productive outcomes. Most experts believe that it will take decades to provide adequate technological solutions to the challenges presented by global climate change. The history of technology cautions that such solutions will themselves embody tradeoffs and spawn unanticipated consequences that will require further solutions.

• Context

Accelerated technological change has both created many of the dilemmas of the modern world and presented opportunities for some of these challenges to be addressed. The debates over whether technology is inherently good or bad and the related debates over the proper relationship of human beings to nature are as old as philosophy itself. Climate change is perhaps the single greatest contemporary instance of those debates, and the practical responses to such abstract questions may well determine the course of both technological and societal change during the coming century. Whether a sustainable balance between the technological activities of human beings and Earth's ecosystems can be achieved remains a fundamental question of the human condition.

Thermocline

• **Category:** Oceanography

• Definition

The global ocean consists of three layers of varying density. The density of ocean water is a function of changes in salinity and temperature. A shallow, mixed layer extends from the surface to a depth of approximately 30 meters. At the bottom of the ocean is a cold layer that extends from approximately 500 meters deep to the ocean floor. The thermocline is the middle layer between these two. Within the thermocline, the temperature of the ocean changes rapidly from approximately 20° Celsius in the mixed layer to 2° Celsius in deep waters.

The thermocline is found only in waters between 60° north and 60° south latitude; it is replaced by a halocline (a layer of rapidly changing salinity) in the polar regions. The precise depth of the thermocline varies with seasonal changes in solar heating and wind strength. It is shallowest in the summer, deepest in the early spring or late fall, and sometimes absent during the winter.

• Significance for Climate Change

The influence of global warming on the thermocline can affect ocean biomes. The thermocline is shallowest and strongest (that is, it has the greatest temperature change over the shortest depth) when surface waters are warmest and they experience relatively weak winds and wave action—typically during the summer. The density of water decreases with increasing temperature, so a column of water is stable when a zone of warm, low-density water (the mixed layer) exists over a layer of cold, high-density water. The thermocline, when it is present, prevents water from the mixed layer from mixing down into the deep ocean.

The surface mixed layer is the region of the ocean where phytoplankton live and produce biomass that forms the base of the food chain. As phytoplankton grow and produce biomass, they take up carbon and nutrients that are dissolved in surface waters. These nutrients are returned to surface waters during the winter, when the thermocline breaks down and disappears. Mixing of surface and deep waters can also return dissolved oxygen to the deep waters.

Thus, when the thermocline is present and prevents mixing between the mixed layer and deep waters, surface nutrients cannot be renewed, and biomass production by phytoplankton eventually stops. Also, since oxygen is not returned to deep waters, they can become uninhabitable by organisms that require dissolved oxygen, such as fish and corals. A warmer climate could cause the development of a permanent, stable thermocline, which, in turn, could lead to decreased biomass production in the surface waters and to the development of large areas in the deep ocean that are uninhabitable by marine life because of extremely low dissolved oxygen concentrations.

Thermohaline circulation

- **Category:** Oceanography

- **Definition**

Thermohaline circulation (THC) is the large-scale circulation of water in the ocean basins, driven by the dense deep water of the polar regions. The density of ocean water is a function of both temperature and salinity. Water increases in density in the polar regions, as surface water cools and its salinity is increased through sea-ice formation. (Salt excluded from sea ice increases the salt content of polar liquid water.) A column of water becomes unstable when surface water has a higher density than deeper water, causing the high-density surface water to sink until it reaches a depth at which it is neutrally buoyant. At that depth, the water will flow horizontally throughout the oceans.

High-density surface water that forms in the Labrador and Greenland Seas sinks to become North Atlantic deep water (NADW), while the high-density water that forms in the Weddell and Ross Seas sinks to become Antarctic bottom water (AABW). Other water masses that sink to intermediate depths form in the Mediterranean Sea (Mediterranean intermediate water) and along the edges of the Antarctic Circumpolar Current (Antarctic intermediate water); yet other water masses downwell in the centers of the subtropical gyres. NADW flows southward in the Atlantic Ocean, until it mixes with north-flowing AABW in the extreme southern Atlantic Ocean. Once mixed, these two masses form Pacific-Indian common water (PICO).

AABW flows north through the South Atlantic Ocean and can be detected as far north as the equator. After forming in the southern polar regions, deep water circulates around Antarctica and then flows northward into the Indian and Pacific Oceans. Although the mechanisms are not yet fully explained, it is thought that deep water ultimately returns to the surface as diffuse flow over a large area of the North Pacific Ocean. The net transport of warm surface water to the polar regions to replace surface water that sinks to become deep water is brought about by wind-driven surface currents.

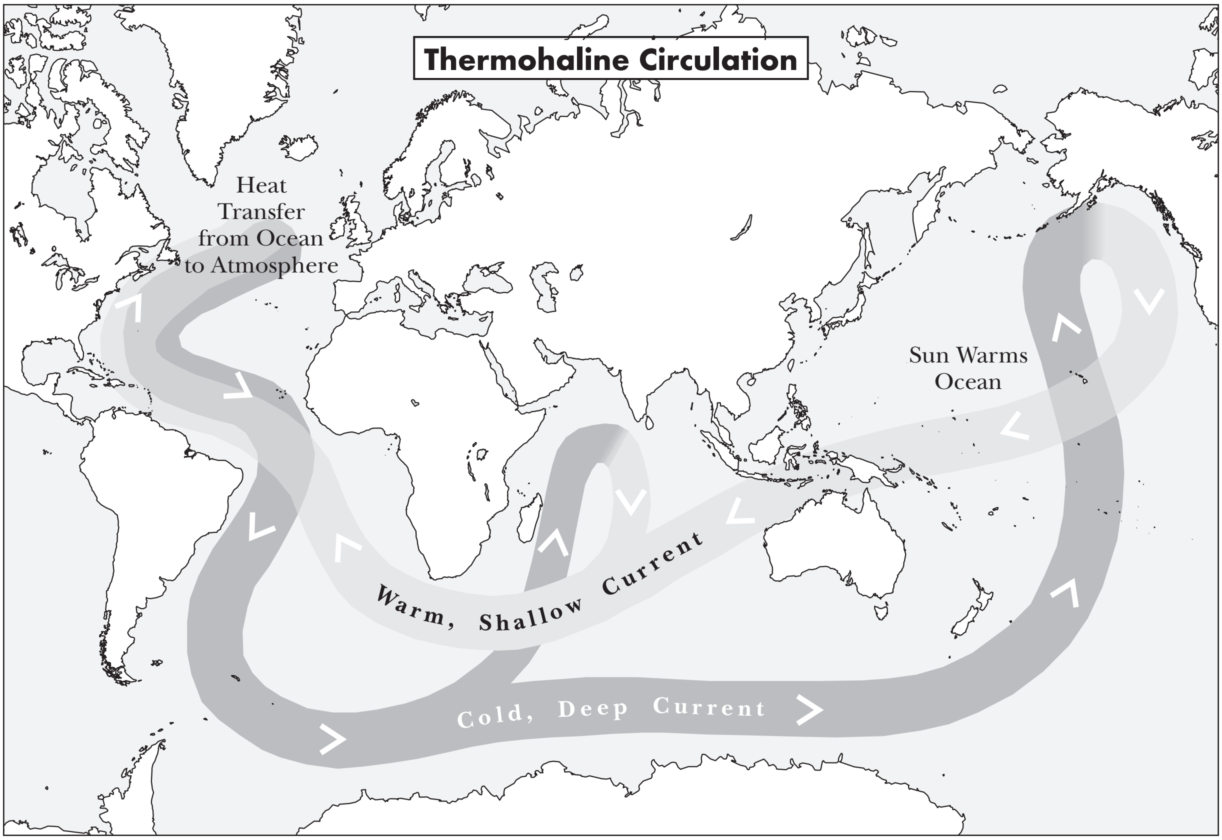
Thermohaline circulation is sometimes used synonymously with meridional overturning circulation (MOC), although this is not technically correct. THC refers to a global circulation pattern linking surface- and deep-ocean circulation, while MOC refers to deep circulation in the Atlantic Ocean.

- **Significance for Climate Change**

THC can be thought of as a large conveyer belt that transports surface water and heat from the equator to the North and South Poles, with a return flow of cold, deep water to the equator along the ocean bottom. THC is driven by water sinking to the ocean depths in a few distinct locations. After sinking, this water returns to the surface via diffuse flow over a broad geographic region in the North Pacific Ocean. THC is relatively slow: A single cycle takes approximately one thousand years.

Because THC redistributes large amounts of heat on the Earth, it is an important facet of global climate and climate change. In particular, global warming could lead to an increase in the freshwater flux into the North Atlantic by melting glaciers or increasing precipitation and river flow. An increase in freshwater flux to the polar regions would lower the density of polar surface water, stabilizing water columns and preventing the surface water from sinking into the ocean depths. An influx of surface freshwater in the Greenland Sea would also serve to block the northward flow of the Gulf Stream, a surface current that brings heat and ocean water to the polar regions.

It has been hypothesized that a shutdown of THC would lead to localized cooling of the Northern Hemisphere. In 2005, scientists from Britain's National Oceanography Centre presented data to suggest that THC in the Atlantic had slowed during the late twentieth century. These data were subsequently challenged by other scientists, who presented other data sets that showed no such slowing.



Despite the controversy regarding whether slowing is occurring, computer models consistently indicate that a shutdown of THC could lead to decreased warming or even cooling in the Northern Hemisphere. Geologic evidence suggests that the Younger Dryas, a time of global cooling that lasted from 12,800 to 11,500 years ago, may have been caused by THC collapse due to a large flux of freshwater from the emptying Glacial Lake Agassiz into the North Atlantic. In addition to climate changes, a shutdown of THC would have other important consequences, including the formation of anoxic conditions in large portions of the world oceans, reduction or collapse of phytoplankton productivity, and more frequent and severe El Niño events.

Thermosphere

- **Category:** Meteorology and atmospheric sciences

High levels of solar activity, including increases in extreme ultraviolet radiation and soft solar X rays, influence the atmospheric chemistry of the thermosphere. Increasing concentrations of CO_2 in the atmosphere have decreased the density of the thermosphere by about 10 percent over thirty-five years, lessening drag and extending satellite lifetimes.

• Key concepts

drag: friction caused by air as an object passes through it

extreme ultraviolet radiation (EUV): electromagnetic radiation with wavelengths between 10 nanometers and 120 nanometers

galactic cosmic rays: protons, electrons, and nuclei of light elements that originate outside the solar system and penetrate Earth's atmosphere

geomagnetic storm: magnetic activity caused when charged particles from solar flares strike Earth's magnetic field

low Earth orbit (LEO): an orbit situated between 160 kilometers and 1,600 kilometers above Earth's surface

soft solar X rays: solar radiation with wavelengths between 0.1 nanometer and 10 nanometers

space weather: conditions in outer space resulting from solar activity

• Background

The lower thermosphere is the region of the atmosphere above the mesopause-lower thermosphere boundary (MLT, about 90 kilometers above the Earth's surface). It extends to an altitude of about 550 kilometers. Atmospheric density decreases with altitude, as the numbers of atoms and molecules decrease and temperatures rise. The lower thermosphere is sometimes called the ionosphere, because the atmosphere there is highly charged by energetic solar photons.

Solar radiation drives photochemical reactions and motions in Earth's atmosphere. Careful monitoring of total solar output has revealed that it can vary by as much as 0.1 percent. This magnitude of variability would have little direct effect on Earth's surface temperatures. However, bursts of activity on the Sun, such as flares and coronal mass ejections, release large amounts of extreme ultraviolet radiation (EUV), soft solar X rays, and radio waves that cause ionization to strengthen in Earth's thermosphere, creating visible auroras over the polar regions. Above altitudes of 100 kilometers, ambient temperatures may be 1,000° Celsius higher at solar maximum than at solar minimum.

The supposition that variations in solar activity could influence Earth's weather and climate began several centuries ago. More than a millennium of solar observations have demonstrated that the appearance of sunspots follows irregular eleven-year and twenty-two-year cycles and that the appearance of auroras in the thermosphere closely follows the appearance of sunspots. Scientific attempts to link auroral appearance to weather patterns at Earth's surface have proved negative. Conclusive scientific evidence that variations in solar activity have caused recent changes in Earth's climate has been elusive.

Auroras occur when geomagnetic storms cause energetic particles to travel toward Earth along magnetic field lines. The high-altitude (300 kilometers) red aurora and middle green aurora result from the excitation of oxygen atoms, and the lower-altitude (75 kilometers) blue aurora is caused by the excitation of nitrogen atoms and molecules. The greater the number of molecules and atoms that are excited, the stronger the coloration of the aurora.

In the late twentieth century, scientific proponents of solar influences on climate began to claim that, when the Sun is very active over a long period of time, global warming occurs. During the period from about 1750 to the early twenty-first century, the Sun experienced more sunspots than it did during the period from 1645 to 1715, a time period referred to as the Maunder Minimum because few sunspots were observed then. The Maunder Minimum corresponds to the coldest portion of the Little Ice Age, which was observed in Europe and North America between the mid-thirteenth century and the mid-nineteenth century. Solar activity has increased since the Industrial Revolution, when anthropogenic greenhouse gas (GHG) emissions began to increase dramatically. Some scientists contend that up to half of the warming observed since the end of the Little Ice Age might be attributable to increased solar activity. This view has been met with skepticism by the international scientific community.

• Space Weather and the Thermosphere

When the Sun is active, the Earth's magnetic field (which extends beyond the thermosphere to the magnetosphere) is strengthened, lessening the number of galactic cosmic rays entering Earth's atmosphere. The solar magnetic flux affecting Earth has doubled in the last one hundred years. Protons in the inner Van Allen belt (700 kilometers to 10,000 kilometers above Earth) having energy above 50 million electron volts are assumed to arise from the decay of neutrons produced by galactic cosmic-ray collisions in the high atmosphere.

• Indirect Human Modifications of the Thermosphere

Carbon dioxide (CO_2) concentration continues to increase in Earth's atmosphere, and increased CO_2 reaching the lower thermosphere has caused cooling. As the thermosphere cools, atmospheric gases settle, causing the air density at an altitude of 400 kilometers to decrease by about 2 percent. This lowered density has decreased drag on satellites, extending their useful lifetimes. Atmospheric drag causes unpowered objects below altitudes of 480 kilometers to fall back to Earth within months. Because drag above this altitude is lower, more debris remains in orbit at that height for extended periods of time.

Most satellites orbit Earth in the lower thermosphere, from communications satellites to the Space Shuttle and International Space Station (ISS) to weather surveillance satellites. They circle the globe in low Earth orbit (LEO), from about 160 kilometers to 1,600 kilometers above the Earth's surface.

• Pollution of the Thermosphere

Low Earth orbit altitudes are monitored for space junk by ground-based radar systems that track objects larger than 5 centimeters. The lower thermosphere is occupied by hundreds of thousands of old satellite parts; on March 11, 2009, the Space Station was temporarily evacuated because of a near miss with a piece of junk about 12 centimeters in diameter.

On February 10, 2009, two LEO satellites (one defunct and one operational) collided over Siberia at an altitude of 750 kilometers, producing over 160,000 pieces of debris. Proliferation of debris by collisions of orbiting space junk is referred to as the Kessler syndrome: As more objects occupy the lower thermosphere, the chance of collision increases, and each collision creates even more debris, further increasing the chance of collisions.

Detonation of a nuclear weapon at an altitude of 420 kilometers above Johnson Island on July 8, 1962, generated an electromagnetic pulse (EMP) that disrupted electrical systems in Hawaii, 1,290 kilometers away. It also damaged most orbiting satellites. Detonation of a few nuclear weapons in the thermosphere at the start of a major war might cripple ground-based retaliation capabilities by destroying conventional communications that use integrated circuits, leaving intact only "hardened," or specially shielded, communications systems. (This was the reason for proposed construction of the extremely low frequency grid in North America.) Speculation has been raised about weapons in space that could be used against selected ground targets, but this option would be very costly and dangerous, leading to another arms race.

Because spy satellites play an important role in information-gathering by major countries including the United States, Russia, and China, eliminating enemy satellites at the start of any major conflict would be advantageous. There is a consensus that this type of satellite warfare would render the lower thermosphere unusable to satellites for many years because of the Kessler syndrome.

• Context

The thermosphere has undergone great change because of anthropogenic activity in the last fifty years. Increased anthropogenic CO_2 emissions have decreased drag at LEO, extending satellite lifetimes. Debris from satellites has rendered LEO more dangerous to piloted space missions and poses a steadily increasing hazard to functioning satellites. During the last century, the Sun has been more active, which may have caused solar influences on the Earth's atmosphere to increase. During active solar periods in the past, Earth's climate has apparently warmed, and when the Sun was less active, global cooling occurred. The mechanisms by which the small increases in total solar output might cause climate change on Earth are not known.

Thoreau, Henry David

American philosopher and writer

Born: July 12, 1817; Concord, Massachusetts
Died: May 6, 1862; Concord, Massachusetts

In Walden, *Thoreau presented an autobiographical account of his two solitary years living on Walden Pond. The work became a seminal statement of conservationism and environmentalism and may be seen as an early guide to global warming solutions from a personal point of view.*

• Life

Henry David Thoreau was born in Concord, Massachusetts, on July 12, 1817. At the age of eleven, he was sent to Concord Academy. Upon graduation, he entered Harvard University and received a bachelor's degree in 1837. After completing his degree, Thoreau had a very brief career in teaching (at Concord Academy). He was fired from the academy, because he refused to use corporal punishment in dealing with the students. He opened a school with his brother, showing his interest in nature by introducing the concept of nature walks to the students.

After four years and the death of his brother, Thoreau closed the school and returned home to join his family's pencil-making business. While at home, he became friends with a community of writers, including Ralph Waldo Emerson and Nathaniel Hawthorne. They encouraged his writing and urged him to publish his works. After a canoe trip, he came to realize that his true interests were nature and poetry. His first published work was entitled "Natural History of Massachusetts" (1842). From 1841 to 1844, Thoreau lived with the Emerson family, as a tutor for the children. In July of 1845, he moved to a small cabin that he had built on the shores of Walden Pond, on land owned by his friend Emerson. He remained there until September of 1847 and spent the subsequent seven years writing and revising his description of his twenty-six months there. This book, *Walden: Or, Life in the Woods* (1854), became his best-known work. He continued to explore nature and write throughout his life, dying in 1862 at age forty-four of sequelae of tuberculosis.

• Climate Work

In the journal he kept during his twenty-six months in solitude, Thoreau recorded information about what he saw in the landscape around Walden Pond during the 1840's. He recorded the migration patterns of birds, the flowering cycles of plants, and observations about wildlife and temperature. Modern-day researchers in Walden are replicating the work of Thoreau, using field notebooks and carefully recording the dates and times when flowers bloom and when birds return each migrating season. By comparing these current data with those obtained by Thoreau, one can determine whether global warming is influencing the behavior of plants and wildlife in this area of New England.

Following his time at Walden Pond, Thoreau remained extremely interested in travel and nature. He became a surveyor and kept very detailed notes on his natural history observations. These notes served as the basis for several of Thoreau's essays dealing with nature. In these essays, Thoreau argued for the necessity of conserving natural resources and preserving wilderness for the good of the planet. For instance, in his essay "Wild Fruits" (pb. 1999), he strongly argued for preserving the wilderness for the good of humankind.

In other essays, Thoreau discussed the destruction of various species (such as wild apples) caused by interference from humankind. He explained how forests were being destroyed through the acts of people or accidentally by fire, and

Generosity at the Roots

In A Week on the Concord and Merrimac Rivers *(1895), Henry David Thoreau described the superiority of nature to human art, locating a great part of it in the sense of boundless abundance in even a sparse wilderness—a sense that would come to seem ever more fragile and endangered in the next century.*

Art can never match the luxury and superfluity of Nature. In the former all is seen; it cannot afford concealed wealth, and is niggardly in comparison; but Nature, even when she is scant and thin outwardly, satisfies us still by the assurance of a certain generosity at the roots. In swamps, where there is only here and there an evergreen tree amid the quaking moss and cranberry beds, the bareness does not suggest poverty. The single-spruce, which I had hardly noticed in gardens, attracts me in such places, and now first I understand why men try to make them grow about their houses. But though there may be very perfect specimens in front-yard plots, their beauty is for the most part ineffectual there, for there is no such assurance of kindred wealth beneath and around them to make them show to advantage. As we have said, Nature is a greater and more perfect art, the art of God ; though, referred to herself, she is genius; and there is a similarity between her operations and man's art even in the details and trifles. When the overhanging pine drops into the water, by the sun and water, and the wind rubbing it against the shore, its boughs are worn into fantastic shapes, and white and smooth, as if turned in a lathe.

how they regenerated afterward when winds or animals spread seeds. In *The Maine Woods* (1864), Thoreau pointed out the important need for forest conservation. Through his work as a naturalist and a prolific author, he helped make the world aware of the need for conservation of resources in order to preserve the planet and avoid inadvertent changes in the environment. Many such changes have since led to global warming. Researchers replicating Thoreau's work at Walden Pond are investigating these changes. By comparing the dates when seasonal changes occurred in the 1840's to the dates of the same changes in the present, scientists are gathering data relevant to understanding global warming.

Thunderstorms

• Category: Meteorology and atmospheric sciences

• Definition

Thunderstorms can be both beneficial and detrimental. Normally formed under warm summertime conditions, they can bring needed rainfall to dry, parched soils. They can also, however, deliver rain with such force that it can cause severe soil erosion and property damage by flooding. Additionally, hail from these storms can wipe out crops and kill people and livestock. Each year, thunderstorms cause over a billion dollars' worth of damage to property, livestock, and crops in the United States. Tornadoes and other high wind events can also be spawned by these storms. However, lightning associated with thunderstorms is the major severe-weather-related cause of death in the United States. More deaths occur from lightning each year than from severe winter storms, hurricanes, and tornadoes combined. Thunderstorms are also associated with flash flooding, another major cause of U.S. weather-related deaths. Over one hundred U.S. deaths occur each year as a result of flash flooding due to thunderstorms, more than the average annual death count associated with tornadoes.

Worldwide, over two thousand thunderstorms are active at any given time. The basic preconditions for a thunderstorm are heat, instability, and moisture. Insolation from the Sun (heat) warms the land but does so inconsistently within the target zone of the storm. Some land surfaces may warm faster than others, creating pockets of warm and cool air. Where this differential heating warms the atmosphere, the air begins to rise, expand, and cool adiabatically. This rising, unstable air releases heat, which in turn generates greater atmospheric instability, more adiabatic cooling, and additional condensation. As this cycle continues, the storm builds.

Thunderstorms develop through a series of stages. The first stage is the cumulus or towering cumulus stage. Cumulus clouds are "cotton ball" type clouds, usually associated with fair weather.

Lightning strikes during a thunderstorm in Budapest, Hungary, in June of 2009. (Reuters/Landov)

However, these clouds develop as a result of atmospheric instability and differential heating. During the cumulus stage, updrafts lift the air to levels at which condensation occurs, sometimes accompanied by precipitation. As precipitation begins to fall from the upper portions of the cloud, the mature stage emerges. This stage is characterized by both an updraft and a downdraft component within the storm. From its beginnings to the mature stage, the storm may reach as high as 6,096 meters.

As the storm develops, more precipitation falls. This precipitation cools the lower levels of the storm and cuts off its updraft component. This dissipating phase is the final stage in storm development. Thunderstorms can spawn other storms around themselves as their gust fronts—cold air flowing out of the main tower of the storm—mechanically lift warm air in the vicinity of the main storm. Thunderstorms at their full development can reach upward to over 12,200 meters. Winds from these storms can range from mild to severe. Downbursts and straight-line winds emerging from the gust front can reach over 97 kilometers per hour. Tornadoes from these storms can produce winds from 64 kilometers per hour to in excess of 312 kilometers per hour.

Thunderstorms can be classified into four general types: single cell storms; multicell, or cluster, storms; multicell lines; and supercell storms. These classifications relate to the characteristic structure of the storm, its duration, and its severity. Single cell storms are rare but can produce 20- to 30-minute storms. Multicell storms contain more than one storm in a cluster. Each storm is in different stages of development. Line storms are multicell clusters associated with squall lines and are notorious for producing heavy rain, large hail, and sometimes tornadoes. The supercell is a single cell multiple kilometers across. The energy of these storms can rotate the storm, producing a mesocyclone. Although rare, supercells pose the greatest threat of damage.

High downburst winds in excess of 128 kilometers per hour are possible, along with baseball-sized hail and violent tornadoes.

• Significance for Climate Change

Additional heat added to the lower atmosphere through general warming of the climate might contribute to an increase in atmospheric instability; however, moisture must be present to generate a thunderstorm. Some studies suggest that precipitation in the tropics, a region known for thunderstorms and atmospheric instability, has increased as a result of warming temperatures. However, the increase in precipitation tends to be over oceanic areas rather than continental regions. In contrast, some climate models suggest that although fewer storms may occur over continental areas, their intensity may be increased by global warming—albeit without accompanying precipitation.

With some areas of the world expected to become drier as the climate changes, so-called dry storms could develop, producing more wind and more lightning. If warming is accompanied by drought, the potential for wildfires fueled by lightning could increase. Additionally, some models suggest that wind shear, the lateral movement of the wind, would give way to more violent updraft conditions. It is generally understood that the combination of wind shear and updraft has the potential to produce tornadic conditions in these kinds of storms. Some climatologists suggest that given the complexity of the physical geography and atmospheric environment, predicting the potential for increased tornadoes in these kinds of storms is not possible.

Tidal power

• **Category:** Energy

• Definition

Of all the ways that humans have sought to obtain power from the sea, harnessing tidal movements has proved the most effective. A traditional tidal power installation requires a dam or barrage placed across a natural bay or river, behind which a large amount of water can be stored. The vertical distance between low tide and high tide must be at least 5 meters, and it is helpful to have a major population center nearby in order to minimize transmission requirements.

At high tide, seawater is impounded behind the dam, producing a hydrostatic head. Then, as sea level falls, electric power is generated as the impounded water moves seaward through the dam's turbines. The world's largest tidal installation of this type is the La Rance power plant on the Rance River in France, which produces 240 megawatts of power. It also has turbines that can be reversed by 180°, so it can generate power on a rising tide as well as when the tide falls. Power can be generated only sixteen to eighteen hours per day, however, as power generation is impossible at slack water. A second major tidal power plant is on the Annapolis River in Nova Scotia. It produces 20 megawatts of power. Smaller plants are located in Russia and China, but their power generation is believed to be 5 megawatts or less.

Because few locations meet the requirements to

La Rance tidal power station, in Brittany, France. (Philippe Cherel/Maxppp/Landov)

harness tidal power using a dam or barrage, offshore turbines have begun to be introduced. They look exactly like the well-known wind farms on land but are anchored underwater in narrow channels that experience strong current flows during the tidal cycle. An early installation consisted of six turbines anchored in 9 meters of water offshore from New York City in the East River. The power generated was added to the city's power grid, but so far the amount has been small. Other installations have either been built as prototypes or are in the planning stages in Canada, Ireland, Scotland, and Norway.

- **Significance for Climate Change**

Environmental concerns are one of the reasons that more traditional tidal power plants have not been built. The Bay of Fundy, for example, which lies between Nova Scotia and New Brunswick in eastern Canada, has the greatest tide differential in the world, averaging more than 15 meters between low tide and high tide, yet no tidal power plant has ever been built here. Some of the environmental concerns preventing such a plant's construction are the potential impact on fisheries and shellfish, the potential damage to bird populations that feed on the tidal mud flats at low tide, and potential changes in the tidal basin behind the dam, such as reductions in water quality due to less flushing, altered tidal cycles, or damaging high-speed currents.

Environmental changes have already been reported from the Rance River, where tidal patterns have been disrupted, high-speed currents have developed around the barrage, and fish stocks have been affected. Construction of the Annapolis River plant has also caused problems. Shellfish beds upstream from the dam have been destroyed, there is increased erosion and flooding due to higher river levels, and lawsuits have resulted from damage to private property. Even offshore turbine installations may have environmental consequences, such as damage to boats and marine life, as well as harmful changes in a channel's currents or the tidal cycle.

Future climate changes will cause even more problems. Because land-based tidal power plants are located at sea level, warming temperatures will flood them as sea levels rise, while falling temperatures will leave them stranded inland as sea levels fall. In addition, higher sea levels will bring damaging waves, especially during storm surges and hurricanes. Underwater installations will be less affected, but locations that are favorable for power generation today may become useless as the shoreline configuration changes. On the other hand, new locations favorable for power generation may appear.

Damage to tidal basins upstream from established tidal power plants will also occur, especially with a rise in sea level. River banks may be eroded, and land may be lost as a result of permanent inundation. Destruction of personal property and loss of life may result as well. In addition, some scientists anticipate damaging saltwater intrusion into wetlands, agricultural soils, and coastal well fields. Tidal patterns may even change upstream and downstream from the tidal power plant, resulting in higher tidal levels; flooded coastal lands; and threatened roads, bridges, structures, wells, sewage systems, salt marshes, and harbors, all of which would result in higher operating costs.

Tornadoes

- **Category:** Meteorology and atmospheric sciences

- **Definition**

A tornado is a violently rotating column of air that is in contact with both the surface of the Earth and, usually pendant (held from above) to a cumulonimbus cloud, or, in very rare cases, the base of a cumulus cloud. It nearly always starts as a funnel cloud and may be accompanied by a loud roaring sound, most often compared to that of a speeding freight train. The funnel, initially filled with visible condensation (due to water vapor becoming visible due to cyclostrophic balance) and later with dirt and debris picked up along its path, has a narrow end that touches the ground.

The funnel cloud often is seen as it forms in the sky, it can stay on a continuous path or take on the effect of a bouncing motion, the latter can be seen from news reports that show several houses on either side of a fairly intact building demolished to their foundations. On a local scale, according to the National Oceanic and Atmospheric Administration (NOAA), a tornado is the most destructive of all atmospheric phenomena.

The majority of tornadoes have wind speeds ranging from 64 to 177 kilometers per hour, are approximately 75 meters across, and travel a few kilometers before breaking up and dispersing. Some tornadoes can achieve wind speeds greater than 480 kilometers per hour and stretch in excess of 1.5 kilometers across. Massive tornadoes such as these can stay on the ground for dozens of kilometers; a particularly devastating tornado in Illinois stayed on the ground for over 60 kilometers, killing almost two dozen people and destroying the then newly built subdivision of Plainfield, within 48 kilometers of the Chicago city limits.

Tornadoes occur primarily in the United States, although they have been spotted on every continent excluding Antarctica. Other global sites of common occurrence are in southern Canada, southern Africa near Johannesburg, central Asia, east-central South America, as well as in several areas of Europe, southeastern Australia, and New Zealand.

3	218-266
4	267-322
5	over 322

Source: Storm Prediction Center, National Oceanic and Atmospheric Administration.

*Three-second gust, in kilometers per hour, estimated at the point of damage.

Types of tornadoes include the multiple vortex tornado (which has two or more funnel clouds), the satellite tornado (as the name suggests, a smaller vortex of wind which circles the main tornado), waterspouts, and land spouts (the last being extremely rare).

The most extreme tornado in recorded history was the Tristate Tornado, which left a path through Missouri, Illinois, and Indiana on March 18, 1925. The Fujita scale, ranging from F1 to F5 and based on the amount of damage caused, is considered to be an F5, although the Fujita scale was not a measurement at that time. This tornado was officially on the ground for 352 kilometers and produced a death toll of nearly seven hundred.

The most extensive outbreak on record (in almost every category) has been labeled the Super Outbreak, affecting the central United States in 1974. For eighteen hours, between April 3 and 4, 148 tornadoes touched ground, 6 were considered F5, and 24 were F4. At the peak of the outbreak, 16 tornadoes were on the ground simultaneously; over three hundred people were killed.

• Significance for Climate Change

Tornadoes are most common in cool seasons, such as early spring and early autumn. An increase in the surface temperatures of the sea (regions of origin such as the Mediterranean Sea and the Gulf of Mexico) increases moisture content, fueling an increase in tornado activity.

Climatic shifts affect tornadoes via teleconnections and shift the jet stream and, therefore, any larger weather patterns. Also, although insufficient support exists to make conclusions, evidence does suggest that El Niño and La Niña can have atmospheric effects ideal for tornado formation.

Possible effects from global warming: there are opposing views towards climatic changes, ranging from global warming being the cause for tornado droughts to an upsurge in more violent storms, as well as funnel clouds forming with more frequency over major metropolitan areas.

In the thirty-county warning area of southeastern Nebraska and north-central Kansas, a prime "tornado alley" in the midwestern United States, there was not a single confirmed tornado for the first six months of 2008. As global warming continues, certain areas will receive more storms, while others will experience less. The National Weather Service could be adversely affected by the absence of twisters, as the area mentioned above may consider discontinuing the NEXRAD radar service, while still utilizing Doppler radar from scattered locations.

In 2007, NASA scientists developed a new climate model that indicates more tornadoes because there will be more rainstorms in a warmer climate. The model was applied to a hypothetical future climate with double the current carbon dioxide level with a surface 2.5° Celsius warmer than the current climate. The central and eastern United States are more prone to severe storms based on this model.

The tornado outbreak—91 in total—of February 5, 2008, in the southeastern United States occurred when record highs were recorded in dozens of cities, 24° Celsius in Memphis as an example, while the Great Lakes area still suffered under winter storm watches with temperatures near freezing. In June of 2008, seven funnel clouds were recorded over Tinley Park, Illinois, a highly populated suburb just 16 kilometers south of Chicago. This is in comparison to the 1989 tornado that destroyed Plainfield, Illinois, the storm breaking up as it went from a primarily rural to a well-populated, urban area. Other tornadoes of record over major population centers include one near downtown Salt Lake City, Utah, in 2004, and one near Dallas, Texas, in 2007.

Trace gases

• **Categories:** Chemistry and geochemistry; meteorology and atmospheric sciences

• **Definition**

Trace gases are gases that exist at low concentrations in an atmosphere, generally less than one part per thousand. The bulk of Earth's atmosphere is made up of "permanent" gases—molecular oxygen and nitrogen—and argon, as well as the "variable" gas water vapor. In addition to these gases, thousands of trace gases are present, including many compounds of such common elements as carbon, sulfur, nitrogen, oxygen, and hydrogen. The atmosphere also contains small amounts of the halogens (fluorine, chlorine, bromine, and iodine) and the noble gases (helium, neon, krypton, and radon), as well as very small quantities of some metallic species such as mercury.

Each of the elements carbon, nitrogen, sulfur, and the halogens exists in numerous forms, ranging from fully reduced (that is, bound to the maximum possible number of hydrogen atoms) to completely oxidized (that is, bound to the maximum possible number of oxygen atoms). Carbon, for example, may exist within methane (CH_4, its fully reduced form) or carbon dioxide (CO_2, its fully oxidized form). Between these two extremes, the element is found in such other species as formaldehyde (H_2CO) and methanol (CH_3OH). Carbon can also be found within larger species containing two or more carbon atoms, including volatile organic compounds.

Hydrogen sulfide (H_2S, the gas associated with the smell of rotten eggs) is the fully reduced form of sulfur, and sulfuric acid (H_2SO_4) is the most oxidized form that is stable in the atmosphere. Nitrogen can be found as ammonia (NH_3, the most reduced form), nitric oxide (NO), nitrogen dioxide (NO_2), the nitrate radical (NO_3, the most oxidized) or other species such as nitric acid (HNO_3). Likewise, the halogens can be found bound to hydrogen or oxygen, as in hydrochloric acid (HCl), chlorine dioxide (ClO_2), and chlorine monoxide (ClO), which play a key role in destruction of the stratospheric ozone layer. (While molecular oxygen, O_2, is a permanent gas, ozone, O_3, is a highly variable and important trace gas.)

Most metals are present in gaseous form only very briefly if at all. Because they have very low volatility, if metals are released in their gas phase (usually in a hot combustion plume), they very quickly enter the aerosol phase. A notable exception is mercury, which has a sufficiently high volatility that its gas phase concentration typically exceeds its aerosol concentration. Most trace gases have both natural and human sources.

• **Significance for Climate Change**

Numerous trace gases have impacts on the Earth's changing climate, some large and others small. All of the major greenhouse gases (GHGs) released by human activities—including CO_2, methane, ozone,

Major GHGs

Gas	*Pre-1750 Concentration (ppb)**	*2008 Concentration (ppb)*	*Global Warming Potential*	*Lifetime (years)*
CO_2	280,000	383,900	1	~100
CH_4	700	1,735-1,857	25	12
N_2O	270	320-321	298	114
O_3	25	34	n/a	days

Data from the Carbon Dioxide Information Analysis Center, Oak Ridge National Laboratory.

*ppb = parts per billion.

and the chlorofluorocarbons—are trace gases. Trace gases make up a tiny fraction of the gases in the atmosphere, currently less than 0.05 percent combined, although this value is creeping up as CO_2 levels rise. However, they have large and disproportionate impacts on several properties of the atmosphere. Trace gases contribute significantly to the strength of the greenhouse effect, the degree to which the atmosphere traps heat received from the Sun. They also influence the rate at which pollutants emitted from the Earth's surface react and are removed from the atmosphere, the thermal structure of the atmosphere, and the healthfulness of the air.

Although present only at very low concentrations, trace species can have such significant effects because the permanent gases behave as though they are not there. Because molecular nitrogen and oxygen are both pairs of identical atoms and argon is a single atom, the permanent gases cannot absorb heat (far infrared light). As a result, all of the energy released by the Earth is available to be absorbed by the trace gases, as well as water vapor. The permanent gases also do not absorb visible light, although most of the trace gases do not either, so this distinction has limited climate importance. However, more than half of the incoming sunlight falls in the region of the electromagnetic spectrum just beyond red (near infrared), which the permanent gases absorb only slightly but CO_2, ozone, and water vapor all absorb strongly.

Nitrogen and argon are unreactive, and oxygen is only mildly reactive, so the chemical reactions of the trace gases are free to dominate the chemistry of the atmosphere. This situation has many climate implications, because it controls the concentrations and lifetimes of most of the anthropogenic pollutants released into the atmosphere.

Throughout most of the lower 90 kilometers of the atmosphere, the average temperature is controlled by atmospheric pressure. At higher altitudes, the pressure decreases. As it does, the air becomes markedly colder by an average of 9.6° Celsius per kilometer increase in altitude. This trend reverses briefly in the stratosphere, however. In this region, the atmosphere becomes warmer with altitude as a result of the stratospheric ozone layer. There is sufficient ozone in this layer to trap a large fraction of the incoming sunlight, heating the air with the Sun's energy. Above the stratospheric ozone layer is the mesosphere, where the atmosphere again cools with rising altitude.

Toxic air contaminants impact climate indirectly, but in some instances significantly. Urban ozone, acid rain, dry acid deposition, and other toxic pollutants can affect forest health for hundreds of kilometers downwind of their sources. Forest ecosystems may die off as a direct result of airborne pollutants. They may also be weakened by pollution, decreasing their ability to resist pests, which in turn may result in loss of forest biomass, either directly or by increasing susceptabilty to fires. Further, the transport and eventual deposition of nitrogen from combustion sources can change substantially the quantity of available nitrogen in soils, which in turn can cause changes in species distributions, net biomass, and fire frequency—again, for hundreds of kilometers downwind of major sources.

Transportation

• **Category:** Economics, industries, and products

• **Definition**

Transportation is a means to facilitate spatially separated activities: for example, individuals travel to work or for leisure purposes; firms ship raw goods or finished products to clients or distribution centers, and employees travel for business. A small percentage of travel occurs for its own sake, such as walks in parks. The most common modes of personal urban transportation are the automobile, public transportation (buses, rail modes, ferries), motorcycles, bicycles, and walking. Personal intercity travel is commonly associated with intercity rail and buses, airplanes, ships, and the automobile. Freight transportation generally distinguishes between trucks, rail, pipelines, airplanes, ships, and barges.

Individual and freight transportation are the backbone of national and international economic activity and can provide benefits to businesses, individuals, and the nation. Transportation can positively impact employment, product prices, and economic growth. Population growth, increasing incomes, more spread-out land uses, and longer distances between activities have contributed to more than a quadrupling of global car ownership and use since 1950.

In 2006, the United States had the highest motor vehicle ownership rate in the world: 776 cars and light trucks per 1,000 population, compared to 97 cars per 1,000 population globally. In 2001, almost 90 percent of all personal trips in the United States were made by automobile, and Americans traveled roughly 24,000 kilometers by car annually. Wealthy European and Asian countries also had high levels of automobile ownership, but public transportation, walking, and cycling accounted for up to 50 percent of personal trips in those countries. Automobile ownership is predicted to increase rapidly in developing countries such as China and India. Transportation and spatial development patterns are closely connected. Faster motorized modes of transportation allow more spread-out human settlements. Low-density settlements in turn necessitate motorized modes of transportation.

• **Significance for Climate Change**

According to the Oak Ridge National Laboratories (ORNL) and the United States Department of Transportation (USDOT), in 2006, transportation was a principal source of greenhouse gas (GHG) emissions, accounting for about 20 percent of all GHG emissions globally and roughly 30 percent of U.S. emissions. Transportation contributes to climate change mainly through the burning of fossil fuels.

Compared to the residential, industrial, and commercial sectors, transportation is uniquely dependent on petroleum. ORNL reports that, in 2006, over 98 percent of all energy used in the transportation sector in the United States was petroleum based. CO_2 emissions accounted for almost 99 percent of all transportation-related GHG emissions. According to the International Energy Agency (IEA), transportation accounted for 23 percent of CO_2 emissions from fuel combustion worldwide, compared to 30 percent in the United States. Within the transportation sector, road transportation accounted for roughly 70 percent of CO_2 emissions from fuel combustion worldwide and 80 percent in the United States. Even among developed nations, the United States is uniquely dependent on the automobile and petroleum-based fuels.

ORNL and USDOT estimate that over 60 percent of all U.S. transportation-related GHG emissions come from automobiles, sports utility vehicles (SUVs), and light passenger trucks; only 20 percent of such emissions are attributable to medium and heavy trucks. Airplanes account for 8 percent and rail, water transportation, and pipelines for another 7 percent of transportation-related GHG emissions.

According to the IEA, global CO_2 emissions from transportation increased by 37 percent from 1990 to 2004, compared to an increase of 26 percent in the United States. In 2004, CO_2 emissions from transportation sources per capita in the United States were three times higher than those of European countries and six times higher than the global average. Even adjusting for economic activity, CO_2 emissions from transportation per unit of gross domestic product (GDP) were 60 percent higher in the United States than in Europe. USDOT predicts a doubling of energy-related CO_2 emissions in China and India from 2004 to 2030, partly fueled by increasing motorization there.

Transportation-related GHG emissions depend on the level of transportation activity (including number of trips and distance traveled), the mode of transportation (motorized or nonmotorized), and the fuel type and its carbon intensity. Reductions in transportation-related GHG emissions can be achieved through technological and behavioral changes. Technological innovation can improve vehicle efficiency and increase the viability of low-carbon or noncarbon fuels. Changes in behavior can reduce the total amount of travel and increase the share of trips on foot, by bike, or by public transportation.

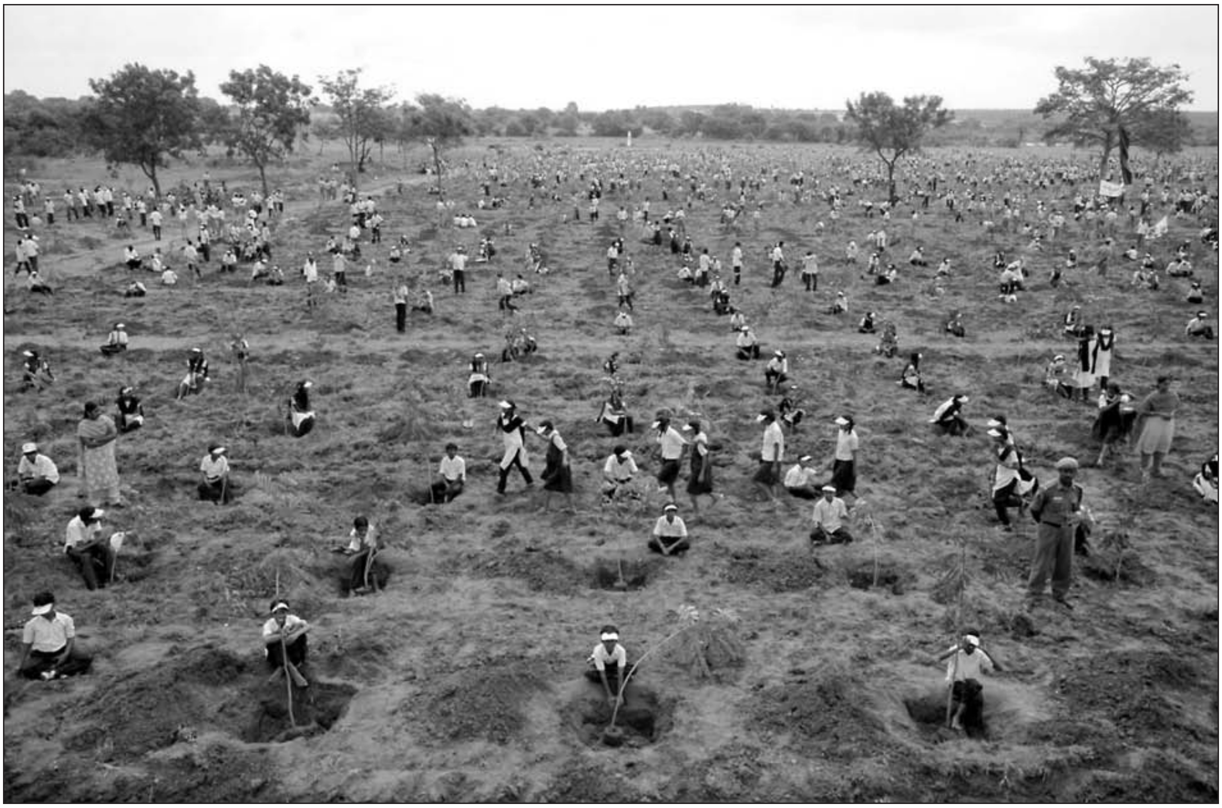
Tree-planting programs

• Categories: Environmentalism, conservation, and ecosystems; Plants and vegetation

• Definition

One of the environmental and economic benefits of trees is their potential to mitigate climate change by absorbing carbon as they grow. Many tree-planting programs exist worldwide, from village-scale community efforts to massive undertakings by the United Nations, national governments, and corporations. These programs vary widely in their approach and their goals. Rarely is climate mitigation the sole motive for tree-planting programs, but it is becoming increasingly important.

Tree-planting falls into several different catego-



Children from Hyderabad, India, participate in a day of tree planting coordinated by the Hyderabad Urban Development Authority. (Krishnendu Halder/Reuters/Landov)

ries defined by prior land use of the planted area. Reforestation is the planting of trees to replace those that have been destroyed by logging, agriculture, fire, or other disturbances. (Without human intervention, the regeneration of a forest is usually termed "forest regrowth.") Afforestation is the planting of a trees on land that was not historically forested. Agroforestry is the integration of trees and agricultural crops on the same land. These definitions may blur or overlap, such as when regrowth is promoted by management practices. Tree-planting often occurs without the need for special programs or incentives; for example, commercial timber operations reforest cleared land to ensure a steady timber supply.

• Significance for Climate Change

Reforestation, afforestation, and agroforestry programs can play a major role in combating climate change, sequestering 10 to 20 percent of global greenhouse gas (GHG) emissions by 2050, according to a 2001 estimate by the Intergovernmental Panel on Climate Change (IPCC). However, estimating the climate benefit of a given project is a technically complex undertaking. The impact depends not only on the number of trees planted, but also their survival and growth rates, their average lifespan, their contribution to soil carbon, their effects on evapotranspiration and surface albedo, and other factors. These factors can be difficult to measure, especially when the tree-planting is implemented on a community scale by many participants. Some standard metrics have been developed, but assumptions and reporting vary greatly.

Under current rules, tree-planting schemes rarely qualify for international funding through the clean development mechanism (CDM) of the Kyoto Protocol. Thus, tree-planting programs that focus on carbon sequestration seek to fund their work through voluntary "carbon offset" payments from individuals and organizations. Such programs include Fondo Bioclimatico in Mexico and the International Small Group and Tree Planting Program (TIST) in East Africa.

Climate mitigation is not the only or even the foremost motivation for tree-planting. Many programs (such as Trees for Life and Trees for the Future) predate widespread concern about global warming. Even programs focused on climate usually acknowledge and pursue other benefits, such as food security, income generation, and wildlife habitat.

Tree-planting campaigns are often run by national governments. The United States was the first country to declare a national tree-planting day, Arbor Day, created in 1872 to promote soil and water conservation. Similar holidays are now observed in dozens of countries as diverse as the Philippines, Venezuela, Belgium, and Algeria. Some countries have year-round initiatives, such as Costa Rica, which in 1996 created a national forestry fund to compensate farmers for protecting and replanting the "cloud forests" upon which the country's hydrology and biodiversity depend.

Nongovernmental organizations (NGOs) also play a major role in tree-planting efforts. A notable example is the Green Belt Movement (GBM), founded by Wangari Maathai, who won the 2004 Nobel Peace Prize for her work. GBM began in Kenya, training women to grow and distribute tree seedlings in their communities, and later expanded to reforestation of public land. Maathai went on to inspire the Billion Tree Campaign, an initiative by the United Nations Environment Programme to coordinate tree-planting efforts worldwide. As of early 2009, nearly 3 billion trees had been planted by 155 participating countries.

Although tree-planting is sometimes perceived as a universal good—for the climate and for other reasons—it is subject to many social and ecological pitfalls. Inappropriately planted trees can disrupt water flows, invade ecosystems, and disempower communities. Furthermore, tree-planting cannot fully substitute for the preservation of mature natural forests, which usually contain not only greater carbon stocks but also unique biological and cultural value.

Tree rings

- **Category:** Plants and vegetation

- **Definition**

Tree rings, also known as growth rings or annual rings, are visible in the woody stems of trees. A woody stem is composed of cells collectively known as secondary xylem. These cells are responsible for moving water and nutrients upward in the plant and provide support for the aboveground portion of the tree.

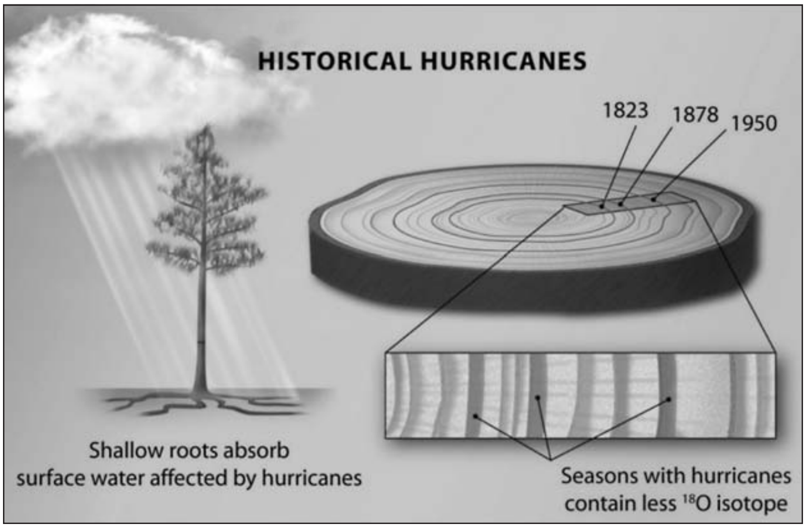
Tree rings are formed by the production of cells of different widths. When growing conditions are more optimal, as is typical in the earlier part of the temperate growing season, the diameters or width of the cells are large and the cells appear light to the naked eye. This growth is typically called early wood. During less optimal growing conditions or later in the season, the diameters of the conducting cells are smaller and more fibers for support are produced. Both fibers and the conducting cells produced in the later portion of the growing season (or under less desirable environmental conditions) are smaller in size and have thicker walls than do the cells in the early wood. Because the cells are smaller and the walls are thicker, the wood appears darker to the eye. This darker, denser wood is often called late wood. Bands of lighter, early wood alternating with bands of darker, denser wood creates the appearance of rings in a cross-section of a tree.

In temperate areas with distinctive seasons, trees typically produce one ring for each growing season. Scientists are able to determine the age of a tree by examining the number of rings in the trunk of the tree. Since the width of the ring correlates to the quality of the growing season, one can infer past climatological information by measuring the width of the growth rings. The information gathered represents localized conditions for that species in that particular environment. In tropical areas, the growth in trees is more continuous and the use of rings to determine age and climatic conditions is less reliable.

Numerous factors contribute to the overall quality of a growing season. Environmental factors include moisture, temperature, nutrient availability, sunlight, carbon dioxide (CO_2) availability, wind, and pollution. Researchers have shown that the width of a ring in most trees is most closely associated with temperature and moisture availability. The age of the tree, competition with other organisms, herbivory, and disease can also influence the growth of a tree.

- **Significance for Climate Change**

Changes in climate affect tree growth. Increasing levels of CO_2 have been shown to enhance the rates of photosynthesis and improve water efficiency in some tree species. This enhancement, however, has been observed in laboratory and modified field environments, for relatively short periods of time (up to three years), on seedlings, under weed-free and insect-free conditions. It is uncertain whether the same result would occur under field conditions with older trees. Enhanced growth would poten-



Because hurricane precipitation contains less oxygen 18 than does most other precipitation, tree rings low in this isotope can be used to construct a record of hurricanes in a given area. (National Science Foundation/Zina Deretsky) tially result in the accumulation of more wood through the production of wider rings.

With increasing CO_2 concentrations and global warming, temperatures are increasing. It is likely that this temperature increase will affect the composition of tree species in some ecosystems. Ranges for many tree species are likely to be extended and will decrease for those species adapted to cooler environments. Temperature is likely to affect conditions such as fire, drought, wind, and ice, thus influencing the growth of trees.

In addition to atmospheric warming, warming of the soil will affect the growth of trees. Research has shown that root growth and root turnover is enhanced with elevated CO_2 and temperatures. Much of the carbon in a tree is stored within its roots. Enhanced root growth might provide additional nutrients for the plant. In addition, as temperature increases, leaf litter decomposition also increases, which in turn increases the cycling of nutrients to the organisms growing in the soil.

Besides increases in CO_2 and temperature, other climatic factors are increasing that could have a significant impact on tree growth. Two such factors are ozone and sulfur. Both have been studied extensively, with seemingly conflicting results. Trees have been shown to be susceptible to increasing levels of ozone and acid rain (the latter produced from sulfur in the atmosphere). This has been well documented in the laboratory, in modified field experiments, in individual field observations, and in highly polluted localized areas. A difference in susceptibility among tree species has also been documented. In mixed forests, some tree species are damaged by acid rain, ozone, and other pollutants, while other species in the forest remain seemingly unaffected.

It has been more difficult for researchers to link pollutants with the decline of entire forests. The most dramatic and best-documented example of the impact of acid rain on a forest is the devastation of the Black Forest in Germany. Clearly the potential for damage by pollutants exists and is a reality in some areas, but additional field research and careful monitoring are needed to understand forest ecosystems and the levels at which pollutants are significantly impacting the ecosystem.

Tropical climate

- **Category:** Meteorology and atmospheric sciences

- **Definition**

The tropics are the equatorial region between the Tropic of Cancer (23.5° north latitude) and the Tropic of Capricorn (23.5° south latitude). Because of an atmospheric circulation pattern known as the Hadley circulation, the tropics tend to be warm and wet. This region contains a variety of ecosystems, including deserts, rain forests, savannas, and several islands. Although each of these ecosystems resembles the others in having hot weather (with the exception of a few mountains, such as Kilimanjaro in Tanzania, which lies only a few degrees south of the equator), they differ widely in average annual rainfall. In parts of Asia, Latin America, and Africa, rain forests are common, with average rainfall of more than 250 centimeters per year. The Sahara Desert also falls within the tropics, and it has some of the driest climate in the world. Some savanna regions, such as those in Kenya, have moderate amounts of rainfall. Indeed, some savannas are at a high enough altitude that they have a fairly wide daily temperature range during some parts of the year. The tropics also include several important coral reefs, such as those off the northern coast of Australia.

• Significance for Climate Change

One aspect of concern related to global climate change is that many of the tropical nations are among the poorest on Earth. These developing nations will be less able to adapt to climate change than the industrial nations of Europe and North America. All of the scenarios generated by the researchers connected with the Intergovernmental Panel on Climate Change (IPCC) indicate that global warming will have less of an impact on the temperature of the tropics than on the temperatures of regions at higher latitudes. Nonetheless, even minor temperature changes coupled with other factors can produce dramatic results.

In 1912, the average snow cover on Mount Kilimanjaro was 12 kilometers thick, yet by 2007 the snow cover had decreased to an average of only 1.5 kilometers thick. If the climate warms, in some places rainfall is expected to increase a great deal, while in other regions, such as northern Australia, drought conditions will intensify. In tropical rain forests in parts of Africa and South America, the intensity of rainstorms is predicted to increase, causing further erosion in cleared regions of the forests. Because many tropical ecosystems are quite fragile, even small changes in temperature, precipitation, and wind patterns will produce large adverse impacts on the affected nations. The major impacts in the tropics will come less from direct increases in temperature and more from changes in precipitation patterns, wind currents, and indirect impacts combining these two with temperature increases.

The impact of climate change on the tropics will differ from region to region, but it will become increasingly severe as global warming increases. For example, the IPCC projects that a 3° Celsius increase in global temperature will lead to a major loss of tropical rain forests, and, with this increase, as many as one-third of all species will become extinct. A 4° Celsius increase in temperature could lead to as many as 70 percent of all species worldwide, many in the tropics, becoming extinct. A temperature increase of this magnitude is also likely to lead increased acidification of the oceans and the bleaching and ultimate death of most coral reefs, many of which are found in the tropics.

Increased rainfall and the resulting runoff in countries such as Bangladesh would lead to extensive flooding, a problem exacerbated in Bangladesh by coastal flooding. Coastal flooding in southern India is projected to threaten the water supplies of many communities by the latter part of the twenty-first century. Because most hurricanes are found in the tropics, tropical peoples have long been concerned by the number and magnitude of hurricanes. Several scientists predict that increasingly warmer oceans would be likely to spawn more hurricanes and cyclones of greater magnitude than in the past.

A combination of climate change and concomitant socioeconomic changes is likely to produce several negative social and economic effects for societies in the tropics. In Nigeria, for example, many people may be forced to migrate from the interior to already-crowded coastal cities. Increasing temperature combined with precipitation changes (either too little or too much) are likely to have a negative impact on the food supplies of tropical regions. In some cases, diseases such as malaria are likely to become more common because of increased standing water.

The various scenarios for climate change accepted by most scientists project an average increase in temperature of between 3° and 7° Celsius by the end of the twenty-first century. Although the temperature is projected to increase less in the tropics than in the temperate zones, the impact is likely to be severe. Many tropical nations lack the resources to adapt to climate change, so there is likely to be widespread suffering, in addition to extensive ecosystem damage.

Tropical storms

- **Category:** Meteorology and atmospheric sciences

Hurricanes thrive in warm water, weakening if sea surface temperatures fall below 27° Celsius. Partly for this reason, the possible effects of global warming upon hurricanes—particularly their frequency and intensity—is a subject of intense debate.

- **Key concepts**

El Niño-Southern Oscillation (ENSO): an ocean-circulation pattern that warms the Pacific Ocean west of Peru, affecting world weather

hurricane: a severe oceanic cyclonic storm in the Atlantic Ocean—called a typhoon in the Pacific Ocean and a cyclone in the Indian Ocean

La Niña: an ocean-circulation pattern that cools the Pacific Ocean west of Peru, affecting world weather

thermodynamic disequilibrium: a state of instability in the energy distribution of a system; indicative of tropical storm intensity

West African monsoon: a seasonal climatic variation that can affect hurricane intensity and frequency in the Atlantic Ocean

- **Background**

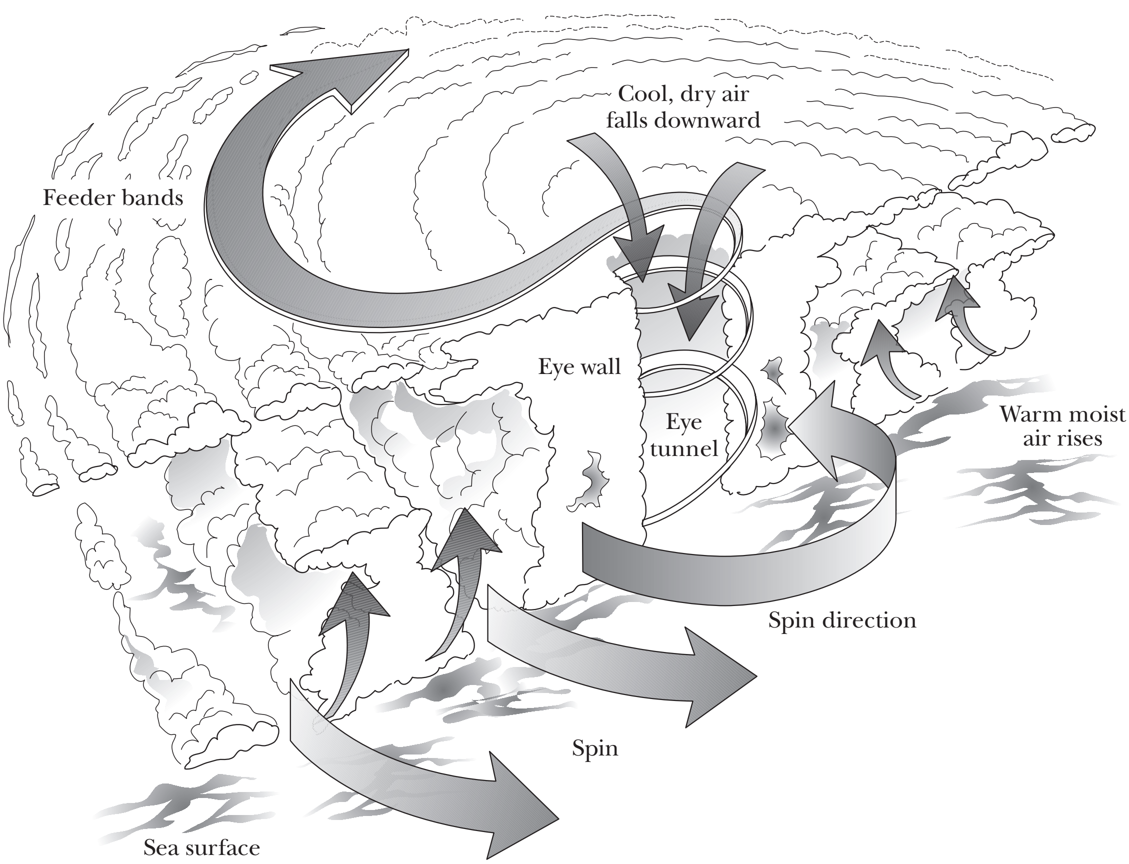
A tropical storm is a cyclonic storm pattern originating in the tropics that has the potential to develop into a hurricane. Sea surface temperatures (SSTs) are believed to play a role in hurricane frequency and intensity, since hurricanes usually require SSTs of at least 27° Celsius to form and sustain themselves. Many other factors contribute to hurricane development, however, making a simple linear association of hurricane intensity with SST, or with global warming generally, difficult to prove.

As is the case with other phenomena, global warming's effect on hurricanes plays out in a broader climatic context. The relationship (or lack thereof) between hurricane intensity and warming atmospheric and oceanic temperatures is complicated by the fact that water temperatures (like air temperatures) sometimes vary over periods of several decades. The long-term effect of rising greenhouse gas (GHG) levels upon climate is only part of the total picture.

Cyclonic oceanic storms that generate over the oceans are known by different names around the world. "Tropical storms" contain winds of less than hurricane strength (under 119 kilometers per hour). Storms that are called "hurricanes" in the Atlantic Ocean are known as "typhoons" in the Pacific Ocean and "cyclones" in the Indian Ocean. These storms also are rated numerically on the Saffir-Simpson scale, from 1, a minimal hurricane, to 5, a storm with winds of more than 251 kilometers per hour that can produce catastrophic damage.

Most research on tropical storms and climate change has been performed on hurricanes. The debate in the United States also has been parsed mainly regarding hurricanes, since these are the

Anatomy of a Hurricane



storms that affect that country. Since tropical storms are similar worldwide, however, this research may be generalized to other regions.

• Hurricane Intensity and Frequency

SSTs in the Atlantic Ocean, which produces nearly all the hurricanes that have an impact on the United States, have been rising slowly but steadily since the 1970's, paralleling a general global rise in air temperatures. Frequency and intensity of hurricanes (as well as the number hitting U.S. coastlines and inflicting major damage) also have been rising during the same period. While heat is important to hurricanes, they are very sensitive to other influences as well. After the devastating hurricane seasons of 2004 and 2005, the next year was very quiet. A major reason for the drastic decrease in hurricane activity in 2006 appears to have been an increase in the level of dust from the Sahara Desert present in the air over the Atlantic Ocean. During the 2006 hurricane season, SSTs also remained relatively cool, and only five hurricanes formed, one-third the number that formed in 2005.

Still other factors influence hurricane number and intensity, including El Niño conditions in the tropical eastern Pacific Ocean and the strength of the West African monsoon. If other conditions are right, a hurricane season can be intense even if SSTs are cooler than usual, and vice versa.

Any study of tropical storms that begins in the 1970's will indicate a very close relationship between ocean warming, hurricane intensity, and air temperatures. However, during the 1950's and 1960's, air temperatures were generally cooler than during the 1970's, but average hurricane intensity was higher. By 2005, this divergence was fueling a debate between some hurricane experts regarding whether, and to what degree, hurricane intensity and frequency is related to an overall warming trend.

• The Temperature-Intensity Argument

In 1988, Kerry Emanuel, a hurricane specialist at the Massachusetts Institute of Technology, published an article in the *Journal of the Atmospheric Sciences* in which he argued that hurricane intensity is governed, in part, by the degree of thermodynamic disequilibrium between the atmosphere and the underlying ocean. Therefore, Emanuel reasoned, warmer ocean waters should breed more intense tropical cyclones. While tracing any specific storm to warming is a tenuous exercise, hurricanes may intensify generally as oceans warm. Hurricanes are essentially heat engines, so storms that approach their upper limits of intensity are expected to be slightly stronger—and produce more rainfall—in warmer climates as a result of higher SSTs.

According to a simulation study by a group of scientists at NOAA's Geophysical Fluid Dynamics Laboratory (GFDL), a 5 to 12 percent increase in wind speeds for the strongest typhoons in the northwest tropical Pacific is projected if tropical SSTs increase by a little over 2° Celsius. Thomas R. Knutson and Robert E. Tuleya's models indicate that given SST increases of 0.8° to 2.4° Celsius, hurricanes would become 14 percent more intense (based on central pressure), with a 6 percent increase in maximum wind speeds and an 18 percent rise in average precipitation rates within 100 kilometers of storm centers.

• Criticism of the Climate-Hurricane Link

A report by Christopher W. Landsea of the National Oceanic and Atmospheric Administration's Miami, Florida, office asserts that an increase in carbon dioxide (CO_2) levels may raise the threshold temperature at which hurricanes thrive (presently 27° Celsius). This change might nullify the increase in strength that is implied by warmer SSTs, because it would increase the amount of thermal energy required to drive a hurricane.

Landsea also speculates that increased frequency of El Niño weather patterns in the Pacific tend to dampen hurricane development in the Atlantic, although storm frequency and intensity often rises in the eastern Pacific under the same conditions. Landsea contends that intensity of Atlantic hurricanes has decreased since the middle of the twentieth century. He believes that any warming-induced change in hurricane frequency and intensity will probably be lost in the noise of year-to-year hurricane variability.

William M. Gray, a professor emeritus of atmospheric sciences at Colorado State University, is a longstanding opponent of the idea that warming temperatures have anything to do with hurricanes. According to his tally, between 1957 and 2006, 83 hurricanes hit the United States, 34 of them major (with wind speeds above 177 kilometers per hour). Between 1900 and 1949, 101 hurricanes hit the same area, 39 of which were major. From 1966 to 2006, according to Gray, only 22 major hurricanes hit the United States, whereas between 1925 and 1965, 39 such storms

Storm Classifications

Tropical Classification	
Gale-force winds	>15 meters/second
Tropical depression	20-34 knots and a closed circulation
Tropical storm (named)	35-64 knots
Hurricane	65+ knots (74+ mph)
Saffir-Simpson Scale for Hurricanes	
Category 1	63-83 knots (74-95 mph)
Category 2	83-95 knots (96-110 mph)
Category 3	96-113 knots (111-130 mph)
Category 4	114-135 knots (131-155 mph)
Category 5	>135 knots (>155 mph)

Notes: 1 knot = 1 nautical mile/hour = 1.152 miles/hour = 1.85 kilometers/hour.
Source: National Aeronautics and Space Administration, Office of Space Science, Planetary Data System. URL: http://atmos.nmsu.edu/jsdap/encyclopediawork.html

hit the same area. Gray's evidence is not universally accepted as conclusive, but it calls into question the hypothesis that global warming will increase the frequency of storms. It has somewhat less bearing on the question of increased intensity among those storms that do reach the level of a major hurricane.

Troposphere

• Category: Meteorology and atmospheric sciences

• Definition

The troposphere is the lowest layer of the Earth's atmosphere. It typically extends from the Earth's surface to an altitude of about 10-16 kilometers high, varying by latitude. In the tropics, the troposphere extends relatively high, whereas in the polar region, its upper boundary is significantly lower.

Because gravity weakens as the distance from a body increases, the atmosphere's density and pressure decrease exponentially with altitude. Most of the air molecules in the atmosphere are located in the atmospheric layers closest to Earth's surface. As altitude increases, the number of atmospheric molecules per unit of volume decreases, so the air becomes thinner.

By contrast, air-temperature changes as a function of altitude are much more complex. The temperature of Earth's atmosphere decreases with altitude to the tropospheric boundary, 10-16 kilometers high. From that point to about 20 kilometers high, there is a "pause" in the temperature change, as temperature remains relatively constant. Above 20 kilometers, the temperature begins to increase. From about 45 to 50 kilometers up and from about 80 to 90 kilometers up, there exist two other zones of relatively constant temperature. Between them, from 50 to 80 kilometers up, the temperature decreases with height. Above 90 kilometers, the temperature increases with height throughout the rest of Earth's atmosphere. These zones of different types of temperature change define the structural layers of Earth's atmosphere: the troposphere, tropopause, stratosphere, stratopause, mesosphere, mesopause, and thermosphere.

Because more than 90 percent of atmospheric molecules are located in the troposphere, most weather and convection happen within this layer of the atmosphere. During the daytime, the Earth's surface warms relatively quickly. This radiative heating is necessary for convection to be generated. Warm, moist air rises, condensing when the air temperature drops at mid-to-high levels of the troposphere. This pattern of convection and condensation is the core process generating weather and storms.

During the nighttime, the air near the Earth's surface cools faster than that above it. Very low in the troposphere, radiative cooling can cause a tem-

The Troposphere at a Glance

- Percentage of Atmospheric Mass: 75 percent
- Percentage of Atmospheric Water Vapor: 99 percent

perature inversion, in which a warm layer of air is situated above the cool air near the surface and below the cold air of the upper troposphere. This temperature structure acts as a lid in the mid-troposphere, limiting convection. This phenomenon is the reason storms do not typically occur in the late night or early morning.

• Significance for Climate Change

The importance of the troposphere to global warming and climate change is twofold. First, most greenhouse gas (GHG) emissions, both natural and anthropogenic, are released into the troposphere, close to Earth's surface. Since gravity keeps more than 90 percent of air molecules within the troposphere, most of the emitted GHGs will stay there as well. Second, because the troposphere is in direct contact with Earth's surface, tropospheric reflections of global warming will be the most sensible and evident atmospheric reflections.

Many scientists predict that global warming will result in a significant increase of tropospheric temperatures. However, some studies based on the analyses of satellite measurements and radiosonde (weather balloon) data have shown no evidence of tropospheric warming. These studies have been critiqued in other studies, which have argued that results indicating no warming or even cooling in the troposphere were based on incomplete analyses, because they failed to take into account the cooling effect exerted by the stratosphere on the troposphere. However, some scientists believe that the overall temperature of the troposphere could remain unchanged or even decrease even while the Earth's surface temperature rises. They argue that an increase in atmospheric GHG concentrations may result in an increase in cloud cover. These clouds would increase Earth's albedo, reflecting solar radiation back into space and acting as a cooling influence.

Most weather occurs inside the troposphere. Thus, any changes affecting the troposphere will inevitably affect Earth's weather patterns. As the example of tropospheric temperature studies illustrates, however, it is difficult to predict the precise nature of these changes and their effects. If the troposphere does warm, it will extend higher than it does currently. If this happens, scientists predict that there will be much stronger convective storms, because an extended troposphere will allow deeper convection and thicker clouds. This is perhaps one reason that the Intergovernmental Panel on Climate Change (IPCC) predicted more severe storms would accompany future climate warming. Another possible effect of tropospheric warmth is an extension of tropical regions poleward. Such an extension would fundamentally alter the environment of many regions on Earth, with significant socioeconomic consequences.

Tsunamis

• **Category:** Meteorology and atmospheric sciences

• Definition

A tsunami (Japanese for "harbor wave") is a train of waves that heaves mountains of water from the ocean onto the shore. Just as dropping a pebble into a pond sends out a series of ripples, the oceanic impact of a mountain-sized asteroid would send out tsunamis, but most tsunamis are caused by explosive volcanic eruptions, earthquakes, or landslides near, or more commonly beneath, the ocean.

Ocean waves resemble wind-driven waves in a wheatfield, where the wave form moves across the field, but the wheat stalks remain rooted to one spot. A given portion of water in an ocean wave makes little forward progress; instead, it moves forward, downward, backward, and then upward, tracing out an orbit of centimeters or tens of centimeters. In normal waves, stacks of these circulation cells begin at the surface and extend downward by meters or tens of meters. Each circulation cell grows smaller than the one above it, until the motion dissipates altogether. In a tsunami, the cells extend all the way to the ocean floor, so vastly more water is in motion than in a normal wave. In deep water, tsunamis can travel at the speed of a jet plane, but they slow considerably as they reach shallow water near shore.

On December 26, 2004, a magnitude 9.2 earthquake struck near Sumatra. Perhaps 1 percent of the quake's energy went into lifting the surface of the ocean by 5 meters over an area nearly the size of Florida. As the lifted water slab sank back into the ocean, it created a series of tsunami waves, both crests and troughs, that struck fourteen countries and killed over 250,000 people.

There is about a 50 percent chance that the trough of a tsunami will arrive onshore before the crest. If this happens, water will retreat rapidly from the shore, emulating an unusally fast and strong lowtide. Such a retreat is a sure sign of an impending tsunami. Many lives were saved in 2004, when people observed the warning retreat and raced for higher ground. Tragically, however, others ran to explore the freshly exposed ocean bottom with its stranded fish; they were drowned when the tsunami arrived.

In the open ocean, tsunami crests are less than a meter high, but as they approach the shore, they can grow significantly. If the water becomes shallow, two factors can build the wave upward and push it onto shore. First, the wave energy near the ocean floor has no way to discharge itself except to hurl the wave upward and onto the shore. Second, the front of the wave slows first, since it reaches shallow water first. This uneven slowing causes the trailing parts of the wave to pile onto the slower front part, building the wave's height. The Aceh region of northern Sumatra experienced such an increase in wave height in the 2004 tsunami. There, the wave reached 24 meters high as it crashed ashore, causing massive damage and numerous deaths. Sri Lanka's experience of the tsunami was different: Because the land rises steeply from the deep ocean at Sri Lanka, the front, middle, and back of the tsunami waves all had the same speed, so they did not pile up. As a result, the tsunamis reaching Sri Lanka resembled especially high tides, rather than violently impacting waves.

• Significance for Climate Change

More than seven times as many people died in the 2004 tsunami than had in the previous worst tsunami on record. In trying to explain this dramatic increase, scientists looked to global warming as a possible factor. Global warming has slowly accumulating affects, but tsunamis are caused by catastrophic events, so there can be no direct link. For example, the idea that the few centimeters of sea-level rise attributed to global warming over the past century made the 12- to 24-meter-high tsunami waves significantly more destructive is simply not credible.

Perhaps there is an indirect link in which warming triggers a catastrophic event. Large amounts of methane ice lie on the ocean floor in some areas. Warming might melt some of the methane ice, and the released methane might cause waves or landslides. Such events do happen, but they are on far too small a scale to cause a tsunami. Similarly, gradually increasing the ocean's depth by melting glaciers may gradually increase the pressure on undersea magma chambers, but that pressure increase would be small compared with pressures in the main magma chamber. It is more likely that the water would cool and strengthen the overlying rock than it is that the increased pressure would trigger an eruption.

Since earthquakes cause tsunamis, whenever a sufficiently large earthquake occurs in a tsunami-prone region, a warning may be given. A much faster and more accurate warning can be given if deep ocean buoys are used. The National Oceanic and Atmospheric Administration (NOAA) developed the deep-ocean assessment and reporting of tsunamis (DART) system, and the Envirtech company developed its tsunami warning system (TWS). Both systems use sensors placed on the ocean bottom that communicate with buoys at the surface, which then communicate with satellites.

A lone mosque stands in a coastal village near Aceh, Indonesia, amid the devastation of the 2004 Sumatra tsunami. (AP/Wide World Photos)

Tsunamis have periods (time between crests) of ten minutes to an hour or more. These periods are far longer than the periods of normal ocean waves, and this is a key to identifying tsunamis. Very sensitive pressure sensors placed on the ocean floor can measure the periods of surface waves so that timely warnings can be given. By contrast, the global positioning system (GPS) displacement method uses GPS radio signals to judge the distances between ground stations. Within fifteen minutes, this method can detect if the distances between stations have changed and determine if tsunamis are likely.

Tundra

- **Category:** Environmentalism, conservation, and ecosystems

- **Definition**

Tundra ecosystems are treeless regions found in the Arctic and on mountaintops. The word "tundra" is derived from the Finnish word *tunturi*, which refers to treeless areas of hills and mountains. There are two types of tundra: those in the north, called Arctic tundra, and those in high mountains, called alpine tundra. Antarctica has some tundra as well. Tundra climate is very harsh, involving extremely cold and snowy winters and short, cool summers with very little precipitation. In the Arctic tundra, the average temperature is between −12° and −7° Celsius. Most Arctic tundra regions have permafrost, a layer of ground below the surface soil that remains permanently frozen. The tundra landscape is shaped by periodic freezing and thawing of soil, which forms cracks and alters drainage.

On the tundra, tree growth is hindered by low temperatures and short growing seasons. The boundary between tundra and forest is known as the tree line, or timberline. The plant species on the tundra are few, and most are low-growing. Tundra vegetation consists mainly of sedges, grasses, dwarf shrubs, wildflowers, mosses, and lichens. During summer months, scattered wildflowers, such as purple mountain saxifrage and Arctic poppies, are also present. The summer growing season is short, only fifty to sixty days, during which the Sun shines twenty-four hours a day. Hardy plants, such as cushion plants, survive by growing in rock depressions, where it is warmer and sheltered from the wind. Plant communities in the tundra have adapted to gusty winds and soil disturbances and are able to photosynthesize at low temperatures and with fluctuating light intensities.

Animal life on the tundra is somewhat limited by the challenging environment. Most Arctic wildlife consists of species that are the same or similar to those found worldwide. Tundra ecosystems also support a variety of animal species that do not live in other areas, such as the Arctic hare, musk oxen, lemming, Arctic ground squirrel, and a grouselike bird called a ptarmigan. Other animals, such as caribou and many species of bird, migrate annually to the Arctic. Arctic foxes, polar bears, some brown bears, gray wolves, and snow geese are also seen on the tundra. Large grazing animals such as caribou and reindeer feed on tundra vegetation. Mountain goats, big-horned sheep, rabbits, and birds inhabit alpine tundra. During summer months, many birds nest in shrubs on the tundra, migrating to warmer climates as winter approaches. Insects such as black

Permafrost thaws in a region of the Siberian tundra, forming thermokarst lakes and releasing sequestered gases and organic materials into the environment. (Reuters/Landov)

flies, mosquitoes, butterflies, and grasshoppers are abundant. Tundra predators include the wolf, arctic fox, and snowy owl.

• Significance for Climate Change

Although it remains one of the least exploited regions on Earth, the Arctic tundra is changing dramatically as a result of warmer temperatures. The tundra ecosystem is extremely sensitive to disturbance, and global warming is consequently likely to have some of its greatest effects in the tundra. Some major impacts associated with rising temperatures in the tundra are thawing of permafrost and advancing tree lines, both of which decrease tundra area and contribute further to global warming.

Permafrost is the foundation for most of the Arctic's unique ecosystem. Thawing permafrost disrupts the tundra landscape by forming bogs and shallow lakes. Shrubs and spruce that previously were not able to grow in the tundra because of permafrost are able to thrive in thawed tundra soil. Permafrost is also believed to contain large amounts of carbon sequestered in frozen soil. As it thaws, greenhouse gases (GHGs), such as carbon dioxide (CO_2), are released into the atmosphere.

As the Earth warms, tundra in northern Canada and Siberia is rapidly being replaced by northern, or boreal, forests. Over the last century, the tree line has advanced into the area, with trees currently living where no tree had previously grown during the last one thousand years. With continued warming, treelines may continue to advance, and tundra landscapes may be transformed into woodland areas. In addition to being a consequence of global warming, the encroaching tree line also contributes to global warming by absorbing larger amounts of sunlight.

Tundra, particularly when it is snow- or ice-covered, has a high albedo, or reflectivity, that helps maintain the region's cooler temperatures by reflecting sunlight rather than absorbing it. Compared to tundra, trees have low reflectivity; consequently, more heat is retained in areas with greater tree growth. The shift in tundra vegetation from grasses to shrubs and trees also increases the risk of wildfire in the tundra by creating more biomass available to burn. Fires in the tundra may potentially release more carbon into the atmosphere, adding to GHGs already contributing to global warming.

As the tundra shrinks, the few plant and animal species that thrive in the harsh environment will be affected. These species are highly vulnerable to environmental stresses such as reduced snow cover and warmer temperatures brought on by global warming. Animal species are affected by changes in the vegetation and in their habitats. Animals that generally live in warmer climates, such as the red fox, have moved onto the tundra and begun competing with Arctic species for territory and food.

Tuvalu

- **Category:** Nations and peoples

• Background

A tiny low-lying archipelago nation in Oceania made up of three reef islands and six coral atolls, Tuvalu began attracting international attention as early as 1995, as rising Pacific Ocean levels, largely from global warming, began to threaten to submerge the nation, likely making its roughly twelve thousand residents the world's first climate-refugees. Located in the South Pacific just below the equator, roughly 3,200 kilometers northeast of Australia, Tuvalu's nine islands are in area roughly 26 square kilometers, 90 percent of which is coastline, making it the world's fourth-smallest country. None of Tuvalu's nine islands rises more than 5 meters above sea level.

• Significance for Climate Change

The island nation became a kind of bellwether—or as the grimmer prognostications began to emerge in the 1990's, a kind of canary in the coal mine—alerting the global community to the reality of the impact of the greenhouse effect, specifically rising sea levels as polar ice reserves gradually melt and ocean temperatures rise, causing thermal expansion. The government of Tuvalu was quick to address the world community, largely through the United Nations and most vigorously during the international debate over the Kyoto Protocol in the late 1990's. Reliable data that extrapolated from the measured rise in sea levels from 1978 to 1995 projected that by the close of the twenty-first century sea levels could rise more than a one-half meter, significant enough to make Tuvalu uninhabitable.

Long-term threats are not the only troubles facing the island nation. In addition to fears over the incremental rise of the ocean, Tuvalu is particularly susceptible to the weather changes that have resulted from rising sea temperatures. More frequent and more intense cyclones ravage the limited farming done on the islands, disrupt the water supply, and spread disease. The gradual rise in tides—particularly the so-called king tides that have become commonplace in the last decades—also threatens Tuvalu, specifically its root crops. Given the reluctance of the government to curb the clearance of the island's forest undergrowth for fuel, the island has stripped itself of its natural protection from the force of windstorms and heavy rains.

The response to the threat of rising sea levels has been two pronged, short-term and long-term. The rhetoric from successive administrations of the Tuvalu government blamed global warming for their country's dire situation. Initially, the Tuvalu government sought the financial resources of Australia and the United States, the two industrial nations most directly responsible for their plight and both of which had refused to ratify the Kyoto Protocol calling for a curb in greenhouse gas (GHG) emissions.

In 2002, litigation was filed on behalf of the Tuvalu government in the World Court against both nations, a move seen less as a likely way to receive significant reparations and more as a way to draw international attention to the plight of the island and its implications for the greater global community. Tuvalu, its representatives tirelessly pointed out, is only the first nation to be affected. Given the reluctance of industrial nations to meet the Kyoto standards and given that the real impact of the current environmental damage will not be felt in rising sea levels for some time, climatologists estimate that by the close of the twenty-first century more than 100 million coastal residents may have to be evacuated on all six inhabited continents.

As tide damage proliferated, eccentric weather patterns expanded, and salt water slowly seeped into the groundwater and ruined the rooted plants of the islands, the Tuvalu government, as early as 2000, began making plans for long-term permanent evacuation of the island's residents. The government steadfastly refused to concede the inevitability of the island's disappearance and claimed that should the islands be entirely submerged the nation itself would continue to exist, its sovereignty intact despite being under the sea. Realistically, the island would be lost long before it was actually submerged. It would be lost when its cash crops, such as breadfruit, bananas, and coconuts, were rendered inedible and the islands' meager water supplies were flooded with seawater.

Plans to create an artificial retaining wall around the capital city of Funafuti were proposed but rejected. To secure the safety of the residents, the government sought the agreement of New Zealand and Australia and Fiji, the nearest countries able to accept a significant number of immigrants, to a long-term (thirty-year) gradual immigration protocol. Only New Zealand agreed. The Australian government claimed any agreement premised upon suspect data they dismissed as speculation would not be in the best interests of its government. Nevertheless, by 2007 nearly one-fourth of the island population had been evacuated, the world's first climate refugees.

Ukraine

- **Category:** Nations and peoples
- **Key facts**

Population: 45,700,395 (July, 2009, estimate)
Area: 603,700 square kilometers
Gross domestic product (GDP): $337 billion (purchasing power parity, 2008 estimate)
Greenhouse gas (GHG) emissions in millions of metric tons of carbon dioxide equivalent (CO_2e): 922 in 1990; 482 in 2000; 443 in 2006
Kyoto Protocol status: Ratified February 4, 2004

• Historical and Geopolitical Context

Only three years after an independent Ukrainian republic was established in 1918, the country was occupied by its Russian neighbors and shortly thereafter, during World War II, became a constituent of the Soviet Union. Following that war, the Soviet Union imposed its repressive communist regime on most of Eastern Europe, including Ukraine. Later, the Soviet Union attenuated its internal repression, but it could not quell the growing political unrest that led to its dissolution in 1991. Peoples in one-fourth of the area of the former Soviet Union, including satellite states such as Ukraine, seceded, forming fourteen independent countries.

Five years before Ukrainian independence was restored, the worst accidental nuclear disaster in history occurred in Ukraine. On April 26, 1986, at 1:23 A.M., a massive explosion tore through the Chernobyl Nuclear Power Plant, destroying the reactor block and igniting nearby buildings with fiery graphite projectiles. The disaster followed a poorly executed experiment conducted at low power under unsuitable cooling conditions. Even though thousands of metric tons of neutralizing agents were poured over the core reactor, the fire continued to burn; the core melted down, solidifying and sealing the entrance to the nuclear plant.

This process took approximately ten days, during which time 71 percent of the radioactive, fuel-containing reactor core remained uncovered. As a result, approximately 135,000 individuals had to be evacuated from the 30-kilometer so-called forbidden zone, which took 800,000 persons called "liquidators" to clean up. It is estimated that the radioactivity released by the Chernobyl explosions was at least two hundred times that of the atomic bombings of Hiroshima and Nagasaki during World War II. Millions of people were put at risk, as deadly radioactive particles raced across the globe from western Russia, through Europe, and across the Northern Hemisphere, where death rates from childhood leukemia increased in Canada and the United States.

The Chernobyl disaster typified the environmental problems the independent Ukraine would inherit from the Soviet Union. These problems had their root in a decaying industrial infrastructure whose decay was exacerbated by substandard workmanship and planning. Adverse health and environmental consequences of the Chernobyl disaster continued to plague survivors, many of whom immigrated to countries both within and outside the former Soviet Union, including the United States. It is in this context that Ukraine's approach to climate change and global warming must be understood.

• Impact of Ukrainian Policies on Climate Change

The United Nations has been instrumental in forming and advancing Ukrainian policies on greenhouse gas (GHG) emissions. Ukraine is an active participant in international initiatives related to improving the global environment and a party to nineteen conventions, including the United Nations Framework Convention on Climate Change (UNFCCC) and the Kyoto Protocol. The protocol introduced so-called flexible mechanisms, such as emissions trading and joint implementation, to help Eastern European Annex I countries achieve their commitments to limit and reduce GHG emissions by trading carbon offsets with wealthier countries such as Japan.

The commitments of Annex I countries include monitoring and reporting GHG emissions. By 2000, the Annex I nations were to have reduced their emissions to the 1990 baseline listed in Annex I of the UNFCCC. Per the Kyoto Protocol, Annex I countries must control their annual GHG emissions, limiting them to specific percentages of their baseline emissions when averaged over the period from 2008 to 2012. The U.N. Development Programme

(UNDP) focuses on legislative documents for procedures and compliance with UNFCCC, as well as creation of infrastructure required for the Kyoto Protocol's flexible mechanisms. Joint implementation allows nations to attain cost-effective reductions in GHG emissions, which may help promote development of new, low-GHG-emission technologies.

In March of 2005, Ukraine presented its policy on climate change and its plan for implementing the UNFCCC and the Kyoto Protocol to a group of Japanese investors. Eighteen projects were submitted to the Commission on Climate Change for a variety of carbon funds, including those directed at energy conservation, renewable energy sources, biogas, and mine methane utilization. Emission reduction units (ERUs) would be transferred to the partner country, Japan.

• Ukraine as a GHG Emitter

Paradoxically, though Ukraine has some of the richest environmental and natural assets in Eastern Europe, it is one of the most heavily polluted and least energy efficient countries. According to the UNDP, Ukraine has a history of substandard environmental management, which has increased its incidence of natural and anthropogenic disasters. As of 2008, 40 percent of Ukraine comprised eroded land, and the area of eroded land within the country was increasing at a rate of 80,000 hectares per year. In addition, most of Ukraine's power plants, installed in the 1930's and 1940's, are considered obsolete and are operating at 28-30 percent of capacity. Not surprisingly, therefore, Ukraine is the seventeenth highest GHG emitter. The top twenty GHG-emitting nations were responsible for 75 percent of all GHG emissions in the year 2000, worldwide.

• Summary and Foresight

Despite these problems, as well as ongoing political unrest in Ukraine and its neighboring former Soviet states, Ukraine wishes to be involved with protecting the environment of planet Earth. A relative newcomer to this cause, Ukraine requires assistance in implementing treaties such as the UNFCCC and Kyoto Protocol, relying on the United Nations. The UNDP, for example, has agreed to help Ukraine in the preservation of bio systems via effective management of natural resources. UNDP is addressing these issues with initiatives that limit GHG emissions by promoting energy efficiency, such as a pilot project in Rivne, Ukraine, that aims to reduce GHGs through improvements in the communal heat supply.

In addition, Ukraine uses carbon trading and is transitioning to sustainable energy development while adhering to the flexible mechanisms set forth by the Kyoto Protocol. However, mitigating the effects of GHG emissions through the practice of carbon offsets is not without its critics; some believe it allows countries, organizations, and even individuals to continue polluting the environment by simply paying a fee, the premise being that if one country can reduce emissions more efficiently than another country, the second country can pay the first one to reduce emissions for both. In addition, loopholes allow poorer countries to sell inexpensive offset credits to heavily polluting countries, which can then sell them for profit.

Ukraine, like other Eastern European and former Soviet Union countries, is an industrialized, developed Annex I nation, but a poor one that has suffered from many wars fought on its land and Soviet-era repression. A top-twenty emitter of GHGs, Ukraine possesses an outdated industrial infrastructure inherited from the Soviet Union. Joint implementation may be a positive solution to Ukraine's environmental problems, allowing carbon trading with wealthy countries. Ukraine could use the resulting funds to improve its environment and transition to a sustainable development model, fostering environmentally responsible economic growth.

Ultraviolet radiation

• Category: Physics and geophysics

• Definition

The Sun produces ultraviolet (UV) light. UV light is a portion of the electromagnetic spectrum with wavelengths shorter than those of visible light but longer than those of X rays. UV light wavelengths—shorter than the shortest wavelength of visible light, violet—are too short to be seen by the human eye (ultraviolet literally means "beyond violet"). UV radiation produced by the Sun is commonly split into three bands: UV-A, with wavelengths of 320-400 nanometers; UV-B, with wavelengths of 320-280 nanometers; and UV-C, with wavelengths of 200-280 nanometers. Most people are familiar with UV light through the painful effects of sunburn. A small amount of UV radiation is necessary for the well-being of humans and other organisms, because it promotes vitamin D synthesis in humans and acts as a germicide, controlling microbial growth. Too much UV radiation, however, is associated with many harmful effects.

Ozone is a very important part of the upper atmosphere, or stratosphere. It absorbs UV rays, forming a physical barrier that protects living organisms from harmful solar UV radiation. Although some of this radiation passes through the ozone layer and reaches the surface, most of the UV-B radiation entering Earth's atmosphere is absorbed by the ozone layer. UV-A radiation is not. Consequently, more than 98 percent of the UV radiation currently reaching Earth's surface is UV-A radiation. When UV-B radiation encounters an ozone (O_3) molecule, it can split O_3 into molecular oxygen (O_2) and atomic oxygen (O), which can then recombine with O_2 to form O_3 in a dynamic equilibrium.

The ozone layer, however, is being destroyed by a variety of environmental factors disrupting this equilibirum. Certain industrial chemicals, such as refrigerants, halons, and methyl bromide (a deadly pesticide used on crops), destroy Earth's ozone layer. Chlorofluorocarbons, chemicals used in many refrigerant systems and aerosols, are broken down by UV light into components that deplete ozone. As atmospheric ozone decreases, UV radiation infiltrates both marine and terrestrial ecosystems with potentially harmful effects. The intensity of UV-B radiation that reaches the Earth increases by 2 percent for every 1 percent decrease in the ozone layer.

• Significance for Climate Change

As the ozone layer decreases in size, it provides less protection from UV light. Consequently, more UV radiation passes through the atmosphere and reaches Earth's surface. Changes in the amount of UV radiation reaching the planetary surface have many potential consequences for climate change, most of which are interrelated. Heat is generated in the stratosphere as the ozone layer absorbs UV radiation. The resultant warming of the stratosphere creates a temperature inversion at the boundary between the stratosphere and the troposphere, helping stabilize climatic conditions. The stratosphere becomes cooler as the ozone layer declines, which could ultimately result in cooling of Earth's surface, despite more UV light reaching the ground.

An ozone monitoring station in Lhasa, Tibet, tracks changes in atmospheric ozone and ultraviolet radiation over the Tibetan Plateau. (Xinhua/Landov)

An increase in greenhouse gases (GHGs), however, may offset such surface cooling. In many cases, the same gases are responsible for both ozone destruction and climate change due to the greenhouse effect. For example, chlorofluorocarbons not only play a major role in ozone layer destruction but also are potent GHGs. As the ozone layer becomes more depleted by GHGs and other chemical contaminants, the amount of UV radiation that reaches Earth's surface will increase.

An increase in UV light reaching Earth's surface impacts human health and the well-being of other organisms and can also degrade nonliving materials. Changes in UV radiation have significant effects on both terrestrial and aquatic ecosystems, with important implications for the cycling of carbon, nitrogen, and other elements. Increased UV light induces carbon release from decaying plant material and nitrogen release from Arctic snow. Changes in UV radiation affect carbon cycling, including its capture through photosynthesis, and net ecosystem CO_2 exchange through storage and release. UV exposure can also affect cycling of the mineral nutrients, such as nitrogen, that plants depend on for growth. In aquatic ecosystems, UV radiation impacts cycling of carbon, nitrogen, sulfur, and metals, affecting numerous life processes.

Many studies have demonstrated that exposure to UV radiation has contributed to a worldwide increase in skin cancers, including malignant melanoma. UV radiation may cause changes in the body's immune system, which may impair its ability to defend against cancer and facilitate the spread of infectious disease. Increased UV-B exposure has also been linked to increased incidence of cataracts, the leading cause of blindness worldwide. Many amphibian population declines have been associated with UV exposure. Increased UV radiation also disrupts insect activity and, consequently, affects organisms that depend on insects.

Plants and animals living in freshwater and marine ecosystems are sensitive to UV radiation. UV-B can penetrate several meters of water and affect the survival and growth of marine invertebrates and algae. High levels of UV radiation can inhibit photosynthesis and growth in some plants, including many food crops, and can also result in declines in forest productivity. UV radiation also damages nonliving material and accelerates the breakdown of many paints and plastics used to construct products and structures regularly exposed to sunlight.

Union of Concerned Scientists

- **Category:** Organizations and agencies
- **Date:** Established 1969
- **Web address:** http://www.ucsusa.org

- **Mission**

The Union of Concerned Scientists, a science-based nonprofit advocacy group based in the United States, combines independent scientific research with citizen action to publicize and address issues pertaining to the environment and international security, including global climate change. Headquartered in Cambridge, Massachusetts, UCS works to influence government policies, corporate practices, and consumer choices through scientific research and citizen advocacy.

UCS was founded by faculty and students at the Massachusetts Institute of Technology on March 4, 1969, a few months after forty-eight senior faculty members signed a statement voicing concern over the militarization of science and technology. The fledgling organization called for research to be diverted away from military efforts and toward solving environmental and societal problems. From its initial focus on nuclear weapons and the military funding of academic research, UCS has since become active in the areas of global climate change, clean vehicles and energy, safety in the nuclear power industry, nuclear weapons reduction, global security, food and agriculture, invasive species, and scientific integrity.

UCS is an alliance of scientists and citizens. The organization's staff includes scientists, engineers, researchers, economists, analysts, advisors, and policy experts. UCS experts are frequently called to testify before state and federal government committees. In addition to issuing reports, videos, position papers, and fact sheets for policy makers, the media, and the general public, UCS coordinates citizen advocacy efforts such as petitioning and letter-writing campaigns. UCS also offers tips for consumers seeking to make environmentally sound choices in their daily lives. At the end of fiscal year 2007, UCS membership numbered over seventy-nine thousand individuals.

• Significance for Climate Change

In November, 1992, in the wake of that summer's United Nations Conference on Environment and Development (UNCED) in Rio de Janeiro, Brazil, UCS issued the "World Scientists' Warning to Humanity." This declaration, signed by more than 1,700 scientists (including 104 Nobel laureates) from seventy-one countries, warned that human activities were putting the living world in peril; it called for fundamental change.

Among the environmental stressors enumerated in the "World Scientists' Warning to Humanity" was the atmospheric accumulation of carbon dioxide released by deforestation and by combustion of fossil fuels—a buildup that had the potential to induce global climate change. The declaration called for scientists in all disciplines; the world's governmental, business, industrial, and religious leaders; and all peoples to work together to effect needed changes. Proposed improvements in humanity's stewardship of the Earth included moving toward clean and sustainable fuels, ending widespread deforestation, and providing developing nations with financial and technological aid to enable them to develop in an environmentally responsible manner.

In 1997, UCS presented a follow-up petition to President Bill Clinton's administration a few months before the Kyoto Climate Summit. "World Scientists' Call for Action" was signed by more than 1,500 scientists from sixty-three countries. Among the signers were 110 Nobel laureates and 60 winners of the United States National Medal of Science. The petition urged government leaders to strengthen the 1992 United Nations Framework Convention on Climate Change (UNFCCC) by completing an effective climate treaty at Kyoto. It called for legally binding commitments and near-term timetables from industrial and developing nations to augment the UNFCCC's voluntary measures regarding greenhouse gas (GHG) emissions. The petition also encouraged the world's scientists and citizens to hold their leaders accountable for mitigating anthropogenic influences on global climate.

In 2004, UCS published "Scientific Integrity in Policy Making," a report criticizing President George W. Bush's administration for its politicization of science. The report included the allegation that climate change research findings at federal agencies had been suppressed and distorted. The White House Office of Science and Technology Policy dismissed the report as biased, but UCS stood by its findings. An associated statement calling for the restoration of scientific integrity in policy making was signed by 62 prominent scientists. After Barack Obama won the presidential election in November, 2008, UCS members met with the president-elect's transition team to discuss scientific integrity in federal policy making.

UCS has published several reports on global warming. *How to Avoid Dangerous Climate Change: A Target for U.S. Emissions Reductions* (2007) sets a long-term target for U.S. reductions in GHG emissions and assesses then-pending federal climate bills in light of the proposed target. *Smoke, Mirrors, and Hot Air* (2007) maintains that ExxonMobil conducted a deliberate campaign of disinformation to delay action, influence legislation, and cloud public opinion regarding global climate change. *Atmosphere of Pressure: Political Interference in Federal Climate Science* (2007), copublished with the Government Accountability Project, documents the suppression and manipulation of findings that many federal climate researchers claim to have experienced under the Bush administration. Other UCS publications include a series of state and regional reports that assess possible climate-change impacts in the United States and available means for mitigation. UCS is one of the national governing-board organizations of the Sustainable Energy Coalition and is an institutional endorser of the 2007 Forests Now Declaration.

United Kingdom

- **Category:** Nations and peoples
- **Key facts**

Population: 61,113,205 (July, 2009, estimate)
Area: 244,820 square kilometers
Gross domestic product (GDP): $2.231 trillion (purchasing power parity, 2008 estimate)
Greenhouse gas (GHG) emissions in millions of metric tons of carbon dioxide equivalent (CO_2e): 776.3 in 1990; approximately 725 in 1995; 659.3 in 2004; 652.3 in 2006
Kyoto Protocol status: Ratified 2002

- **Historical and Political Context**

The United Kingdom is composed of England, Scotland, Wales, and Northern Ireland. England and Wales were united in 1536. Scotland was joined to its two neighboring countries, England and Wales, in 1707. Ireland became part of the nation in 1801 but many Irish were in rebellion against the union. The Anglo-Irish Treaty created the Irish Free State, and in 1922 six northern counties recognized as Northern Ireland became part of the United Kingdom. Each of the countries has maintained a certain amount of political autonomy, especially in the area of legislative control.

In the thirteenth century, Great Britain evolved its parliamentary form of government. This system, composed of the monarch, a House of Lords, and a House of Commons, has become the model for the governments of many nations throughout the world. In the fifteenth century, Great Britain began exploring the world and claiming new lands. The United Kingdom has played a major role globally throughout its history. During the sixteenth and seventeenth centuries, the United Kingdom was an important seafaring power and one of the major colonizing countries in the world. The United Kingdom's preeminence as a colonial power continued into the following centuries, as did its power on the seas.

The eighteenth century was the period in which two world-significant revolutions began in the United Kingdom: the agricultural revolution and the Industrial Revolution. Both were made possible by scientific discoveries and inventions and each transformed its specific economic sector. The agricultural revolution changed methods of farming as crop rotation, improved machinery, and scientific breeding, as well as other innovations, were introduced.

The Industrial Revolution changed manufacturing of goods and created a new lifestyle for workers. New machines improved production, first of textiles and then of all types of products, and led to the building of factories and mass production. This increase in the amount of goods produced required more and better means of transport and provided the impetus for the building of railroads and more roads and canals in the country. Britain's revolutionized economic system soon began to spread to and industrialize the European continent.

By the early nineteenth century, the United Kingdom was the strongest and most influential European power. With industrial development in the United States and Germany, the nation lost some of its position but remained economically important. The world wars of the twentieth century and the damage suffered by the United Kingdom placed it in a position of rebuilding during the late 1940's.

The United Kingdom, like the rest of the war-torn European countries, regained its economic and political importance during the 1950's and 1960's. In 1949, the United Kingdom joined the North Atlantic Treaty Organization (NATO). The United Kingdom has close economic and political ties with both the United States and the continental European countries. It was one of the founding members of the European Free Trade Association (EFTA), which was formed in 1959. In 1973, the United Kingdom became a member of the European Economic Community (EEC) and a founding member of the G-8 in 1977. The United Kingdom is a member of the European Union. It ranks as the second-largest economy among EU members. Worldwide, the United Kingdom is the fifth-largest economy and plays a major role in global trade.

• Impact of British Policies on Climate Change

The United Kingdom has implemented a number of policies to positively affect the world's climate and to reduce the amount of detrimental climate change. One of its main concerns is the increase in temperature, which threatens to result in erratic weather patterns producing severe storms and a significant rise in sea level. This could result in disastrous ice melting in the Arctic and reduction of fish populations due to increased water temperature. The government is particularly targeting the areas of energy production and consumption, transport, and agriculture with incentives and regulations to improve energy efficiency and reduce greenhouse gas (GHG) emissions.

One of the major programs is the Renewables Obligation, introduced in April of 2002. This program requires energy suppliers who supply electricity to end-consumers to use renewable resources, not fossil fuels, to generate a certain set amount of the electricity. The projected requirement incorporates a yearly increase in the amount of electricity to be generated from renewable resources through 2015. The starting percentage in 2002 of 2 percent will increase to 15.4 percent by 2015. The program also requires the coal-firing of biomass to be eliminated by 2016. Through various programs, the United Kingdom is providing money for the installation of renewable energy sources in private homes and community buildings.

The United Kingdom is also hoping to enact a law putting in place a renewable transport fuel obligation. The obligation would require that 2 to 5.75 percent of road fuel be either bioethanol or biodiesel. To implement this program, the country would need to produce the biomass from which the bioethanol and biodiesel fuel were made. Experts and analysts in the field believe that this is possible if the country were to use all of its net wheat exports to produce the biomass.

Concern over climate change and commitment to work actively to stop detrimental climate change has not been limited to the national level of government in the United Kingdom. As early as 2000 with the creation of documents such as the Nottingham Declaration, local governmental units and private citizens were becoming involved in programs and activities related to climate change. The Nottingham Declaration, when signed by a local council, commits them to support the national programs and to work locally to reduce GHG emissions and factors producing negative effects on climate.

• The United Kingdom as a GHG Emitter

According to data collected by the European Environment Agency (EEA), the United Kingdom ranked second in GHG emissions in both the EU15 and the EU27 in 2006. Ranked by GHG emissions per capita, the nation ranked tenth among the EU15 and thirteenth among the EU27. However, the United Kingdom reduced its GHG emissions by 16 percent, while the European Union achieved an average of 2.7 percent reduction in GHG emissions. The United Kingdom's 2006 emissions of 652.3 million metric tons were 18 percent below those of its base year (1990) which were 776.3 million metric tons and also a greater reduction than its burden-sharing target of −12.5 percent. The United Kingdom projects that it can reduce its GHG emissions to 16 percent below those of the base year by 2010. The United Kingdom believes that it not only will reach its burden-sharing target but will surpass the reductions it committed to achive in the Kyoto Protocol agreement.

• Summary and Foresight

The United Kingdom is one of the world's largest consumers of energy and the only EU country exporting any significant amount of energy. In 2007, according to the United Nations Framework Convention on Climate Change, the country ranked eighth in the world for GHG emissions from the burning of fossil fuels with some 587,261 metric tons. The country is working to replace fossil fuels with renewable energy resources. The United Kingdom has significantly reduced its GHG emissions. It has made significant reductions in emissions from household use and from petroleum refining. However, the production of electricity and heat has shown a rise in emissions. The Renewables Obligation program, enacted in 2002, is addressing this issue. In addition, the use of natural gas rather than coal as an energy source is helping to reduce emissions. GHG emissions from transport have continued to increase at a steady rate. The United Kingdom is taking steps to stop this rate of increase by implementing a program requiring the use of fuel that contains a percentage of either bioethanol or biodiesel.

The United Kingdom continues to play a committed role in the efforts to reduce GHG emissions and positively affect climate change by minimizing temperature increase. The United Kingdom signed the Kyoto Protocol and accepted the commitment to reduction of GHG emissions to 12.5 percent below the levels of the base year (1990). In view of the amount of GHGs being produced within its borders, the United Kingdom, fearing it would not meet its target, began considering an emissions regulatory system to apply to itself.

In 2000, the Royal Commission on Environmental Pollution presented its conclusion that if the United Kingdom, and other countries as well, would accept a target of a reduction of 60 percent by 2050 holding emissions to 550 parts per million, the rise in temperature could be held to 2° Celsius. Then in 2005, an assessment of GHG emissions presented at the international conference Avoiding Dangerous Climate Change proposed that a greater reduction was necessary to limit the rise in temperature to 2° Celsius. The report stated that the emissions had to be held to less than 400 parts per million. An 80 percent reduction rather than a 60 percent reduction would be necessary.

In response to this evidence, the United Kingdom turned its attention to enacting a law that would target a significant reduction in GHG emissions, set in place mechanisms of regulation, and enable the country to become a low-carbon economy. Political conservatives and liberals, the Confederation of British Industry, and the Trade Unions Congress all supported the bill. On November 26, 2008, the Climate Change Act became law. It set the reduction target for the United Kingdom at 80 percent below the base year level by 2050. It also gave the ministers authority to enact various measures to ensure that the target is met. The United Kingdom was the first nation to pass a law regulating carbon emissions reduction and providing the means to achieve the target set.

United Nations Climate Change Conference

- **Category:** Conferences and meetings
- **Date:** December 3-14, 2007

• Background

In 1994, the United Nations Framework Convention on Climate Change (UNFCCC) entered into force, and the nations, or parties, that ratified it have met annually in different cities in what are called the Conferences of the Parties to the Framework Convention on Climate Change (COP). It was during the third annual meeting in 1997, or COP-3, that the Kyoto Protocol was adopted. COP-11, held in Montreal, Canada, included the first official meeting of the parties (MOP) of the Kyoto Protocol since the protocol was adopted, and the group agreed to continue to meet annually. The United Nations Climate Change Conference (also known as the Bali Conference) was hosted December 3-14, 2007, by the Indonesian government and held in the Bali International Convention Center.

The conference was attended by over ten thousand governmental representatives, members of nongovernmental organizations, and journalists, from more than 180 countries. It comprised several separate but related events, including COP-13 and MOP-3, as well as an annual meeting of the Subsidiary Body for Scientific and Technological Advice, the Subsidiary Body for Implementation, and the Ad Hoc Working Group on Further Commitments for Annex I Parties under the Kyoto Protocol.

Going into the Bali Conference, serious tensions and conflicts existed between several major parties. The United States was at odds with most of the rest of the European and the developing nations, because it did not believe that any nation should be bound by internationally determined targets. The United States hoped to persuade other nations that global warming could be addressed by each nation voluntarily setting its own targets and procedures for reaching them.

• Summary of Provisions

The focus of the Bali Conference was preparing for what will happen after 2012, the last year covered by the Kyoto Protocol. Most experts agree that, however difficult it has been for the world to reach Kyoto Protocol targets for emissions reductions, even greater reductions will be necessary after 2012 if global warming is to be effectively addressed. At the end of the conference, representatives from both developed and developing nations adopted the Bali Roadmap, a series of future steps to reduce global warming. One part of the roadmap, the Bali Action Plan, outlines a two-year process for a series of negotiations that would determine how countries would reduce their greenhouse gas (GHG) emissions after 2012. The negotiations were scheduled to occur four times in 2008, with a major meeting at COP-14, in Poznan, Poland, and to conclude with a binding agreement at COP-15, in Copenhagen, Denmark, in 2009.

The roadmap included the launching of the Adaptation Fund, which will finance projects for developing clean energy technologies in developing countries. The fund had been devised in 1997 at the Kyoto Conference, to be paid for through proceeds from the clean development mechanism, but it had not actually been created. As established at Bali, the fund is administered by a board of sixteen members that will meet twice each year to consider projects. Also included in the roadmap were clarifications and agreements on the scope of Article 9 of the Kyoto Protocol, which calls for periodic scientific review of global warming and its effects. The roadmap also included agreements about how developed nations can effectively transfer clean energy technology to developing nations and how deforestation, which increases the harmful effects of GHG emissions, can be reduced.

Former U.S. vice president Al Gore addresses the United Nations Climate Change Conference in Bali, Indonesia, on December 13, 2007. (SUPRI/Reuters/Landov)

• Significance for Climate Change

The Bali Conference had the potential to draw more participants into concrete plans to reduce emissions than had been involved previously. The roadmap, while it does not specify reduction targets overall or for any individual country, leaves open the likelihood that the two-year negotiation process will result in reduction commitments from additional nations. China, India, and Brazil, countries whose economies have grown quickly in the twenty-first century and that are among the largest emitters of GHGs, will likely be called upon to reduce their emissions after 2012.

United Nations Conference on Environment and Development

• **Categories:** Conferences and meetings; environmentalism, conservation, and ecosystems
• **Date:** June 3-14, 1992, Rio de Janeiro, Brazil

• Background

During the twenty years following the 1972 U.N. Conference on the Human Environment, the deterioration of the global environment continued to accelerate with depletion of the ozone layer and natural resources, while global warming and pollution increased. Little had been accomplished over these years to integrate environmental issues with national economics and development. However, in 1983, Gro Harlem Brundtland of Norway, head of the World Commission on Environment and Development, put forth the notion of sustainable development. Based on the Brundtland Report, the U.N. General Assembly requested that a conference be convened that specifically focused on the environment and development. As a result, UNCED, or the Earth Summit, was held in Rio de Janeiro from June 3 to June 14, 1992.

• Summary of the Conference

The aim of UNCED was to arrive at an understanding of development that would provide a basis for global collaboration between the developed and the developing nations so as to bolster socioeconomic development and halt the deterioration of the Earth's environment. Governments of 108 countries adopted five significant agreements with the goals of improving the environment and redefining the traditional concept of development.

Agenda 21 was the only product of UNCED that encompassed the whole environment and development agenda. It entailed a comprehensive program of global action that covered all aspects of sustainable development with the aim of readying the world for the twenty-first century. Proposals called for social and economic action, including fighting poverty, considering global demographics, and balancing patterns of production with those of consumption. It was agreed that protecting the oceans, freshwater, the atmosphere, forests, and other natural resources, while promoting biodiversity and integrating environmental and developmental concerns, would improve conditions for all states, ensuring a prosperous and healthy future for planet Earth.

The Rio Declaration on Environment and Development was a series of principles that supported Agenda 21 by elucidating the rights and responsibilities of states. For example, people are entitled to live in harmony with nature via sustainable development; states have the right to use their own resources, but must not damage the environment of other states; reducing global disparities and eradicating poverty are necessary for sustainable development, which can be aided by strengthening the role of women, youth, farmers, indigenous peoples, and local authorities in the process.

The Statement of Forest Principles describes the legally nonbinding set of principles that underlie the sustainable management of forests. This was the first global consensus on forests that called for all nations, particularly the developed countries, to engage in forest conservation and reforestation. Moreover, it proclaimed that all states have the right to develop forests compatible with their socioeconomic needs and sustainable development policies.

The United Nations Framework Convention on Climate Change (UNFCCC), an environmental, nonbinding treaty, was ratified in March, 1994, with the intent to stabilize their greenhouse gas (GHG) emissions at 1990 levels by 2000. The principle of "common but differentiated responsibilities" was agreed upon, with the developed coun-

U.N. secretary-general Boutros Boutros-Ghali stands flanked by the conference organizers during the opening ceremonies of the United Nations Conference on Environment and Development. (AP/Wide World Photos) tries bearing the greater burden of accountability. The Convention on Biodiversity had several aims: sustaining and conserving biodiversity, sharing gene stocks, and commercial access to biotechnology with acceptance of associated liabilities.

• Significance for Climate Change

From June 23 to 27, 1997, more than fifty-three heads of state or government attended a special session of the U.N. General Assembly in New York City to review and appraise the implementation of Agenda 21. Called Earth Summit +5, its participants determined that the global environment had deteriorated since UNCED convened in 1992; the final document adopted by delegates from 165 nations agreed that while some headway had been made in forestalling climate change and loss of forest and freshwater, there were few commitments to reduce GHGs and help fund sustainable development, mainly because of North-South differences. Minister Msuya Waldi Mangachi of Tanzania, who represented 133 developing countries, stated that disagreements arose because financial pledges made by the developed countries had not been kept. In 1995, a U.N. panel of scientists found a discernible human influence on global climate. While the UNFCCC was ratified by more than 190 countries, few developed countries met the goal of reducing GHG emissions to 1990 levels by 2000. Parties to the UNFCCC were asked to adopt legally binding targets for developed countries by signing the Kyoto Protocol. On the positive side, one of the first accomplishments of the UNFCCC was creation of a national GHG inventory to keep track of gases and their removal from the atmosphere. Signers of the UNFCCC must update their accounts on a regular basis and release them to the UNFCCC. U.S. president George H. W. Bush presented the UNFCCC to the U.S. Senate, which ratified it in October, 1992. The Earth Summit also catalyzed many new institutional arrangements, such as the Commission on Sustainable Development (CSD), which became a central forum to review implementation of Agenda 21, and the U.N. Interagency Committee on Sustainable Development.

United Nations Conference on the Human Environment

- **Categories:** Conferences and meetings; environmentalism, conservation, and ecosystems
- **Date:** June 5-16, 1972

• Background

In 1968, at the forty-fifth session of the United Nations Economic and Social Council, a resolution was passed underscoring the immediate need for intensified action at the national and the international levels to halt the continuing deterioration of the "human environment." The council reasoned that proper attention to the problems of the human environment was necessary for sound global economic and social development, and it recommended that the U.N. General Assembly convene the United Nations Conference on the Human Environment (also known as the Stockholm Conference). In response, the General Assembly, at its twenty-third session, endorsed the council's recommendations and issued U.N. Resolution 2398, resolving to hold the conference in order to explore the problems associated with the human environment, focusing on challenges that could be properly addressed only by international collaboration and agreement.

Accepting an invitation from the Swedish government to hold the event in Sweden, Secretary-General U Thant appointed the head of the Canadian Foreign Aid Agency, Maurice F. Strong, to oversee a conference preparatory committee that met from 1970 to 1972. At the urgent request of developing nations, matters concerning development were added to the conference agenda. While 114 nations and over 400 inter- and nongovernmental agencies sent representatives to the meeting, the entire Eastern Bloc boycotted the conference because of conflicts over the political division of postwar Germany. In addition, eighteen thousand persons attended simultaneous events that were sponsored by a trio of nongovernmental organizations (NGOs)—the People's Forum, the Environment Forum, and Dai Dong—and held outside the grounds of the conference. These events and their participants produced their own set of environmental principles.

• Summary of the Conference

Having considered the need for a common outlook and shared principles that might inspire and guide the world's nations to preserve and enhance the human environment, the conference put forth a declaration composed of twenty-six principles on the environment and development. The first principle broadly stated,

> Man has the fundamental right to freedom, equality and adequate conditions of life, in an environment that permits a life of dignity and well-being, and he bears a solemn responsibility to protect and improve the environment for present and future generations.

The twenty-first of these principles is the best known and is believed by many international legal scholars to be the foundation for much of the environmental diplomacy that has occurred since the Stockholm meeting, because it acknowledges that states have,

> in accordance with the UN Charter and international law . . . the sovereign right to exploit their own resources pursuant to their own environmental policies, and the responsibility to ensure that activities within their own jurisdiction do not cause damage to the environment of other States.

Other principles stress the need for scientific research and technology, education for youth and adults alike, rational planning, and international cooperation to protect the global environment. In addition to the declaration, an action plan was put forth comprising 109 recommendations encompassing six general topics, including educational, informational, social, and cultural aspects of the environment. For example, recommendation 95 called for

> providing countries with . . . technical and financial assistance in preparing national reports on the environment, in setting up machinery for monitoring environmental development . . . and drawing up national social, educational and cultural programmes.

Recommendation 96 called for the secretary general and the U.N. organizational system, particularly the U.N. Educational, Scientific, and Cultural Organization, ". . . to establish an international programme in environmental education, interdisciplinary in approach, [and] encompassing all levels of education and directed toward the general public."

Other recommendations addressed financial support for these endeavors, as well as "managing global pollution, natural resources, and human settlements." Importantly, the Stockholm conference acknowledged the need to articulate "third generation human rights," those that exceed the merely civil and social but are legally difficult to enact. Broadly based, these rights include the right to a healthy environment; to preservation of natural resources through sustainable practices, and to economic and social development. However, while development was included as a Stockholm Conference agenda issue, it was not dealt with in later follow-ups.

• Significance for Climate Change

The first international conference of its kind, the U.N. Conference on the Human Environment focused attention on the need for global collaboration to decrease general and marine pollution and created environmental monitoring networks, both regional and global. It provided the framework for future environmental collaboration, leading to the establishment of the U.N. Environment Programme (UNEP). UNEP coordinates U.N. environmental activities, helping developing countries implement environmentally sound policies by encouraging sustainable environmental practices. Importantly, the Stockholm Conference and the scientific conferences on the environment that it preceded significantly influenced the environmental policies of the European Union. As an example, in 1973, the union established the Environmental and Consumer Protection Directorate and the first Environmental Action Program. Increased awareness and interest in the global environment have stimulated research on climate change and led to further understanding of global warming and agreements such as the Kyoto Protocol.

United Nations Convention on the Law of the Sea

• **Category:** Laws, treaties, and protocols

Among the goals set forward in the U.N. Convention on the Law of the Sea is that of establishing parameters for sovereignty among the nations of the world, and the international community as a whole, over coastal and oceanic waters. This sovereignty includes responsibility for and administration over the use and abuse of the maritime environment and its resources.

• Key concepts

contiguous zone: area between 22.2 and 44.4 kilometers from a nation's coastline within which the nation enjoys partial but not full sovereignty *exclusive economic zone (EEZ):* a zone extending from a nation's coast up to 370, or even 650, kilometers that is considered that nation's sole legal preserve to regulate and exploit economically

International Seabed Authority: an independent international organization set up to regulate and authorize the exploitation of seabed resources within international waters

international waters: all areas lying beyond EEZs and considered open to all nations for all legitimate, nonbelligerent purposes; also known as the high seas

territorial waters: the seas within 22 kilometers of a national coast that are considered a nation's exclusive jurisdiction and through which foreign vessels are allowed "innocent passage"

• **Participating nations:** *1982:* Fiji; *1983:* Bahamas, Belize, Egypt, Ghana, Jamaica, Mexico, Namibia, Zambia; *1984:* Côte d'Ivoire, Cuba, Gambia, Philippines, Senegal; *1985:* Bahrain, Cameroon, Guinea, Iceland, Iraq, Mali, Saint Lucia, Sudan, Togo, Tunisia, United Republic of Tanzania; *1986:* Guinea-Bissau, Indonesia, Kuwait, Nigeria, Paraguay, Trinidad and Tobago; *1987:* Cape Verde, São Tomé and Príncipe, Yemen; *1988:* Brazil, Cyprus; *1989:* Antigua and Barbuda, Democratic Republic of the Congo, Kenya, Oman, Somalia; *1990:* Angola, Botswana, Uganda; *1991:* Djibouti, Dominica, Grenada, Marshall Islands, Micronesia, Seychelles; *1992:* Costa Rica, Uruguay; *1993:* Barbados, Guyana, Honduras, Malta, Saint Kitts and Nevis, Saint Vincent and the Grenadines, Zimbabwe; *1994:* Australia, Bosnia and Herzegovina, Comoros, Germany, Mauritius, Sierra Leone, Singapore, Sri Lanka, the former Yugoslav Republic of Macedonia, Vietnam; *1995:* Argentina, Austria, Bolivia, Cook Islands, Croatia, Greece, India, Italy, Jordan, Lebanon, Samoa, Slovenia, Tonga; *1996:* Algeria, Brunei Darussalam, Bulgaria, China, Czech Republic, Finland, France, Georgia, Haiti, Ireland, Japan, Malaysia, Mauritania, Monaco, Mongolia, Myanmar, Nauru, Netherlands, New Zealand, Norway, Palau, Panama, Republic of Korea, Romania, Saudi Arabia, Slovakia, Sweden; *1997:* Benin, Chile, Equatorial Guinea, Guatemala, Mozambique, Pakistan, Papua New Guinea, Portugal, Russian Federation, Solomon Islands, South Africa, Spain, United Kingdom; *1998:* Belgium, European Community, Gabon, Lao People's Democratic Republic, Nepal, Poland, Suriname; *1999:* Ukraine, Vanuatu; *2000:* Luxembourg, Maldives, Nicaragua; *2001:* Bangladesh, Madagascar, Serbia; *2002:* Armenia, Hungary, Qatar, Tuvalu; *2003:* Albania, Canada, Kiribati, Lithuania; *2004:* Denmark, Latvia; *2005:* Burkina Faso, Estonia; *2006:* Belarus, Montenegro, Niue; *2007:* Lesotho, Morocco, Republic of Moldova; *2008:* Congo, Liberia; *2009:* Switzerland

• Background

In the strictest sense, the Law of the Sea may refer to the United Nations Convention on the Law of the Sea (UNCLOS), which has been in official operation only since November 16, 1994. The process that brought this law about, however, dates back to quite a few years prior to that date, and the concept of a law of the sea within international law and relations is much older still. Control over the coastline and over the sea and seabed resources has been a bone of contention that figured in disputes and even wars from the ancient through the medieval eras of history. It was, however, the rise of the western European nation-states and the opening of the Atlantic and Indian Ocean seaways for trade and transportation that led to the first attempts to formulate a definitive maritime law regarding sovereignty over coastal waters.

The Dutch legal philosopher Hugo Grotius (1583-1645)—his country alarmed at the prospect of being forced out of both the East and the West Indies trade by England, Spain, France, and Portugal—wrote in *Mare Liberum* (1609; *Freedom of the Seas*, 1916) that the seas should be a free area, where ships of all nations should be able to travel unfettered and unmolested. Grotius's concept was further solidified by Cornelius van Bynkershoek (1673-1743), who set the boundary between a country's territorial waters, over which it had legal jurisdiction, and Grotius' "high seas," which were free to be used by all nations. Territorial waters were seen as falling within "cannon shot" range (at that time, 5.5 kilometers).

• Role of the United Nations

From its inception, however, Grotius's concept was not universally accepted: The British philosopher-spokesman John Selden (1584-1654) argued as early as 1635 that sovereign states had the right to allot and subdivide the oceans in the same way as was done with land. Ambiguity over this question on the occasion of wartime naval blockades could sometimes lead to armed conflict. Cases in point include the British naval impressment of American sailors, which served as a partial cause for the War of 1812, and Germany's "unrestricted submarine warfare" policy, which contributed to the United States' decision to enter World War I on the Allied side in 1917.

In order to arrive at a universal agreement on maritime jurisdiction and to forestall future sources of conflict, the first United Nations Conference on the Law of the Sea convened at Geneva, Switzerland, in 1958. This was followed by the second conference in 1960 at Geneva, and a third in New York in 1973. The third conference deliberated over the course of more than nine years until, on December 10, 1982, the final UNCLOS document was signed at Montego Bay, Jamaica. It needed, however, to be separately ratified by sixty countries before it could take effect, and this did not happen until November 16, 1994, with ratification by Guyana.

• Provisions and Organization

UNCLOS spells out the legal definitions of territorial waters (which had largely been expanded from 5.5 to 22.2 kilometers long prior to 1982); a 22.2- to 44.4-kilometer offshore contiguous zone of quasi sovereignty; an exclusive economic zone (EEZ) of 370 to 650 kilometers of resource jurisdiction; and the international "high seas." The International Tribunal for the Law of the Sea (ITLOS) was inaugurated as a special court of twenty-one judges to convene in Hamburg, Germany, to arbitrate disputes among UNCLOS members. The court is composed of four chambers: Summary Procedure; Fisheries Disputes; Marine Environmental Disputes; and Conservation and Sustainable Exploitation of Swordfish Stocks in the South-Eastern Pacific Ocean. Part 11 of UNCLOS, one of the more controversial provisions, set into motion the International Seabed Authority, which operates apart from the United Nations as an international consortium to license and administer scientific research and exploration, as well as potential exploitation of all ocean floor (mainly mineral) resources outside the EEZs.

• Context

Some 156 countries ratified UNCLOS, though the United States has not, chiefly due to objections over Part 11 as being potentially detrimental to U.S. defense policies and discriminatory against U.S. business enterprises. On the issues of environment and climate change, opinions seem to be divided over the effects of UNCLOS. On one hand, there is the assertion that a regulatory agency such as the International Seabed Authority could exert control to prevent possible drastic anthropogenic climate changes resulting from overexploitation of oceanic resources. On the other hand, it is argued the greater likelihood exists that the authority may open the seabed to misdirected or excessive exploitation—such as overfishing, over-mining, or drilling—and thus trigger global climatic shifts that might have unforeseen results.

United Nations Convention to Combat Desertification

- **Category:** Laws, treaties, and protocols
- **Date:** Adopted by the United Nations June 17, 1994; entered into force December 26, 1996
- **Participating nations:** *1995:* Afghanistan, Canada, Cape Verde, Denmark, Ecuador, Egypt, Finland, Guinea-Bissau, Lesotho, Mali, Mexico, Netherlands, Peru, Senegal, Sudan, Sweden, Togo, Tunisia, Uzbekistan; *1996:* Algeria, Bangladesh, Benin, Bolivia, Botswana, Burkina Faso, Central African Republic, Chad, Eritrea, Gabon, Gambia, Germany, Ghana, Haiti, India, Israel, Jordan, Lao People's Democratic Republic, Lebanon, Libyan Arab Jamahiriya, Malawi, Mauritania, Mauritius, Micronesia, Mongolia, Morocco, Nepal, Niger, Norway, Oman, Panama, Portugal, Spain, Swaziland, Switzerland, Turkmenistan, United Kingdom, Zambia; *1997:* Angola, Antigua and Barbuda, Argentina, Armenia, Austria, Bahrain, Barbados, Belgium, Brazil, Burundi, Cambodia, Cameroon, Chile, China, Côte d'Ivoire, Cuba, Democratic Republic of Congo, Djibouti, Dominica, Dominican Republic, El Salvador, Equatorial Guinea, Ethiopia, France, Greece, Grenada, Guinea, Guyana, Honduras, Iceland, Iran, Ireland, Italy, Jamaica, Kazakhstan, Kenya, Kuwait, Kyrgyzstan, Luxembourg, Madagascar, Malaysia, Mozambique, Myanmar, Namibia, Nigeria, Pakistan, Paraguay, Saint Kitts and Nevis, Saint Lucia, Saudi Arabia, Seychelles, Sierra Leone, South Africa, Syrian Arab Republic, Tajikistan, Tanzania, Uganda, Yemen, Zimbabwe; *1998:* Costa Rica, Malta, Nicaragua, Liberia, Comoros, Saint Vincent and the Grenadines, European Community, Turkey, Marshall Islands, Venezuela, São Tomé and Príncipe, Belize, Azerbaijan, Niue, Romania, Cook Islands, Samoa, Vietnam, Fiji, Indonesia, Kiribati, Guatemala, Japan, Tuvalu, Nauru, Tonga, United Arab Emirates, Rwanda, Sri Lanka; *1999:* Colombia, Republic of the Congo, Georgia, Hungary, Republic of Korea, Liechtenstein, Republic of Moldova, Monaco, Palau, Qatar, San Marino, Singapore, Solomon Islands, Uruguay, Vanuatu; *2000:* Albania, Australia, Bahamas, Croatia, Cyprus, Czech Republic, New Zealand, Papua New Guinea, Philippines, Suriname, Trinidad and Tobago, United States; *2001:* Belarus, Bulgaria, Poland, Slovenia, Thailand; *2002:* Andorra, Bosnia and Herzegovina, Brunei Darussalam, Latvia, Macedonia, Maldives, Slovak Republic, Somalia, Ukraine; *2003:* Bhutan, Democratic People's Republic of Korea, Lithuania, Russian Federation, Timor Leste; *2007:* Montenegro, Serbia

• Background

The United Nations Convention to Combat Desertification in those Countries Experiencing Serious Drought and/or Desertification, Particularly in Africa (UNCCD; also known as the Desertification Convention) was developed following concerns expressed in 1991 by the United Nations Environment Programme (UNEP). UNEP indicated that the Plan of Action to Combat Desertification (PACD), which had been developed as a result of the 1977 United Nations Conference on Desertification (UNCOD), was ineffective. Since the plan's implementation, the problem of land degradation in arid, semiarid, and dry sub-humid areas had intensified rather than diminished. The PACD's ineffectiveness was seen as due in part to the "top down" approach it had adopted and to the low priority given to desertification by many governments.

As a result of pressure from African states, the participants in the 1992 United Nations Conference on Environment and Development (UNCED) in Rio de Janeiro supported a new approach to de-

Participants in a 2008 international conference on desertification in Beijing, China. Chinese vice premier Hui Liangyu addressed the conference, calling upon all parties to the Convention to Combat Desertification to honor their commitments. (Xinhua/Landov)

sertification, emphasizing integrated action and sustainable development at the community level. They proposed a new international treaty addressing the issue of desertification. Despite a lukewarm reception from many developed nations, the U.N. General Assembly established an international committee to negotiate a desertification convention, and the convention was adopted on June 17, 1994, after intensive debate. The UNCCD frames desertification at both an environmental and a political level and emphasizes local action and the involvement of communities and nongovernmental organizations (NGOs) in providing solutions and developing national action programs.

• Summary of Provisions

The UNCCD aims to combat desertification and mitigate the effects of drought in affected areas, especially in Africa, via action at all levels of society and government, with support from international cooperation and partnerships. The convention promotes an integrated approach to arid and semiarid environmental problems in order to achieve sustainable development in these areas. It recognizes the fragile nature of dryland environments and their vulnerability to climate change and variability, including prolonged episodes of regional drought.

• Significance for Climate Change

Global warming has been associated with expanding deserts in several parts of the world, especially Saharan Africa. Warmer air holds more moisture, allowing greater evaporation and removing freshwater and groundwater from the land. Moreover, climate change is associated with alterations in global wind and weather patterns that have brought drought and desertification to several areas in the past few decades. It was the need to respond to this growing desertification that created the pressing need for an international agreement on the subject. The Desertification Convention is unlikely to reverse desertification, but it may minimize the human suffering and ecological damage caused by this process.

United Nations Division for Sustainable Development

- **Categories:** Organizations and agencies; economics, industries, and products
- **Date:** Established 1992
- **Web address:** http://www.un.org/esa/dsd/index.shtml

• Mission

An agency of the United Nations, the Division for Sustainable Development supports and helps implement programs of the Commission on Sustainable Development. The commission and division were created by the General Assembly of the United Nations to carry out the Rio Declaration on Environment and Development, which was adopted at the Earth Summit held in June, 1992. Climate change is one of the areas specifically assigned to this organization as part of its responsibilities in natural resources management.

The Division for Sustainable Development (DSD) has the mission of enabling economic development in such a manner that it not only works in the present but also will be viable in the foreseeable future. The DSD is to provide assistance and information to all organizations seeking to implement sustainable development. This includes research to define what are central factors preventing sustainable development as well as seeking solutions to overcome these factors. It seeks to work with other groups within the United Nations, as well as encouraging regional and global cooperation to implement successful patterns of sustainable development.

The DSD does not have the power to mandate actions by the members of the United Nations, nongovernmental organizations (NGOs), or citizens of any country. However, it does work to facilitate changes in the way economic development is implemented. It does this through securing funding for pilot projects, research, and educational efforts. The basic document defining the mission of the DSD, as the staff for the Commission on Sustainable Development (CSD), is Agenda 21. Agenda 21 was adopted at the United Nations Conference on Environment and Development held in Rio de Janeiro, Brazil.

The 1992 document is composed of the Rio Declaration and the Statement of Principles for the Sustainable Management of Forests. The main section focusing on climatic issues is chapter 9, "Protection of the Atmosphere." In 2002, a meeting was held in Johannesburg, South Africa, to evaluate what progress had been made toward reaching the goals of Agenda 21 and what obstacles were preventing positive movement on the issues. This meeting adopted the Johannesburg Plan of Implementation, which contains specific steps to be taken toward the goals.

As the portion of the U.N. secretariat charged with fulfilling the implementation plan, the DSD works with a wide variety of organizations to move toward the goal of sustainable development. Climate change, including global warming and desertification, is an area of special focus. The DSD also works with the Small Island Developing States network, a special work group established in 1997 because of the special vulnerability of small islands to any rise in ocean levels. Such a sea-level rise could occur if global warming causes the melting of the polar ice caps.

• Significance for Climate Change

Development is not sustainable if it creates climatic or other environmental changes that interfere with the continuation of proposed economic enterprises. It is for this reason that diligent research is undertaken on all development proposals to discern if any factor of a proposal might increase any type of pollution. The DSD has accepted a finding by the Intergovernmental Panel on Climate Change that it is more than 90 percent likely that the current fossil-fuel-based energy system emits greenhouse gases (GHGs) that cause global warming.

While recognizing that fossil fuels will remain part of the energy system in the short run, the DSD seeks the means to move to alternative sources of energy as rapidly as possible. An example of this program is the electrification of rural areas of Kiribati. These areas are not connected to the urban electrical grid, which relies mainly on imported fossil fuels. Instead, a DSD-sponsored pilot project installed solar panels and batteries on private houses to power electric lights. The project proved the practicality and reliability of such systems in relatively isolated areas, as well as investigating the minimum number of panels and batteries needed in an area to allow an economically feasible support structure to operate. Providing the support structure also made it possible for individuals to consider adding more solar panels to power refrigeration and other applications.

In addition to providing numerous publications and online forums, the CSD holds annual conferences that generally focus on selected issues. In 2002, the World Summit on Sustainable Development was held. This meeting encouraged all nations to develop sustainable development plans. In 2007, the DSD sponsored an experts' meeting on the topic of "Integrating Climate Change into National Sustainable Development Strategies." The philosophy behind this meeting is summarized in this statement from the "Concept Note" regarding the rationale for the conference: "Its objective is to strengthen sustainable development as the most effective framework within which to tackle climate change." Thus, while the DSD has a broad charge, going well beyond just climate change and global warming, it does envision sustainable development as the key to solving anthropogenic climatic problems.

United Nations Environment Programme

- **Categories:** Organizations and agencies; environmentalism, conservation, and ecosystems
- **Date:** Established 1972
- **Web address:** http://www.unep.org/

• Mission

The United Nations Environment Programme (UNEP) is a designated agency of the United Nations system on environment that develops international agreements; assesses global, regional, and national environmental events; and fosters international partnerships. UNEP has a mission to provide leadership and develop partnerships in caring for the environment by working with countries and their people to improve the quality of life of present and future generations. The program provides environmental data and information that governments around the world use in planning and executing sustainable development projects. It develops policy guidelines to address salient environmental issues, such as lack of freshwater, degradation of the marine environment, and atmospheric pollution. UNEP assists governments in anticipating, responding to, and managing disasters caused by environmental factors. It also helps assess the environmental effects of wars and provides postwar cleanup and mitigation advice. It builds national environmental capacity and helps develop international environmental law.

UNEP's headquarters are in Nairobi, Kenya. The program has additional regional offices in Bangkok, Thailand; Geneva, Switzerland; Mexico City; Washington, D.C.; and Manama, Bahrain. UNEP

Achim Steiner, executive director of the United Nations Environment Programme, addresses the eighth Conference of the Parties to the Basel Convention in November, 2006. (Xinhua/Landov)

also supports several centers of excellence, such as the UNEP Collaborating Center on Energy and Environment (UCCEE), the UNEP World Conservation Monitoring Centre (UNEP-WCMC), and the Global Resource Information Database (GRID).

UNEP is organized into eight divisions that work toward promoting and facilitating effective environmental management for sustainable development. These include the divisions for Early Warning and Assessment; Policy Development and Law; Environmental Policy Implementation; Technology, Industry and Economics; Regional Cooperation; Environmental Conventions; Communications and Public Information; and Global Environment Facility Coordination. UNEP focuses on five priority areas: environmental assessment and early warning; development of policy instruments; enhanced coordination with environmental conventions; technology transfer; and providing particular support to African nations.

UNEP is the host for several environmental convention secretariats. Some of these include the Secretariat of the Vienna Convention for the Protection of the Ozone Layer, in Nairobi; the Multilateral Fund of the Montreal Protocol, in Montreal, Canada; the Convention on International Trade in Endangered Species (CITES), in Geneva; the Convention on Biological Diversity, in Montreal; the Convention on Migratory Species of Wild Animals, in Bonn, Germany; the Basel Convention on the Transboundary Movement of Hazardous and Other Wastes, in Geneva; the Stockholm Convention on Persistent Organic Pollutants (POPs), in Geneva; and the Rotterdam Convention on Prior Informed Consent, also in Geneva.

• Significance for Climate Change

UNEP makes periodic assessments and forecasts of environmental threats. It has obtained support for effective national and international responses to such threats and has developed effective coordination of environmental issues within the United Nations. Since 2000, on the directions of the U.N. General Assembly, UNEP has started an annual Global Ministerial Environment Forum (GMEF). This forum's participants review policy issues in the field of environment and try to build consensus. Based on the work of the forum in 2000, environmental sustainability was listed in the Millennium Declaration as one of eight millennium development goals.

Several international environmental agreements have been established with the help of UNEP. Examples of such agreements include the Montreal Protocol to restore the ozone layer in 1987, the United Nations Framework Convention on Climate Change (UNFCCC) in 1992, and the Kyoto Protocol to the UNFCCC in 1997. The program has also aided in the framing of several treaties that govern the production, transportation, use, release, and disposal of chemicals, as well as several treaties that protect global biodiversity.

UNEP has been involved in the development of environmental programs that affect climate. An example of such a project is the OzonAction program, which implements the Montreal Protocol and helps restore Earth's ozone layer by phasing out ozone-depleting substances. Another project is the Global Programme of Action, which protects the marine environment from common land-based sources of pollution by promoting integrated management of river basins and coastal zones. The International Coral Reef Action Network fosters the conservation and sustainable management of the world's coral reefs, while the Great Apes Survival Project (GRASP) mobilizes political will toward preserving apes and their forest habitats.

United Nations Framework Convention on Climate Change

• **Category:** Laws, treaties, and protocols
• **Date:** Entered into force March 21, 1994

The UNFCCC was the first comprehensive global agreement seeking to control the atmospheric factors contributing to global warming. Although the initial agreement did not identify specific environmental changes, it established a process through which pollution-control agreements could be made. The Kyoto Protocol is the most well known of these subsequent agreements.

• Background

Although the environmental movement had been around for decades, it initially dealt with localized problems or changes that could be easily seen. Some individuals considered the broader picture, but the size of the Earth made many assume that people could not make significant changes on a global scale. In the late 1960's, partially as a result of the moon landings, people saw how small the Earth is within the universe. More people became concerned about the environment, as seen in movements such as Earth Day.

Funding for the scientific collection of environmental data grew, and the understanding of what was happening to the global system, especially the atmosphere, increased. Some scientists began to issue warnings about anthropogenic damage to the global system. In the United States, two examples helped people accept these warnings: acid rain and the depletion of the ozone layer. While acid rain was a problem only for specific locations and treated at that level, depletion of the ozone was seen as a global problem. Scientists could demonstrate how chlorofluorocarbons and related compounds were causing the expansion of holes in the ozone layer. A result was the Montreal Protocol of 1987, which limited the production and use of ozone-depleting chemicals. Within the agreement, countries were divided into developed and developing categories, with different regulations applying to each group. This proved to be an important precedent for future environmental treaties.

In June, 1992, the United Nations hosted the Conference on Environment and Development in Rio de Janeiro, Brazil (the Earth Summit). Among the items passed by the conference was the United Nations Framework Convention on Climate Change (UNFCCC). After enough countries ratified the agreement, it went into effect in March, 1994. The UNFCCC recognizes that greenhouse gases (GHGs) created by human activities are a major factor in global warming and mandates that member nations reduce their GHG emissions to a level that will not cause environmental harm.

• Summary of Provisions

Scientific study of the role that GHGs play in regulating the temperature of the Earth has indicated that they contribute to an increase in the atmosphere's average temperature. Leading up to the Earth Summit, a major point of contention was whether or not the agreement to be negotiated there should contain specific limits on GHG emissions, with the United States arguing against setting such limits. The UNFCCC accepted the premise that anthropogenic GHGs are a major factor causing global warming, said that GHG emissions would be monitored, and established a system for future discussions for specific steps to be taken. Since the UNFCCC did not contain specific limits, the United States agreed and was the first industrialized country to ratify this agreement.

The UNFCCC established three steps toward reducing GHG emissions, in addition to establishing the framework for future negotiations. These included an agreement in principle to reduce GHG emissions to below their 1990 levels, the establishment of a market for trading emission credits, and the creation of a mechanism for industrialized countries to help developing countries acquire low-polluting systems. In addition, Annex I of the convention listed the parties that were industrialized nations, and it committed only those nations to make significant, albeit unspecified, GHG reductions. Developing, non-Annex I parties were given no such commitments. A secretariat was established in Bonn, Germany, to facilitate the implementation of these measures.

• The Kyoto Protocol and Implementation

Beginning in 1995, there has been an annual Conference of the Parties (COP) to the UNFCCC. Meeting in Kyoto in 1997, the conference adopted the Kyoto Protocol. It stated that the developed countries must reduce their GHG emissions during the period from 2008 to 2012. The base year for measuring these reductions was 1990. The goals set varied for the developed countries, but the 7 percent reduction assigned to the United States was relatively typical.

The United States signed the protocol, but President George W. Bush never sent it to the Senate for ratification, so it is not binding on the United States. Using the system already established to record the amount of GHGs emitted, plans were to be developed in each country to reduce those emissions.

Principles of the U.N. Framework Convention on Climate Change

Article 3 of the UNFCCC sets out the five principles that should guide all parties to the convention in all actions relating to the convention.

1. The Parties should protect the climate system for the benefit of present and future generations of humankind, on the basis of equity and in accordance with their common but differentiated responsibilities and respective capabilities. Accordingly, the developed country Parties should take the lead in combating climate change and the adverse effects thereof.

2. The specific needs and special circumstances of developing country Parties, especially those that are particularly vulnerable to the adverse effects of climate change, and of those Parties, especially developing country Parties, that would have to bear a disproportionate or abnormal burden under the Convention, should be given full consideration.

3. The Parties should take precautionary measures to anticipate, prevent or minimize the causes of climate change and mitigate its adverse effects. Where there are threats of serious or irreversible damage, lack of full scientific certainty should not be used as a reason for postponing such measures, taking into account that policies and measures to deal with climate change should be cost-effective so as to ensure global benefits at the lowest possible cost. To achieve this, such policies and measures should take into account different socio-economic contexts, be comprehensive, cover all relevant sources, sinks and reservoirs of greenhouse gases and adaptation, and comprise all economic sectors. Efforts to address climate change may be carried out cooperatively by interested Parties.

4. The Parties have a right to, and should, promote sustainable development. Policies and measures to protect the climate system against human-induced change should be appropriate for the specific conditions of each Party and should be integrated with national development programmes, taking into account that economic development is essential for adopting measures to address climate change.

5. The Parties should cooperate to promote a supportive and open international economic system that would lead to sustainable economic growth and development in all Parties, particularly developing country Parties, thus enabling them better to address the problems of climate change. Measures taken to combat climate change, including unilateral ones, should not constitute a means of arbitrary or unjustifiable discrimination or a disguised restriction on international trade.

The Kyoto Protocol also set the standards for reporting this information to the Climate Change Secretariat. A compliance committee was established to ensure that the goals were met. At each annual COP meeting, issues regarding the implementation of current agreements or proposals for new ones are discussed.

• Context

In 1994 not all governments were convinced that human activities were a major factor in global warming. That is no longer the case. The gradual acceptance of this proposition has pushed forward the agenda of controlling GHG emissions. However, this situation falls into the category of being a political problem of the commons: No one country is the cause, nor can any country's response be a full solution. The more countries act, the better for everyone, so some nations see their ideal response as being to let everyone else work toward the solution, sharing in the benefits without experiencing any costs. This is the mind-set that the Earth Summit and the UNFCCC had to overcome.

With more than 190 nations as parties, the UNFCCC has overcome the problem of nonparticipation, at least on paper. By this measure, it is one of the most successful venues of international cooperation, with virtually every country in the world as a member. The division of the membership into different categories, with differing responsibilities, has made possible progress toward the goal of reducing global warming. The UNFCCC institutes a system that philosophically resembles a progressive tax system, in which the nations with the greatest economic resources are asked to make the greatest contributions toward reducing GHG emissions.

This division between industrialized and developing nations enables developing nations to continue developing, whereas requiring equal concessions from all nations would reinforce the status quo of economic relations, ensuring that the poor nations would remain poor. This provision has proven crucial to obtaining widespread cooperation. On the other hand, the UNFCCC gives economically developed countries the incentive to develop and use new technologies, which some believe will allow them to continue their economic dominance. Thus, while climate change is a physical change, how it is dealt with has many political and economic consequences.

United States

- **Category:** Nations and peoples
- **Key facts**

Population: 307,212,123 (July, 2009, estimate)
Area: 9,552,058 square kilometers
Gross domestic product (GDP): $14.29 trillion (purchasing power parity, 2008 estimate)
Greenhouse gas (GHG) emissions in millions of metric tons of carbon dioxide equivalent (CO_2e): 6,135 in 1990; 6,928 in 2000; 7,017 in 2006
Kyoto Protocol status: Not ratified

• Historical and Geopolitical Context

The United States is bordered by Canada on the north, Mexico on the south, the Atlantic Ocean on the east, and the Pacific Ocean to the the west. It includes the island state of Hawaii, and the state of Alaska is located northwest of Canada. Despite its relatively self-contained and geographically isolated situation, the country has eschewed isolationism and assumed a leadership role in the free world. The United States is a relatively young nation but a rich one, though the U.S. national debt may climb to between $10 and $15 trillion. On January 20, 2009, the forty-fourth president of the United States, Barack Obama, was inaugurated in Washington, D.C., the nation's capital. Upon seeing the first man of color sworn into the office, Americans and people across the globe anticipated changes in U.S. policy that might help alleviate the world's problems, such as starvation and disease in developing countries, as well as climate change.

The Obama administration faced wars in Iraq and Afghanistan, a slumping economy, and an unsustainable dependence on foreign oil. Many compare the plight of President Obama to that of President Franklin D. Roosevelt, elected in 1932 during the Great Depression. The U.S. economy began to recover from that depression when the United States entered World War II in 1941. The war ended when the atomic bomb was used in Nagasaki and Hiroshima, Japan. With the end of the Cold War and collapse of the Soviet Union in 1991, the United States became the world's sole superpower.

U.S. GHG Emissions by Sector, 2004

Sector	*GHG Emissions (%)*
Industry	30
Transportation	28
Commercial	17
Residential	17
Agriculture	8
Total	100

Data from the U.S. Environmental Protection Agency.

• Impact of American Policies on Climate Change

From 2000 to 2007, U.S. greenhouse gas (GHG) emissions increased by 3 percent, air pollution (fine particles) decreased by 12 percent, and renewable energy increased as a share of total energy consumption from 5.4 to 6.7 percent. The first large and highly successful "cap-and-trade" program in the United States followed the Clean Air Act Amendments of 1990, which mandated a 50 percent decrease over ten years in sulfur dioxide (SO_2) emissions produced by the coal and petroleum industries. This led to anticipated savings in health care costs. In 2007, the 110th U.S. Congress passed the Energy and Security Act of 2007, which aimed to increase production of clean, renewable fuels and the energy performance of the federal government.

Individual states, academic institutions, and business enterprises have begun enacting their own initiatives to address global warming: In 2008, California governor Arnold Schwarzenegger signed a state law to integrate GHG emissions reduction into California's transportation planning decisions. President Obama asked federal regulators to act on applications by California and ten other states to set stricter fuel efficiency standards for vehicles. Nine governors signed on to the Midwestern GHG Reduction Accord in 2007, and New York City won an international award for sustainable transport.

In January, 2009, outgoing president George W. Bush designated 505,770 square kilometers of Pacific Ocean reefs, islands, surface waters, and sea floor as marine national monuments, thereby restricting fishing, oil exploration, and mining in those areas. Also in 2009, the U.S. Senate advanced legislation to preserve over 809,000 hectares of land in nine states as wilderness. On the downside, a sludge spill in Tennessee of almost 1 million kilograms of toxic materials brought into question the notion of clean coal. The outgoing Bush administration announced a plan to make 3.64 million hectares in Utah available for energy exploration.

• The United States as a GHG Emitter

According to Reuters, China may have replaced the United States as the top GHG emitter in the world in 2007; China has reported that its GHG emissions have caught up with those of the United States and that China's dependence on coal would make curbing GHG emissions difficult. Of note, total U.S. GHG emissions in 2007 were 1.4 percent above the 2006 total. This increase was largely the result of an increase in CO_2 emissions attributable to poor weather conditions, which led to greater demand for heating or cooling in buildings, and to a decrease in accessible hydropower resulting in a greater demand for fossil fuels such as coal and natural gas.

The Kyoto Protocol established carbon quotas for member countries, which may use carbon sinks (reservoirs of foliage or forests) as a form of "carbon offset." This ability may be useful to countries with large areas of forest or vegetation. However, for industrial, developed nations such as the United States, land use would have little effect in meeting Kyoto Protocol quotas, since most of the lands have already been cultivated. In addition, developing countries such as Brazil and Indonesia are not compelled to restrict their GHG emissions, which may come from land-use choices such as cultivating crops and destroying forests. As a result, the United States has refused to ratify the Kyoto Protocol.

While the Gulf states who are members of the Organization of Petroleum Exporting Countries (OPEC) have the highest GHG emissions, data from 2000 shows that—of the top twenty emitters—those with highest per capita emissions were the industrialized, or Annex I, countries. Australia, the United States, and Canada ranked fifth, seventh, and ninth, respectively. Their per capita emissions (7.0, 6.6, and 6.1 metric tons per person) were approximately double the emissions of the highest-ranked developing country in the top twenty (South Korea, at 3.0 metric tons), and they were six times those of China (1.1 metric tons). The reasons the United States has such high per capita GHG emissions include its dependence on fossil fuels to transport people and goods over large distances and its relatively low population density, fifty persons per square kilometer as of 2006.

• Summary and Foresight

The European Union has pledged to cut GHG emissions 20-30 percent by 2020, below 1990 levels, if other large GHG emitters such as the United States would follow suit. Sir Nicholas Stern, an adviser to the British government, has testified before the U.S. Congress: Stern had authored a report asking the global community to either take "urgent action" on global warming or face severe economic consequences that would "rival the Depression of 1929." The Americans responded that Stern's study was "50 years ahead of its time." Sir Stern may have been prophetic; the economic downturn of 2008 and following has focused on the plight of the U.S. automobile industry with its high-GHG-emitting vehicles, which appear to be losing out to their more energy-efficient foreign counterparts.

The Obama administration has linked the rescue and restructuring of the U.S. auto industry to a redesign of its products to be more fuel efficient and has

asked the Department of Transportation to enforce a 2007 law that would increase fuel efficiency standards that would affect vehicles sold in 2011. During the Great Depression, President Roosevelt blamed the bankers and drafted the New Deal, which focused on the U.S. farmer. Today, many believe the United States needs a "Green New Deal," which would turn environmentally friendly products and techniques into the nation's major growth sector, driving recovery. Indeed, fostering green energy may be key to rebuilding the U.S. economy.

Urban heat island

- **Category:** Economics, industries, and products

- **Definition**

An urban heat island is a metropolitan area that is significantly warmer in surface and air temperature than its suburban and rural surroundings. English amateur meteorologist Luke Howard, in his book *The Climate of London* (1818), described temperature differences between London and its surrounding countryside. He noted that it was warmer at night in London than in the country and speculated that the cause might be the burning of fuels. Research over the subsequent two centuries has charted a variety of differences between cities and their surroundings, as distinctive urban landscapes, domestic and industrial structures, and the behavior of urban dwellers affect the ways in which solar and other heat enters and exits the area. Urbanization causes changes to the preexisting natural landscape, as original materials (soil, vegetation, rock, water, and so on) are gradually replaced or modified with materials (concrete, tile, and many others) that, in conjunction with the activities and life patterns of a city's inhabitants, result in greater heat retention. This heat retention can in turn affect weather patterns.

- **Significance for Climate Change**

Scientists have identified many interconnected causes for the urban heat island effect. During the day, the Sun warms buildings and roadways. Pollution from automotive traffic and industrial processes contributes to the formation of clouds and smog, which help trap heat, and tall buildings limit the ability of winds to disperse such formations (the "canyon effect"). The predominance of land structures and the paucity of bodies of water lessen the influence of evaporation, which would use some of the heat energy for the formation of water vapor. Instead, that energy raises the ambient temperature. The concentration of human bodies in cities also contributes to their heat level. The increase in city heat in turn encourages activities, such as the use of air conditioning, that further contribute to localized heat increases, since air conditioners make interiors cooler by making the exterior city warmer. Moreover, increased power plant emissions resulting from the additional consumption of electricity will contribute to global warming.

To the extent that urban areas encourage structures or behaviors that stimulate additional activities, increasing emission of greenhouse gases (GHGs), urban heat islands may be viewed as contributing indirectly to global warming. (If cities are hotter than rural areas, then those who move to cities will be more likely to use energy to cool themselves than they otherwise would be.) As large metropolitan areas fuse into megalopolises, or megacities, the problems only become exacerbated. Accordingly, students of the urban heat island effect have seen the need for various degrees of urban redesign as a key element in attempts to mitigate the noxious consequences of the effect. Chief among these is increase in, and optimal distribution of, urban vegetation and green space, including the planting and sustaining of suitable trees.

The urban heat island effect must be taken into account in any attempt to read the historical record of Earth's temperature. To compare today's temperature with that of a century ago requires comparability, and that can be affected by urban growth. Places where temperatures were measured in the past often have since experienced significant urban growth, with the associated increased temperature measurements. This growth makes direct comparisons of present and past measurements difficult. In light of this problem, climatologists must adjust the data on the basis of their best guess about distorting factors.

U.S. and European politics

• **Category:** Nations and peoples

The United States accounts for about 25 percent of the world's GHG emissions, while the countries of Europe account for about 14 percent. The technological capabilities and innovative potential of these nations create an opportunity for major reductions in GHG emissions, but such reductions would almost certainly need to be mandated by the American and European governments, subjecting them to the vagaries of democratic political practices.

• Key concepts

European Union: a supra-governmental organization to which many European countries belong and that has been given many powers traditionally associated with national governments

green politics: a political orientation founded upon environmental concerns

greenhouse gases (GHGs): gases, such as carbon dioxide, that tend to keep heat in the atmosphere rather than allowing it to dissipate into space

parliamentary system: the system in most European countries, where the chief executive of the government (the prime minister) is elected by the members of the legislative body

presidential system: the system in the United States, where the chief executive of the government (the president) is elected by the people

• Background

Politics is a social choice mechanism established to create an orderly society. Democratic theory assumes that people will vote for candidates who will best serve the interests of the people. Most European countries and the United States are well established democracies in which the choice mechanisms of politics and economics freely interact. Environmental concerns, including climate change, are a part of both the political and economic arena. In Europe the environment tends to be seen as social/political, while in the United States it is economic.

• European Politics and Policy

Most European countries use some form of the parliamentary system. In a parliamentary system the majority party can usually pass its desired laws and implement its desired policies because the same person leads the legislative and executive branches. When the citizens of a country push for policies to limit climate change, it happens much more quickly. Having had a relatively high population density for centuries, the human effect on the environment seems to be more easily understood by Europeans. When evidence that human activity caused climate change became clear, Europeans generally responded to it much more quickly than Americans.

At the end of his first week in office, President Barack Obama signs an executive order dealing with climate change and energy independence. Behind him are Environmental Protection Agency administrator Lisa Jackson and Transportation Secretary Ray LaHood. (Chuck Kennedy/MCT/Landov)

As a whole, the fifteen members (in 1997 when the Kyoto Protocol was signed) of the European Union are expected to reduce their GHG emissions by eight percent from 1990 levels. The European Union allocated this among its members, as it understood that not all countries could reduce their emissions the same amount. The two most industrialized countries in Europe, Germany and the United Kingdom, create about fifty percent of the GHG emissions. However, they volunteered to accept more than their share of GHG emission reductions to lead the community. Throughout Europe, whether conservative or liberal parties govern, they accept much tougher antipollution standards than does the United States. The United Kingdom had already met its 2012 goals prior to 2008, as was the case for Finland, France, and Sweden. The only two European Union countries that might not reach their 2012 goals are Spain and Portugal. The European Parliament passed the necessary legislation to set up an emissions trading network to add market pressures for GHG emission reductions. Overall, Europe has come to the understanding that the rights of the community outweigh the rights of individuals when it comes to GHG emissions and climate change.

- **United States Politics and Policy**

In the United States, the dominant economic view is that the individual has most of the rights in determining how to make use of the environment. This does not mean that there are no regulations, but when in doubt, the individual's rights are generally seen as stronger than the community's. This is the case with pollution controls and GHG emissions. While leading European countries were reducing their GHG emissions, the United States' emissions increased by sixteen percent from 1990 to 2004. Some states, such as California, have enacted laws to try to contain pollution; others continue with few regulations. Texas has more GHG emissions than any European country except Germany. The basic stance of many politicians is that the free market economy can take care of any problem, including GHG emissions. If consumers do not want products made by polluting factories, they will buy other products. When it becomes more economical to use nonpolluting technologies, then businesses will use nonpolluting technology. This does not lead to a strong anti-GHG emission policy.

A second problem in creating change in the United States is the fact that the American political system has more checks and balances than do most European systems of government. Thus the separate executive and legislative branches are often in conflict, even when controlled by the same political party. No major piece of environmental legislation was passed during the presidencies of Bill Clinton or George W. Bush. The year the Kyoto Protocol was negotiated, the U.S. Senate passed a resolution stating it would not ratify it. President Clinton signed it and said the United States would strive to reach its goals under the agreement; however, President Bush rescinded this effort. In 2003, the Senate for first time actually allowed GHG limit legislation to reach the floor for a vote. In 2005, Congress passed a resolution calling for GHG limits consistent with a free market economy.

- **Context**

While the collective effect of actions by individuals can make a significant difference in global warming, national policies can make changes much more rapidly. With scientific predictions of increased global warming affecting all forms of life, a rapid response to the situation is needed. If the major nations of the world take the initiative to combat global warming, the possibility to avert catastrophic consequences increases greatly. However, democracies only respond to the will of the people. When political parties believe that support of policies combating climate change will help them win elections, these policies become incorporated into a party's platform. It has been several decades since all political parties have accepted the need to unsure clean water for the citizens and proper sewage treatment. More recently, lower atmospheric air quality became a common concern and laws were passed regarding many types of air pollution. With the developing concern regarding GHG pollution, stronger citizen expressions of that concern are being made. As these expressions become more widespread, it is logical to assume that most political parties will incorporate GHG reduction into their stated goals. When this happens, decisions on global warming policy will no longer be seen as a political action. Combating climate change will be seen as a nonpartisan action, like unsuring a safe water supply, which is a proper area of governmental involvement.

U.S. Climate Action Report, 2002

- **Category:** Laws, treaties, and protocols
- **Date:** Submitted May 28, 2002

With the U.S. Climate Action Report, 2002*, the Bush administration acknowledged for the first time that global warming has anthropogenic causes and that if warming remains unchecked it will seriously harm the environment of the United States.*

- **Background**

The United Nations Framework Convention on Climate Change (UNFCCC) was signed by President George H. W. Bush in June, 1992. Under the terms of the convention and of later agreements of the UNFCCC Conference of the Parties (COP), signatory nations were to report their progress toward reducing global warming. The United States submitted its first two climate action reports in 1994 and 1997 under President Bill Clinton and its third and fourth reports in 2002 and 2007 under President George W. Bush.

From the time Bush took office, his administration denied the scientific validity of the theories that human action was causing global warming and that global warming posed a serious threat. Instead, the administration's official position was that there was no scientific consensus on the subject and that more research was needed to determine whether or not global warming should be taken seriously. Although in 2000 the *National Assessment of the Potential Consequences of Climate Variability and Change,* a report commissioned by the U.S. Congress, had warned of serious consequences if global warming was not addressed, the Bush administration rejected these findings.

• Summary of Provisions

The findings of the *U.S. Climate Action Report, 2002,* which was prepared by the Environmental Protection Agency (EPA), are strikingly similar to those of the 2000 *National Assessment.* The report states that the Earth's air and ocean temperatures are increasing, primarily as a result of the accumulation of anthropogenic greenhouse gas (GHG) emissions, although natural fluctuations in temperature are also mentioned. If GHG emissions continue to increase and temperatures continue to rise, the report says, serious damage will occur.

If global warming continues, according to the report, some of the Barrier Islands of the Atlantic Coast and alpine meadows in the Rocky Mountains will likely disappear. Forests in the Southeast and the habitats of several migratory species will be disrupted, heat waves will become more severe and more common, and roads and other elements of infrastructure will suffer damage because of rising water levels or melting permafrost.

The report also describes potential environmental and economic benefits of global warming. Warmer temperatures will lead to longer growing seasons in parts of the country, increasing agricultural output and forest growth. In addition, the report states, increased rainfall will aid crops, as will higher concentrations of carbon dioxide (CO_2) in the atmosphere.

The report emphasizes the idea that no matter what is done in the future to slow GHG emissions, there is no way to stop the damage from the GHGs that are already in the atmosphere. Because environmental harm is irreversible, the report calls only for voluntary measures to reduce GHG emissions, but it encourages businesses and policy makers to begin to adapt to the inevitable changes. It notes that while total U.S. GHG emissions have continued to increase, the amount of emissions per capita—which the report refers to as "greenhouse gas intensity"—decreased between 1990 and 2002.

• Significance for Climate Change

While the *U.S. Climate Action Report, 2002* acknowledged the role that the burning of fossil fuels plays in causing global warming, it did not recommend any major changes in government policy to reduce GHG emissions. Rather, it called on the United States to make broad changes to accommodate or accept inevitable environmental destruction.

The report was sent quietly to the United Nations Secretariat without a press conference or press release from the White House. It nevertheless attracted a great deal of media attention. It put the Bush administration at odds with business and industry interests with which it was usually allied. Those interests disagreed with the position that theories about global warming were based in science. Environmental groups, meanwhile, complained that the report did not call for any substantive action. The administration itself acknowledged that the report was of little significance, as it represented no change in American policy or in American interpretation of international treaties.

U.S. energy policy

• **Categories:** Nations and peoples; laws, treaties, and protocols

The energy policy of the United States is set by the president and guides both the recommendations of the executive to Congress and the instructions issued by the executive to the cabinet. Twenty-first century energy policy has dealt largely with the question of the best ways to transition from an economy dependent on foreign and polluting sources of energy to an economy that produces its own, cleaner energy.

• Key concepts

alternative energy: fuels and other energy resources that are renewable, nonpolluting, or both and have the potential to replace fossil fuels and other traditional energy resources

energy independence: the ability of a nation to generate energy sufficient for its needs domestically, without relying on foreign imports

fossil fuels: energy resources formed from decayed organic matter under geological pressures over millions of years

greenhouse gases (GHGs): atmospheric trace gases that trap heat, preventing it from escaping into space

policy: the broad set of principles guiding governmental actions and legislation in a specific arena, such as energy or foreign affairs

• Background

U.S. energy policy addresses issues of energy production, consumption, and economic and environmental impact. The direction of the policy is established by the president, but it is also defined by legislation, acts, treaties, tax codes, subsidies, and other government actions. The earliest policies of the late eighteenth century dealt with timber for heating and industry and were directly tied to land management at the federal level. In the nineteenth century, natural gas, coal, and oil dominated energy concerns. Around 1950, oil overtook coal as the most consumed energy source and continued to gain in importance, especially when highways made the automobile the preferred mode of transportation. In the second half of the twentieth century, nuclear power was added to the nation's energy concerns.

• Natural Gas

In the nineteenth century, natural gas was widely used as lighting fuel until the advent of electricity in the 1890's. Later on, the development of steel pipelines allowed for large quantities of natural gas to be safely transported over great distances, resulting in the modern natural gas industry. The first natural gas pipeline, which was more than 320 kilometers in length, was built in 1925, connecting Louisiana to Texas. Thereafter, U.S. demand for natural gas increased with rapidity, especially at the conclusion of World War II. Between 1906 and 1970, residential demand for natural gas grew fifty-fold. The United States was self-sufficient in natural gas until the late 1980's, when consumption began to significantly outpace production and the need for imports increased.

The U.S. economic slump of 2009 contributed to a decrease in domestic natural gas consumption, especially in the industrial sector, resulting in lower prices. In June, 2009, estimations of U.S. reserves of natural gas were revised upward by 35 percent, to 58.736 trillion cubic meters in 2008. The Energy Information Administration (EIA) estimates that U.S. domestic consumption and production of natural gas will increase as a result of greater demand for electricity; net imports are projected to decrease from 16 percent in 2007 to less than 3 percent in 2030 because of the increasing use of onshore resources in Alaska and offshore reserves in the Gulf of Mexico.

• Coal

Prior to 1800, the amount of coal consumed in the United States was an estimated 98,000 metric tons, much of it imported. The demand for coal expanded slowly, and it was not until 1885 that the United States burned more coal than wood. However, the advent of the Industrial Revolution—and the expansion of the railroad system in the mid-1800's—initiated a period of increasing production and use of coal that continued. In 2007, U.S. production of coal reached a record 1.06 billion metric tons (1.16 billion tons), second only to China.

Producing 27 percent of the global coal supply, the United States has the world's largest reserves of coal, totaling 444 billion metric tons at the beginning of 2008. Plentiful and inexpensive, coal generates 50 percent of the electricity in the United States. Because the cost of constructing and operating coal-fired plants is rising as a result of clean air standards, current U.S. policy on coal focuses on research and development of clean, efficient, and price-competitive technology both for domestic use and for export. In the long term, coal-generated electricity is predicted to decrease by 4 percent from 2007 to 2025 but increase once more as new plants are constructed in 2030.

• Oil

The modern petroleum age began in Pennsylvania, in 1859, when "Colonel" Edwin L. Drake's homemade drilling rig struck oil. The rapid acceptance and use of the internal combustion engine in the late 1800's increased demand for oil in the United States and globally. Up until the 1950's, the United States was self-sufficient in petroleum with 22,268 billion barrels (bl) of proven reserves. U.S. oil reserves peaked at 35,300 billion bl in 1973; in 1994, the United States imported more petroleum than it produced for the first time.

In 2008, total petroleum consumption in the United States decreased by 1.2 million barrels per day (bl/d), the steepest drop since 1980. This drop paralleled a decrease in the price of crude oil, which fell steeply. As a result, the Organization of Petroleum Exporting Countries (OPEC) agreed to production cutbacks. With demand for liquid fuel expected to rise by just one million bl/d from 2007 to 2030, in addition to the greater use of domestic biofuels, as well as increasing domestic oil production, the net import of total liquid fuels is predicted to decrease by 40 percent by 2025.

• U.S. Energy Policy in the Twentieth Century

At the beginning of the twentieth century, conservationist Theodore Roosevelt, the twenty-sixth president of the United States (1901-1909) preserved U.S. national forests and parks, as well as oil, mineral, and coal lands. His cousin, Franklin Delano Roosevelt (FDR), was elected in 1932, during the Great Depression. In 1941, during FDR's presidency, the United States joined forces with the Soviet Union and Great Britain and entered World War II. Franklin Delano Roosevelt's successor, Harry S. Truman, ordered the atomic bombing of Hiroshima and Nagasaki in Japan, thus ending the Pacific campaign and World War II. However, the use of nuclear weapons resulted in one of the worst human-made environmental disasters and long-term radioactive contamination. Twenty years later, John F. Kennedy, the thirty-fifth president of the United States (1961-1963), facilitated the limited Nuclear Test-Ban Treaty, and in September, 1996, the United Nations adopted the Comprehensive Nuclear Test-Ban Treaty. Kennedy was succeeded by Lyndon B. Johnson, who was lauded for his civil rights programs but criticized for escalating the Vietnam War and using the environmentally harmful herbicide Agent Orange in Vietnam.

In the early 1950's, both the United States and Western Europe had become net importers of Middle Eastern crude oil. It was thought that nuclear power would provide a less expensive alternative to oil. In 1959, President Dwight D. Eisenhower (1953-1961) attempted to dampen the country's reliance on foreign oil with the Oil Import Program, which limited imports of crude oil east of the Rocky Mountains. However, the American appetite for costly fossil fuels was unabated, culminating in the oil crisis of 1973. Richard M. Nixon, the thirty-seventh president (1969-1974), imposed mandatory price controls on twenty-three of the largest oil companies and later instituted a sixty-day country-wide price freeze. Following the Arab-Israeli war of October 6, 1973, OPEC raised the price of oil by 70 percent and embargoed oil shipments to the United States and other countries friendly to Israel. Gasoline prices dramatically increased in the United States thereby reducing demand for large, American-made, gas-guzzling automobiles and increasing the popularity of foreign and U.S. compact cars.

In 1979, the overthrow of the Shah of Iran by Islamic revolutionaries led to yet another Middle East crisis. Five hundred Iranian students seized the American embassy in Tehran, detaining fifty-two hostages for more than two years. President Jimmy Carter (1977-1981) halted oil imports from Iran and froze Iranian assets in the United States. Diplomatic efforts to rescue the detainees and an attempted U.S. military rescue mission failed. Even though President Carter brokered a peace treaty between Egypt and Israel, he lost the 1980 presidential election to Ronald Reagan. President Reagan facilitated the Intermediate Nuclear Forces (INF) treaty with the Soviet Union. However, in 1987 during the Iran-Iraq war (1980-1988), U.S. officials in the Reagan administration brokered a sale of arms to Iran in exchange for hostages, the so-called Iran-Contra scandal.

President Reagan's successor, George H. W. Bush, later engaged the United States in a war in the oil-rich Middle East involving Kuwait and its attacker, Iraq. Under his watch, the Clean Air Act of 1990 was passed. In 1997, the Kyoto Protocol was set forth by the United Nations to address climate change. Although Bill Clinton, the forty-first U.S. president (1993-2001), approved of the Kyoto Protocol, the United States did not ratify the treaty. President Clinton promoted globalism and increased U.S. trade via the North American Free Trade Agreement (NAFTA). In 2008, President Clinton's vice president, Al Gore, was awarded the Nobel Prize for his work on climate change.

• U.S. Energy Policy in the Twenty-first Century

George W. Bush, the son of President George H. W. Bush, was elected the forty-third U.S. president (2001-2009), and, once more, the United States focused on the Middle East following terrorist attacks on the United States by al-Qaeda on September 11, 2001. In retaliation, the first U.S. president of the twenty-first century invaded oil-rich Iraq on the premise of destroying its weapons of mass destruction, which were never recovered. At the end of the first decade of the twenty-first century, the United States was dealing with ending the war in Iraq, while confronting the U.S. dependence on fossil fuels and its environmental consequences. President Bush embraced federalism and advocated state's rights; he believed that individual states, cities, and industries could facilitate their own measures to combat global warming. His policy of laissez-faire translated into attenuation of federal regulation of industries regarding air and water pollution. Globally, the Bush administration chose not to ratify the Kyoto Protocol because it differentiated responsibilities between industrialized Annex I nations, such as the United States, and developing, non-Annex I nations, such as India and China.

During Bush's presidency, the United States became the largest purveyor of biofuels. His policies aimed at increasing the use of renewable energy included the Renewable Electricity Production Tax Credit, the Renewable Portfolio Standards (RPS), and the Renewable Energy Certificates/Credits (RECs). President Bush signed into law the Energy Policy Act of 2005, which encouraged energy conservation and efficiency through modernization of the energy infrastructure and through diversification of the U.S. energy supply, including nuclear energy development.

Two years later, the 110th U.S. Congress passed the Energy and Security Act of 2007 with the aim of increasing production of clean, renewable fuels and enhancing the "energy performance" of the federal government. In early 2009, President Bush designated 505,736 square kilomters of U.S. Pacific Ocean reefs, islands, surface waters, and seafloor as "marine national monuments," thereby restricting fishing, oil exploration, and mining in the region. On the other hand, the outgoing Bush administration supported a plan to make available 3.6 million hectares in Utah for energy exploration, such as prospecting for minerals. At the end of President Bush's term, the Environmental Protection Agency (EPA) began an "aggressive review" of mountaintop coal mining permits, while expressing concern about strip mining procedures that blast the tops off mountains, spewing rocks and waste into surface water in violation of the Clean Water Act of 1972.

President Barack Obama became the forty-fourth U.S. president in 2009, the first man of color to hold the office. President Obama came into office with promises to change U.S. energy policy in ways that would better address problems such as climate change. President Obama also entered the office confronting wars in Iraq and Afghanistan, a slumping economy, and an unsustainable dependence on oil imports. In February, 2009, Congress agreed to a $787 billion package of tax breaks and funding called the American Recovery and Reinvestment Act of 2009 (ARRA). President Obama's energy agenda allotted more than $20 billion for tax incentives for renewable energy providers and activities that encourage the use of renewable energy sources. About $1 billion would go to the National Aeronautics and Space Administration (NASA), and $1.6 billion to the Department of Energy for research and development in climate science.

President Obama called on Congress to put forth legislation that places a market-driven cap on carbon and increases the production of renewable energy. Of note, the Clean Air Act of 1990 preceded the first highly successful "cap and trade" program in the United States, which mandated a 50 percent decrease over ten years in sulfur dioxide emissions produced by the coal and petroleum industries. In addition, President Obama's $800 billion economic stimulus proposal included $50.8 billion for energy and water development, $20 billion of which was allocated for building a smart-grid power network and a high-tech infrastructure to draw upon renewable energy sources—such as wind turbines and solar panels—which could handle uneven energy production.

On February 24, 2009, a federal appeals court ordered the EPA to reconsider the standards regulated by the Clean Air Act it had adopted in 2006 for the pollutants and fine particles associated with heart and lung diseases. In 2006, EPA scientists had recommended that allowable levels for fine particles be adjusted downward, though action was not taken. In April, 2009, the EPA officially proposed that GHGs be considered a danger to public health and welfare in response to a Supreme Court decision in 2007 that found GHG emissions to be subject to federal Clean Air Act standards.

• Context

The famous English poet Sir Geoffrey Chaucer said that the "past is prologue," and nowhere is this more apparent than the U.S. government's energy policies of the twentieth and twenty-first centuries; over and again, three themes are repeated: first, the U.S. addiction to fossil fuels; second, the country's dependence on foreign countries (mainly in the Middle East) to fulfill its energy needs; and third, the inadequate response of the United States to address climate change. Though president George W. Bush acknowledged the need for renewable energy sources, he advocated state's rights and attenuated federal regulations on pollution.

Upon his election, President Obama called on Americans and U.S. policymakers to move forward with investments in clean, efficient renewable energy, and he submitted a federal budget that included $150 billion for creating "green" jobs, reducing dependence on foreign fossil fuels, and preventing the dire consequences of global warming. However, the pundits warn that while renewable energy is gaining momentum, it is not a panacea. For it to be truly effective, renewable energy has to have zero-carbon output such as that obtained by recycling heat. Eco-friendly and water-sparing renewable energy should not require an inordinate amount of energy for production, or it defeats its own purpose.

Will conversion to clean, efficient renewable energies happen in time to forestall the consequences of global warming? Sharon Begley of *Newsweek* magazine is pessimistic about the ability to reduce GHG emissions using current methods, "even if we scale up existing technologies to mind-bending levels . . . we'll still fall short of how much low-carbon energy will be needed to keep atmospheric levels of carbon dioxide below the 'point of no return' in order to prevent a climate crisis in 2050."

U.S. legislation

• Category: Laws, treaties, and protocols

U.S. climate-related legislation has attempted to reverse or reduce some of the damage done to the environment, to minimize resource depletion, and to prevent or mitigate GHG emissions and other climate-related pollution.

• Key concepts

carbon dioxide: a colorless, odorless greenhouse gas that is emitted by burning fossil fuels

climate action plan: a plan that identifies cost-effective ways to reduce GHG emissions

climate change: changes in long-term trends in the average weather of a given region

emissions cap: a mandatory limit on the amount of GHG emissions that can be released into the atmosphere by a given nation, business, or other specific entity

greenhouse effect: the process whereby certain gases in a planet's atmosphere prevent heat from escaping into space

greenhouse gases (GHGs): gases that contribute to the greenhouse effect

• Background

Climate change is the result of a complex of changes in atmospheric and oceanic composition and dynamics, and it has been suspected that Earth's climate is warming. Many scientists believe that available data indicate that human activity—particularly increased emissions of greenhouse gases (GHGs)—is contributing to this warming. Global warming, in turn, is expected to affect supplies of food and water, air quality, energy resources, biodiversity, and human and nonhuman migration patterns. Over the past several decades, therefore, legislation has been proposed and passed in the United States in an attempt to ameliorate the effects of global warming.

• Air Pollution Control Act

The first federal legislation regarding air pollution was the 1955 Air Pollution Control Act. This law established funding requirements for federal research on air pollution but did nothing to control that pollution. It was not until the Clean Air Act of 1963 that an attempt was made to place controls on emissions of air pollutants, mostly through monitoring manufacturing techniques. On the international scene, the following year saw the establishment of a new international organization. Originally called the Group of 77 and China (because it consisted of seventy-seven developing countries and China), this group met periodically to discuss and negotiate policy related to climate-change issues.

• Clean Air Act and Its Amendments

The Clean Air Act of 1963 was amended in 1970. The Clean Air Act Amendments led to the development of regulatory programs including the National Ambient Air Quality Standards (NAAQS), state implementation plans, new source performance standards, and national emissions standards for hazardous air pollutants. At the same time that this legislation was adopted, the Environmental Protection Agency (EPA) was being developed through the National Environmental Policy Act of 1970. The EPA was officially launched in 1971. Between the Clean Air Act and its 1970 amendments, Congress enacted the Air Quality Act (1967), which enhanced procedures to monitor interstate air pollution transport and expanded studies of air pollution emissions and control techniques.

A series of additional amendments was passed as the Clean Air Act Amendments of 1977, which were concerned with maintenance issues regarding NAAQS. In 1990, the authority and responsibilities of the government to regulate air quality were increased through the Clean Air Act Amendments of 1990. New programs were created to control acid rain and emissions that compromised atmospheric ozone. The 1990 revisions increased research programs and the federal government's authority to enforce standards. The 1990 amendments also established permit program requirements.

• Foreign Operations Appropriations Act

The Foreign Operations Appropriations Act was signed into law in 2002, providing funding to support U.S. foreign policy objectives. It required the president to submit a report of expenditures on climate change activities and constituted a major amendment to the Clean Air Act of 1990. Also formulated in 1990 was the United States' first Na-

Enacted U.S. Legislation Relating Directly to Climate Change

Year	*Act*	*Effect*
1978	National Climate Program Act	Establishes a nationally coordinated program of climate monitoring and prediction
1990	Global Change Research Act	Funds research into global climate change
1997	Byrd-Hagel Resolution	Expresses the sense of the Senate that the United States should join only those climate change treaties that do not harm the domestic economy and that require developing nations, as well as developed nations, to take action against global warming
2005	Energy Policy Act of 2005	Supports voluntary reductions in carbon-intensive activities and the export to developing nations of technologies to reduce carbon intensity

Proposed U.S. Legislation Relating Directly to Climate Change

Congress	*Years in Session*	*Number of Bills Relating to Climate Change*
106th	1999-2000	27
107th	2001-2002	67
108th	2003-2004	92
109th	2005-2006	106
110th	2007-2008	235

Source: Pew Center on Global Climate Change.

tional Environmental Action Plan (NEAP). It was established both to manage existing environmental issues and to devise ways to anticipate and meet future challenges.

• U.S. Stance on International Agreements

The first significant international agreement related to climate change was the Montreal Protocol, which entered into force in 1989. Its goal was to eliminate the use of substances that deplete the ozone layer. In 1997, the Kyoto Protocol was adopted as an amendment to the United Nations Framework Convention on Climate Change (UNFCCC). The UNFCCC recognized that climate resources are shared among nations and that the stability of Earth is dependent upon all countries' compliance with efforts to reduce emissions of GHGs. The UNFCCC outlined intergovernmental efforts necessary to provide financial and technological cooperation in adapting to the impacts of global warming.

The Kyoto Protocol required industrialized nations to limit GHG emissions and set 2008-2012 targets for each country relative to that country's 1990 emissions. The GHGs targeted for reduction were carbon dioxide (CO_2), methane, nitrous oxide, sulfur hexafluoride, hydrofluorocarbons (HFCs), and perfluorocarbons (PFCs). The protocol also created mechanisms that would allow the industrialized nations to fulfil their reduction targets in part by funding environmentally friendly projects in developing nations, in lieu of making actual reductions at home. Nations that reduced their emissions to below their target level could also sell excess emission credits to nations whose emissions exceeded their targets. U.S. president George W. Bush rejected the Kyoto Protocol in 2001, because he opposed mandatory emission-reduction requirements. However, in April of 2008 he articulated a goal to decrease GHG emissions by 2025.

• Twenty-First Century

The focus of legislation at the beginning of the twenty-first century—particularly in the wake of the terrorist attacks in the United States on September 11, 2001—was on ensuring national security, but legislation was also passed to fund commissions to study climate change. In the first decade of the new millennium, executive or legislative commissions examined the consequences of climate change. Efforts were made to implement mandatory reporting of GHG emissions and economy-wide GHG reductions and standards.

In Alaska, for example, a Climate Impact Assessment Commission addressed ways to reduce the impacts of climate change. Other states taking similar initiatives included Montana, Arizona, Oregon, Washington, California, and New Mexico. In 2005, the North Carolina Legislative Commission on Global Climate Change was created to study the issues related to global warming, and a similar commission was formed in Arkansas, called the Arkansas Governor's Commission on Global Warming. The Arizona Climate Action Initiative and an executive order in Kansas established advisory groups to recommend ways to reduce GHG emissions.

State climate action plans have been developed to reduce GHGs. The first was the Maine Climate Action Plan (2003), followed by the Connecticut Climate Action Plan (2004). In 2007, the Colorado Climate Action Plan and the Florida Energy and Climate Action Plan were established. Each plan identified cost-effective ways to reduce GHG emissions based on the characteristics of its particular state, including the state's political structure, economy, and resource base.

In addition, registries that aim to measure and report emissions have been established. In Wisconsin, the Voluntary Greenhouse Gas Registry (1999) required the Department of Natural Resources to establish and operate systems to register decreases in GHGs, and the Wisconsin Mandatory Greenhouse Gas Reporting legislation required the reporting of emissions and air containment. In 2000, the California Climate Action Registry was established. It created specific penalties for violations of emissions requirements. In 2007, the West Virginia Inventory and Reporting program was established to inventory emissions and reductions in GHGs, and the Climate Registry established a general reporting protocol.

Economy-wide GHG reductions have also been targeted. In Hawaii, the goal has been to reduce GHG emissions by 2020. A Minnesota bill (2007) involved conservation efforts, and a California bill (2006) required a state board to adopt regulations to report and enforce the rules, establishing economy-wide GHG reductions, with targets for the entire state.

Just as important as the need to establish commissions, boards, action plans, and registries is the need for standards to ensure that all electricity used in a state is produced within regulations. In 2006, California prohibited electric utility companies from establishing any agreements that did not comply with GHG requirements. That same year, a bill was passed to prohibit the recovery of certain costs of electricity services in Minnesota. In 2007, Washington State passed legislation to increase green jobs and reduce GHG emissions.

Standards for vehicles have also been established in California. A 2002 act related to air quality was passed, reducing GHG emissions in machines. Other states have adopted or begun the process of adopting these standards, including Arizona, Connecticut, Maine, Maryland, Massachusetts, New Jersey, New York, Oregon, Pennsylvania, Rhode Island, Vermont, and Washington. The states projected to adopt California's standards were planning to apply them to 2009 and later models of cars and light trucks to control emissions from tailpipes. A report released in 2004 (two years after California's law was passed) provided light vehicle regulations to consider for adoption. These standards were adopted in September of 2004.

The auto industry opposed these regulations, arguing that GHG emissions and fuel economy standards should be set only by the U.S. Department of Transportation. Interestingly, analysis of the impact of these regulations indicated only a small national effect on energy demand and fuel prices. Results depend on the number of states that adopt the program, as well as the response of consumers and manufacturers. The required improvements in car fuel economy are more stringent than those required for light trucks. Both New Jersey and Washington State passed legislation to establish standards related to vehicle emissions, and in 2008 Washington also passed an act to create a framework to reduce GHG emissions in the transportation sector.

In 2005, the Climate Stewardship Act and the New Apollo Energy Act were passed, focusing on achieving reductions in greenhouse gases. Requirements would be broader than in the past, applying to the electricity, transportation, industry, and commercial sectors. These federal acts were similar to those already enacted on a state level. In the same year, the Energy Policy Act established the first national energy plan in over a decade. It was intended to encourage energy efficiency and energy conservation through the promotion of efficiency in the home, as well as through the promotion of alternative and renewable energy sources for the federal government. It also sought to reduce U.S. dependence on foreign sources of energy while supporting continued research and offering tax credits for making home improvements (using residential solar energy systems). It also included tax credits to consumers for purchasing hybrid cars.

The Safe Climate Act of 2006 granted the EPA broad authority to establish regulations. It was followed by several proposed amendments to existing acts, including the Climate Security Bill of 2007, a global warming bill considered by the U.S. Senate to reduce greenhouse gases. Also known as the Lieberman-Warner bill (because it was introduced by Senators Joseph Lieberman, independent of Connecticut, and John Warner, Republican of Virginia), this bill was filibustered and effectively killed in June of 2008, with forty-eight senators voting to invoke cloture and end debate, thirty-six opposing that motion, and sixteen abstaining or absent. However, because six of the absent senators indicated that they would have supported the cloture motion, the 2008 vote represented the first time that a majority of the U.S. Senate seemed to support legislation mandating GHG reductions through a cap-and-trade system. In such a system, limits are placed on total permissible GHG emissions, and permits are issued to polluters to emit specific amounts of GHGs. These permits are tradable commodities, so the market functions to motivate emission reductions.

In 2007, President Bush signed the Energy Independence and Security Act, which was designed to improve vehicle fuel economy and increase incentives to create subsidies for alternative fuels. The act mandated energy efficiency of lightbulbs, changed the efficiency standards for appliances, and aimed to reduce total energy use in federal buildings by 30 percent.

Following the inauguration of President Barack Obama in 2009, passage of cap-and-trade legislation became a top priority of the new administration. In May of 2009, U.S. representatives Henry Waxman of California and Edward Markey of Massachusetts introduced a new cap-and-trade bill, the American Clean Energy and Security Act of 2009, known informally as the Waxman-Markey bill. The economic crisis of 2008-2009 rendered the bill controversial, however. Critics worried that the bill would increase the cost of producing energy and thereby increase the price of every manufactured and transported good. Supporters minimized the immediate impact of the bill on prices and emphasized the urgency of addressing global warming while it was still possible. The bill narrowly passed the House in June by a vote of 219 to 212, marking the first time either house of Congress had passed a cap-and-trade law.

• Context

Although U.S. legislation since the 1960's has attempted to decrease the negative effects of climate change, the causes of and solutions to climate change problems are not clear-cut. In fact, there is still controversy about the nature, extent, causes, and very existence of global warming. What is clear is that all countries must assess and understand the roles they need to play in decreasing the risk of serious consequences, including incorporating a collaborative international response and thinking globally.

Because the United States is among the top GHG emitters, and particularly because the United States plays a global leadership role, it is especially important that Americans lead the way both in developing policies that can address the negative impacts of climate change and in working collaboratively with world nations to implement action that meets the needs of many stakeholders. Doing nothing could have catastrophic effects on the environment, while taking action could harm the national economy. Legislation must balance these concerns.

Venice

- **Category:** Geology and geography

Venice is susceptible to episodic flooding, owing to a concurrence of high tides, storm surges, and excessive rainfall. Therefore, Venice serves as an excellent indicator of long-term changes in sea level, such as those due to global warming.

• Key concepts

acqua alta: Italian for high water—flooding

Lidi: the chain of barrier islands protecting the Venetian lagoon

MOSE: abbreviation for *modulo sperimentale elettromeccanico*, a prototype sea gate; the name also alludes to Moses, punning on his ability to part the seas

storm surge: high water associated with a storm, especially that caused by wind action

subsidence: lowering of land surface owing, for instance, to compression by the weight of overlying land or depletion of an aquifer

Venetian lagoon: the body of water in which Venice, formerly an island, is situated

• Background

On November 4, 1966, Venice was inundated by a flood of 1.94 meters above mean high water. This remains the record for high water (*acqua alta*) in the city. The extent of the flood reflected the combination of high lunar tides, heavy rainfall, and fierce, persistent winds. The storm surge overwhelmed the Lidi, destroying sea walls. Meanwhile, flooding rivers poured freshwater into the brackish lagoon, causing ecological harm. Bases of historic buildings were immersed in lagoon water for two days, producing considerable damage.

• Sensitivity to Flooding

Venice is a particularly sensitive indicator of long-term changes in sea level, because several factors causing the lagoon water to rise, or the land level to sink, are poised against human interventions, such as dike building and diversion of rivers. Sources of flood waters are rivers that originally emptied into the lagoon, including the Piave and the Sile in the east and the Brenta and Bacchiglione in the west. All these rivers have been diverted away from the lagoon, but during episodes of heavy rainfall they manage to overflow into the lagoon anyway. Heavy rains over the ocean can also augment storm surges in raising sea level.

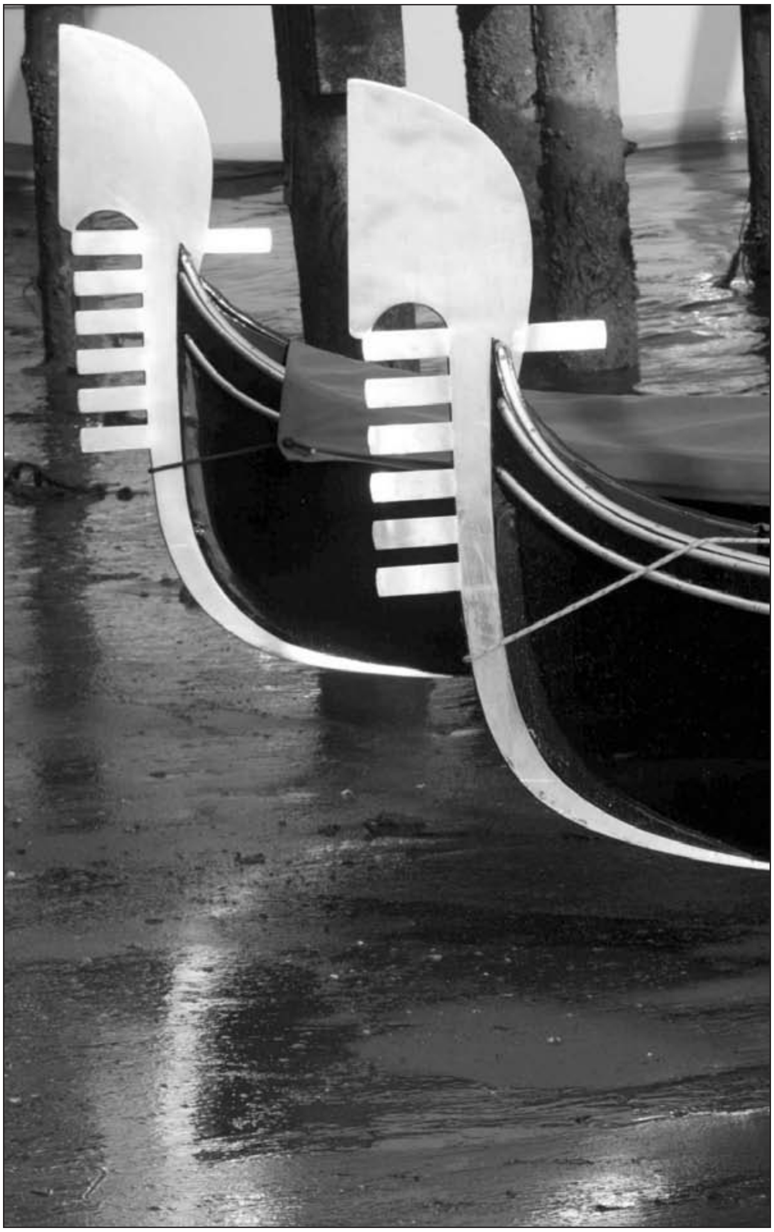
Venice itself, meanwhile, has been sinking in a process called subsidence. Subsidence can be natural, as when sediment is compressed by the weight of soil and water above it, or artificial, caused, for example, by removal of water from an underlying aquifer for industrial purposes. Such removal was forbidden by statute in the 1970's, and Venetian subsidence has been substantially reduced as a result.

• Historical Remediation Efforts

Throughout its long history, Venice has been both threatened and protected by the proximity of its lagoon, and its citizens have acted to minimize threats while promoting protection. Thus, the lagoon has been kept intact but with efforts to prevent storm-related changes in sea level. One task has centered on the rivers that could otherwise transport sediment and gradually convert the lagoon into dry land with pockets of freshwater, which would harbor malaria-transmitting mosquitoes. The island town of Torcello succumbed in medieval times to a combination of silt from the Sile river and resulting malaria. Therefore, the courses of the several rivers in the area were progressively diverted to avoid the lagoon, beginning in 1324 with a canal receiving water from the Brenta. Additional links were completed in 1507 and 1613, the last one allowing the waters from several rivers to flow into the Adriatic Sea through a common mouth. Meanwhile, dikes and seawalls were built, including the great St. Mark's Dike to the north of the lagoon (1534) and others protecting the barrier islands (Lidi).

Acqua alta episodes in the twentieth century led to demands for government intervention, resulting in Special Law 798. Earlier such special laws had been ineffectual, but this one was different. It called for creation of a committee (the Comitatone, or "big committee") with the prime minister as chair. The committee proposed several interventions, the most dramatic of which was a system of movable sea gates in the three passages separating the barrier islands.

To investigate this strategy, a prototype gate, the *modulo sperimentale elettromeccanico*, or MOSE, was constructed and towed into place in one of the channels. It spent from 1988 until 1992 in place and, by most accounts, performed well. The principle of its operation was simple: Most of the time, the gates would be submerged owing to the weight of water in their tanks. When a flood threatened, the water would be expelled and the gates would rise to block any storm surge. The single MOSE gate cost the equivalent of about 13.3 million dollars, and a total of about eighty gates would be required for the entire system to function.



Gondolas lie beached in the Venetian canals in February, 2008, after the canals plunged to 80 centimeters below average sea level. (Manuel Silvestri/Reuters/Landov)

In addition to the great cost of the project, critics have questioned its adequacy, especially in light of the rate of sea-level rise from global warming. They fear that, on its proposed completion in 2013, the gate system will already need to be deployed so often that the lagoon will have insufficient time to flush itself, and shipping will be seriously hindered.

• Changing Frequency of *Acqua Alta* Events

In the early 1900's, St. Mark's Square on the Venetian island was flooded seven times per year; in the 1950's, the frequency was twenty times per year. In 1996 alone, it was flooded ninety-nine times. This progression reflects two aspects of climate change: a general rise of sea level and a related increase in the number and severity of storms. In all events, the frequency of *acqua alta* occurrences seems to provide a measure of climate warming and to support the notion of Venice as a useful indicator of its extent.

• Context

Venice is not the only location in the world vulnerable to sea-level rise. Many cities are located on estuaries and coastlines and thus are affected by even modest sea-level rise. For instance, London is situated on the Thames estuary and has experienced repeated floods throughout its history. Small wonder that a storm-surge barrier has been under discussion through most of the twentieth century, was begun in 1973, and was completed in 1983. As climate-related sea-level rise proceeds, more and more coastal cities will become at risk, and many will not have the option of an estuarine barrier. For many of these cities, moving a sizable population will be the only remedy, with great cost and social dislocation. Much worse will be flooding of low-lying agricultural lands in countries such as Bangladesh, where extreme poverty and cultural dependence on rice culture will give rise to widespread suffering. Finally, coral-based Pacific island nations will simply vanish beneath the waves. It appears that the only available solution to such calamity is a worldwide reduction of greenhouse gas emissions.

Volatile organic compounds

• **Category:** Chemistry and geochemistry

• Definition

Volatile organic compounds (VOCs) are substances consisting primarily of a carbon backbone, with most or all of the remaining bonds being occupied by hydrogen atoms. Organic compounds may also contain atoms such as sulfur, oxygen, nitrogen, or chlorine. VOCs are volatile in that they evaporate under the conditions typically found at Earth's surface. As a result, VOCs generally include compounds with 12-14 or fewer carbon atoms. Compounds that evaporate more slowly are often referred to as semivolatile organic compounds, or SVOCs, and typically include 10-18 carbon atoms, with or without oxygen or other atoms.

Carbon dioxide (CO_2) does not fit the definition of a VOC, because it is not organic; methane, by contrast, does. However, because methane is more abundant than almost all other VOCs (by a factor of ten or more), is removed from the atmosphere more slowly than other VOCs (by a factor of fifty or more), and is itself an important greenhouse gas (GHG), methane is generally not included in the category of VOCs. The term VOC is nevertheless more commonly used than is the more precise term "nonmethane organic compounds," or NMOCs. The bulk of VOCs that are released into the atmosphere are members of the subclass hydrocarbons and thus are frequently termed nonmethane hydrocarbons, or NMHCs.

• Significance for Climate Change

VOCs are, like methane, very strong absorbers of infrared light and have the potential to contribute to greenhouse warming. They have short lifetimes, however, ranging from minutes to months, and thus have low concentrations except very close to their sources. As a result, their direct contribution to climate change is small. Their indirect contributions are significant, however. Ozone, the third ranking GHG, is not released into the atmosphere but is rather formed in the atmosphere from reactions of VOCs, oxides of nitrogen, and sunlight.

U.S. VOC Emissions by Source Sector

Source Sector	*Total Emissions (tons)*
On-road vehicles	4,660,578
Solvent use	4,267,952
Fires	3,036,428
Nonroad equipment	2,623,774
Industrial processes	1,680,541
Residential wood combustion	1,222,840
Miscellaneous	1,199,065
Waste disposal	464,152
Fossil-fuel combustion	146,198
Electricity generation	49,110
Fertilizer and livestock	42,192
Road dust	1

Data from the U.S. Environmental Protection Agency.

VOCs also affect the Earth's climate by forming secondary organic aerosols (SOAs). The formation of these aerosols is not understood well enough to determine whether the burden of SOAs has changed appreciably as a result of human activities. Because the organic aerosols are so prevalent, they make a large contribution to the Earth's energy balance and are thus critical to accurate predictions of changes in the Earth's climate.

VOCs generally enter the atmosphere as compounds containing carbon and hydrogen and are progressively oxidized, so they contain increasing amounts of oxygen and nitrogen, forming ozone as a by-product. As the reacting VOCs collect more and more oxygen and nitrogen, they become less and less volatile and eventually enter the condensed phase. The resulting tiny aerosol particles are clear and act to cool the Earth system by scattering and reflecting incoming sunlight.

About 1.3 quadrillion grams of VOCs are released annually by natural sources and human activities combined. Of this amount, about 1.2 quadrillion grams are natural in origin, and about 100 trillion grams are anthropogenic. In the temperate, developed nations, the contribution of human activities to VOC levels is larger; for example, in the United States, anthropogenic VOC emissions are roughly equal to those from natural sources: Each class of sources produces about 15 to 20 trillion grams per year.

At least 95 percent of the natural global VOC burden arises from vegetation, primarily trees. Deciduous trees release more VOCs than do evergreen trees, the former releasing roughly 1 percent of the CO_2 fixed in photosynthesis as VOCs. These natural VOCs are dominated by species with structures common in plant biosynthetic pathways. Vegetation releases isoprene (2-methyl-1,3-butadiene); its $C_{10}H_{16}$ dimers, known as terpenes; and $C_{15}H_{24}$ trimers, known as sesqueterpenes; and a wide variety of closely related compounds, some with alcohol and carbonyl groups attached. Deciduous trees preferentially emit isoprene, and evergreen trees preferentially emit terpenes. Many of the terpenes and their derivatives are easily recognized by their characteristic odors of pine, turpentine, lemon, orange blossom, and many other plant-derived scents.

In the Earth's atmosphere, VOCs react primarily with the hydroxyl radical (OH). They react repeatedly until they are removed from the atmosphere—whether by colliding with a surface such as a leaf or an aerosol particle, by being intercepted and removed by rain drops, or by being completely oxidized to become CO_2 (oxidized VOCs are a negligible source of CO_2). The speed at which molecules react determines both their concentration in the atmosphere and their ability to generate ozone and SOAs. The quantity of ozone formed depends on the concentration of its VOC and NO_x precursors, but after being released VOCs are constantly diluted in the atmosphere, so species that react more rapidly can generate higher quantities of ozone.

Each VOC has a different ability to generate ozone and SOA; however, several generalizations can be made. Alkanes, molecules consisting only of carbon-carbon single bonds, react relatively slowly and have lifetimes in the atmosphere of several hours to several days. The bulk of the anthropogenic VOCs are alkanes; examples include ethane, isobutane, and n-octane.

Alkenes are molecules with one or more double bonds. Double bonds render molecules much more reactive, and alkenes have lifetimes from minutes to hours. Most of the VOCs released from natural sources (primarily trees) are alkenes, including isoprene and the terpenes. A small fraction of anthropogenic VOCs have double bonds (generally less than 10 percent). Reducing the content of alkenes in motor vehicle fuel is a proven strategy for reducing ozone in urban areas. A very small fraction of VOCs emitted into the atmosphere have triple bonds, and these species react very slowly and are of little concern.

A fourth chemical class of VOCs is aromatics; species with conjugated double bonds arranged in one or more rings. Aromatics are almost entirely anthropogenic and have intermediate reactivities. SOA formation is highest from alkenes, followed by aromatics and then alkanes. A substantial fraction of VOCs from both natural and human sources contain one or more oxygen atoms, including aldehydes, ketones, alcohols, and organic acids. More of these oxygenates form as the VOCs are oxidized as they react in the atmosphere. Aldehydes react rapidly and speed ozone formation, while alcohols and acids frequently form SOA after undergoing one or two reactions.

Volcanoes

• Category: Geology and geography

• Definition

Volcanic activity has played a major geological and environmental role in the evolution of the Earth since the planet's formation. As the proto-planetary Earth cooled and formed a solid crust, widespread volcanic activity dominated its surface. The Earth's interior at this time retained a considerable amount of heat from accretion and the decay of short-lived radioactive isotopes. With interior temperatures well above the melting point of most Earth materials, high-density metals sank to the Earth's center of gravity, while lower-density, silicate-rich materials were displaced toward the surface. It is believed that this process took place within the first 50 million years of Earth history, resulting in the present crust-mantle-core structure.

Little geological evidence remains of the period between the formation of a solid crust and the beginnings of plate tectonics. Scientists believe that during this 2-billion-year interval, massive volcanic structures gradually built up into continental masses. Plate tectonics, as it is known today, began about 2.5 billion years ago. It may have taken that long for the Earth's upper mantle to become sufficiently hot and fluid to create convection cells that could fracture the crust and spread these huge sections apart from one another. It is along these plate boundaries where the majority of earthquakes and volcanic eruptions take place.

Volcanic eruptions have a significant impact on the environment. During such eruptions, huge amounts of gases and dust are expelled into the atmosphere. Water vapor accounts for over 90 percent of the total expelled gas, with the remainder being a mixture of carbon dioxide, sulfur dioxide, hydrogen sulfide, hydrogen, and fluorine. These gases can become harmful to life. When sulfur dioxide reacts with water droplets in the atmosphere, it becomes acid rain, which is highly corrosive and particularly harmful to vegetation. The tremendous amount of ash thrown from volcanic eruptions can also mix with water to form dangerous mudslides, or it can release fluorine, poisoning the

Mount Soputan, Indonesia, erupts in October of 2008. (AP/Wide World Photos)

animals that graze upon ash-coved vegetation. On a global scale, volcanic ash has its greatest effect on the upper atmosphere, where it prevents transmitted sunlight from reaching the Earth's surface and eventually causes a reduction in global temperatures.

• Significance for Climate Change

Throughout Earth's history, life has been closely associated with volcanic activity. One theory suggests that life on Earth may have had its origin in volcanic hot springs that were rich in organic compounds. Continuous volcanic eruptions also contributed to the water that would later become the oceans. With life flourishing in the oceans and later on land, volcanic activity became a major influencing factor on the continuing evolution and periodic mass extinctions of Earth's biological inhabitants.

One reason for the occurrence of mass extinctions is a dramatic change in the Earth's surface conditions. Most species live in what can be called a "habitable zone" based upon a suitable range in temperature, the availability of sufficient water, and the right amount of sunlight. When a particular species is exposed to conditions outside of this zone, it either adapts to the changing conditions or dies. As compared to life in the oceans, life on land seems to be more fragile and more susceptible to change. Recent theories for the cause of mass extinctions have concentrated on cosmic impacts or extensive volcanic activity. In each case, the apparent mechanism can be related to a blockage of sunlight by the huge amounts of dust and debris that an impact or volcano would eject into the upper atmosphere. The reduction of even a small amount of sunlight could disrupt the photosynthetic process and through it Earth's food chain. A break in the food chain not only affects all the species that depend upon that link for their nourishment, but also all the species that depend on those species, and so on.

Violent volcanic eruptions have also played an important role over the course of human history from both a social and environmental perspective. Perhaps the most famous volcanic eruption in history occurred in 79 C.E., when Mount Vesuvius erupted and buried the Roman city of Pompeii under a thick blanket of ash and debris. As devastating as the Vesuvius eruption was, it was a relatively minor eruption when compared to the eruptions of Mount Tambora in 1815 and Krakatoa (Krakatau) in 1883. Each volcano produced enough ash and dust to affect global climatic conditions for several years after its eruption.

The Indonesian volcano Tambora was the most powerful volcanic eruption in recorded history. Its ash cloud lowered worldwide temperatures by 3° Celsius, particularly affecting the Northern Hemisphere. The following year, 1816, was known as "the year without summer." The United States and Canada experienced killing summer frosts and predominantly cloudy and cool days. Worldwide, with a shorter growing season, many people faced starvation.

Scientific studies of more recent volcanic eruptions, such as those of Mount St. Helens (1980), El Chichon (1982), and Mount Pinatubo (1991), have confirmed how much of an effect a single volcanic eruption can have on global weather conditions. One can only imagine the devastating effects that another giant volcanic eruption such as the one that created the Yellowstone Basin in Wyoming (48 kilometers in diameter) would have on the world.

Walker, Gilbert
English physicist and statistician

Born: June 14, 1868; Rochdale, Lancashire, England
Died: November 4, 1958; Cousdon, Surrey, England

Walker is best known for his discovery of the Southern Oscillation in 1923. He also pioneered statistical weather forecasting.

• Life
Gilbert Walker was born in England, one of seven children. Growing up in England, he always excelled in mathematics, receiving a master of arts in mathematics in 1893. While in school, he demonstrated great interest in spinning tops and boomerangs, earning the nickname of Boomerang Walker. After applying for a variety of jobs, mainly at universities, he was offered a position at the Indian Meteorological Department in Calcutta, India, in 1901. While he had no background in meteorology or weather, he was recruited because of his strong mathematical and statistical background.

John Eliot, the second director of the Indian Meteorological Department and Walker's predecessor, was seeking a replacement who could apply his mathematical and statistical skills to forecasting the weather, especially in relation to monsoons. The Institute for Meteorological Development had begun to forecast monsoons and related rainfall in 1881 but was quite unsuccessful in its attempts. Eliot felt that a mathematician or statistician would be able to handle more successfully these forecasts and thus recruited Walker even though he had no training in meteorology.

In order to acquaint himself with meteorology, Walker toured several meteorological laboratories throughout the world, including in the United Kingdom, the United States, France, and Germany in 1902 and 1903. After spending much time with Cleveland Abbe, the founding director of the U.S. Weather Bureau, in 1903, he returned to India. On January 1, 1904, he was appointed the director general of observatories in India. Later that year, he received a doctor of science degree from Cambridge, and in 1905 he became a fellow of the Royal Meteorological Society. Walker remained director of the observatories in India until the end of 1923, right after his discovery of the Southern Oscillation. He then returned to England, was knighted by the king, and took a position as professor of mathematics at the Imperial College of Science and Technology. He remained there until his retirement in 1934.

• Climate Work
Walker is best known for integrating statistics into the forecasting of weather and for the discovery of the Southern Oscillation and its related Southern Oscillation Index (SOI). Early in his career at the Institute for Meteorological Development, he collected large amounts of data relating to weather conditions throughout the world. Analyzing these data statistically (mainly using correlations), Walker was able dramatically to advance the field of weather forecasting and to discover the phenomenon known as the Southern Oscillation.

According to Walker, the Southern Oscillation involves the tendency of pressure at stations in the Pacific Ocean to increase, while pressures in the region of the Indian Ocean decrease. It technically is defined as the difference in barometric pressure at sea level between Tahiti and Darwin, Australia. The Southern Oscillation appears causally related to El Niño, which seems to influence the weather throughout the world.

Walker found that there are two distinct patterns of air pressure at sea level in the South Pacific. The SOI measures the monthly or seasonal fluctuations in the differences between the surface air pressure from Tahiti to Darwin, Australia (east-west). When air pressure is higher near Tahiti (east) than it is in Darwin (west), surface air tends to flow westward. When atmospheric pressures change, so that barometric pressure increases in the west (Darwin) and falls in the east (Tahiti), surface winds weaken and retreat eastward. When this set of conditions occurs, it is usually accompanied by El Niño conditions.

The Southern Oscillation was only linked to El Niño in the 1960's (after Walker's death) but is now felt to be one of the major factors in predicting weather throughout the world, including monsoon rainfalls in India and weather patterns over the North American continent in the winter months. Thus, Walker dramatically advanced the field of weather forcasting, as well as scientific understanding of the factors influencing climate throughout the world.

Walker circulation

- **Category:** Meteorology and atmospheric sciences

- **Definition**

The Walker circulation was discovered and named for Gilbert Walker. The Walker circulation is a cell of airflow across an ocean along the equator. The most well known cell is across the Pacific Ocean but cells also exist across the Indian and the Atlantic Oceans. In the western Pacific or Atlantic, hot air rises carrying moisture and creating a wet climate. As the air travels eastward, it cools and creates a cooler, drier climate in the eastern Pacific. An ocean current follows the same pattern. The water warmed by the Sun flows to the west. The Indian Ocean Walker cell flows in the opposite direction, making the eastern side the warm, moist climate.

- **Significance for Climate Change**

When a Walker circulation weakens or reverses, an El Niño results. The ocean surface temperature is higher than normal and the normal upwelling of cold water is less if at all. This means that plankton are not brought up to the surface and the fishermen from Peru suffer from small catches of fish that eat plankton. A shift in the Walker cell has also been shown to cause drought and flooding in Australia. An El Niño year may cause the central or eastern region of the Pacific to be as warm as the western Pacific. The ocean around Australia is cooler with less moisture in the atmosphere, which causes a drier eastern and northern Australia. A stronger than normal Walker circulation, called La Niña, can cause severe flooding in Australia as the airflow carries more moisture, the ocean is warmer, and there is more rainfall. This also means more cyclones in Southeast Asia, droughts in South America, and colder winters in North America.

An El Niño year will have fewer hurricanes as strong western winds, normally blocked by the Walker circulation, form and disrupt hurricane formation. The drier western Pacific will include not only Australia but also Indonesia. The western Pacific region, such as Chile and Peru, will have greater rainfall. Canada will have colder temperatures but Europe will have wetter, milder winters. A study by the University of Toronto indicates that a weaker Walker cell has such wide-ranging effects as less summer rainfall in West Africa and in north China and a reduced snow accumulation in southern Himalaya. There is evidence that the Walker circulation has been weakening for most of the twentieth century. An article published in *Nature*, May, 2006, assets that global warming is the cause of the weakening of the Walker circulation. If the Walker circulation continues to weaken, it will change the world's climate.

Water quality

• **Category:** Water resources

• **Definition**

Water quality refers to the physical, chemical, and biological characteristics of water in relation to the standards created to test its suitability for a particular use, such as irrigating, swimming, fishing, or drinking. Water quality standards for drinking are more stringent than those for any other use.

A variety of impurities or pollutants are able to harm water quality, and they may enter into water bodies from various sources, such as agricultural, industrial, and municipal activities. Typical harmful materials include organic wastes, nutrients, sediments, minerals, persistent synthetic chemicals, toxic chemicals, and radiological waste products. While some pollutants, such as organic wastes, can be assimilated quickly, the others are persistent in water and are therefore designated as nondegradable pollutants. It is the accumulation of excess pollutants that causes damage to the environment, affecting people and ecosystems. In the case of organic wastes, such as fecal matter, crop debris, and foodstuffs, water quality declines, because aerobic bacteria attack the organic matter and consume large amounts of the oxygen available in the surrounding water. The decomposition process may deprive aquatic life of the oxygen it needs to survive.

• **Significance for Climate Change**

Climate change is expected to cause higher water temperatures, sea-level rise, and changes in the frequency and intensity of precipitation and flooding. All these consequences of climate change can impact water quality. Higher water temperature reduces the oxygen available for aquatic life, because warm water is less capable of holding dissolved oxygen than is cold water. Increases in water temperature also cause higher rates of photosynthesis and so increase the number of plants, which eventually die and are decomposed by aerobic bacteria. In addition, higher temperature increases the metabolic rate of aquatic organisms, causing a higher demand for dissolved oxygen. All these factors contribute to deprive aquatic life of the oxygen it needs to survive.

Precipitation—expected to occur more frequently with higher-intensity rainfalls—can increase agricultural runoff and land erosion. As a result, more nutrients and sediments will be transported into rivers, lakes, and groundwater systems, worsening water quality. In addition, flooding can cause large volumes of water to carry pollutants into water bodies.

In addition to higher temperature and precipitation, sea-level rise can affect water quality in a different way: Studies predict sea-level increase in the range from 19 to 58 centimeters by the end of the twenty-first century. Higher sea levels will make salt water intrude into rivers and groundwater systems and so affect freshwater supplies in coastal regions.

Water resources, global

• **Category:** Water resources

Global warming is anticipated to have a significant negative effect on the global supply and quality of water. Potential factors contributing to this effect include warmer winters, changes in precipitation patterns, increasing evaporation, melting snow peaks, rising sea levels, saltwater intrusion into coastal aquifers, dry soil, and increasing storm-water runoff.

Yemeni women collect water from a reservoir and carry it on donkeys back to their village. Yemen's groundwater supply is insufficient to support its growing population. (Khaled Abdullah/Reuters/Landov)

• Key concepts

aquifer: a subsurface formation that is permeable and therefore allows water storage and flow
concentration: the ratio, by weight, of a dissolved chemical compound to its solvent (such as water)
desalination: distillation and reverse osmosis of salt water to obtain freshwater
evaporation: the transformation of a substance from its liquid to its gaseous state
infiltration: the process of surface water entering soil
precipitation: the condensation of atmospheric water, which then falls to Earth's surface
runoff: storm water flowing on Earth's surface
saltwater intrusion: a process along coastlines in which salt water flows inland into a freshwater aquifer
sediment: particulate matter that is transported by water and eventually deposited
sediment load: the quantity of undissolved organic and inorganic particles carried by water
water basin: an area of land where surface water and groundwater flow in the same direction
watershed: an area of land where water flows into the same watercourse

• Background

A water resource is any surface or underground source of water that can be utilized by humans. Typical resources include water basins, aquifers, oceans, rivers, lakes, natural and artificial reservoirs, ice, snow, and wetlands. The hydrologic cycle renews freshwater resources, but these resources decrease when their withdrawal rate is faster than their recharge rate. Increases in population, industrialization, and other factors that increase demand can contribute to this depletion of resources. Environmental degradation and global warming also contribute to the decrease of available water. Water is an important factor in conflicts among stakeholders at the local, regional, national, and international levels. Water conflicts take many forms, but they almost always arise from the fact that the freshwater resources of the world are not partitioned to match political borders, nor are they evenly distributed in space and time.

• Changes in Quantity of Water Resources

The amount of water on Earth undergoes continuous changes due to the hydrologic cycle. The amount of freshwater in an area might increase as a result of higher precipitation or melting ice or snow. However, for water supplies to increase, other requirements must be met that allow freshwater to be captured in aquifers and other stable, uncontaminated reservoirs. These requirements include longer rainy seasons that provide enough time for freshwater to infiltrate aquifers, limitations on the amount of runoff that flows into oceans and other saltwater bodies, and sufficient soil and aquifer permeability and thickness. Aquifer recharge is also increased by relatively cool air temperatures and relatively low rates of evaporation from the ground's surface.

The overall temperature increases caused by greenhouse gases (GHGs) have significant effects on the environment and the quantity and quality of water resources. Higher temperatures increase the evaporation rate, which in turn increases the number and intensity of storms. Dry soil becomes difficult for water to infiltrate, and the violent precipitation of storms erodes soil, further decreasing the permeability of the ground's surface layer. As a result, storm water is unlikely to recharge aquifers, and a high proportion of surface storm water is likely to run off into rivers and oceans. In addition, higher temperatures cause ice caps to melt and raise sea levels, which in some coastal regions can introduce saltwater intrusion into aquifers.

• Changes in the Quality of Water Resources

Climate change can greatly affect water quality. Melting snow in the mountains increases river flow and erosion and transports large amounts of sediment, usually in winter or in rainy seasons. Such increased river flow can create flood hazards and heighten the potential for destruction of dams and levees. On the other hand, reduced river flow in summer can also have severe implications, because demand for water for irrigation, hydropower, and other uses is at its peak in summertime.

Evaporation rates increase with temperature. High evaporation rates in some areas reduce the ratio of water to its solutes, increasing the concentration of salts and chemicals and thereby decreasing water quality. The resulting increases in water salinity can cause changes in the rate of oxygen release into water. These changes in turn affect the plants in water reservoirs and the animals and plants in the surrounding environment. Furthermore, an increase in temperature and a consequent increase in the rate of ice melt can create a positive feedback loop. The melting away of ground ice, which reflects the Sun's rays, decreases regional albedo, causing the ground to absorb more solar energy and raising the temperature of the region.

Water resources can be renewable or nonrenewable. Basins that are consistently recharged by the hydrologic cycle (primarily through precipitation) and thus are not generally affected by water withdrawals and use are renewable. Nonrenewable water resources, are recharged at a rate significantly slower than their rate of withdrawal. Human actions, such as modifying watersheds, cutting forests, or paving land, can affect hydrogeologic balance and reduce the recharge or flow characteristics of a given area, altering the availability and renewability of water. Thus, it is possible for human activity to transform renewable water resources into nonrenewable water resources.

Freshwater helps sustain humans, animals, and plants. Relatively large bodies of water, such as the Great Lakes, affect regional climate and weather conditions. Large-scale withdrawal or transfers may reduce the size or quality of a water body, significantly influencing both climate and ecosystem services. Changes to the timing of river flows may alter ecological conditions. Such changes have led to many ecological and human disasters. For example, changes to the Amu Dar'ya and Syr Dar'ya rivers in Central Asia caused the destruction of the Aral Sea ecosystem, the extinction of the sea's endemic fish populations, shrinking of the sea, and local human health problems attributable to exposure to salt aerosols released into the air when the sea shrank.

Coral bleaching and other diseases of corals increased dramatically beginning in the late twentieth century. The increase of these diseases correlated with concurrent increases in sea surface temperatures. Thus, one consequence of global warming could be the mass destruction of coral reefs caused by emerging coral diseases and by the lack of epidemiological and biochemical information on even the known diseases.

Withdrawals of water from many rivers and streams in North America and Europe have led to reductions and extinctions of many fish populations (particularly anadromous fish). Decreased river flows have severely damaged river deltas and local communities, such as in the Sacramento/San Joaquin delta in California, the Nile River delta in Egypt, and the Colorado River delta in Mexico, where the local Cocopa tribal communities have been affected.

The world's water is unevenly distributed. As a result, complex and expensive water systems have been built over centuries to capture water during wet periods for use during dry periods and to move water from water-rich regions to water-poor regions. Many markets for freshwater have been created by the growing demand generated by the industrial and agricultural sectors. These emerging markets led to the creation of various forms of international water trading and exchange. The continuing growth of water demand in the face of population growth, climate change, and other factors is motivating states and corporations to find new ways to transfer water, including pipelines, bottles, tankers, and giant bags.

The increasing demands placed on the global water supply threaten biodiversity, human food production, and other vital human needs. Water shortages already exist in many regions, and more than one billion people lack adequate drinking water. In addition, 90 percent of the infectious diseases in developing countries are transmitted by polluted water. Agriculture consumes about 70 percent of freshwater worldwide; for example, approximately 1,000 liters of water are required to produce 1 kilogram of cereal grain, and 43,000 liters are required to produce 1 kilogram of beef. New water supplies are likely to result from conservation, recycling, and improved water-use efficiency rather than from large development projects.

The Pacific Island developing countries (PIDCs), which are among the nations least responsible for contributing to the global warming problem, are among those that will most significantly suffer its consequences. These countries are responsible for less than one percent of the world's carbon dioxide (CO_2) emissions; however, it is predicted that they will experience the earliest and the most severe effects of climate change over the next two centuries. In addition to rising sea levels and saltwater intrusion, climate change poses a long-term threat to freshwater quality and availability in these countries. Of the thirty thousand islands in the Pacific Ocean, one thousand are populated. Almost all islands rely on groundwater resources for their freshwater; some high islands, such as French Polynesia, Nauru, Palau, and the Cook Islands, rely on surface water, which does not require pumping, because it is transported by gravity. Rapid increases in population place a strain on limited water resources, and over-pumping of fragile groundwater aquifers will cause saltwater intrusion and the loss of supplies. Rapid urbanization, increases in pollutants, and inadequate sewage disposal infrastructure greatly affect Pacific Island water supply systems, because most such islands have thin and highly permeable soil zones.

Anthropogenic global warming is projected to result in the global temperature increasing by 1.4° Celsius to 5.8° Celsius by the end of the twenty-first century. Global mean sea level is projected to rise by 9 to 88 centimeters during the same period as a result of thermal expansion and loss of mass from melting glaciers and ice caps. Rising sea levels place freshwater resources at risk from saltwater intrusion.

• Context

Based on the predicted impacts of increased GHGs in the atmosphere and observed climate change, a host of national and international organizations has acted to preserve global water resources. The United Nations Framework Convention on Climate Change (UNFCCC), for example, is taking action to reduce GHG emissions and to develop adaptive protection strategies to save and conserve freshwater resources. The following measures are planned to be adapted by the PIDCs:

- Comprehensive projections of future water demand
- A sustainable research program to assess freshwater-resource availability
- Electronic data logging and hydrological data-processing software
- Rehabilitation and maintenance of water catchment and distribution systems to render them capable of surviving violent storms
- Evaluation of proposed development projects and existing infrastructure in terms of their impact upon coastal freshwater resources
- Implementation of leak-control measures in existing water systems

Public awareness and water conservation projects are also being developed in the Middle East to address the critical water issues specific to that region.

Many environmental stressors contribute to ecosystem degradation in general and water-resource depletion in particular. These include rapid population growth and industrialization, increased weather-related water shortages, soil salinization, and contamination by residual pesticides and heavy metals. All such stressors threaten human health. To understand the interdependencies of water, climate, and health, the United States Geological Survey (USGS) developed a program that documents environmental quality along the U.S.-Mexico border by integrating the data sets of both countries. The USGS has also implemented data collection and training programs in such Middle Eastern nations as Jordan and the United Arab Emirates. Such efforts are at the forefront of efforts to analyze, understand, and respond to the increasing need for and decreasing availability of water throughout the globe.

Water resources, North American

- **Category:** Water resources

The climate of the western United States has been predicted to become drier with global warming. This could result in the United States asking Canada or even Mexico for additional water supplies.

Key concepts

conservation of water: reduction in the use of water

desalination: removal of salt from seawater or groundwater so that it may be used for drinking or irrigation

hydroelectric power: electricity generated by moving water in turbines

interbasin diversions: water that is removed from one drainage basin to another one so that the water is not available for use within the original basin

preservation of water: protection of usable water resources from contamination and other threats

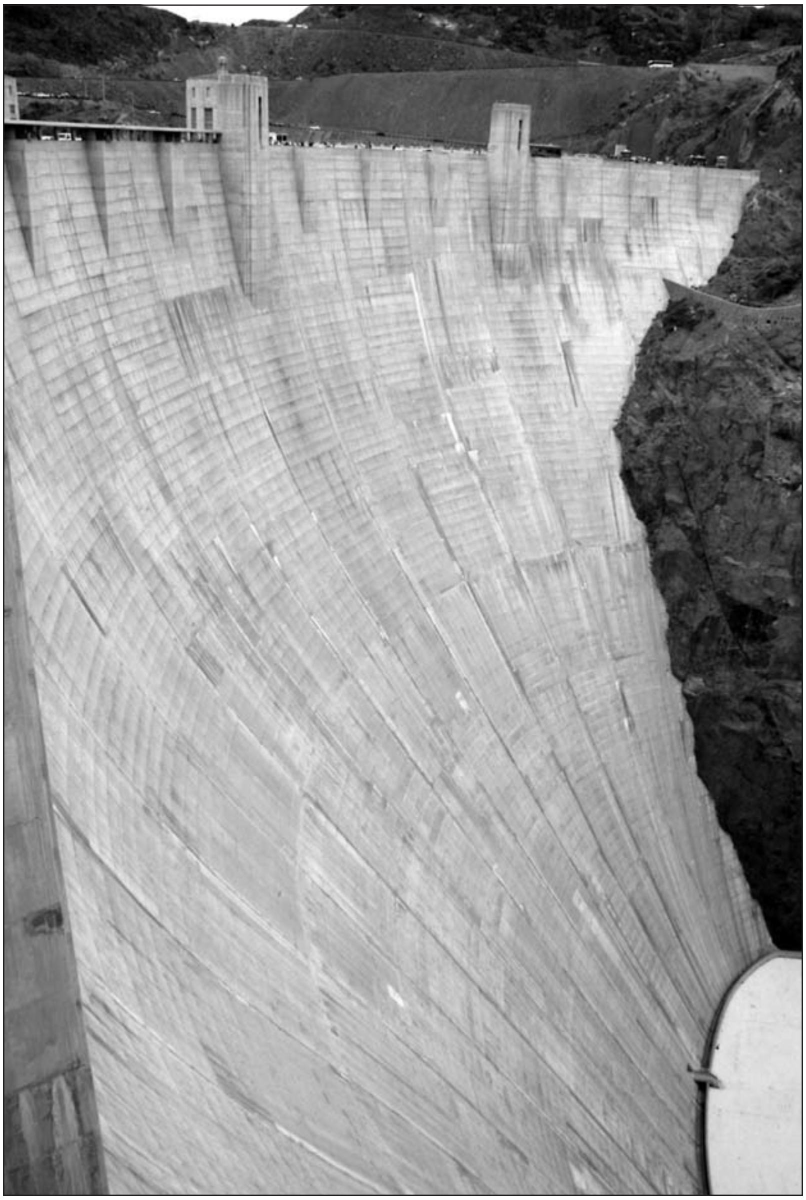
• Background

The United States will need to encourage water conservation in the use of water and potentially move water from wetter areas to drier areas. For example, much of the water from the Colorado River system has been diverted for many years to areas such as southern California to help quench the thirst of the growing population. Even larger scale water diversions have been proposed, such as moving freshwater from the Great Lakes or from other large bodies of water in Canada such as James Bay to the western United States.

• Current Water Agreements and U.S.-Canada Relations

Both the United States and Canada have a reasonable supply of freshwater at about 6.5 percent to 7 percent respectively of the world's freshwater, although it is not always found in the best places. For instance, the central and eastern United States has a reasonable amount of water, whereas the western United States is drier in most places. The water problems in the dry western states are complicated by the many people moving into dry states such as Texas, Arizona, and California and by the lack of water conservation.

Most of the movement of water from more water-rich areas to drier areas has been done locally between water drainage basins for irrigation, water supplies, and hydroelectric power. For example, the movement of water from the Colorado River basin to California was mentioned above. The only water use shared between the United States and Canadian communities has been done locally with small volumes of water. For instance, water has been shared between Point Roberts, Washington, and Vancouver, British Columbia. There is also little movement of bottled beverages between the United States and Canada except for some beer and soft drinks. Canada and the United States have also cooperated on the man-



Hoover Dam provides water and power to more than 20 million people in the American West and Southwest. (Barry Sweet/Landov) agement of water such as the Great Lakes and rivers that flow along or cross the border of the two countries. There has been little discussion between the two governments, however, on the possibility of large-scale exports of water from Canada to the United States. Many Canadians fear what may happen to their water if the United States decides it needs water from Canada.

• Water Conservation in the United States

The United States has not only looked for new sources of water in dry areas, but it has also encouraged or required water conservation to lower water use. Water conservation practices include the recycling of wastewater, drip irrigation, low-water-flow appliances (such as toilets, washing machines, and dishwashers), and the harvesting of rain. San Antonio, Texas, for example, has reduced its use of water per person by forty percent since 1980 by giving rebates to households to conserve water. California has not increased its water use much since 1970 even though its population has doubled. Also, the desalination of seawater along the Pacific Ocean and the Gulf of Mexico has begun to be added to domestic water supplies.

Of course water conservation has not been considered in some actions of the United States government as it continues to give subsidies to grow certain agricultural products. For example, the United States government has given subsidies to farmers in the dry western states to grow a high water consumption product, corn, to be used for ethanol, instead of growing a lower water use product like cotton. This action has led to an increased use of irrigation.

• Long-Distance Transport of Water

If the conservation practices and shorter range transport option for water in the United States are not sufficient to supply the demand for water, then the United States may decide to look for long distance water transport from other regions such as Alaska, Canada, and even Mexico. Alaska, has about a third of the renewable water in the United States, and it has expressed an interest in selling its water to other states. The water could be moved south by large pipelines. There appears to also be excess water in the Columbia River, which borders Washington and Oregon that could potentially be transported to the southwestern states in the Colorado River basin. Mexico is very dry in regions near the United States so that using their limited water supplies would be a last resort.

• Context

If the United States decides it needs more water in the future, then it may turn to Canada or Mexico for use of some of their water. Some have proposed that the United States could pay Canada for their water just north of the boundary between the two countries. The main problem is that most people in Canada live in the southern part of the country and need the water for themselves. The population is less in the northern part of the country, but the rivers flow to the north, so that reversing the flow toward the United States would be expensive.

If none of the above options would work, the United States might consider taking a much larger share of water located along the border of the two countries. The easiest place to take such water would be from the Great Lakes. The United States would not even have to take water directly from Canada since it could simply enlarge a canal already in place in Illinois that drains water from Lake Michigan. The United States has the legal right to take water from Lake Michigan because of a 1909 treaty (Border Water Treaty) between Canada and the United States. At present a United States Supreme Court order (1967), however, has limited any further diversion of water out of Lake Michigan. This could change if the demand for water is great enough.

Water rights

• **Categories:** Water resources; laws, treaties, and protocols

• Definition

Water rights are legal rights to draw water from a particular source, such as rivers, streams, and groundwater, for some beneficial purposes, such as drinking or irrigating. In areas where sources of water are plentiful relative to the demand of the users, the allocation of water rights does not matter. However, in areas where available water is insufficient to meet demand, conflicting claims to that water must be resolved. Over time, population growth together with economic development have increased water demand and consequently inflated the relative scarcity of the resource. In order to resolve conflicts between users of water, there exist various mechanisms across regions to allocate water.

The United States may serve as an example to explain how water right systems evolved over time in response to increasing conflicts over water use. Within the United States, two primary systems of water rights are based on the riparian and prior appropriate doctrines. The riparian doctrine holds that the owner of the land adjacent to water has right to use that water. This principle of property right, derived from English common law, was appropriate in the earliest days of American settlement in the arid western region. At that time, settlements tended nearby sources of water, and they had easy access to the water, so the riparian right system was a practical solution. With population growth and the consequent rise in land scarcity, as well as an increase in the demand for water for other uses such as mining, the riparian doctrine became less appropriate. The prior appropriate doctrine evolved to replace the riparian doctrine, and it allows those who arrive first at a source of water to have the superior claim to that water.

In practice, each region can have its own variations upon these two basic principles, depending on characteristics of geography, custom, culture, and legislation in the region. Some regional authorities devise laws that include elements of both systems. In some cases, government may reserve water rights for special purposes, such as national wildlife refuges, federal forests, and military bases.

• Significance for Climate Change

Climate change can cause higher water temperatures, sea-level rise, and changes in the frequency and intensity of precipitation and flooding. All these consequences of climate change can have effects on the quality and availability of water, which, in turn, heavily affects the competition for water rights. Higher water temperature causes a higher rate of photosynthesis and a consequent rise in the number of plants in an area. When these plants die and are decomposed by aerobic bacteria, more nutrients are released into the ecosystem, which may introduce impurities into the water. In addition, flooding can cause pollution to be washed into existing water sources. Rising sea levels resulting from snowmelt can make salt water intrude into rivers and groundwater systems. Those effects of climate change degrade water quality.

In addition to water quality, water availability can be negatively affected by climate change. Average temperature is predicted to rise globally, but greater increases are generally expected to happen in inland areas and at higher latitudes. Higher temperatures will increase the rate of evaporation and consequently reduce water availability. In addition, increases in temperature can shrink the volume and shorten the duration of snow cover which, in turn, will change the timing of streamflow. Peak

Apple and cherry grower Bob Brammer looks out over the Columbia River. He has been attempting to gain increased water rights to the river for more than a decade. (AP/Wide World Photos)

streamflow may move from late spring to early spring or late winter. It is also expected that higher proportions of winter precipitation may arrive as rain rather than snow. Together, these changes can lead to more frequent and severe summer droughts, especially in snow-fed basins.

While decreasing the availability and quality of a region's water supply, drier climate can inflate the volume of water demanded for such uses as irrigation and drinking. As a result of water shortages, water-related tensions can emerge on various geographical scales: international, national, and local. In fact, disputes and conflicts over water rights have erupted worldwide, especially in arid regions.

On the international scale, drier climate has aggravated the conflict over water rights between upstream and downstream countries that share a river basin. In the Middle East, Egypt has warned neighboring countries that it was prepared to use its army to protect its access to the waters of the Nile, which also runs through Ethiopia and Sudan. Lebanon has several times accused Israel of manipulating the waters of the river Litani. In Asia, Bangladesh is a nation especially vulnerable to changes in climate. As a country lying in a low delta, it would see a decline in available drinking water should sea levels rise. Refugees from such conditions would likely flee across the border into India. In order to protect water rights for their people, Indian officials built a large fence along the border with Bangladesh.

On a national scale, Sudan is an example of a nation where climate change triggers conflicts between different interest groups over water rights. As temperatures rise and rainfall drops, there occur clashes between pastoral herders and agricultural farmers over access to shared water bodies. Even worse, the Sudanese government has diverted limited water in eastern Sudan from grazing land to commercial irrigation, leading to fighting in the region. In the United States, tension over water rights between states is emerging, fueled by climate change. Kansas has fought Wyoming over water right issues. Montana has sued Wyoming. The latter state disagrees with claims by Montana that the Yellowstone River Compact signed in 1950 grants the rights to both surface and underground water sources to Montana.

Although involving some uncertainty, predicted impacts of climatic change offer a glimpse into the likely water quality and availability issues that may arise in this century. Varying by region, the effects in general can lead to water shortages and a consequent rise of water right issues, which will be more pervasive in arid regions.

Water vapor

• **Category:** Chemistry and geochemistry

• Definition

Water vapor is water in its gaseous state. Water vapor may form by evaporation of liquid water or by sublimation of solid water (ice). Water vapor (H_2O) is a chemical combination of two atoms of hydrogen and one of oxygen in which both the hydrogen and oxygen possess isotopes. Thus, the molecular weight of water vapor may vary from a low of 18 u to a high of (typically) 22 u. A u is equal to 1.66×10^{-27} kilogram. For a sample of water at a given temperature, the molecules of lower mass move with higher speeds than the more massive molecules and therefore more readily evaporate or sublimate. Thus, atmospheric water vapor is enriched in the lighter forms. In epochs of higher average planetary surface temperature, more low-mass water vapor forms, some of which is ultimately deposited as snow and ice in polar regions. The ratio of low-to-high mass water in ice cores yields a profile of how temperature has varied through time.

• Significance for Climate Change

Water vapor is the principle atmospheric gas responsible for greenhouse warming of the Earth's surface. In terms of its ability to absorb infrared radiation, wavelengths from approximately 0.7 micron to 100 microns, water vapor is about one hundred times more effective as a greenhouse gas (GHG) than is carbon dioxide (CO_2) and four times more effective than methane (CH_4). The concentration of water vapor in Earth's atmosphere varies with height and also varies both regionally and seasonally from 0 percent to 4 percent. Normally, it is the third most abundant gas in the atmosphere after nitrogen and oxygen.

The highest concentrations of water vapor in Earth's atmosphere occur in the planet's equatorial regions over the oceans and rain forests. In contrast, over continental deserts such as the Gobi and Sahara the water vapor concentration approaches zero percent as it does in the frigid air of the polar regions. Nearly all of atmospheric water vapor is found within the troposphere, a region of Earth's atmosphere that varies in thickness from about 20 kilometers over equatorial regions and thinning to about 5 kilometers over the poles. The mean persistence time of a molecule of water vapor in the atmosphere is the days before it is precipitated.

Deducing the effects of atmospheric water vapor on global climate change is extremely complex. As the surface temperature rises, the rate of evaporation increases, thus leading to a higher average concentration of water vapor in the atmosphere. This result considered alone suggests that the higher concentration of water vapor would lead to a higher surface temperature, a positive feedback that would amplify the warming caused by some other factor, such as an increase in solar radiation incident on Earth or the increase in concentration of some other GHG. The increase in the amount of water vapor in the atmosphere, however, also contributes to an increase in cloudiness, thus making Earth more reflective and serving to cool the planet by lowering the amount of solar radiation reaching the surface.

The by-products of industrial activity inject small particles into the atmosphere that serve as nucleation centers for the condensation of water vapor, stimulating the formation of clouds. In the condensation process, latent heat of vaporization is released. This deposition of energy within the atmosphere powers convection and the formation of storms that redistribute the energy to cooler regions of the atmosphere. These various effects are notoriously difficult to model.

Human activity contributes significantly to increasing levels of atmospheric water vapor. The combustion of fuels produces both water vapor and CO_2. The most significant deposition of water vapor into the atmosphere, however, does not result from combustion but from the irrigation of land for agricultural purposes. Making marginal regions such as steppes and grasslands agriculturally productive requires intensive irrigation. River and lake water or water from underground aquifers is spread across the landscape where evaporation and transpiration by plants increase the water vapor concentration.

In the case of pumping sequestered underground water to the surface and spreading it over crop fields, water that was formerly removed from the atmosphere and not subject to the global water cycle now participates. For example, the Ogallala Aquifer, located beneath the Great Plains of the United States west of the Mississippi River, is being depleted at a rate of 12 billion cubic meters of water per year, a rate equivalent to eighteen times the flow of the Colorado River. Some 90 percent of the water removed from the Ogallala is used for agricultural irrigation. Most of this water is deposited in the atmosphere; very little percolates back into the ground to recharge the aquifer.

Similarly, the semiarid American Southwest becomes agriculturally productive when irrigated by water removed from the Colorado River and other water transported from the Northwest. As this water evaporates, it enters the atmosphere and contributes to further greenhouse warming. Extensive irrigation projects across the globe, such as China's Three Gorges Project, Libya's Great Man-Made River Project, and the draining of the Caspian Sea, exacerbate global warming.

Wave power

- **Category:** Energy

- **Definition**

Wave-power devices extract mechanical or electric power from the oscillatory motion of water, or from pressure fluctuations below the surface that are due to surface waves. Wave-power plants are set up either on the coast or anchored further out in the ocean. Schemes for extracting steady power from waves are based on the predictable, repetitive nature of waves. However, they must be able to withstand the immense forces of extreme sea states and the corrosiveness of salt water. Installation costs exceed $15 per watt, too high to compete with other power sources.

Waves transmit energy through a medium. Ocean surface waves are usually driven by winds. While this kinetic energy itself is transmitted rapidly, the water propagating the wave moves little. The movement of the water as a wave passes follows an elliptical path around its mean position. The resulting waves are called surface gravity waves, because water rises and falls as a wave passes in an exchange between hydrodynamic pressure and gravity. In deep seawater, defined as deeper than half of the wavelength between successive wave crests, the theoretical value of wave power in kilowatts per meter length along a wave crest is 0.489 times the product of the square of the wave height in meters and the time between waves in seconds, or

$$0.489 \times TH^2$$

where T is the time between waves and H is the height of the wave. Thus, a wave height of 2 meters, repeated every 15 seconds, generates roughly 29 kilowatts per meter. Estimates of coastal wave power range from 20 to 70 megawatts per kilometer. Waves lose energy quickly as they come into shallow water, but the wave height grows.

The most efficient capture of wave power is in a resonant device, whose natural frequency matches that of the waves. The Salter Duck concept claims to extract over 94 percent of the power in ocean waves using actively controlled cam and float devices. Its proponents claim that the maximum stresses in the device never exceed those associated with power extraction, and that the device can survive the largest and sharpest breakers without capsizing or breaking. Full-scale devices are large and complex and require substantial initial costs to construct and deploy. The Energren system comprises several floats and lever arms and extracts energy over a large surface area, repeatedly using each wave. The Pelamis wave energy converter uses hydraulic cylinders that are pressurized using lever arms attached to floats.

Terminator devices extend perpendicular to the direction of wave motion and capture or reflect the power. One version is an oscillating water column, in which seawater passes through submerged inlets, compressing and expanding a trapped air column above it. The alternatively compressed and expanded air is used to drive turbines.

Point absorbers are floating structures with linkages that extract work. The buoyancy of water pushes long vertical cylinders up and down as a wave goes by. An example is the 40 kilowatt, 4 meter diameter, 16 meter long Power Buoy used in a commercial facility at Reedsport, Oregon. The Aqua Buoy tested in Portugal uses the vertical motion due to waves to run a two-stroke pump driving seawater through a continuous turbine. Some large seagoing vessels also direct wave-driven water through turbines and extract electric power.

Overtopping devices use tapered channels to increase wave height and pour water into reservoirs above the mean sea level. When the water is released to fall through turbines, energy is extracted. Attenuator devices are long, floating structures oriented parallel to the direction of the waves, with multiple sections. Height differences of waves along the length of the device, attributed to phase differences between the waves at different points, cause flexing and drive hydraulic pumps. A Pendulor device is a rectangular box open to the sea at one end. A hinged flap swings back and forth and drives a hydraulic pump and generator.

Wave power is also used to run desalination by reverse osmosis. A piston pump anchored to the sea bottom rises and falls, driven by wave action, driving seawater through the membrane. North American wave projects as of 2006 included a single 40 kilowatt Power Buoy deployed at Kaneohe, Oahu, Hawaii in 2004; a set of four Aqua Buoys producing 1 megawatt at Makah Bay, Washington, and a single OWC producing 500 kilowatts at Point Judith, Rhode Island. Some projects are being considered and tested in Europe, including an Aqua Buoy in Portugal.

• Significance for Climate Change

Wave power is clean and renewable. Proponents estimate that over 10 gigawatts of electricity can be brought on-line within a decade and that a potential 250 terawatt-hours can be economically harvested from the U.S. coastline. As a renewable energy source with no emissions to speak of, wave power, to the extent that it is viable, represents a carbon-neutral source of energy and a means to reduce anthropogenic contributions to global warming.

Weather forecasting

• **Category:** Meteorology and atmospheric sciences

• Definition

Weather forecasting is the branch of meteorology devoted to making short-term predictions about the weather. Early, nonscientific attempts at weather forecasting were based simply on people's past experience and observations. Modern science is based on more detailed understandings of relevant mechanisms and much more precise observations. However, all weather forecasting, scientific or not, is an extrapolation of human knowledge and observations from the past and present into the future.

Advances in science and technology have endowed meteorologists with the ability to make more objective judgments and inferences than were previously possible. Modern weather forecasting includes three components: sophisticated and accurate instruments for making atmospheric observations and measurements, a mathematically precise forecast model, and a powerful computer. Forecasting based on these components is called "numerical weather prediction" (NWP).

Many advanced technologies are employed in modern-day atmospheric observation and measurement, including satellites, aircraft, radar, and lidar. These technologies have made possible more frequent and accurate descriptions of atmospheric conditions, providing a good starting point for predicting the evolution of the atmosphere in the future. The treatment of observed data and the procedure for using these data in a weather-forecasting model are collectively called "data assimilation," and the product resulting from this preprocessing of data is analysis. An analysis provides a complete description of the current weather situation, and it forms the initial set of conditions from which a model projects future conditions.

A forecast model is composed of a set of physical laws governing atmospheric motion and other properties. These laws are typically expressed in a set of mathematical and statistical equations. Such equations can then be digitalized using computer programs, becoming a large set of computer codes. A numerical forecast model typically includes two parts: a dynamics core and a family of physical parameterization schemes. The dynamics core is the central part of the programs that represents the essential physical laws governing atmospheric motion. Physical parameterizations are sets of additional parameterized relations that interpret various physical processes that operate on scales that the discretized forecast model cannot resolve.

Once generated, the computer codes representing a forecast model are fed into a powerful computer. With accurate observations of current atmospheric conditions as the initial data, the computer will run its codes and output solutions representing future atmospheric conditions. Meteorologists then interpret these computer-generated solutions using various weather charts.

• Significance for Climate Change

Climate is an averaged state of long-term weather conditions. Therefore, climate can provide a general reference and guideline for weather forecasting. In fact, meteorologists use climate information in various weather forecasting methods, such as persistence forecasting, trend forecasting, and analog forecasting. On the other hand, weather forecasting may provide researchers with a snapshot of climate change. For example, global warming may manifest itself in alterations in the daily forecast of maximum and minimum temperatures. Although a particular day's weather forecast may vary significantly, a persistent change in weather pattern over some period of time may indicate a change in the Earth's climate system.

One of the issues raised by climate change is its consequences for future day-to-day weather patterns. The Intergovernmental Panel on Climate Change (IPCC) in its 2007 assessment report found that in a future warm climate, global weather would likely exhibit the following changes: higher maximum temperatures; more hot days and heat waves over nearly all land areas; higher minimum temperatures; fewer cold days, frost days, and cold waves over nearly all land areas; more intense precipitation events; increased summer drying over most midlatitude continental interiors and increased associated risks of drought; increases in tropical cyclone peak wind intensities, as well as mean and peak precipitation intensities; intensified droughts and floods associated with El Niño events in many different regions; increased Asian summer monsoon precipitation variability; and increased intensity of midlatitude storms.

These projected changes will certainly pose new challenges for weather forecasting should they come to pass, since models based on past atmospheric dynamics may need to be dramatically refined to respond to a new climate regime. At the same time, refinement of weather-forecasting models will enable climatologists to improve their related long-term climate models as well, increasing the reliability of climate projections alongside weather forecasts. The longest feasible weather forecast range is about two weeks. Error rates in forecasts increase rapidly beyond a two-week threshold. Such short-term projections are useful in helping people plan their daily lives. For climate outlooks and projections to be useful, however, they must operate on timescales of months, seasons, years, or even millennia. More accurate weather data and more sophisticated forecast models will help climatologists develop models reliable on those scales.

Weather vs. climate

• Category: Meteorology and atmospheric sciences

Weather is the set of temporally or spatially local meteorological phenomena: It is the concrete set of events that actually occur over time. Climate is an abstraction from weather: It is the set of the averages of meteorological measurements taken in a given place over a given time period. Changes in climate may be used as predictors of future weather patterns.

• Key concepts

archaeological record: the human-made objects and residues of the past that are used by archaeologists to reconstruct history

desert climate: a hot climate characterized by extremely low and sometimes deficit amounts of precipitation

insolation: the amount of solar energy received at a given point on the Earth

orographic barrier: a mountain or a hilly area that acts as a control on the climate on either side

semiarid climate: a climate of low annual precipitation (250-500 millimeters)

tropical climate: a climate generally found in equatorial or tropical regions that exhibit high temperatures and precipitation year-round

west coast marine climate: a mild, annually moist climate found along the western coasts of continents

• Background

The weather is one of the most obvious and tangible aspects of Earth's atmospheric environment. One can see, feel, hear, smell, and even taste weather. It consists of the measurable meteorological conditions of the atmosphere at any given time. In contrast, climate is a concept that is constructed by the averages of the component elements of the weather: temperature, wind, pressure, precipitation, clouds, and visibility. Complicating the understanding of climate is the fact that the Earth's atmosphere reflects many kinds of climates over many different areas at any given time.

• Weather

The term meteorology, the study of the weather, originates from the work *Aristotelous peri geneseōs kai phthoras* (n.d.; *Meteorologica*, 1812), by the Greek philosopher Aristotle (384-322 B.C.E.). Much of what Aristotle wrote was based around his assumptions about how the weather worked; he provided a model that was accepted without question for nearly two thousand years. However, with the advent of weather instruments (1600-1850's) such as the thermometer, barometer, and hydrometer, a science of meteorology slowly emerged. The invention of the telegraph in 1844 allowed for the rapid distribution of weather observations accumulated from a large geographical area. It was the telegraph that assisted meteorologists in constructing the first weather maps and charts.

• Modern Observations

Today, meteorologists depend on a wide range of instruments and communication systems to measure and distribute information about the weather. Weather observations at the surface of the Earth include measurements of wind direction and velocity, air temperature, visibility, types of observed clouds, atmospheric pressure, precipitation amount and type, and humidity. Usually, weather stations record surface conditions. However, some stations take observations of the upper atmosphere with the aid of a balloon (radiosonde). Many stations use Doppler radar. Hourly weather observations are logged at these stations. These observations are then sent to forecasters, who use them to develop long-term forecasts.

Climate is defined as the average amount of precipitation and average temperature at a given location within a given season. A location's climate is determined by its latitude, altitude, and locational characteristics. The latitude of a station determines

Top Weather, Water, and Climate Events of the Twentieth Century

	Year

the amount of insolation the station will receive at any given time during the year. Higher latitudes experience less insolation than do stations located within the tropics. Altitude is the elevation of a station. Given the environmental lapse rate, or the general decline in temperature with altitude (4° Celsius per 1,000 meters), stations found at higher elevations exhibit generally cooler climates. A station's climate is also controlled by its location with respect to land and water.

Seattle, Washington, although somewhat high in latitude, is also climatically influenced by its orientation with respect to Puget Sound. Its maritime location keeps Seattle's climate from exhibiting extreme temperatures. In contrast, locations such as Wenatchee, Washington, less than 160 kilometers to the east but on the leeward side of the Cascades, is located in a more continental position. Temperatures there are considerably colder in the winter and warmer in the summer. Additionally, the Cascades act as an orographic barrier to precipitation, making, Wenatchee's climate a desert.

• Climate

To understand climate, scientists must have access to weather data over long periods of time. Relatively accurate weather observations have only been available for a minute period of time. However, past climatic conditions can also be studied by indirectly interpreting the signature left by the movement of animals and plants, as well as the archaeological record of human activity. For example, seven-thousand-year-old cave drawings in the Sahara Desert suggest that in the past this desert region retained a climate that was conducive to habitation. From 400 to 1200 C.E., historic records suggest, the Vikings exploited the warm, ice-free conditions on their coastlines and ventured out in ships in exploratory enterprises, settling Greenland and Iceland during this time. However, historic records are subject to problems of precision and human interpretation. It would not be until the late 1800's that weather records would be scientifically collected in the United States. It is the reliability of these meteorological data that dictates how accurate scientists' understanding of climate can become.

• Climate Classification

Climates on the Earth can be classified and defined by their characteristics and their environmental qualities. However, classification systems are limited by the number of variables they utilize. One way to classify climate is to look at the distribution of different types of animals or plants that live within that climate. For example, the Köppen classification system uses temperature and moisture levels related to plants to define the patterns of climate types. On the other hand, humans are found in every climatic type on Earth.

• Present Climate Distributions

The general categories of climates include: climates of the tropics, equatorial climates, savanna climates in areas such as the African region of the Sudan and Sahel and tropical semiarid climates. Additionally, desert climates can be found anywhere the geographical conditions are right for moisture to be depleted from the air. Monsoonal climates are found in India, Northern Australia, and regions within Southeast Asia. Mediterranean climates are located around the Mediterranean Sea, but they can also be found in Central Chile, California, and South Africa. Humid subtropical climates are found on the eastern margins of continents, in regions such as the southeastern United States, Uruguay, Brazil, Argentina, southern Japan, the Natal of South Africa, Taiwan, and parts of Eastern China.

West coast marine cool temperature climates are found along the west coasts of continents and in the middle latitudes. Seattle is a good example of this climate, which is also found on the Atlantic coasts of France and the United Kingdom. The warm summer continental climates are found in areas such as the central United States, northeastern China, and Korea. Cool summer continental climates are found in the northeastern United States, northern Japan, and Eastern Europe. Steppe climates are found in continental areas of North America, Argentina, and Patagonia. Sub-Arctic climates are known as the Taiga, a Russian term for the coniferous forests found in the areas of Siberia and Canada. Tundra is a cold climate just below the Arctic region. Ice cap climates are found at the North and South Poles. Vegetation does not grow, and precipitation is sparse.

• Context

In contrast to weather, climate is an abstract concept made up of the measured averages and extremes of weather. Climate, then, cannot be experienced firsthand. Over the course of a year, one can experience the change of seasons, but only on the basis of what one might expect the weather for those seasons to bring. Complicating this further is the variation in the types of climate that exist and the limitations to the models by which they are defined. The evidence for changes in climate is clearly found in the fossil record, as well as in geologic structures showing the advance and retreat of ice over the land. Additionally, the archeological record indicates climate change by shifts in cultural activity. Core samples from glaciers can be analyzed to reveal oxygen content and thermal conditions of past atmospheres. Ice from these past periods continues its hold on parts of the globe.

Wegener, Alfred

German meteorologist

Born: November 1, 1880; Berlin, Germany
Died: Winter of 1930; Greenland

Wegener's fascination with the late Paleozoic ice age in the Southern Hemisphere led him to formulate the theory of continental drift to explain its geographic extent.

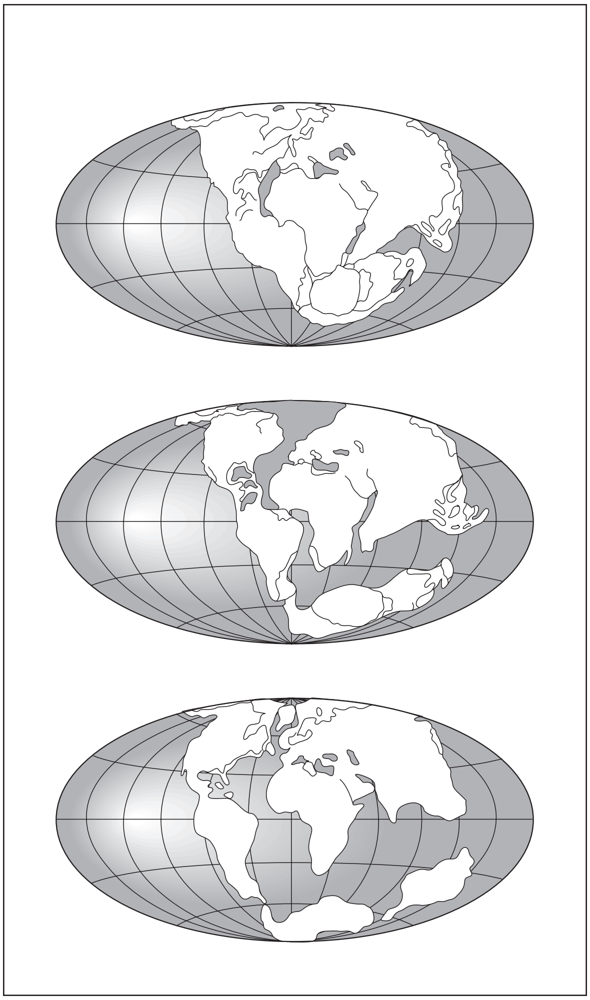
• Life

Alfred Wegener was born in Berlin in 1880, the son of a preacher in an evangelical church. He got his secondary education at the Köllnisches Gymnasium in Berlin and subsequently enrolled at the Universities of Heidelberg, Innsbruck, and Berlin, receiving a Ph.D. in astronomy from the University of Berlin in 1905. Following graduation, he realized that he had lost interest in the field of astronomy, so he decided to pursue a career in the recently established field of meteorology, finding employment as an assistant at the Royal Prussian Aeronautical Observatory at Lindenberg. He experimented with kites and balloons and broke the world's record for long-distance flight in a free balloon, drifting for fifty-two hours across Germany, Denmark, and the Baltic Sea.

Wegener was fascinated with the ice-covered island of Greenland, so when the long-awaited opportunity for a visit presented itself, he resigned his position at the observatory and joined the 1906-1908 Denmark Expedition to Greenland as the official meteorologist. Following his return in 1908, he taught at the Universities of Marburg, Hamburg, and Graz in Austria, with time out for military service in 1914-1915. He also continued his meteorological investigations, and in 1930 he agreed to make another trip to Greenland, this time as leader of the German Inland Ice Expedition. Unfortunately, this expedition cost him his life. In an attempt to rescue starving team members, he and a companion set out for the middle of the ice cap in late October. When the supplies they brought with them were lost en route, he decided to go back before the polar night set in. He never made it, dying en route, possibly of a heart attack. His Eskimo companion sewed his body in a sleeping bag and buried him in the snow with upright skis as a marker. He remains buried there today.

• Climate Work

Wegener used evidence of past climate changes to support his famous theory of continental drift. In this theory, he proposed that the Earth's continents were once joined together in a giant supercontinent named Pangaea. Wegener believed that during the Mesozoic Era, about 200 million years ago, Pangaea fragmented into two parts. Laurasia was the northern part, a supercontinent consisting of North America and Eurasia, which subsequently drifted apart from each other. The southern part became a supercontinent known as Gondwanaland, which subsequently broke apart into the present-day Southern Hemisphere continents of South America, Africa, Australia, and Antarctica, with India drifting north to become part of Eurasia.



Alfred Wegener theorized that the continents began as one great landmass, Pangaea, more than 200 million years ago (top), which drifted apart beginning about 190 million years ago (middle), eventually resembling the world as we know it today (bottom).

Wegener presented his ideas on continental drift in a slender volume, *The Origins of the Continents and Oceans* (1915). He and others who supported the continental drift theory found several lines of evidence to support their point of view. One was the seeming jigsaw-puzzle "fit" of the continental boundaries on opposite sides of the Atlantic Ocean, a conclusion that became more compelling as globes were improved. Similar rock types were found on continents that were now far distant from each other, and geologic features such as mountain ranges ended abruptly on the coast of one continent, only to appear again on the facing coast of a continent across the sea. Wegener was also intrigued by the discovery of certain land-dwelling plants and animals that appeared simultaneously in the fossil record on widely separated continents. The fossil fern Glossopteris and the fresh-water reptile Mesosaurus are the two best-known examples.

Evidence for a late Paleozoic ice age in the Southern Hemisphere provided Wegener with some of the most compelling evidence for his theory. Deposits of ancient glacial debris are found in many localities in South America, Antarctica, Australia, South Africa, and parts of India. They have distinctive features that cannot be mistaken for any other type of sediment. A period of worldwide glaciation cannot explain these deposits, because (with the exception of Antarctica), all of the deposits lie close to the equator today, and there is no evidence for glaciers in the Northern Hemisphere at the time they formed.

Regional mapping of the striations and grooves left by the ancient Southern Hemisphere glaciers suggests that the ice accumulated in the ocean and moved inland, which is impossible. When the Southern Hemisphere continents are grouped together as Wegener proposed, however, then all the glaciated areas are seen to be contiguous, with the flow lines of the striations and grooves moving outward from the South Pole area, where the main ice mass must have been located.

Western Fuels Association

• **Categories:** Organizations and agencies; energy
• **Date:** Established 1973
• **Web address:** http://www.westernfuels.org

• **Mission**

Headquartered in Westminster, Colorado, Western Fuels Association (WFA) is a nonprofit cooperative that provides services to consumer-owned electric utilities, both rural and municipal, in the Great Plains, Rocky Mountains, and Southwest regions. A twelve-member board, selected from its member utilities, oversees the association. Its chief executive officer and staff handle daily operations.

WFA purchases coal and transports it to its member utilities, thus removing the expense for them of maintaining their own procurement staff. WFA supplies approximately 15.4 million metric tons of coal annually from lands leased from the federal government in the Powder River Basin of southeast Montana and northeast Wyoming. It acquires further coal supplies through affiliated companies in Wyoming and Colorado. To move the coal to its members, WFA reserves more than seventeen hundred railroad cars, as well as operating the Escalante-Western Railway in New Mexico. WFA also offers consultation services on management, marketing, mining engineering, location of new coal fields, litigation, regulation, and taxation.

WFA members belong to one of three classes. Class A members rely on WFA for the fuels to generate power; class B members use WFA coal for some power plants; and class C members use WFA transportation and expertise as needed.

• **Significance for Climate Change**

The WFA promotes the use of coal for generating energy in the American West, subscribing to the view that the carbon dioxide produced thereby does not contribute significantly to global warming and may actually be beneficial. WFA's 2006-2007 annual report makes no mention of climate change, although its previous report refers to the uncertainty of environmental issues. However, WFA's web site offers news items and links to organizations that challenge scientific findings about global warming and environmentalist initiatives.

Among the organizations WFA supports is the World Climate Report. WFA's web site describes it as a "concise, hard-hitting and scientifically correct response to the global change reports which gain attention in the literature and popular press." The World Climate Report's Web site champions what it calls the mainstream skeptic point of view, "which is that climate change is a largely overblown issue and that the best expectation is modest change over the next 100 years."

Another organization that WFA supports is the Center for the Study of Carbon Dioxide and Global Change. Its Web site, CO_2 Science, argues that little global warming has occurred during the last seventy years and that the increase of carbon dioxide in the atmosphere may actually improve human health.

Wetlands

• **Category:** Environmentalism, conservation, and ecosystems

• **Definition**

Wetlands are found from the equatorial region to the arctic regions of Canada. Even in the deserts, wetlands are found near oases. Wetlands are important to society as they provide sanctuary for fish and wildlife, water resources for streams and aquifers, and, in most cases, serve to mitigate the severity of flooding. Wetlands also provide support for fishing, hunting, and other recreational and educational activities such as bird watching, photography, painting, tourism, and research. They provide humans and wildlife with food sources and function as sources of energy and sinks for greenhouse gases (GHGs), sequestering carbon through the formation of peat, a precursor to the formation of coal.

Wetlands can be harbingers for disease-causing insects and may limit some human activities, such as construction and farming. Some wetlands can also contribute to flooding in some cases, as they reduce the rate at which water is removed from the surface. Wetlands are great sources of methane gas, as plants account for about 20 percent of the methane found in wetlands. Wetlands are sometimes referred to as ecotones, transition zones between open bodies of water and land, and sometimes are described as the kidneys of the landscape or as biological supermarkets because of the roles they play.

Because of the varied nature of wetlands, it is often difficult to say what a wetland is and is not. Wetlands have different meanings to different people, depending on their background, exposure, knowledge, and political stand. There is no universal definition of what a wetland is, even within the United States. The main reason wetlands are difficult to define is that they are found in widely varied locations, have different climates, soils, landscapes, water quantity and quality, flora, fauna, and other characteristics, including human disturbances such as dikes, draining, pollution, and so on. The definition of wetland depends on the specific purpose for defining it, such as research studies, general habitat classification, natural resource inventories, or environmental regulations.

All wetland definitions fall into two categories: regulatory definitions and nonregulatory definitions. Because there are myriad, variable definitions and changes in definitions, there is some confusion among legislative and regulatory bodies. This confusion has caused several isolated wetlands to be destroyed, as these wetlands were not connected to navigable waters and may not have seemed to qualify for protection.

Three criteria are necessary to define an area as a wetland: hydrology, hydric soil, and hydrophytes (vegetation adapted to wet conditions). Wetlands are areas that are typically wet most of the time or where the groundwater is very close to the surface. Hydrology is the main factor for identifying wetlands, because not all wetlands exhibit hydric soil conditions. Water quantity and quality determine soil characteristics and which plants and wildlife communities can inhabit the area. The soil, plants, and wildlife affect water quantity and quality.

Wetlands can be broadly divided into two major types: coastal wetlands and inland wetlands. Coastal wetlands are found along the oceans and seas, whereas inland wetlands are found along rivers and streams, near lakes, in low-lying land depressions, or where the groundwater meets the surface. Because of these conditions, the major types of wetlands that have been recognized are bogs, swamps, marshes, fens, potholes, and player lakes.

• **Significance for Climate Change**

Any climate change could modify, create, or eliminate several types of wetlands. With an increase in global warming and sea-level rise, most of the coastal wetlands may be altered, destroyed, or eliminated.

However, with the demise of coastal wetlands, new wetlands would be created in places such as Canada and Siberia's arctic regions as glaciers melt. Change in the climate would affect the effectiveness of wetlands to remove nutrients from flow-through systems such as lakes or riparian wetlands. Aquatic life forms would be lost as a result of prolonged nutrient loading to such wetlands. Wetland values would be altered, as the hydrology regime was altered in those wetlands. Climate change that would involve a sea-level rise would be detrimental to coastal regions and human life.

Many of the world's largest cities, located near coastal areas, have wetlands buffering the effect of ocean waves or flooding. Any meaningful sea-level rise would cause serious problems to these wetlands, changing the water chemistry and thus the flora and fauna. It would also affect those coastal cities by increasing the risk, incidence, and severity of flooding. Global warming would lead to destruction of some coastal wetlands and the creation of new wetlands, mainly in the Northern Hemisphere. Tourism may suffer in places where tourism helps the economy, such as the Florida Everglades, with shifts in locations of wetlands. Southeast Asian wetlands may be decimated with a rise in sea level resulting from climate change.

The wetlands of the Nisqually National Wildlife Refuge in Washington State. (AP/Wide World Photos)

The use of wetlands to reduce GHGs may not be beneficial across the board, as it has been found that developmental strategy may be better for developing nations than emission reduction of GHGs. Specific regions would need to assess their wetlands according to their sustainability and economic persuasions, noting that wetlands play significant roles in relation to carbon and GHGs such as methane. They can be carbon storage sinks, sequestering several metric tons of organic carbon and helping offset carbon emissions elsewhere.

WGII LESS scenarios

- **Category:** Laws, treaties, and protocols
- **Date:** Published as part of the Second Assessment Report in 1995

- **Definition**

WGII LESS scenarios were developed for the Second Assessment Report of Working Group II (WGII) of the Intergovernmental Panel on Climate Change (IPCC) to assess low-emissions supply systems (LESS). The mission of Working Group II was to study the physical, ecological, human-health-related, and socioeconomic impacts of climate change. The overall goal of the IPCC is to determine the history, present situation, and likely future of Earth's climate and to make recommendations as to the best climate policies to preserve the health and welfare of the world's peoples and ecosystems. As part of that mission, WGII was tasked to review the technical and economic feasibility of various adaptation and mitigation strategies relevant to climate change.

- **Significance for Climate Change**

WGII examined various cost-effective adaptation and mitigation techniques, beginning with existing commercial-scale technologies that would increase efficiencies in energy generation and distribution by 10-30 percent with little net cost increases. Gains of 50-60 percent in energy efficiency are technically feasible in the developed world, but they would require significant capital expenditures on the global commercial-energy system. Such costs would be prohibitive for the developing world. Even a switch to more efficient energy technology might not lead to an overall reduction in total greenhouse gas (GHG) emissions, given the rising global demand for energy.

The five LESS scenarios explored by WGII are:

- Nuclear-intensive (NI)
- Natural-gas-intensive (NGI)
- Coal-intensive (CI)
- Biomass-intensive (BI)
- High-demand variant (HD)

WGII considered the options involved in switching to low-carbon fossil fuels. This switch would favor electric power generation using oil or natural gas rather than coal. Sufficient technologies exist to allow for the decarbonization of fossil fuel and the storage of carbon dioxide (CO_2) for use in producing hydrogen fuels. Technologies also exist to capture methane emissions in the energy-generation-and-distribution process. Commercial-scale implementation of decarbonization and methane capture are not, however, economically attractive solutions.

WGII considered energy generation by means of nuclear power. This option is technically and economically possible and cost-effective, but it is very unattractive to a segment of the public as a result of problems with reactor safety, radioactive-waste transfer and storage, and a lack of clear authority to force nuclear-reactor builders and operators to adhere to international quality-control standards.

WGII also considered energy generation by means of renewable sources of energy, either exclusively or in combination with fossil-fuel sources. In this area, WGII constructed five scenarios using varying degrees of renewable energy technologies that were then available or could become available on a commercial scale at an economically justifiable cost. Technologies that were not cost competitive for CO_2 LESS up to the year 2100 were eliminated from consideration.

WGII investigated the coal-intensive option using an experimental stem-injected aeroderivative gas turbine developed by General Electric. In comparing the efficiencies of coal and biomass energy generation, WGII found that either a steam-injected or an oxygen-blown gasifier turbine used in conjunction with coal would result in "hot gas" cleanup costs without removing any sulfur in the combustion process. Available technologies do not allow coal to be burned as cleanly as biomass fuels. Research in this area continues, however.

The natural-gas-intensive scenario is based on estimates of recoverable natural gas resources provided by the 1994 U.S. Geological Survey. Should these estimates prove inaccurate, or should the resources prove too expensive to recover, the natural-gas-intensive option will decrease in feasibility. LESS natural-gas-intensive practices include CO_2 sequestration, an additional cost factor.

The high-demand variant scenario is based on a fourfold increase in global energy demand. The HD variant involves a mixture of coal, biomass, and alternative energy sources such as wind and solar power. It also includes decarbonization of coal and natural gas and high degrees of energy efficiency across the board. It was judged to be cost prohibitive given current levels of technology in the developing world.

The biomass-intensive scenario shows much promise for reducing global GHG emissions in a cost-effective manner. Biomass feed stocks must be high-density materials, such as wood chips. In order to combust with maximum efficiency, the wood chips produced from fast-growing trees must be dried using superheated steam, which can then be recovered and utilized in the energy production process. Biomass power plants can be smaller in scale than traditional coal plants and possibly located nearer to energy consumers, thus increasing efficiency in distribution networks.

WGII also considered the use of intermittent renewable energy sources such as solar and wind in combination with other fuels for electricity generation. It determined that up to 30 percent of electrical energy can by produced by renewable sources without significant cost increases in electrical storage capacity.

Information and results from the WGII Second Assessment Report indicate that a combination of different low-emission energy-generating methods, all operating at maximum achievable efficiency in different regions of the world, will be necessary to stabilize and possibly reduce global GHG emissions. Energy demands will increase in the foreseeable future as a result of global population growth and economic development, and no single technology will satisfy those demands, nor is any single technology suitable for universal adoption by all nations. However, the WGII LESS scenarios may help each nation in evaluating the proper combination of clean energy technologies for its needs and increase the global adoption of clean energy.

Whales

- **Category:** Animals

- **Definition**

Whales are marine mammals that occur in all the world's oceans. They belong to the Order Cetacea, along with dolphins and porpoises. Although all cetaceans may be considered whales, the term "whales" traditionally refers to the members of this order that exceed 6 meters in length. These include the baleen whales, such as the blue whale and right whale, sperm whales, pilot whales and killer whales.

Whales include the largest animals ever to exist. The mass of a blue whale, for example, is several times greater than that of the largest dinosaur known. Despite their fish-like appearance, whales are air-breathing mammals that have hair and mammary glands like other mammals and must come to the surface to breathe. Their ancestors of 50 million years ago were hippopotamus-like creatures distantly related to modern hippos. Modern whales form two distinct groups, the baleen whales—also known as the rorquals—that feed on krill and the toothed whales—such as the sperm whales, dolphins, and porpoises—that feed on fish and larger marine invertebrates.

All the world's whales are carnivores, and therefore many of the great whales are migratory, spending summer months in colder polar waters were food is plentiful and then returning to more tropical or subtropical waters to winter and spawn their calves. California gray whales, for example, feed along the northern pack ice of the Arctic but winter in warmer lagoon waters off Baja, California. Their twice annual seasonal migrations northward along the California coast provide a popular pastime for wildlife enthusiasts, who line the shores to spot these leviathans on their migratory journeys.

- **Significance for Climate Change**

Whaling is the commercial harvesting of whales for food, blubber, oil, whalebone, and other products. Whaling is a centuries-old industry that probably began when native peoples harvested beached whales for food. Whaling as a commercial venture started with the Basques of northern Spain and the peoples of the Azore Islands, who pursued slower whales such as the right whale. The activity soon spread to other European countries. By the nineteenth and twentieth centuries, whaling ships regularly departed from ports in New England, Iceland, Norway, the Netherlands, and other locales for Arctic and Antarctic waters of the Pacific on cruises that lasted many years.

Commercial whaling reached its peak following World War II, when whaling fleets accompanied by floating whale processing factories took to the seas to harvest record numbers of whales. The whale slaughter that resulted from this efficient combination greatly exceeded the recruitment ability of major whaling stocks, and many of the largest whales including blue, fin, sei, and sperm whales drastically declined under this onslaught. Alarmed by the precipitous decline in numbers, the United Nations declared a moratorium on whaling and whale products, and many other nations of the world followed suit. Some countries, such as Japan and Russia, continued whaling activities but on a much reduced scale, although Japan continues to harvest certain species for research purposes. Following curtailment of high-seas commercial whaling, most of the whale populations have slowly recovered, although the threats posed by global warming may once again threaten the population stability of many of the great whales.

The higher temperatures and greater rainfall associated with global climate change are warming surface seawaters and hastening melting of the Arctic and Antarctic pack ice and of the Greenland glacier, all of which is resulting in changes in icy polar habitats and the food supply of most of the world's whales. In the Arctic, the rapid melting of the ice cover is threatening stocks of northern whales such as the narwhale, beluga, and bowhead whales, as well as gray whales that feed in these waters during summer months. Rainwater, along with water from the melting ice, dilutes seawater, sharply reducing its salinity and destroying the populations of marine organisms on which these northern whales depend.

Gray whales returning to their wintering grounds off Baja, California, to breed appear underfed, and their breeding success has declined. Furthermore,

A beached whale in Sarzeau, France. (Thierry Creux/Maxppp/Landov)

the melting of the Arctic ice cover has also awakened prospects for the development of northern sea trade routes and the exploitation of resources that underlie the ocean floor. Russia, Canada, and the United States have already expressed interest in petroleum deposits on their respective continental shelves as the Arctic pack ice melts. Increased trafficking associated with exploration and economic development such as commercial shipping, mining, and oil extraction poses a major threat to the fragile Arctic habitat and its cetacean inhabitants.

At the other end of the Earth, rapid melting of Antarctic pack ice is threatening southern baleen whales that gather to feed in these once krill-rich waters. Krill feed on plankton populations that grow beneath the pack ice and that are disappearing as rapidly as the melting ice. Lack of plankton causes loss of krill, forcing baleen whales northward into warmer subtropical water in desperate search for food that is not there. The lack of krill also results in loss of life-sustaining blubber, increasing susceptibility to both disease and starvation. Overall, the combination of these global warming factors may lead to the loss of the largest animals ever to exist on this planet.

Wind power

- **Category:** Energy

- **Definition**

Wind power is generated by extracting kinetic energy from the wind. During this process, an oncoming stream of relatively high velocity wind passes through a mechanical device that slows the wind

A wind farm near Dessau, Germany. (Fabrizio Bensch/Reuters/Landov)

down and simultaneously extracts part of the wind's kinetic energy and converts it into useful work. The energy can be used in various ways, such as pumping water, grinding grain, operating machinery, or running a generator to produce electricity. Such devices are commonly called wind turbines, although years ago they were called windmills. The terms are often used interchangeably.

Many types of windmill designs have been proposed, but the most common types in use are the Darrieus wind turbine, Savonius wind turbine, and horizontal axis propeller-type turbine. The Darrieus turbine looks much like a giant eggbeater mounted vertically. It has the advantage of being able to handle wind direction changes without having to move a large mass of windmill structure to reorient itself with the oncoming wind. Its main disadvantage is that it is not self-starting. An external source of energy is required to start the turbine spinning, even if the wind is already blowing.

The Savonius windmill is mechanically very simple but inefficient. It has an "S"-shaped cross section and can be made simply by cutting an oil drum in half vertically and welding the two halves together to create two scoops to catch the wind. In principle, it operates exactly the way the cup-type anemometers commonly used to measure windspeed operate. The propeller-type turbine uses a horizontal-axis propeller with its blades pitched and twisted in such a way that they catch a high velocity stream of wind and slow it down, producing useful shaft torque in the process. A horizontal-axis propeller turbine operates in precisely the opposite way that an aircraft propeller does.

• Significance for Climate Change

Since a wind turbine produces energy without any type of combustion process, it does not contribute to global warming by either rejecting waste heat or generating exhaust gases that contribute to the greenhouse effect. Thus, increasing the use of wind power to produce electricity would slow the progress of global warming. The technology of wind power is well developed, and holds much promise for slowing global warming, but only if some obstacles can be overcome to greatly increase the number of wind turbines in use.

The main obstacle appears to be community acceptance and aesthetics. In principle, most people are supportive of wind turbines, as long as they are situated far away from their homes. However, if wind turbines are to be installed nearby, members of the community often object, because they worry about the noise and appearance. In actual practice, wind turbines are generally quiet. A typical 600 kilowatt machine would produce 40 decibels of noise at a distance of 250 meters. This noise level is midway between that of a conversation and an average office. However, a wind turbine can make a loud noise when it is turning in response to a change in wind direction. Some European nations have overcome the perceived aesthetics problem by working with local communities, providing open disclosure of all aspects of the turbines right from the start, as well as involving the community economically as partial stockholders or owners of the turbines.

Using figures for year 2000 technology, wind turbine energy generation costs (capital investment plus fuel) run from 5 to 7 U.S. cents per kilowatt-hour, which is a similar cost to that of combined-cycle gas turbine plants. For coal steam turbine plants, this cost is between 3 and 4 cents per kilowatt-hour. Solar power plants are still much more expensive. In the United States, wind energy provided less than 1 percent of electrical power in 1997. It is estimated that wind could provide up to 10 percent of that power by 2020. By contrast, in Denmark in 2001, 15 percent of the country's electricity was produced by wind turbines. By 2030, the Danish government's energy plan is to have 50 percent of all electricity production provided by wind turbines.

Environmentalists worry about wind turbines causing bird strikes and disruption of migratory bird flight paths. However, it seems this worry has been exaggerated. The Cape Wind Project, currently in planning for Nantucket Sound, has received preliminary approval from the Massachusetts Audubon Society, indicating that the society finds bird strikes to pose only a small worry. Furthermore, the society strongly supports wind power in general.

World Bank

- **Categories:** Organizations and agencies; economics, industries, and products
- **Date:** Established 1945
- **Web address:** http://www.worldbank.org

• Mission

Named the International Bank for Reconstruction and Development, the World Bank was established in 1945 with the aim of promoting the post-World War II reconstruction. It has since evolved and become strongly focused on worldwide poverty alleviation, in conjunction with its affiliate, the International Development Association. The bank also deals with humanitarian emergencies and post-conflict rehabilitation affecting developing and transition economies.

Actor Harrison Ford participates in the launch of a World Bank-sponsored program to protect the world's tiger population. (Kevin Lamarque/Reuters/Landov)

• Significance for Climate Change

In December, 2007, Robert Zoellick, president of the World Bank Group, said at the Climate Change Conference in Bali, Indonesia: "Climate change is a development, economic, and investment challenge. It offers an opportunity for economic and social transformation that can lead to an inclusive and sustainable globalization." His comment is crucial in two respects: First, it demonstrates that the bank places climate change high in its development agenda. Second, it shows that the bank considers climate change as offering new opportunities for long-term poverty reduction and sustainable development.

The bank takes its climate change agenda seriously, because, according to its own research, a 1° Celsius increase in temperature will lead to a 10 percent loss in average net revenues per hectare in Africa. By 2020, it is estimated that between 75 million and 250 million people in Africa will suffer from water stress due to climate change. These scenarios will affect millions of poor people in developing countries, because they are dependent on natural resources for livelihoods such as agriculture, forestry, and fishing. Water and energy resources are also sensitive to climate change. The expected rise in sea level will also cause loss of farmland and result in migration and increased risk of conflicts over scarce resources. Poor people are least capable of adapting to climate changes because of inadequate infrastructure, low institutional capacity, and poor governance. As a result, climate change will increase vulnerability and malnutrition and lead to the outbreak of diseases. These challenges will undermine efforts to achieve the Millennium Development Goals.

The bank accepts that poor countries are least responsible for climate change and that they need assistance to overcome the threats posed by that change. Accordingly, the bank has developed its Strategic Framework for Climate Change, which aims to make poor nations' development activities more climate-resilient. It intends to integrate climate change policies into poverty and sustainable development strategies and to make climate risk management more consistent with good development practice.

The strategic framework comprises four elements: mitigation, adaptation, finance, and knowledge and capacity building. The bank's mitigation strategies focus largely on the energy sector. According to the Clean Energy Investment Framework and Action Plan, the emphasis will be placed on the transition to low-carbon development and on helping poor countries, especially those in sub-Saharan Africa, to obtain access to energy by investing in clean energy. The bank has launched Carbon Finance to help developing countries create and manage carbon assets. Working with the United Nations Permanent Forum on Indigenous People, the bank will design a carbon fund that will promote sustainable forest management and reduce forest degradation and deforestation.

In the adaptation side, the bank enhances poor countries' capacity to face climate variability. It places emphasis on sustainable and innovative technology in improving the local environment and integrates adaptation into national development planning. For instance, better land-use planning helps reduce construction on coastal regions subject to storm damage and river shorelines subject to frequent floods. Improving building standards can ensure some level of robustness against hurricanes and other extreme events. Creating reservoirs for flood control and dikes to reroute flood water are a few engineering interventions that promote farming practices to withstand climate variability.

Financially, the bank has set up two adaptation funds: the Special Climate Change Fund and the Least Developed Countries Fund, which will provide $150 million to $400 million a year. The Clean Technology Fund, as part of the mitigation strategies, will provide $5 billion to $10 billion. The bank acknowledges that these figures are insufficient to make changes in all developing countries.

Climate change affects countries differently, so the World Bank pays attention to country-specific adaptation strategies. It improves climate information, forecasting, and communication to facilitate disaster-risk assessment. It integrates risk reduction into sector development plans. It reckons the significance of collaborative efforts with other multilateral development banks and partners to assist vulnerable communities. It streamlines existing coordination mechanisms and enhances regional dialogue and cooperation in existing country partnership strategies, such as transboundary water governance.

In achieving mitigation-adaptation synergy, the bank promotes more community-driven development to avoid overgrazing and land degradation. More decentralised policies are implemented, so communities and social groups can develop their own adaptation strategies for climate-related challenges. The private and business sectors provide services and additional funding opportunities. The domestic insurance market, for example, aims to protect poor people against catastrophic losses. The public-private partnership, policy reforms, institutional development, and development of basic knowledge about adaptive technologies create incentives for the private sector.

The bank has, however, been criticised by some nongovernmental organizations and academics for lacking wide consultation with stakeholders and for lacking transparency in implementing climate change strategies. The design process of setting the Climate Investment Funds remains a donor-driven endeavor that can marginalize local communities. The imposition of conditionality in lending is also accused of reinforcing postcolonial power inequalities.

World Health Organization

- **Categories:** Organizations and agencies; diseases and health effects
- **Date:** Established 1948
- **Web address:** http://www.who.int/en/

• Mission

The World Health Organization (WHO) is the directing and coordinating agency on health within the United Nations system. The WHO is responsible for providing leadership on health issues, supporting and promoting health research, establishing guidelines and standards in health, developing health policies, and building the capacity of countries.

The headquarters of the WHO are in Geneva, Switzerland. It has six regional offices in Copenhagen, Denmark; Cairo, Egypt; Washington, D.C.; Brazzaville, Congo; New Delhi, India; and Manila, Philippines. The membership of the WHO consists of 193 countries and two associate members. Together, they constitute the World Health Assembly, which meets every year in Geneva. During the annual meeting, policies of the organization are decided and a budget is approved. Every five years, the World Health Assembly appoints the director general, who serves as head of the agency. The World Health Assembly also elects a thirty-four-member executive board.

The WHO is responsible for developing international health regulations, the rules that countries must follow to identify disease outbreaks and stop them from spreading. The WHO works closely with countries to ensure that they have the skills and people to carry out this task. In the process, it provides training and shares expertise with countries. The WHO has also formed the Strategic Health Operations Center, which coordinates information and response between countries in times of disease outbreaks and humanitarian emergencies. In terms of environment and climate change issues, the WHO shares its health expertise and collaborates with the United Nations Framework Convention on Climate Change (UNFCCC), World Meteorological Organization (WMO), United Nations Development Programme (UNDP), and United Nations Environment Programme (UNEP).

The WHO also has a Health Action in Crises team that works with member states to minimize suffering and death in crisis situations. The WHO helps build the capacity of countries to manage all types of crises and to deal in an effective and timely fashion with emergencies. The organization helps strengthen local health structures within countries. It also works with member states to plan, educate, and manage the health workforce.

• Significance for Climate Change

In the area of climate change, the WHO has raised awareness; strengthened public health systems to cope with the threats posed by climate change; enhanced the capacity of member countries to respond to public health emergencies; provided technical guidance for global and regional assessments in sectors that include energy, transport, water, and sanitation; enhanced applied research on health protection from climate change; and developed interdisciplinary partnerships. Since 2000, the WHO has convened several workshops on climate change. It has collaborated with the United Nations Development Programme to pilot test approaches in seven countries to protect health under a changing climate.

Since 1990, the WHO has published several reports discussing the health risks from climate change and climate variability. The regional offices and country offices of the WHO serve as foci for partnerships on health impacts from climate change.

The WHO also collaborates with health research organizations and U.N. agencies that are involved in adapting to climate change.

The WHO has several notable accomplishments in the area of health. One of its major achievements was the eradication of smallpox. Between 1967 and 1979, the WHO coordinated a campaign to eradicate smallpox and was successful in completely removing this disease from the world.

The WHO negotiated the first global health treaty on tobacco, the WHO Framework Convention on Tobacco Control (WHO FCTC), which entered into force on February 27, 2005. It sets standards on tobacco control measures, such as tobacco prices and tax increases, advertising and sponsorship, product warning labels, and environmental tobacco smoke.

World Heritage Sites

• **Category:** Environmentalism, conservation, and ecosystems

• Definition

World Heritage Sites are locations that have been designated by The United Nations Educational, Scientific, and Cultural Organization (UNESCO) as having "outstanding value to humanity." Locations can be of natural significance, such as Australia's Great Barrier Reef, or cultural significance, such as the Egyptian pyramids. UNESCO encourages the identification and preservation of these locations, keeping them in trust for humanity as a whole, not just for the country in which they are located.

One of the earliest examples of preservation on a global scale was the effort to protect the Abu Simbel and Philae temples in Egypt. The temples, which date back to the thirteenth century B.C.E., were in danger of being flooded by the Nile River during the construction of the Aswan High Dam. In 1959, UNESCO responded to a request for assistance from Egypt and Sudan to preserve the temples. Fifty countries financially contributed to the effort to relocate the monuments to high ground, which was completed in 1968. This global cooperation effort let to similar projects in Venice, Italy; Moenjodaro, Pakistan; and the Borobodur Temple Compounds in Indonesia.

In 1965, a conference at the White House recommended the establishment of a "world heritage trust" to encourage international cooperation to protect similar sites of global significance. A similar plan was proposed by the International Union for Conservation of Nature (IUCN) in 1968. At the United Nations Conference on the Human Envi-

Total	144	679	174	25	878	100

Source: United Nations Educational, Scientific, and Cultural Organization.
*The Uvs Nuur Basin straddles Europe and Asia. It is counted in this table as part of the Asian region.

ronment in 1972, the two plans were presented, the result being the Convention Concerning the Protection of World Cultural and Natural Heritage, which was adopted by the General Conference of UNESCO on November 16, 1972.

Some 185 nations have ratified the convention and are eligible to nominate locations to be considered for protection under its terms. By doing so, the member nation (called a "State Party") is expected to oversee each location and provide periodic updates. It can also request monetary assistance if needed. This process is overseen by the World Heritage Committee, which consists of twenty-one states that traditionally serve four-year terms and are elected by the General Assembly of State Parties.

As of 2008, there were more than 875 designated World Heritage Sites in 145 countries. To be considered for World Heritage designation, a site must "be of outstanding universal value" and meet at least one of ten selection criteria. For cultural sites, this includes architecture, human settlements, technological achievement, or "a masterpiece of human creative genius." Natural sites must exhibit ongoing ecological or biological processes, contain significant or unique ecological habitat, display stages of Earth's history, or exhibit "superlative natural phenomena or areas of exceptional natural beauty."

• Significance for Climate Change

The process for identifying and protecting World Heritage Sites can be traced back to two separate groups of people: those interested in nature conservation and those interested in protection of natural sites. The goal of the World Heritage Program is to present these sites as worthy of preservation from both natural and cultural standpoints. The sites remain the property of the country in which they are located, but those countries are assisted in maintaining and promoting the site.

There are many benefits to having a site designated as a World Heritage Site, with tourism being the most obvious. Locations that would otherwise go unvisited become known, and some travelers are eager to visit culturally significant sites before they disappear. Tourism benefits local economies, which in turn brings in the revenue needed to maintain the sites, a problem that is especially acute in developing countries. The downside to this is that increased tourist traffic can threaten the integrity of an already-threatened site. World Heritage status can help national and local governments manage the delicate balance between no interest and too much interest. Through the Preservation Fund, World Heritage can provide financial assistance for protection and restoration of designated sites.

One function of the 1972 convention is to identify sites that are in immediate danger. Melting glaciers, deforestation, and pollution are just a few of the environmental factors that can disrupt or destroy an ecologically sensitive site. Warmer sea and ocean temperatures could bring about a loss of biodiversity in an already-threatened location such as Australia's Great Barrier Reef.

Human-made sites are also threatened by the changing climate. Acid rain, changes in temperature and humidity, and rising sea levels can wreak havoc on ancient stone, and some scientists are predicting that the historic city of Venice, Italy, a designated World Heritage Site, could see daily flooding by the end of the twenty-first century.

World Meteorological Organization

• Categories: Organizations and agencies; meteorology and atmospheric sciences
• Date: Established 1950
• Web address: http://www.wmo.int/pages/index_en.html

• Mission

An international clearinghouse on the weather and the environment, the World Meteorological Organization (WMO) is a principal supplier of scientific information to researchers assessing climate change. The WMO is an agency of the United Nations, dedicated to monitoring Earth's atmosphere, atmospheric interaction with the oceans, climate, and water resources. Headquartered in Geneva, Switzerland, WMO's secretariat, headed by the secretary-general, oversees its daily operations. Its thirty-seven-member executive council meets yearly to review programs and the budget. The World Meteorological Congress convenes every four years, at which time representatives of its 188 member states and territories decide on policies, consider applications for membership, pass regulations, and make long-term plans.

The WMO's purpose is to contribute to the safety of humanity through various programs, such as the World Weather Watch Program, and services investigating the environment. It promotes networks for gathering data about the weather, climate, water resources, and geophysical phenomena, not only to increase fundamental scientific knowledge but also to warn of possible natural disasters. It assists technology transfers to this end, encourages collaboration among the national meteorological and hydrological organizations of its members, and provides information to public weather, agriculture, aviation, environmental, and shipping services. The WMO also holds forums on the status of regional climate to foster consensus among climate experts and help emergency responders and governments in disaster prevention.

• Significance for Climate Change

In 1988, the WMO, in conjunction with the United Nations Environment Programme, established the Intergovernmental Panel on Climate Change (IPCC). The WMO's observational programs supply IPCC scientists with much of the data on which to base their conclusion that Earth's atmosphere is warming because of human activities and that climate change will have many adverse effects on civilization. In April, 2008, Deputy Secretary-General Hong Yan reaffirmed the WMO's support for the IPCC's work as vital to world peace. A statement about climate on the WMO's web site explains,

> Climate affects the lives and livelihoods of people everywhere. Global warming poses threats to society in various ways. Increased and extended droughts are a direct threat to millions of people. Millions more are affected by reduced crop and fishing harvests. Heatwaves, especially in urban situations, have recently caused the death of thousands of people, notably the elderly and infirm. The economy of many countries, especially small island States, depends on tourism. They are particularly vulnerable to sea-level rise, coastal erosion, saltwater intrusion, lack of freshwater, and the destruction of the natural environment, all adverse impacts of climate change.

Roger Smith

World Trade Organization

- **Categories:** Organizations and agencies; economics, industries, and products
- **Date:** Established 1995
- **Web address:** http://www.wto.int

• Mission

Established to reduce the financial and logistical costs to world trade, the World Trade Organization (WTO) faces the challenges of combating global warming. Measures for such combat require increased regulation and costs for new equipment. The WTO facilitates the creation and maintenance of commercial treaties among its 153 member nations, committed to global free trade. It began in 1947 as the General Agreement on Tariffs and Trade (GATT) and focused on removing barriers to trade in goods. In 1995, GATT became the WTO with a purview not only for goods but also services and intellectual property. Located in Geneva, Switzerland, the WTO headquarters monitor and adjudicate the multilateral treaties negotiated at meetings around the world, known as "rounds." The Geneva Round, the first, occurred in 1947 and lasted seven months. It achieved tens of thousands of tariff concessions worth billions of dollars. Rounds have become successively longer with ever weightier consequences. The Tokyo Round, the seventh, lasted from 1973 to 1979 and achieved trade economies in the hundreds of billions dollars. The Uruguay Round of the eighties and the Doha Round, the first after the establishment of the WTO, have further multiplied trade.

• Significance for Climate Change

The WTO has created the modern phenomenon of globalization. Trade requires energy for manufacturing and transportation. During the last third of the twentieth century, energy consumption doubled. Production of energy primarily involved the use of coal, gas, and oil, fossil fuels that release atmospheric carbons when activated. As accumulated carbons have accelerated global warming, the massive role of world trade has emerged as tellingly obvious. However, the WTO is poorly constituted to confront this problem. Among its many agencies, there is an Environment and Trade Committee. However, the committee applies itself only to cases in which the environmental practices of one country interfere directly with the trade prospects of another.

The driving purpose of the WTO is to increase trade by removing or reducing legal and financial barriers. To combat global warming, extensive regulation of carbon emissions is necessary, requiring expensive new factory and automotive equipment. By adding to the cost and logistics of trade, the combating of global warming runs counter to the efficiencies and economies of free trade. In the short run, thereby, measures against global warming burden global commerce. In the long run, nevertheless, they are essential in allowing it to survive.

Younger Dryas

- **Category:** Climatic events and epochs

- **Definition**

After the Pleistocene epoch ended, Earth's climate began a variable warming trend, punctuated by episodes of cooler temperatures and reglaciations. The Younger Dryas, occurring 12,900 to 11,600 years ago, was a well-defined climatic event during which cool temperatures returned and ice sheets reformed. The term "Dryas" denotes the arctic-alpine herb, *Dryas octopetala*. Early evidence for the Younger Dryas were *Dryas octopetala* macrofossils found in Scandinavian terrestrial deposits that overlie warmer climate deposits.

After the Scandinavian discovery, pollen studies of European lake and bog sediments were undertaken during the 1930's. This field research found that tundra pollen is characteristic of the Younger Dryas and tundra pollen always appears after the deposition of forest pollen (which indicates a warmer climate). The occurrence of the Younger Dryas is documented by vegetation changes; faunal changes; higher dust levels; and elevated atmospheric chemical concentrations, as identified in ice cores.

Since early Younger Dryas evidence was collected in Europe, Scandinavia, and Greenland, it was thought that the Younger Dryas was confined to these northern geographic areas. However, vegetation changes from mixed conifer-deciduous forest to cooler climate boreal trees in southern New England indicate Younger Dryas events occurred in North America as well. The replacement of shrub tundra with herb tundra in northern Nova Scotia along with shrub tundra replacing spruce forest in southern New Brunswick and central Nova Scotia also indicates Younger Dryas occurrence in North America. In addition, Younger Dryas evidence is found in mid-America, on the coast of the Pacific Northwest, British Columbia, and Alaska.

Prior to the onset of the Younger Dryas, glaciers had retreated from Great Britain; Scandinavian and Laurentide ice sheets were in regression; and, according to global sea-level records, ice covered less than 15 percent of Earth's surface. After the inception of the Younger Dryas, glaciers reformed in Europe and North America—from Scotland to the western Rocky Mountains. At the close of the Younger Dryas, temperatures rose quickly, 5°-10° Celsius within ten years. They continued to increase to 15° Celsius warmer than they had been. This abrupt rise in temperatures, as revealed in Greenland ice cores, was surprising to climate scientists. The Greenland cores had revealed other rapid climate changes—the abrupt deglaciation at the end of the Pleistocene.

- **Significance for Climate Change**

Results from ice cores, glaciers, and land and deep-sea sediments disclose that large areas of Earth have had almost synchronous changes from glacial to interglacial in short intervals of ten to thirty years. This means the entire climate regime (cold-warm) can reorganize in less than one lifetime. With the reality of rapid changes in global climate regimes, there is the threat that anthropogenic global climate change might initiate abrupt shifts in climate, leaving human populations unprepared.

Antarctic ice cores indicate a high ratio of oxygen 18 (O^{18}) to oxygen 16 (O^{16}) during interglacials, suggesting that ice formed when atmospheric temperatures were elevated; also, high concentrations of carbon dioxide (CO_2) and methane (CH_4) have been reported. High levels of greenhouse gases (GHGs), trapped in ice core air bubbles, indicate a period of atmospheric warming. GHGs are reduced during glacial periods.

Today, as a result of deforestation and fossil fuel burning, air temperatures, CO_2, and CH_4 levels are all rising. The CO_2 generated before the Industrial Revolution occurred naturally; rising atmospheric CO_2 after 1830 was generated by humans. This can be demonstrated, because the CO_2 isotope of fossil fuels has a characteristic signature that matches current CO_2. Climate models of high CO_2 demonstrate that nighttime low temperatures should increase and that daily temperature variation should be reduced. Climate data collected from the last century confirm this prediction—the effects of global warming.

Research undertaken to discover the cause of the Younger Dryas points to perturbation of the global ocean thermohaline circulation (THC), which transports tropical heat to higher latitudes.

North Atlantic Ocean cooling is triggered by the addition of large amounts of terrestrial freshwater. Cyclic changes in quantities of meltwater (such as glacial lake outbursts or icebergs carrying glacial water), can supply large volumes of freshwater to the northern Atlantic Ocean, causing the THC to slow or stop.

The Younger Dryas event has significance for global warming: At its close, abrupt change of climate from glacial to warm conditions occurred, demonstrating that climatic processes are not gradual but rapid and dramatic, with the potential to plunge human populations, in less than a decade, into cold or warm conditions and back again. The Younger Dryas was initiated by some imbalance in the THC, such as flood waters or lake-bearing icebergs. Global warming may supply copious amounts of melted glacial water, thus triggering a perturbation of the THC and initiating a "Younger Dryas-like" event in the Northern Hemisphere.

Appendixes

Biographical Dictionary of Key Figures in Global Warming

The figures described below are important in the history of global-warming and climate-change research. Asterisked individuals are covered in greater depth in separate essays within these volumes.

Agassiz, Louis* (1807-1873): Swiss naturalist, paleontologist, geologist, and glaciologist. Agassiz originated the concept of the Great Ice Age, an idea of fundamental importance to the understanding of cyclic change in Earth's climate.

Akasofu, Syun-Ichi (b. 1930): Japanese American geophysicist and director of the International Arctic Research Center at the University of Alaska, Fairbanks, until 2007. Akasofu has argued that the method of study used by the Intergovernmental Panel on Climate Change is fundamentally flawed and that the recovery from the Little Ice Age and the multidecadal oscillation probably caused the recent global warming.

Allègre, Claude (b. 1937): French geochemist and politician. In the 1980's Allègre asserted that human fossil fuel consumption was causing global warming, but in 2007 he reversed himself, saying the causes are unknown. He served as France's minister of education, research, and technology and was a prominent researcher at the Institute of Geophysics in Paris.

Alley, Richard B. (b. 1957): American glaciologist. Alley studies the relation between the Earth's coldest regions and climate change. He authored one chapter of the Intergovernmental Panel on Climate Change's Fourth Assessment Report (2007): "Observations: Changes in Snow, Ice, and Frozen Ground."

Arrhenius, Gustaf* (b. 1922): Swedish American oceanographer and geochemist. Arrhenius determined that ocean sedimentation can reveal what the climate was like in ancient times. This provides a basis for knowing what might happen in modern times.

Arrhenius, Svante August* (1859-1927): Swedish physical chemist. Sometimes called the "father of climate change," Arrhenius was the first to quantify the relationship between enhanced or diminished atmospheric carbon dioxide concentrations and the elevation or depression of the Earth's surface temperature, which later stimulated others to develop more sophisticated mathematical models of global warming.

Axelrod, Daniel* (1910-1998): American paleoecologist. Axelrod showed how past climate change caused the plants of an area to change. Scientists can apply his methods to predict vegetation change likely to result from future changes in climate.

Ball, Tim: Canadian geographer. A retired professor at the University of Winnipeg and head of the National Resources Stewardship Project, Ball is a prominent global warming skeptic. He has denied the role of fossil fuel emissions in global warming and of chlorofluorocarbons in thinning the ozone layer. He argues that global warming could be beneficial to humanity.

Balling, Robert C., Jr. (b. 1952): American geographer and past director of Arizona State University's Office of Climatology, Balling is a prominent skeptic in the global warming controversy. In 2005, however, he wrote that there is substantial evidence of nonsolar control of atmospheric temperatures, for which greenhouse gases are a potential explanation.

Bennett, Hugh Hammond* (1881-1960): American soil conservationist. Bennett recognized that climate influenced soil erosion and incorporated assessments of temperature, precipitation, and other climatic factors in soil conservation techniques.

Bjerknes, Vilhelm (1862-1951): Norwegian meteorologist. A researcher in fluid dynamics and thermodynamics, Bjerknes produced the first mathematical formulas for weather forecasting, which were the basis for modern climate modeling.

Bradley, Raymond S. (b. 1948): English American climatologist. Bradley has argued, on the basis of reconstructions of the temperature record for the past millennium, that natural mechanisms cannot account for the modern warming of the climate.

Bradshaw, William E. (b. 1942): American evolutionary biologist. Bradshaw and his wife, Christina M. Holzapfel, both of the University of Oregon's Center for Ecology and Evolutionary Biology, were the first to find definite evidence that global warming has forced evolutionary changes in a modern species.

Briffa, Keith (b. 1952): English dendroclimatologist. A faculty member of the University of East Anglia's Climatic Research Center, Briffa is a pioneer in studying climate change in Europe during the past ten thousand years by examining tree rings and relative isotope concentrations.

Broecker, Wallace Smith (b. 1931): American geophysicist. A professor at Columbia University's Lamont-Doherty Earth Observatory, Broecker was among the first to warn that humans are causing global warming. He investigates cycles in the oceans, including the thermohaline cycle, in order to compile a record of climate change during the Pleistocene epoch and after.

Bryden, Harry L. (b. 1946): English oceanographer. Bryden, a professor at the University of Southampton, examines the role of ocean heat and freshwater transport in global climate. In 2004 his research team from the National Oceanography Centre found that the Atlantic had slowed its circulation by nearly a third.

Cane, Mark A. (b. 1944): American oceanographer and climate scientist. A researcher at Columbia University's Lamont-Doherty Earth Observatory, Cane was among the researchers who in 1985 used mathematical modeling to forecast accurately the onset of the El Niño-Southern Oscillation. He also studies mechanisms of abrupt climate change.

Carson, Rachel* (1907-1964): American naturalist, ecologist, and writer. Although at the time she published *Silent Spring* (1962) Carson did not attribute global warming to human causes, she was well aware of climate change and held the view that humans were distinguished largely by their power to alter nature, perhaps irreversibly.

Charney, Jule Gregory (1917-1981): American meteorologist. Charney was among the first to use computers to model the hydrodynamics of the atmosphere in order to forecast weather (beginning in 1948), and from 1968 to 1971 he led the Global Atmospheric Research Program, an international effort at systematic observation of global circulation patterns.

Christy, John R. (b. 1951): American atmospheric scientist. A professor of atmospheric science at the University of Alabama, Christy specializes in compiling a temperature record based on satellite observations. He has expressed caution about the human contribution to global warming, saying that it undoubtedly exists but that scientists should refrain from making sensationalist predictions. He has also suggested that global warming from increased carbon dioxide could have a net benefit.

Chylek, Petr (b. 1937): Canadian atmospheric physicist. Chylek is an adjunct professor at Dalhousie University in Halifax, Nova Scotia. He is noted for researching atmospheric conditions related to climate change with remote sensing. He has concluded from his data that the rise in atmospheric carbon dioxide will have a smaller influence on global temperatures than the consensus estimate by the Intergovernmental Panel on Climate Change.

Corell, Robert (b. 1934): American oceanographer. Corell chaired the council of the National Science Foundation that produced the Arctic Climate Impact Assessment. It found average temperatures rising faster and earlier ice-melting than anticipated, and Corell forecast that the next century will see a 50 percent reduction of Arctic sea ice during the summertime.

Cotton, William R. (b. 1940): American physicist and meteorologist. Cotton is a pioneer in computer simulation of cloud dynamics and thunderstorms and in forecasting their effects on agriculture and aviation. He has said that it remains an open question how extensively humans have contributed to climate change.

Crichton, Michael (1942-2008): American writer and physician. Crichton published the best-selling novel *State of Fear* in 2004. Its plot arises from a conspiracy among environmentalists to cause public alarm about global warming, which is portrayed as supported by flimsy evidence. Following the story are pages of footnotes and a bibliography supporting the conspiracy-theory claim.

The novel was embraced by global-warming deniers.

Crutzen, Paul J. (b. 1933): Dutch atmospheric chemist. Crutzen shared the 1995 Nobel Prize in Chemistry for his investigation of the hole in the ozone layer. He proposes strenuous measures to forestall global warming—for instance, by placing sulfur particles in the upper atmosphere to deflect light. With Eugene F. Stoermer, in 2000 Crutzen suggested the current geological era be called the "anthropocene" because of humanity's impact on the environment. *See also* Molina, Mario J.; Rowland, F. Sherwood.

Dansgaard, Willi (b. 1922): Danish paleoclimatologist. Dansgaard discovered that oxygen 18 and deuterium concentrations in glaciers provide information about climate change in the past and used the resulting technique to analyze samples from the Greenland ice sheet. Sequences of abrupt climate change that surfaced in the data are now called Dansgaard-Oeschger events. *See also* Oeschger, Hans.

De Freitas, Chris (b. 1948): New Zealand climatologist. Acknowledging that evidence points to global warming, de Freitas is a spokesperson for the view that emissions from fossil fuels may not be responsible and that natural variation theories of warming are valid. He is a professor at the University of Auckland, New Zealand, and studies tourism climatology.

deMenocal, Peter (b. 1960): American oceanographer and marine geologist. A researcher at Columbia University's Lamont-Doherty Earth Observatory, deMenocal analyzes the chemical components of marine sediments to study climate change during the Holocene epoch in North Africa and the North Atlantic, especially as it relates to human evolution.

Dickens, Gerald R.: American paleoceanographer. Dickens studies the distribution and composition of clathrate hydrates (icy combinations of water and gases, usually methane) on the ocean floors. The Rice University professor found evidence that rapid conversion of clathrates to gas in the past may have contributed to abrupt climate change.

Elton, Charles Sutherland* (1900-1991): English ecologist. Elton was the first person to describe invasions by animals and plants. As the climate changes, all indications are that invasions will be more frequent and have greater effect.

Emanuel, Kerry (b. 1955): American meteorologist. Highly regarded for his research in atmospheric dynamics, Emanuel said in 2008 that a 10 percent increase in hurricane intensity during the previous thirty years was in part caused by global warming, which also may effect a decrease in hurricane frequency.

Emiliani, Cesare* (1922-1995): Italian American paleoceanographer. Emiliani developed the oxygen isotopic abundance method to study the history of the oceans and their climate changes.

England, Matthew (b. 1966): Australian oceanographer and climate scientist. England studies ocean currents, especially in the Southern Hemisphere, and their effects on climate. He helped organize the 2007 "Bali Climate Declaration by Scientists" and codirects the Climate Change Research Centre at the University of New South Wales.

Flannery, Tim (b. 1956): Australian paleontologist. At first a skeptic about anthropogenic global warming, by 2004 Flannery, a professor at Macquarie University, changed his mind and wrote an influential popular account of the problem and possible solutions, *The Weather Makers: The History and Future Impact of Climate Change* (2005).

Fourier, Joseph (1768-1830): French physicist and mathematician. Although best known for his mathematical discoveries, in 1824 Fourier advanced the idea that atmospheric gases warm the planet by trapping infrared energy from sunlight, the phenomenon later called the greenhouse effect.

Fung, Inez Y. (b. 1949): American meteorologist. Fung is codirector of the Berkeley Institute of the Environment at the University of California, Berkeley. She is an expert on the structure of hurricanes, climate modeling, and climate change, and she advocates strict regulation of carbon dioxide emissions.

Glacken, Clarence J.* (1909-1989): American geographer. An environmental historian who specialized in studying the relationships between culture and nature, Glacken was one of the first twentieth century scientists to recognize the connection between human activities and the environment. His masterwork, *Traces on the Rhodian Shore* (1967), analyzes nature and Western human thought from ancient times through the nineteenth century.

Gore, Al* (b. 1948): American statesman and environmental activist. A longtime congressional and administrative governmental advocate for environmental and global-warming issues, former vice president Gore, along with the Intergovernmental Panel on Climate Change, was awarded the 2007 Nobel Peace Prize for his work in raising global environmental awareness. He is the author of *An Inconvenient Truth* (2006) and *The Assault on Reason* (2007).

Hansen, James E. (b. 1941): American physicist and director of the Goddard Institute for Space Studies of the National Aeronautics and Space Administration. Hansen came to the public's attention when he testified before Congress in 1988 that humans were causing global warming. He was already renowned among scientists for correctly predicting warming trends. He is a frequent spokesperson on behalf of measures to curb climate change.

Haug, Gerald H.: Swiss paleoclimatologist. Haug's research corroborated the view that climate in the last two thousand years has been volatile and that extended droughts contributed to the decline of the Mayan civilization.

Haywood, Alan: English paleoclimatologist. The principal investigator for the British Antarctic Survey, Haywood published a paper in 2005 that concluded that increased levels of carbon dioxide three million years ago caused extensive polar ice melting. He points out that the carbon dioxide levels were similar to those of today.

Henderson-Sellers, Ann (b. 1952): Australian physical geographer and director of the World Climate Research Program from 2006 to 2007. Henderson-Sellers is a professor at Macquarie University, heads collaborative measurement projects, and was a lead author for the Intergovernmental Panel on Climate Change's Second Assessment Report (1995).

Hoegh-Guldberg, Ove (b. 1959): Australian marine biologist. Hoegh-Guldberg, a professor at the University of Queensland, published a paper in 1999 reporting that rising sea temperatures are contributing to the destruction of coral reefs worldwide.

Hoerling, Martin P.: American meteorologist. Hoerling and his colleague Arun Kumar at the National Oceanic and Atmospheric Administration's Climate Diagnostics Center published the results of a computer model that suggested global warming would cause pervasive drought at midlatitudes, including large regions in the United States and Africa.

Hoffert, Martin (b. 1938): American physicist and aeronautical engineer. Hoffert is a proponent of a space-based solar power plant as a major replacement for fossil fuels. A retired professor at New York University, he argues that to reduce greenhouse gas emissions significantly, modern industrial society must make drastic infrastructure changes.

Hoffman, Paul F. *See* Schrag, Daniel P.

Holzapfel, Christina M. *See* Bradshaw, William E.

Houghton, John T. (b. 1931): Welsh atmospheric physicist. Houghton cochaired the Intergovernmental Panel on Climate Change when the group received the 2007 Nobel Peace Prize. He is a founder of England's Hadley Center for Climate Change and chairman of the John Ray Initiative, which seeks to find common purpose among scientists and Christians concerning the environment.

Howat, Ian M.: American glaciologist. Howat led a team studying Greenland's Helheim Glacier from 2000 to 2005. They found that the ice had thinned 40 meters, much faster than expected. He is a professor at Ohio State University's Byrd Polar Research Center.

Idso, Craig D.: American geographer. Idso founded and chairs the Center for the Study of Carbon Dioxide and Global Change. He conducts research on carbon sequestration and aspects of environmental change. He argues that atmospheric carbon dioxide does affect air temperature and that it may be good for plant growth.

Idso, Sherwood B. (b. 1942): American physicist. An expert in remote sensing, Idso studies the relation of agriculture to climate and became president of his brother Craig's Center for the Study of Carbon Dioxide and Global Change. He has published papers skeptical of the role of carbon dioxide in global warming.

Inhofe, James (b. 1934): U.S. senator from Oklahoma. Inhofe became the political leader of deniers when in 2003, before the U.S. Senate, he claimed to have compelling evidence compiled by leading scientists that global warming is a hoax.

Jones, Phil (b. 1952): English climatologist. A professor at the University of East Anglia and director of the Intergovernmental Panel on Climate Change's (IPCC) Climate Research Unit, Jones compiled a time series of hemispheric and global surface temperatures, updated monthly, that was foundational evidence for the IPCC's Third Assessment Report in 2001.

Joyce, Terrence: American physical oceanographer. A senior scientist at Woods Hole Oceanographic Institution, Joyce was one of the authors for *Climate Change 2007: The Physical Science Basis*. He monitors data from the Deep Western Boundary Current to test the theory that its alterations reflect large changes in thermohaline circulation in the North Atlantic.

Karl, Thomas R. (b. 1951): American meteorologist. Karl directs the National Oceanic and Atmospheric Administration's National Climatic Data Center, was the cochair of the U.S. National Assessment of Climate Variability and Change, and is an editor of the *Journal of Climate*. He has also been a lead author for the Intergovernmental Panel on Climate Change.

Keeling, Charles (1928-2005): American chemist and oceanographer. Keeling began recording atmospheric carbon dioxide levels atop Mauna Loa in Hawaii in 1958 and compiled the longest continuous record. The data established the Keeling Curve, which shows a steady increase in the gas. It provides basic evidence for global warming related to fossil fuel emissions.

Kumar, Arun. *See* Hoerling, Martin P.

Lamb, Hubert Horace* (1913-1997): English climatologist. Lamb was a pioneer in examining climate change from a historical perspective. He was one of the early students of the human impact on climate. Although some of his interpretations have been superseded, he pioneered the field and enhanced the scientific understanding of the factors that contribute to climate change.

Lambeck, Kurt (b. 1941): Australian geophysicist. Lambeck is president of the Australian Academy of Sciences, professor at the Australian National University, and past director of the Research School of Earth Sciences. He conducts research about the interactions among surface features, such as ice sheets, oceans, and solid earth.

Lash, Jonathan (b. 1945): American lawyer. As president of the World Resources Institute, an influential Washington, D.C., think tank, Lash advocates sustainable practices to prevent environment degradation. As a government official and agent of private organizations, he acquired a reputation for expertise in policy issues related to greenhouse gases.

Lindzen, Richard (b. 1940): American atmospheric physicist. A professor of meteorology at the Massachusetts Institute of Technology, Lindzen is noted for his studies of atmospheric dynamics. He has suggested that a negative feedback loop is activated when increased tropical sea surface temperature results in less cloud cover and more infrared radiation escaping into space, thus slowing global warming. This concept is known as the iris hypothesis.

Lovelock, James E. (b. 1919): English climatologist and inventor. An independent researcher, Lovelock is best known for detecting in the 1960's the increase in chlorofluorocarbons (CFCs) in the atmosphere. These compounds were later implicated in chemical reactions that cause depletion of Earth's protective ozone layer. Lovelock also proposed the Gaia hypothesis, first published in 1970, which proposes that the biosphere and Earth are interrelated in such a way as to be self-regulating, a superorganism.

Lubchenco, Jane (b. 1947): American marine ecologist. A specialist in coastal marine ecosystems and the effects of environmental change on them, Lubchenco was appointed administrator of the National Oceanic and Atmospheric Administration in 2009.

Malthus, Thomas Robert* (1766-1834): English demographer and economist. Malthus is best remembered for his hypothesis that while food supplies increase in an arithmetical progression, populations increase in a geometric progression. Therefore, with the increase in population, the food supply will be insufficient, resulting in famines and increased poverty. Malthus's predictions failed to materialize.

Manabe, Syukuro* (b. 1931): Japanese meteorologist. Manabe pioneered the use of computer models to simulate the impact of greenhouse gases on climate change. In 1967, he and Richard Wetherald demonstrated that increased carbon dioxide in the atmosphere would increase the altitude at which the atmosphere reradiated heat into space, thereby providing supporting evidence for the greenhouse theory.

Mann, Michael E. (b. 1965): American climatologist. A lead author for the Intergovernmental Panel on Climate Change's Third Assessment Report (2001), Mann is prominent in the field of paleoclimatology and helped compile the temperature graph known as the hockey stick graph (1998). Covering the last millennium and based on various data, the graph shows a sudden temperature spike during the last 150 years after a long, gradual decline. The graph has been cited as key evidence in the argument for human-caused global warming, although its accuracy has been questioned and it remains controversial.

Marsh, George Perkins* (1801-1882): American statesman. In his seminal work *Man and Nature*, Marsh put forth the idea that humans, from their very beginning, have been active agents of change upon their environment.

Mayewski, Paul (b. 1946): American paleoclimatologist and director of the University of Maine's Climate Change Institute. An expert in ice-core geochemistry, Mayewski has documented human-caused changes in atmospheric chemistry, ice loss in the Antarctic and the Himalayas, abrupt climate change events, and associations between climate and disruptions to civilizations.

Michaels, Patrick J. (b. 1950): American climatologist. A retired professor at the University of Virginia and fellow of the Cato Institute, Michaels wrote several popular books that expressed moderate skepticism about scenarios related to global warming, arguing that change will be slow and moderate.

Milanković, Milutin* (1879-1958): Serbian mathematician. The Milanković theory begins with a curve demonstrating the variation in intensity of summer sunlight over the past 600,000 years. Thereby past relationships among solar radiation, eccentricity, and climate can be examined and future trends extrapolated. Research into future climate regimes, without considering global warming, predicts that the present interglacial cycle may continue for twenty-five thousand years.

Mitchell, John F. B. (b. 1948): English physicist and climatologist. Chief scientist at England's Hadley Centre for Climate Prediction and Research, Mitchell also served as a lead author for the Intergovernmental Panel on Climate Change and studies extreme events caused by climate change.

Molina, Mario J. (b. 1943): Mexican chemist. Molina shared the 1995 Nobel Prize in Chemistry for discovering that chlorofluorocarbons (CFCs) were destroying Earth's protective ozone layer. In 2004 he founded the Mario Molina Center for Energy and the Environment. *See also* Crutzen, Paul J.; Rowland, F. Sherwood.

Oeschger, Hans (1927-1998): Swiss physicist. Oeschger used the tritium content of firn and ice to gather information about past climates. In Greenland, he helped study ice cores and with Willi Dansgaard detected series of abrupt climate fluctuations, now called Dansgaard-Oeschger events. *See also* Dansgaard, Willi.

Pacala, Stephen. *See* Socolow, Robert.

Pachauri, Rajendra K. (b. 1940): Indian economist. Beginning in 2002, when he became chairman of the Intergovernmental Panel on Climate Change, Pachauri oversaw its influential assessment reports, issued every five or six years. He also became chair of The Energy and Resources Institute (TERI) in New Delhi, India, which promotes research on sustainable development.

Parker, David: English climatologist. Parker heads climate monitoring at the Hadley Centre for Climate Prediction and Research in England and is an expert on the urban heat island effect.

Peltier, William Richard (b. 1943): Canadian physicist. Peltier is a professor at the University of Toronto and director of the Centre for Global

Change Science. He conducts research on atmospheric and oceanic dynamics and on Earth's climate and interior.

Pierrehumbert, Raymond T. (b. 1954): American geophysicist. A professor at the University of Chicago, Pierrehumbert uses mathematical models to study climate as a system on Earth and other planets. He served as a lead author of the Intergovernmental Panel on Climate Change's Third Assessment Report in 2001 and was a coauthor of a National Research Council study of abrupt climate change.

Pinchot, Gifford* (1865-1946): American federal administrator and forester. As first head of the U.S. Forest Service, Pinchot emphasized management of forest and park preserves to maintain healthy forests and to slow deforestation.

Pitman, Andrew (b. 1964): English atmospheric scientist and codirector of the Climate Change Research Centre at the University of New South Wales, Australia. Pitman studies carbon dioxide production and storage and their role in climate modeling. He is also an editor of the *Journal of Climate*.

Rahmstorf, Stefan (b. 1960): German oceanographer. One of the lead authors of the Intergovernmental Panel on Climate Change's Fourth Assessment Report (2007), Rahmstorf is a professor at Potsdam University and an expert on sea-level rise and the thermohaline cycle.

Ramanathan, Veerabhadran (b. 1944): Indian American atmospheric scientist and oceanographer. A professor at the Scripps Institution of Oceanography, Ramanathan studies atmospheric chemistry, circulation, and heat transfer. He participated in the development of the first global circulation models and found that chlorofluorocarbons (CFCs) contribute to the greenhouse effect. In 2007 he coauthored a paper on Project Surya, an attempt to counteract the effects of greenhouse-gas-producing biofuel stoves used in rural India by replacing them with solar cookers.

Revelle, Roger* (1909-1991): American oceanographer. In an article coauthored with Hans E. Suess in 1957, Revelle proposed the idea of the greenhouse effect, indicating that this phenomenon would lead eventually to global warming. Later in his career, Revelle served on the faculty of Harvard University, where he taught Al Gore, among others. *See also* Suess, Hans E.

Romanovsky, Vladimir (b. 1953): Russian American geophysicist. Romanovsky is a professor at the University of Alaska, Fairbanks, and studies the behavior of ice and permafrost. He has found that permafrost in Siberia and Alaska that dates from the last ice age is beginning to melt during the summers and could rapidly release carbon dioxide in large quantities.

Rowland, F. Sherwood* (b. 1927): American chemist. The award of the 1995 Nobel Prize in Chemistry to Rowland, his coworker Mario J. Molina, and Paul J. Crutzen "for their work in atmospheric chemistry, particularly concerning the formation and decomposition of ozone" is considered a vindication of environmental science, hitherto belittled by mainstream science. *See also* Crutzen, Paul J.; Molina, Mario J.

Sauer, Carl* (1889-1975): American geographer. Sauer's essay "The Morphology of Landscape" established the idea of cultural landscapes. For this work, he is known as the founder of American cultural geography.

Schrag, Daniel P. (b. 1966): American geologist and director of Harvard University's Laboratory for Geochemical Oceanography. Schrag studies climate change based on ocean circulation and marine sediments, compiling temperature records. His research into glaciation 600-700 million years ago led him to formulate, with Paul F. Hoffman, the Snowball Earth hypothesis, which holds that the entire planet was coated with ice for long periods that ended violently under extreme greenhouse conditions.

Schumacher, E. F. (1911-1977): German British economist. Schumacher foresaw the problems that would be caused by societies that embraced the exploitation of resources for immediate gain without considering the long-term effects of such exploitation. His book *Small Is Beautiful* (1973) introduced the development theories of intermediate size and intermediate technology, forerunners of sustainability. Today, the E. F. Schumacher Society is devoted to "strong local economies that link people, land, and community."

Schwartz, Stephen E. (b. 1941): American atmospheric scientist. A researcher at Brookhaven National Laboratory, since 2004 Schwartz has served as senior scientist for the Department of Energy's Atmospheric Science Program, which has the long-term goal of comprehensively understanding the atmospheric processes governing the transport, transformation, and end state of trace chemicals and dust.

Socolow, Robert (b. 1937): American aerospace engineer. A professor at Princeton University, Socolow is co-principal investigator with Stephen Pacala for the Carbon Mitigation Initiative, which focuses on global carbon management and sequestration.

Solomon, Susan (b. 1956): American atmospheric chemist. Solomon is credited as the first scientist to propose that chlorofluorocarbons (CFCs) caused the Antarctic ozone hole, and she led the National Ozone Expedition to McMurdo Sound in 1986. Her results were crucial to creation of the United Nations' Montreal Protocol on Substances That Deplete the Ozone Layer (in force as of 1989). She directs the Chemistry and Climate Processes Group of the National Oceanic and Atmospheric Administration.

Somerville, Richard C. J. (b. 1941): American meteorologist. A professor emeritus at Scripps Institution of Oceanography, Somerville specializes in the physics of clouds and in the theoretical meteorology used in computer simulations of the atmosphere.

Steffen, Konrad (b. 1952): Swiss geographer. Steffen measures temperature changes in the Arctic and uses them to evaluate potential sea-level rise and its effects on climate. He participated in a study of the Greenland ice sheet that found a spike in temperatures and accelerating melting. He directs the University of Colorado's Cooperative Institute for Research in Environmental Sciences.

Stoermer, Eugene F. *See* Crutzen, Paul J.

Strong, Maurice F. (b. 1929): Canadian environmentalist and diplomat. Strong served as secretary-general of the 1972 United Nations Conference on the Human Environment and of its 1992 Conference on Environment and Development (the Earth Summit at Rio de Janeiro), where the first attempts were made to establish a global treaty on the overall environment.

Suess, Hans E. (1909-1993): Austrian chemist. A specialist in carbon 14 and tritium in the oceans and atmosphere, Suess helped calibrate the radiocarbon dating scale and formulated the Suess effect, which concerns the dilution of carbon isotope concentrations in the atmosphere by the addition of carbon dioxide from the burning of fossil fuels. *See also* Revelle, Roger.

Svensmark, Henrik (b. 1958): Danish physicist and director of Sun-climate research at the Danish National Space Institute. Svensmark specializes in cosmic rays and their effect on cloud formation. His findings suggest that cosmic rays have become scarcer over the last century because of increased solar activity, and the result is fewer clouds and rising temperature. He downplays the role of carbon dioxide in global warming.

Sverdrup, Harald (1888-1957): Norwegian oceanographer and meteorologist. The Sverdrup balance, described in 1947, was an important early theory of the relation of wind stress to ocean circulation. Sverdrup directed the Scripps Institution of Oceanography and later the Norwegian Polar Institute. A sverdrup, named in his honor, is a unit of measurement for volume transport in ocean currents.

Tett, Simon: English climatologist. The chair of Earth system dynamics and modeling at the University of Edinburgh, Tett specializes in climate modeling, particularly based on increasing levels of greenhouse gases and sulfate aerosols during the past five hundred years.

Thejll, Peter (b. 1956): Danish astrophysicist and meteorologist. Thejll's work demonstrated that the variations in solar energy after 1980 cannot account for rising global temperatures in the Northern Hemisphere, which implies that the greenhouse effect is responsible. He is a scientist at the Danish Meteorological Institute and fellow of the Niels Bohr Institute.

Thoreau, Henry David* (1817-1862): American philosopher and writer. In *Walden: Or, Life in the Woods* (1854), Thoreau presented an autobiographical account of his solitary life (over a two-year period) on Walden Pond. This work is now viewed as an early guide to global warming solutions from a personal point of view. Thoreau also indicated the need for conservation of natural resources to ensure preservation of the planet and environment.

Trenberth, Kevin E. (b. 1944): New Zealand meteorologist. A lead author for the 1995, 2001, and 2007 assessment reports on climate change for the Intergovernmental Panel on Climate Change, Trenberth has conducted research on the El Niño-Southern Oscillation (ENSO). He directs the Climate Analysis Section of the National Center for Atmospheric Research in the United States.

Walker, Gilbert* (1868-1958): English physicist and statistician. Walker is best known for his discovery of the Southern Oscillation in 1923. He is also recognized as a pioneer in statistical weather forecasting.

Wallace, John Michael (b. 1940): American atmospheric scientist. A professor at the University of Washington, Seattle, Wallace follows the observational data of global climate on a year-to-year and decade-to-decade basis. His work elucidated the dynamics of equatorial winds and the effects of El Niños.

Wegener, Alfred* (1880-1930): German meteorologist. Wegener became fascinated with the late Paleozoic ice age in the Southern Hemisphere and formulated the theory of continental drift to explain its geographic extent. His work laid the foundation for work by Harold Hess and others that led to the widely accepted theory of plate tectonics.

Weiss, Harvey (b. 1945): American archaeologist. A professor at Yale University, Weiss is best known for his theory that major climate changes helped foster some civilizations and caused others to collapse.

Wetherald, Richard. *See* Manabe, Syukuro.

Wunsch, Carl (b. 1941): American oceanographer. A professor at the Massachusetts Institute of Technology, Wunsch researches the effects of ocean circulation on climate. He is noted for warning that, although there definitely is a human component to climate change that poses a major threat to humanity, this human impact is complex and scientists must be wary of predictions about the near future.

Zwally, H. Jay: American physicist. A researcher for the National Aeronautics and Space Administration, Zwally mapped polar ice in Greenland and Antarctica to study its mass and variability. His research confirmed that in West (Lesser) Antarctica and Greenland, melting of the ice sheets is accelerating. He predicted that the Arctic Sea could become ice-free during late summers sometime in the 2010's.

Popular Culture About Global Warming

Much if not most fiction and film about global warming remains highly speculative and sensational. There is, however, a burgeoning subgenre focusing on the potential impacts of climate change. Although the works listed below are to be taken skeptically from a scientific standpoint, they may serve to prompt serious discussion about the social issues surrounding both anthropogenic and naturally induced changes in the global climate and environment. The works below are listed alphabetically by title: fiction first, followed by films.

• FICTION

AD2516: After Global Warming
- *Author:* Noel Hodson
- *First published:* 2005
- *Synopsis:* Two men and a woman are resuscitated five centuries after being frozen in the polar ice cap and are introduced to a well-adjusted world of 11 billion people and sea levels 100 feet higher than today. The scenario serves as a backdrop for social satire of environmentalists' gloomy predictions of the future.

The Apocalypse Rising
- *Author:* Jim Sampson
- *First published:* 2009
- *Synopsis:* Five huge volcanoes erupt simultaneously in Antarctica and worldwide temperature levels zoom, creating chaotic weather. A desperate rescue attempt to remove scientists trapped near the volcanoes is undertaken while colleagues struggle to understand the extent of the climate change that looms.

Arctic Drift
- *Authors:* Clive Cussler and Dirk Cussler
- *First published:* 2008
- *Synopsis:* This twentieth novel in Clive Cussler's series about adventurer Dirk Pitt has him investigating murders and international incidents related to a possible means to reverse global warming with a mysterious mineral, ruthenium: more derring-do and intrigue than science.

At Winter's End
- *Author:* Robert Silverberg
- *First published:* 1988/2005
- *Synopsis:* In this fantasy adventure, a band of humans emerges from underground and struggles to reclaim their lost civilization following a seven-hundred-century winter caused by a natural cataclysm.

Big Ice
- *Author:* Christopher Bonn Jonnes
- *First published:* 2003
- *Synopsis:* A publicity-shunning scientist is chased by ecoterrorists who want to stop him from making public his discovery of a method to predict calving from the Antarctic ice sheet because of global warming and his belief that a major event, which will imperil islands and coastal cities, is imminent. An exaggerated scenario, but within the possibilities of science.

Birmingham, Thirty-five Miles
- *Author:* James Braziel
- *First published:* 2008
- *Synopsis:* Set in 2044, the story follows the characters' attempts to live in the Deep South, rendered arid and barren following shifts in wind patterns and destruction of the ozone layer overhead. The author is concerned with the emotional effects of climate change rather than its causes.

The Carbon Diaries, 2015
- *Author:* Saci Lloyd
- *First published:* 2009
- *Synopsis:* Following a superstorm that hits London, the British government puts the nation on a severe emissions diet; a teenager records her experiences during the rationing and further environmental disasters.

Carbon Dreams
- *Author:* Susan M. Gaines
- *First published:* 2001
- *Synopsis:* Based on realistic science and realistic

depictions of how scientists behave, the plot, set in the early 1980's, follows a scientist battling to test her theory of dating marine sediments while maintaining a relationship with an environmental activist worried about global warming.

A Chilling Warmth: A Tale of Global Warming
- *Author:* Jay Kaplan
- *First published:* 2002
- *Synopsis:* An alien spaceship lands on Earth in 2223. It is a dismal, stormy place devoid of humans because of global warming and nuclear war. Two of the crew intend to return to 2003 in order to persuade a key scientist to change his views on global warming so that the world can avoid catastrophe.

The Doomsday Report: A Novel
- *Author:* Rock Brynner
- *First published:* 1998
- *Synopsis:* A media storm and terrorism erupt after publication of the Belacqua Report, which, based on ostensibly reputable science, proves that human-caused climate change has already doomed humanity within the next half century. The report, however, proves to be false.

Earth
- *Author:* David Brin
- *First published:* 1991
- *Synopsis:* Fifty years in the future sea levels have risen because of global warming, creating millions of refugees, and the thinning ozone layer is causing widespread skin cancer, but these are nothing compared to the danger from a mini-black hole that has fallen into the Earth. In this thriller, prophetic in several ways, scientists, Internet-bound virtual humans, and even aliens struggle to save the Earth.

The Elementals
- *Author:* Morgan Llywelyn
- *First published:* 1993
- *Synopsis:* These four fantasy tales represent the ancient elements of fire, earth, air, and water; one concerns fifty women and three men who reach Ireland and try to reclaim a semblance of civilization after floods decimate humanity worldwide, and a second follows a twenty-first century scientist's attempts to prevent destruction of the atmosphere.

Empire Builder
- *Author:* Ben Bova
- *First published:* 1993
- *Synopsis:* An adventurer-businessman discovers that an environmental disaster looms that will inundate coastal cities, which his enemies hope to use as an excuse to monopolize the world economy. On the lam from Earth to the Moon, he finds a way to expose his enemies in this doomsday-scenario thriller.

Enclave
- *Author:* Kit Reed
- *First published:* 2009
- *Synopsis:* Following environmental devastation, war, and plagues, rich parents seek safety for their spoiled children by sending them to a fortress school, Clotho Academy.

Fallen Angels
- *Authors:* Larry Niven, Jerry Pournelle, and Michael Flynn
- *First published:* 1991
- *Synopsis:* The fallen angels are two astronauts from a space station-based culture who have crash-landed in the United States, which is hostile to technology and spacefarers. A new ice age and rapidly advancing glaciers, somehow "caused by environmentalism," complicate a rescue attempt.

Fatal Climate
- *Author:* David Hood
- *First published:* 2000
- *Synopsis:* This technothriller concerns a secret plot by the president of the United States to suppress, violently, any attempt to publicize the results of a computer simulation predicting imminent collapse of the environment because of global warming.

The Final Warning: A Maximum Ride Novel
- *Author:* James Patterson
- *First published:* 2008
- *Synopsis:* Dodging killer robots and monster storms, a group of mutant kids helps scientists study global warming. Interspersed among the teenage angst, sarcasm, and derring-do are clear, sober passages written about the mechanisms behind climate change and its possible consequences.

Finitude
- *Author:* Hamish MacDonald
- *First published:* 2009
- *Synopsis:* After thirty years of rationing as a means to counteract global warming has taken place, the prime minister of England declares victory, but the story's protagonist, an insurance salesman, has inside information that disaster is coming—and yearns for it—in this comic tale.

Flood
- *Author:* Stephen Baxter
- *First published:* 2008
- *Synopsis:* Anthropogenic global warming induces the release of vast water reserves from Earth's mantle. The oceans rise to cover all land within a generation. An imaginative leap from actual science, the scenario depicts humanity violently decimated and culture permanently transformed.

The Flood
- *Author:* Maggie Gee
- *First published:* 2004
- *Synopsis:* Endless rain over England floods London, but the social elite, safe on high ground, pretends nothing has really happened. The poor suffer as the waters rise. The author uses the scenario to expose the complacency of the privileged and socioeconomic inequities.

Forbidden Light: A Novel of Discovery
- *Author:* Tom Rybolt
- *First published:* 2004
- *Synopsis:* The protagonist, a graduate student, discovers a cheap way to produce hydrogen for fuel. Set in Atlanta, Georgia, in the near future, the plot pits the hero and his solution to the world's energy and global warming problems against the industries and academia dependent on the status quo.

A Friend of the Earth
- *Author:* T. C. Boyle
- *First published:* 2000
- *Synopsis:* In 2025, an ex-ecoterrorist lives on the estate of a wealthy singer who wants to preserve endangered species through a breeding program, but the wild weather created by global warming defeats the project, and the protagonist must flee with his ex-wife to a mountain cabin in hopes of reclaiming some measure of domestic life in an increasingly volatile world.

Frozen Fire
- *Authors:* Bill Evans and Marianna Jameson
- *First published:* 2009
- *Synopsis:* Ecoterrorists blow up drill rigs that a developer is using to exploit methane clathrates for a new energy source, but they overdo it and release massive amounts of methane into the atmosphere, killing many and starting runaway global warming. The protagonists find a way to plug the narrow leak.

Gaia Weeps: The Crisis of Global Warming
- *Author:* Kevin E. Ready
- *First published:* 1998
- *Synopsis:* Ready uses the novel form as a docudrama, featuring deadly droughts, floods, heat waves, and unprecedented weather, to make the threat of global warming visceral rather than an assortment of statistics and experts' assertions.

The Galileo Syndrome
- *Author:* Daniel H. Gottlieb
- *First published:* 2004
- *Synopsis:* The story follows Carlos Jordan, who has grown up under the draconian but insufficient Greenhouse Laws, as he becomes an adult and tries to save some remnant of humanity from an environment ruined by global warming.

Genesis
- *Author:* Bernard Beckett
- *First published:* 2006
- *Synopsis:* Attempts to halt environmental destruction from global warming trigger a war that eventually extinguishes humanity and leaves a society of androids that imitates Plato's *The Republic.*

Global Bogeymen
- *Author:* Charles E. Weaver
- *First published:* 2000
- *Synopsis:* The author writes of scientists and politics suspiciously as the novel tracks the construction of a nuclear waste repository, acts of terrorism, and

natural disasters that compromise the facility's site in North Carolina.

Global Cooling: The World of the Gagababas

- *Authors:* Weng Foo Chua and David Ayala
- *First published:* 2007
- *Synopsis:* Inhabits of the planet Gon, the Gagababas, suffer for the pollution created in their greed for energy. The planet is on the verge of an ice age unless its aged king can find a solution. This is a morality tale for young readers.

Global Reset: A Suspense Novel

- *Author:* Nick Raybourne
- *First published:* 2008
- *Synopsis:* Overpopulation, global warming, and political and cultural conflicts make the world ever more turbulent, and the United States government is behind a plot to bring about a catastrophic event, which the hero, a software entrepreneur, works to prevent.

Global Warming

- *Author:* Paul Zetter
- *First published:* 2001
- *Synopsis:* A businessman attempts to stage a coup in an island nation rich in oil.

Global Warning

- *Author:* Perla Sarabia Johnson
- *First published:* 2008
- *Synopsis:* Hellish temperatures speed up the evolutionary process, enlarging species; protagonists try to protect humanity, now subterranean for safety, from the changes.

Gray/Guardians

- *Author:* Kathy Porter
- *First published:* 2006
- *Synopsis:* Humanity hopes to escape Earth and its degraded, disease-ridden environment, by taking up an offer for refuge from an alien race. However, another alien race warns that it is a trick.

The Great Colorado River War

- *Author:* Melvin Eisenstadt
- *First published:* 2007
- *Synopsis:* In 2020, a visionary Navajo engineer wants to build a solar-powered plant to produce hydrogen (technically feasible) to replace fossil fuels, but his plans to use Lake Powell water for the process starts a struggle among many factions, including organized crime.

Greenhouse Summer

- *Author:* Norman Spinrad
- *First published:* 1999
- *Synopsis:* With melted ice caps and enlarged deserts, Earth supports humanity precariously, and evidence emerges of a runaway greenhouse effect, as on Venus. Nevertheless, factions battle for narrow interests in this grim tale that is concerned with action more than science.

Greensword: A Tale of Extreme Global Warming

- *Author:* Donald J. Bingle
- *First published:* 2009
- *Synopsis:* A group of Three Stooges-like environmentalists, desperate for attention, try to reverse global warming by exploding a thermonuclear bomb on Mt. Rainier, creating an eruption, and blanketing the world in ash. This farce pays almost no attention to science.

Hell on Earth

- *Author:* Mark Tushingham
- *First published:* 2008
- *Synopsis:* This sequel to *Hotter than Hell* follows the travails of a tyrannical American general determined to survive in an environment devastated by heat and drought.

Hello World

- *Author:* Dean Joseph
- *First published:* 2008
- *Synopsis:* An unstoppable computer virus cripples world infrastructure, and chaos ensues. Meanwhile, climate change intensifies humanity's problems.

Hot Planet

- *Author:* Michael Burns
- *First published:* 1994
- *Synopsis:* In the near future, long-standing pollution triggers accelerate global warming and melt ice caps as ecoradicals battle government forces

in the Southwest; plot driven rather than science based.

Hot Sky at Midnight
- *Author:* Robert Silverberg
- *First published:* 1994
- *Synopsis:* Centuries in the future, Earth's hot environment is unsuited to humans, who must either immigrate to another planet or genetically alter themselves radically; factions compete to profit from the options.

Hotter than Hell
- *Author:* Mark Tushingham
- *First published:* 2005
- *Synopsis:* Water shortages exacerbated by global warming inspire an Army general to lead an invasion of Canada as chaos erupts in the United States. The plot rests on a possible, but extreme, interpretation of global warming's potential effects.

The Ice Goddess
- *Author:* Paul Edwards
- *First published:* 1974
- *Synopsis:* In this thriller, droughts and flooding spread through the United States, and the ice caps begin to melt as an elite spy sets out to rescue a beautiful young scientist who may have the explanation for the weather anomalies.

The Ice People
- *Author:* Maggie Gee
- *First published:* 1999
- *Synopsis:* In the near future global warming triggers a negative feedback mechanisms that starts a new ice age. Civilization gradually fails, and Europeans become refugees fleeing to Africa. Told by a member of the last generation to enjoy the benefits of technology and government.

The Last Boy
- *Author:* Robert H. Lieberman
- *First published:* 2003
- *Synopsis:* A kidnapped five-year-old boy unexpectedly returns to his frantic mother after six months, but drastically changed: He cannot stay indoors, will not eat meat, and is mature in many ways. He and his kidnapper, when caught, personify how humanity will have to change to avoid environmental catastrophe.

Lear's Daughters
- *Authors:* Marjorie B. Kellogg and William B. Rossow
- *First published:* 1986/2009
- *Synopsis:* A science expedition, trying to find the means to save an Earth overwhelmed by environmental degradation, studies a volatile planet populated by a seemingly primitive race only to discover that the natives are the survivors of an ancient attempt at environmental engineering.

Lowboy
- *Author:* John Wray
- *First published:* 2009
- *Synopsis:* A schizophrenic teenager believes he can personally rescue the world from the effects of climate change by cooling his own overheated body with sex and, pursued by a missing-person specialist, is on a quest to find the right girl.

The Man Who Made It Rain: A True Story Based on the Experiences of J. Dietrich Stroeh
- *Author:* Michael McCarthy
- *First published:* 2006
- *Synopsis:* Not fiction but a work of dramatic journalism, this book tells the story of a manager of the water district in Marin County, California, who was blamed for an emergency during the drought of 1976 and 1977. The author presents a monitory tale about what may happen with climate change.

The Man Who Watched Trash
- *Author:* Russ Madison
- *First published:* 2001
- *Synopsis:* Despite storms and threats from American spies and Russian submarines, a young environmentalist sails an immense iceberg into New York Harbor to supply drinking water to the city and to raise awareness about the damaged ozone layer.

Mara and Dann
- *Author:* Doris Lessing
- *First published:* 1999
- *Synopsis:* Two children must flee their home on the continent Ifrik in the distant future. They join

refugees from lands plagued by drought, heading toward a northern ocean but are shanghaied into opposing armies in a region where diminishing resources, a cause of climate change, give rise to wars.

Moby and Ahab on a Plutonium Sea
- *Author:* Scott E. Douglas
- *First published:* 2005
- *Synopsis:* A nuclear explosion near South Africa creates international tensions; meanwhile, the effects of global warming on the ice sheet are accelerated, leading to rapid melting in this tale based loosely on the historical Vela Incident but not on science.

The New Revolution
- *Author:* Fredwyn Haynes
- *First published:* 2008
- *Synopsis:* In the 2020's a fascist government in England is expelling immigrants and trying to hold together the nation as it bakes under a permanent heat wave. A meteorology professor has a scheme to save the planet.

Noah's Millennium
- *Author:* Melvin Eisenstadt
- *First published:* 2005
- *Synopsis:* A businessman, an engineer, and a meteorologist team to save the world from fossil fuel emissions and runaway global warming in 2050 by building an orbiting solar power planet to supply energy needs—a technically difficult solution but one that is frequently discussed by scientists.

The North Pole Is Sinking!
- *Authors:* Ethan Khiem Matsuda and Michael Matsuda
- *First published:* 2005
- *Synopsis:* In this tale for children, Santa Claus struggles to keep his toy factory working as global warming melts the ice underneath it at the North Pole.

Nothing Human
- *Author:* Nancy Kress
- *First published:* 2003
- *Synopsis:* Earthlings face the choice of ecological disaster and possible extinction or a solution to climate change from aliens that promises to alter the human race fundamentally.

One World Manga Passages: Volumes 1-6
- *Author:* Annette Roman
- *First published:* 2006
- *Synopsis:* The teenage martial arts hero of this *manga* confronts major modern problems, including global warming, with fantasy bravado and inattention to basic science.

Overshoot
- *Author:* Mona Clee
- *First published:* 1998
- *Synopsis:* An elderly Californian witnesses a new order of society emerge as political tumult and global warming cause the old culture to fail. The author uses the character as a touchstone to compare the old and new ways. The theme is moral rather than scientific: that humanity will have to change to survive.

The Owl and the Oak: The Climate Change Novel
- *Author:* Robert Emmett Morris
- *First published:* 2007
- *Synopsis:* A political thriller about the rise of environmental activists and their struggles with the oil industry as destructive weather intensifies the atmosphere of peril.

Prelude to a Journey
- *Author:* William H. Venable
- *First published:* 2002
- *Synopsis:* The narrator and Smart, a highly intelligent burro, set off on a car trip to discover the extent of problems caused by global warming. Along the way they discuss the socioeconomic solutions necessary to preserve humanity beyond the next couple of generations.

Pump Six and Other Stories
- *Author:* Paolo Bacigalupi
- *First published:* 2008
- *Synopsis:* Two stories provide grim commentary and black humor about the future: "The People of Sand and Slag" is set in a contaminated wasteland, and "The Tamarisk Hunter" concerns water issues in the Southwest, an area further desiccated by global warming.

Reality Crash

- *Authors:* Cyd Ropp and Lou Grantt
- *First published:* 2008
- *Synopsis:* The hero joins ecoterrorists who want to destroy Virtual Vision Network, a computer simulation whose idyllic programs divert people from the environmental catastrophe surrounding them.

The Rising: Journeys in the Wake of Global Warming

- *Authors:* Tom Pollock and Jack Seybold
- *First published:* 2004
- *Synopsis:* Based on cutting-edge science, this tale concerns the effects of global warming. Collapsed ice sheets raise sea levels and causes tsunamis, devastating coasts. In California civil society disintegrates and people must reappraise their fundamental values.

The Road

- *Author:* Cormac McCarthy
- *First published:* 2006
- *Synopsis:* An unexplained catastrophe has destroyed civilization and many species. A father and son walk to the sea despite grotesque adventures, and the father dies there, leaving his son to strangers and a murky future in this dour parable of wasted chances and humanity's self-destructiveness.

Runaway

- *Author:* John A. Topping
- *First published:* 2002
- *Synopsis:* Extrapolating from the possibilities of climate science, this ecothriller concerns a scientist after his discovery that global warming is accelerating. He tries to stop it as the agents of big business and government oppose him.

Science in the Capital series: Forty Signs of Rain (2004), Fifty Degrees Below (2005), and Sixty Days and Counting (2007)

- *Author:* Kim Stanley Robinson
- *First published:* 2004-2007
- *Synopsis:* Each novel portrays a major catastrophic event caused by global warming in the near future: flood, freeze, and rising seas. The science behind it all is realistic; the measures taken to forestall catastrophe are spectacular but within the realm of the possible. However, the real strength of this series is its portrayal of scientists and their relation to government.

Second Atlantis

- *Author:* James Follett
- *First published:* 1998
- *Synopsis:* First published as *Ice* (1978), this fantasy novel concerns a geologist who has discovered gouges in the sea floor left by ancient icebergs and realizes the Antarctic ice sheet could do the same today. He further discovers that the catastrophic event could produce a second Atlantis.

Second Summer: The Turnback Time

- *Authors:* Amelia Walsh and James Stambaugh
- *First published:* 2008
- *Synopsis:* Set in the Pacific Northwest, this fantasy has a race of intelligent dinosaurs awakened by global warming. Humans compete to manipulate the Mesozoic species to their own financial or ideological advantage.

Seeds of Change

- *Editor:* John Joseph Adams
- *First published:* 2008
- *Synopsis:* Nine stories project current problems into the near future and discuss their culture-changing outcomes, including global warming and energy production.

September Snow

- *Author:* Robert Balmanno
- *First published:* 2006
- *Synopsis:* By 2051 climate change has caused havoc. A new eco-centric religion, Gaia, has arisen because of it but has become perverted and tyrannical. A beautiful genius leads a rebellion to topple the theocratic regime and begin an era of healing.

Shelter

- *Author:* Susan Palwick
- *First published:* 2007
- *Synopsis:* A group of family and friends, some human and some created by artificial intelligence, reunite and seek forgiveness for a horrific tragedy in their past while a titanic storm, for which global warming is somehow responsible, devastates San Francisco.

Sinking into Summer's Arms
- *Author:* Tom Slattery
- *First published:* 2000
- *Synopsis:* A mountain glacier, receding because of global warming, reveals a Neanderthal, whose mind is re-created by Dutch scientists. Meanwhile, reactionaries plot to assassinate the United Nations Emergency Secretary for Global Warming, who, to prevent worldwide panic, is trying to keep secret mounting evidence that Earth will slip into a new ice age.

Snowfall Trilogy: Snowfall (2002), Kingdom River (2003), and Moonrise (2004)
- *Author:* Mitchell Smith
- *First published:* 2002-2004
- *Synopsis:* In these fantasy thrillers set six centuries in the future, the remnants of humanity try to survive and rebuild civilization after extreme climate change—caused by an alteration in Jupiter's orbit—has left the world largely frozen.

Snowglobe Seven
- *Author:* Mike Tucker
- *First published:* 2008
- *Synopsis:* In this edition of Dr. Who, ice caps are melting because of global warming. Dr. Who and Martha battle an alien threat and a plague while in a domed habitat cooled by remnants of the polar ice.

Solix Resettles Blue Mountain
- *Author:* Robert E. Dansby
- *First published:* 2006
- *Synopsis:* A dramatization of actual ecological change caused by a warming climate, this book for young readers follows the experiences of birds (especially the protagonist, an owl) and animals.

Solstice
- *Author:* David Hewson
- *First published:* 1999
- *Synopsis:* A rapidly heating atmosphere and record solar storms threaten mass destruction as ecoterrorists make matters much worse by hijacking a deadly satellite. Only an intrepid scientist and a CIA agent prevent the group from destroying modern civilization in its apocalyptic attempt to save Earth from humanity.

State of Fear
- *Author:* Michael Crichton
- *First published:* 2004
- *Synopsis:* A terrorist conspiracy among environmentalists to incite public alarm about global warming, which is portrayed as supported by flimsy evidence, prompts a desperate attempt to stop them on the part of a scientist and a federal agent. Following the story are pages of footnotes and bibliography supporting the contention that global warming is a sham.

The Story of General Dann and Mara's Daughter, Griot, and the Snow Dog
- *Author:* Doris Lessing
- *First published:* 2005
- *Synopsis:* A sequel to *Mara and Dann*, this dreamy cautionary tale follows a small group of young soldiers who try to reclaim lost knowledge and cultural value as the next ice age thaws and the oceans rise to cover their ragged, war-ravaged villages in North Africa.

Terminal Freeze
- *Author:* Lincoln Child
- *First published:* 2009
- *Synopsis:* Studying the effects of global warming on a fast-retreating glacier in Alaska, a team of scientists finds and accidentally releases an ancient monster, which briefly wreaks havoc. Climate change serves as merely the backdrop for this fantasy tale.

Threat to the Life Force
- *Author:* Nelly Comperatore
- *First published:* 2004
- *Synopsis:* In 2065, two scientists develop a space vehicle to preserve life as pollution, environmental degradation wrought by global warming, and disease threaten to destroy humanity.

Ultimatum
- *Author:* Matthew Glass
- *First published:* 2009
- *Synopsis:* A newly elected U.S. president learns that global warming is progressing much faster than heretofore admitted, and he will go to any lengths, including nuclear war, to impose an inter-

national regime of remediation in order to avoid catastrophe for humanity.

Unnatural Sights
- *Author:* Joe Jeney
- *First published:* 2008
- *Synopsis:* Global warming, war, and an energy crisis move an astronaut to accept a mission to Jupiter's moon Europa in search of oil shale. Discovery of life on the moon poses a dilemma because it could be harmed if the oil is extracted.

Venus
- *Author:* Ben Bova
- *First published:* 2000
- *Synopsis:* Late in the twenty-first century a rich man offers a $10 billion reward to anyone who can retrieve his son's body from the surface of Venus. Descriptions of the planet's atmosphere and surface, which is extremely hot because of the greenhouse effect, raise comparisons to global warming on Earth. Sound planetary science serves as the background for this science-fiction thriller.

Water Rites
- *Author:* Mary Rosenblum
- *First published:* 2007
- *Synopsis:* Because of global warming, Earth is arid, and the hero, a major in the U.S. Army Corps of Engineers, must negotiate fiercely competing demands to supply the water needed to preserve civilization in the American West.

Weather Warden series: Ill Wind (2003), Heat Stroke (2004), Chill Factor (2005), Windfall (2005), Firestorm (2006), Thin Air (2007), Gale Force (2008), and Cape Storm (2009)
- *Author:* Rachel Caine
- *First published:* 2003-2009
- *Synopsis:* These fantasy romantic thrillers concern supernatural agents—the weather wardens and djinni—who are supposed to protect humanity from the catastrophic weather phenomena caused by climate change.

Winston of Churchill: One Bear's Battle Against Global Warming
- *Author:* Jean Davies Okimoto
- *First published:* 2007
- *Synopsis:* In this children's book, a polar bear in Churchill, Manitoba, Canada, urges fellow bears to mount a protest against global warming, which is ruining their icy environment.

• FILMS

Addicted to Oil: Thomas L. Friedman Reporting
- *Production company:* Discovery Productions
- *Released:* 2006
- *Synopsis:* A renowned *New York Times* columnist reports on America's dependence on fossil fuels and the alternative energy technologies that could replace them.

After the Warming
- *Production company:* Film Australia
- *Released:* 1989
- *Synopsis:* Through computer simulations James Burke explains past ice ages and warming trends and discusses various consequences that the greenhouse effect may have before 2050.

The Age of Stupid
- *Production company:* Spanner Films
- *Released:* 2009
- *Synopsis:* This British documentary takes place in 2055, when the environment is ruined. An archivist looks at images from the early 2000's—such as melting glaciers and the aftermath of Hurricane Katrina—and wonders why people did not save their world when they could.

Age of Warming
- *Production company:* Columbia Broadcasting System
- *Released:* 2007
- *Synopsis:* An episode of *60 Minutes* takes readers to a glacier in Chile to show the speed with which it is melting because of global warming.

The Antarctica Challenge
- *Production company:* Polar Cap Productions
- *Released:* 2009
- *Synopsis:* This hour-long documentary covers the latest research into global warming on the seventh continent.

The Anti-Global Warming League
- *Production company:* Sterling Video Productions
- *Released:* 2008
- *Synopsis:* This ten-minute spoof has school kids stopping global warming so that they can have a snow day and stay home from school.

Arctic Tale
- *Production company:* Visionbox Pictures
- *Released:* 2007
- *Synopsis:* During the eight years covered by this feature-length documentary, a polar bear cub and walrus pup grow to maturity as global warming melts part of the icy environment that they need to survive.

The Arrival
- *Production company:* Live Entertainment
- *Released:* 1996
- *Synopsis:* Global warming is progressing rapidly in this science-fiction thriller, but it is caused by aliens, not humans, and an astronomer uncovers their plot to take over the earth.

Artificial Intelligence: AI
- *Production company:* Warner Bros. Pictures
- *Released:* 2001
- *Synopsis:* With the ice caps melted, the United States retreats from submerged coastlines and continues its technological advance. The plot concerns household robots, who eventually replace humanity.

The Big Ask
- *Production company:* Friends of the Earth
- *Released:* 2008
- *Synopsis:* In this four-minute short, a small girl, playing on the beach, wonders why she can recognize the perils of global warming but politicians cannot, and she recounts the dangers.

Big Spuds, Little Spuds
- *Production company:* Bullfrog Films
- *Released:* 1999
- *Synopsis:* This documentary examines the effects of climate change and modern agriculture on the production of potatoes in the Andes of Peru.

Blade Runner
- *Production company:* Ladd Company
- *Released:* 1982
- *Synopsis:* This noir science-fiction masterpiece takes place in a vast city with nonstop rain, teeming streets, and a poisoned environment, which the wealthy flee off-planet. Killer androids return to Earth seeking longer life, and it is the job of the hero, a blade runner, to track them down and kill them.

The Burning Season
- *Production company:* Hatchling Productions
- *Released:* 2008
- *Synopsis:* This documentary follows an entrepreneur who is looking for alternative agricultural methods in Indonesia, where locals annually set fires in order to clear their land, emitting a great deal of carbon dioxide into the environment.

Category 7: The End of the World
- *Production company:* Luisa Filmproduktions
- *Released:* 2005
- *Synopsis:* Among other environmental catastrophes spawned by global warming, a superstorm develops, and three scientists rush in to stop it in this credulity-busting disaster story.

Changing Climates, Changing Times
- *Production company:* Cape Drama
- *Released:* 2008
- *Synopsis:* This television drama depicting conditions in 2075 assumes the state of the environment will be much worse than was predicted early in the century, with extreme heat, drought, flooding, and plagues. Although there is political turmoil, various characters carry on with a measure of hope.

Chilly Beach: The World Is Hot Enough
- *Production company:* March Entertainment
- *Released:* 2008
- *Synopsis:* In this animated movie, a pair of Canadians want to attract tourists to their area by building a device to change the climate. However, their invention works too well, threatening to destroy the biosphere, and to escape the onslaught of government agents and cults the pair travel back in time to stop themselves.

Climate Change Cartoon No. 1: Empty Spaces
- *Released:* 2009
- *Synopsis:* This brief animation offers an apocalyptic vision of the world if global warming is ignored.

Climate Chaos
- *Production company:* British Broadcasting Corporation
- *Released:* 2006
- *Synopsis:* Hosted by David Attenborough, this television series examines environmental issues, climate change, places susceptible to disaster, alterations in agriculture, and the politics behind treaties to control greenhouse gas emissions.

The Cloud Mystery
- *Production company:* Mortensenfilm
- *Released:* 2008
- *Synopsis:* This documentary discusses the theories of Danish physicist Henrik Svensmark, who argues that global temperature change is caused by the cosmic rays that influence Earth's cloud cover, and not by the human use of fossil fuels.

The Day After Tomorrow
- *Production company:* Twentieth Century Fox
- *Released:* 2004
- *Synopsis:* Global warming triggers an unbelievably swift deep freeze in the Northern Hemisphere, and a leading scientist sets off to rescue his son trapped in New York City. This thriller was reportedly the source of great hilarity among real climate scientists.

The Day the Earth Stood Still
- *Production company:* Twentieth Century Fox
- *Released:* 2008
- *Synopsis:* In this eco-friendly remake of a 1951 Cold War classic, aliens arrive on Earth to cleanse it from the environmental damage wrought by humanity and to eradicate the race in the process. However, an intrepid astrobiologist and her stepson convince the alien agent in charge to stop the destruction.

The Day the Oceans Boiled
- *Production company:* Equinox
- *Released:* 2001
- *Synopsis:* This television documentary discusses a dramatic rise in global temperature 55 million years ago and then ponders whether Earth today could undergo a similar process.

Designing the New World: Turning Crisis into Potential
- *Production company:* Activist Entertainment
- *Released:* 2009
- *Synopsis:* This opinion piece urges people to take personal responsibility in facing looming crises, such as climate change, in order to improve the future with "mindful living" and not be diverted by the fear-centered tactics of the media.

The Disappearing of Tuvalu: Trouble in Paradise
- *Production company:* Documentary Educational Resources
- *Released:* 2004
- *Synopsis:* The South Pacific island nation of Tuvalu stands to be the first sovereign nation lost beneath the ocean because of global warming, and this feature-length documentary recounts the citizens' struggle to cope as sea water invades their land.

Doomsday Called Off
- *Production company:* Lars Mortensen TV-Produktion
- *Released:* 2004
- *Synopsis:* This Danish documentary critiques the arguments that humanity is causing a potentially disasterous global change in climate.

Earth
- *Production company:* Greenlight Media AG
- *Released:* 2007
- *Synopsis:* This feature-length version of the television series *Planet Earth* follows four families of animals in order to examine how they are affected by climate change.

Earth: The Climate Wars
- *Production company:* British Broadcasting Corporation
- *Released:* 2008
- *Synopsis:* This three-episode documentary ("Battle Begins," "Fightback," and "Fight for the Future") includes interviews with prominent scientists on both sides of the global warming debate.

An Earth Story: An Alternative to Extinction
- *Production company:* Mayan Animations Productions
- *Released:* 2007
- *Synopsis:* This animated documentary argues that humanity has the technology to prevent catastrophic climate change and just needs the will to convert to it and thereby reduce carbon emissions.

The 11th Hour
- *Production company:* Appian Way
- *Released:* 2007
- *Synopsis:* Actor Leonardo DiCaprio takes viewers through an array of interviews of leaders and scientists to explain the peril from climate change and ways to halt it in this feature-length documentary. Stunning footage shows both beautiful and frightening natural scenery.

The End of the World
- *Production company:* Albino Blacksheep
- *Released:* 2006
- *Synopsis:* This animated lampoon of modern anxieties includes jabs at global warming and nuclear winter.

Energy Crossroads
- *Production company:* Tiroir A Films
- *Released:* 2007
- *Synopsis:* This documentary explores looming problems with fossil fuel use, including emissions that cause the greenhouse effect and the possibility of economic collapse after demand exceeds supply.

Energy Report IV: Change in the Air
- *Production company:* Television Trust for the Environment
- *Released:* 2000
- *Synopsis:* This documentary surveys areas of the United States that have undergone environmental change from global warming and damage from pollution.

Environmental Hysteria
- *Production company:* Penn & Teller
- *Released:* 2003
- *Synopsis:* This episode of *Penn & Teller: Bullshit!* debunks the extreme claims of environmentalists.

Everything's Cool
- *Production company:* Toxic Comedy Pictures
- *Released:* 2007
- *Synopsis:* This documentary, featuring dozens of public figures and scientists, recounts the desperate political battles behind the debate about global warming and the difficulty of getting an easily diverted public to pay attention.

Extreme Ice
- *Production company:* Public Broadcasting Service
- *Released:* 2009
- *Synopsis:* This *Nova* episode depicts the melting of arctic glaciers and discusses the causes and likely outcomes.

The Fateful Balance
- *Production company:* Lightscape Motion Picture Company
- *Released:* 1990
- *Synopsis:* Scientists debate the possibility of climate change and how to distinguish natural change from changes induced by human use of fossil fuels in this documentary.

A Floridian's Guide to Climate Change
- *Production company:* BFA Documentary
- *Released:* 2009
- *Synopsis:* Its long, low, and heavily populated coastline leaves Florida particularly vulnerable if

sea levels rise from global warming, as this nine-minute documentary details.

Forecast Earth
- *Production company:* Atlas Media
- *Released:* 2003-2008
- *Synopsis:* This television series addresses such topics as El Niños, destructive storms, alternative fuels, environmentalists, and ecotourism.

Future of the Great Barrier Reef
- *Production company:* Green.tv
- *Released:* 2003
- *Synopsis:* In this Australian documentary, scientists discuss the bleaching of coral reefs caused by rising ocean temperatures, while images reveal blighted underseascapes.

Global Warming: Science and Solutions
- *Production company:* Center Films Ltd.
- *Released:* 2006
- *Synopsis:* In a two-hour presentation, this documentary describes humanity's historical impact on the environment, particularly the warming caused by fossil fuel consumption in the twentieth century. Computer animations clarify the science behind climate change, and alternative fuel sources are discussed.

Global Warming: The New Challenge
- *Production company:* Peacock Productions
- *Released:* 2009
- *Synopsis:* A follow-up on *Global Warming: What You Need to Know.*

Global Warming: The Signs and the Science
- *Production company:* Public Broadcasting Service
- *Released:* 2005
- *Synopsis:* Through interviews with scientists and footage revealing climate change in the United States, Asia, and South America, this documentary explores the consequences of this change and the people who are trying to avert disaster.

Global Warming: What You Need to Know
- *Production company:* British Broadcast Corporation
- *Released:* 2006
- *Synopsis:* News anchorman Tom Brokaw interviews experts about what Americans should expect from global warming and about methods of mitigating its effects.

Global Warming Reflection Video
- *Released:* 2004
- *Synopsis:* Rapid images of environmental devastation are shown as the Finnish power metal band Sonata Arctica sings "Wrecking the Sphere."

Global Warming Song
- *Production company:* Snappy Greetings
- *Released:* 2006
- *Synopsis:* Caricatures of Al Gore and his wife Tipper sing a parody of his global warming message to the tune of "You're the One That I Want."

A Global Warning?
- *Production company:* Pioneer Productions
- *Released:* 2007
- *Synopsis:* In interviews with scientists, alternating with footage of landscapes worldwide, this two-hour television documentary considers whether global warming is part of a natural cycle or is caused by humans.

Global Warning
- *Production company:* Sandorp Pictures
- *Released:* 2008
- *Synopsis:* In this four-minute drama, a clueless businesswoman lives a privileged life, ignoring all signs of environmental trouble, until she suddenly feels its impact.

Global Warning: The Thaw of War
- *Production company:* Lena Film
- *Released:* 2010
- *Synopsis:* This feature-length documentary shows retreating glaciers that reveal soldiers frozen in past wars, and footage of modern wars raises the question about the immediate future: Can nations overcome rivalries in the face of a common environmental threat?

The Great Global Warming Swindle
- *Production company:* WAGtv
- *Released:* 2007
- *Synopsis:* Through interviews with scientists, economists, politicians, and writers, this British documentary seeks to expose global warming as the biggest scam of all time, based on flawed science manipulated by vested interests, especially the Intergovernmental Panel on Climate Change. The British media regulator Ofcom ruled that the film falsified some data to make its claims.

The Great Warming
- *Production company:* Stonehaven Productions
- *Released:* 2006
- *Synopsis:* Interviews with scientists and commentators and dramatic footage of scenery underscore a message of urgency in combating global warming and climate change in this call-to-action documentary based on a 2003 Canadian television series.

Green: The New Red, White and Blue
- *Production company:* Optomen Productions
- *Released:* 2007
- *Synopsis: New York Times* columnist Thomas L. Friedman surveys green technologies to replace fossil fuels and reduce greenhouse gas emissions.

Home
- *Production company:* Elzévir Films
- *Released:* 2009
- *Synopsis:* Aerial footage of fifty-four countries reveals the intimate environmental and cultural interconnections of the world and the extent of problems facing humanity from destructive agriculture and deforestation.

How to Boil a Frog
- *Production company:* Fools Bay Entertainment
- *Released:* 2009
- *Synopsis:* Billed as an "eco-comedy," this documentary promotes personal solutions for surviving the effects of climate change, which is treated as one facet of the larger problem of overpopulation.

I Saved the World from Global Warming!
- *Released:* 2008
- *Synopsis:* This short comedy concerns a man who announces a solution to global warming but finds that nobody cares.

Ice
- *Production company:* Alexander/Enright & Associates
- *Released:* 1998
- *Synopsis:* In this television drama, characters escape from Los Angeles after the entire Northern Hemisphere freezes and board a ship bound for warmer climes.

Ice Bears of Beaufort
- *Production company:* PolarArt Productions
- *Released:* 2009
- *Synopsis:* This documentary concerns the habitat for polar bears in Alaska's Beaufort Sea, threatened by offshore oil wells and by ice melting because of global warming.

An Inconvenient Truth
- *Production company:* Lawrence Bender Productions
- *Released:* 2006
- *Synopsis:* This documentary follows former vice President Al Gore's lecture tour to inform the world about global warming and its consequences. It mixes segments of lectures with entertaining graphics and interviews in a presentation that won two Academy Awards.

Inuit Observations on Climate Change
- *Production company:* International Institute for Sustainable Development
- *Released:* 2000
- *Synopsis:* Inuvialuit hunters on Banks Island in the Arctic note significant changes in their environment—summer heat melting more ice, delayed freezing in winter, and new species—in this forty-two-minute documentary.

Jon Saves the Planet
- *Production company:* Insight Productions Company
- *Released:* 2009
- *Synopsis:* In this episode of Canada's *Jon Dore* comedy series, the hero is upbraided for burning his garbage because it contributes to greenhouse gases.

Just in Case
- *Production company:* Earthworm Productions
- *Released:* 2008
- *Synopsis:* This one-minute animation depicts climate change.

Katastrofin aineksia
- *Production company:* Magic Hour Films
- *Released:* 2008
- *Synopsis:* This Finnish-Danish comedy has a director convince his family to go on a strict regime to reduce their carbon footprint, and they go from one mishap to another trying to maintain their middle-class life.

Knowing
- *Production company:* Summit Entertainment
- *Released:* 2009
- *Synopsis:* In this disaster film, a massive solar flare finishes the job of global warming, incinerating the Earth and all humanity except for a select group of children rescued by aliens.

Lazarus Taxon
- *Production company:* Polar Star Films
- *Released:* 2008
- *Synopsis:* A mixture of horror and science fiction, this short Catalan-language film depicts the gruesome consequences of global warming.

Legacy of the Great Aletsch
- *Production company:* Aletschfilm
- *Released:* 2009
- *Synopsis:* The Great Aletsch is a large glacier in the Swiss Alps, now swiftly retreating because of global warming. This documentary reports its cultural and economic importance to locals.

Live Earth
- *Production company:* Bob Bains Productions
- *Released:* 2007
- *Synopsis:* This film features dozens of recording stars performing in a concert series aimed at highlighting the climate change crisis.

Lost City Raiders
- *Production company:* Tandem Communications
- *Released:* 2008
- *Synopsis:* In this television science-fiction movie, the Earth is largely covered by water. A father-son team salvage valuables from submerged buildings and are sent on a mission by the New Vatican.

Man vs. Nature—Who Will Win?
- *Production company:* VCI Home Video
- *Released:* 1999
- *Synopsis:* This episode of *Secrets of the Millennium* argues that humanity is out of balance with nature, polluting the environment with greenhouse gases, mismanaging resources, and destroying other species. It implies that humanity will have to suffer for its carelessness.

The March
- *Production company:* British Broadcasting Corporation
- *Released:* 1990
- *Synopsis:* Racial conflict and international tensions erupt as global warming forces Africans to migrate to an already overpopulated Europe in this drama set in the near future.

Med Triton I Ishavet
- *Production company:* Danmarks Radio
- *Released:* 2003
- *Synopsis:* In this made-for-television half-hour drama, Danish scientists in a naval vessel investigate dramatic climate change on the northeastern Greenland coast and go ashore on an island heretofore icebound.

Meltdown: A Global Warming Journey
- *Production company:* British Broadcasting Corporation
- *Released:* 2006
- *Synopsis:* This hour-long documentary considers the divergent points of view about global warming in order to separate fact from polemic.

Melting Lands
- *Production company:* HemmingsHouse Pictures
- *Released:* 2008
- *Synopsis:* Ice in the Canadian northlands is melting faster each year, and this documentary examines how an Inuit community is affected by these climate changes.

Nuclear Climate Change
- *Released:* 2008
- *Synopsis:* This documentary explores the benefits and dangers of nuclear power as an alternative to fossil fuels and as a means of reducing greenhouse gas emissions.

The Nuclear Comeback
- *Production company:* Icarus Films
- *Released:* 2007
- *Synopsis:* This documentary surveys the nuclear power industry worldwide, considering whether, as an alternative to fossil fuels, nuclear power is a reasonable way to combat global warming.

Out of Balance: ExxonMobil's Impact on Climate Change
- *Production company:* ADL Films
- *Released:* 2007
- *Synopsis:* Exxon is the world's largest company, according to this documentary, which accuses the oil company of ignoring climate science for the sake of profits. The film also discusses the kinds of social changes that are needed to ensure a livable planet.

Owning the Weather
- *Production company:* 4th Row Films
- *Released:* 2009
- *Synopsis:* With dramatic images of extreme weather and interviews with dozens of scientists, leaders, and citizens, this documentary considers the wisdom of geoengineering to control weather and other effects of global warming.

Proof or Propaganda: Climate Change—It's Not What You Think
- *Production company:* Ceilings Unlimited
- *Released:* 2008
- *Synopsis:* Based on interviews with scientists and business people, this ninety-minute documentary portrays climate change as an opportunity for economic growth.

Rain Shadow
- *Production company:* Australian Broadcasting Corporation
- *Released:* 2007
- *Synopsis:* This television miniseries shows farmers struggling to adapt to an extended drought that is a feature of Australian climate change.

Renewal
- *Production company:* Fine Cut Productions
- *Released:* 2008
- *Synopsis:* The movement in America among religious people to be environmentally conscious is growing, according to this documentary, which offers eight stories about involvement and hope.

Repeat Photography and the Albedo Effect
- *Production company:* Squeaky Wheel Media Arts Center
- *Released:* 2008
- *Synopsis:* Brutal boxing-match scenes segue into a white background as a voice-over discusses the effects of global warming on glaciers in this experimental eight-minute film.

Ribbon of Sand
- *Production company:* Public Broadcasting Service
- *Released:* 2008
- *Synopsis:* Like many low-lying islands, North Carolina's Outer Banks will disappear if sea levels rise, and this short documentary describes the area's natural history as a testimony to what would be lost.

Rising Waters: Global Warming and the Fate of the Pacific Islands
- *Production company:* Bullfrog Films
- *Released:* 2000
- *Synopsis:* Through personal stories, this hour-long documentary reveals the threat that global warming poses to South Pacific islands: bleached corral, distressed fisheries, and inundated territory.

A Sea Change
- *Production company:* Niijii Films
- *Released:* 2009
- *Synopsis:* An outdoorsman investigates the effects of carbon dioxide emissions on the world's oceans and the future consequences for people in this full-length documentary.

Seed Hunter
- *Production company:* 360 Degrees Films
- *Released:* 2008
- *Synopsis:* This documentary concerns an Australian scientist who searches in Central Asia for seeds that will be hardy enough to survive the effects of global warming and will replace regional food crops elsewhere that cannot survive the climate changes.

Serious Arctic
- *Production company:* British Broadcasting Corporation
- *Released:* 2005
- *Synopsis:* In a documentary for young audiences, eight teenage volunteers travel to Grinnell Glacier in the Canadian Arctic to help scientists study the effects of global warming, especially on polar bears.

Silent Sentinels
- *Production company:* Bullfrog Films
- *Released:* 2000
- *Synopsis:* This hour-long documentary considers whether the large-scale bleaching of coral reefs in 1998 constitutes evidence of global warming.

Six Degrees Could Change the World
- *Production company:* National Geographic
- *Released:* 2008
- *Synopsis:* This documentary explains and depicts the possible changes to world climate with each degree of increased average temperature, based on the book *Six Degrees* by Mark Lynas.

Sizzle: A Global Warming Comedy
- *Production company:* Prairie Starfish Productions
- *Released:* 2008
- *Synopsis:* This partly mocking, partly serious documentary interviews various scientists about global warming in an attempt to grasp the public confusion over it.

Split Second
- *Production company:* Challenge Film Corporation
- *Released:* 1992
- *Synopsis:* Because of global warming and melting ice, much of London is underwater in this futurist horror film, and a policeman discovers that a monster has invaded the city.

SUV Taggers
- *Production company:* Stone Harbor Films
- *Released:* 2004
- *Synopsis:* This documentary short shows a pair of eco-vandals adorning large cars with bumper stickers in order to call attention to the polluting emissions of large vehicles.

Tales from the Arctic Circle
- *Production company:* Wonderdog Productions
- *Released:* 2005
- *Synopsis:* Four short films reveal the cultural life in Iqaluit, an Inuit community in the Arctic. Among the problems facing the people are abnormal snow melts and environmental change.

A Terrifying Message from Al Gore
- *Production company:* 20th Century Fox Television
- *Released:* 2006
- *Synopsis:* In an animated short, Al Gore and the *Futurama* robot Bender promote *An Inconvenient Truth.*

They Will Come to Town
- *Production company:* Filmakademie Baden-Württemberg
- *Released:* 2008
- *Synopsis:* This one-minute dramatic animation shows fish swimming in inundated cities.

Too Hot Not to Handle
- *Production company:* Lovett Productions
- *Released:* 2006
- *Synopsis:* This documentary elaborates on possible effects from global warming in the United States: heat waves, melting glaciers, submerged sea coasts, new pests, and catastrophic storms.

Tornado Terror

- *Production company:* Fast (Tornado) Productions
- *Released:* 2008
- *Synopsis:* The premise of this two-hour drama is that global warming will create conditions spawning immense tornadoes, and it focuses on one tornado that appears to have a grudge against New York City.

Turning Down the Heat: The New Energy Revolution

- *Production company:* National Film Board of Canada
- *Released:* 1999
- *Synopsis:* Alternative energy sources could free countries from dependency on foreign oil, provide greater economic justice, and undercut climate change, according to this documentary.

2050

- *Production company:* TV Siete
- *Released:* 2006
- *Synopsis:* Based on a 2004 report from the Pentagon warning of the security dangers that global warming could pose, this documentary concentrates on the consequences of climate change to basic resources.

2012

- *Production company:* Centropolis Entertainment
- *Released:* 2009
- *Synopsis:* In accordance with an ancient Mayan prediction, cataclysmic environmental events threaten to destroy civilization, and characters struggle to cope in this disaster drama.

Under the Sea 3D

- *Production company:* Howard Hall Productions
- *Released:* 2009
- *Synopsis:* This IMAX three-dimensional feature presents the underwater environment around New Guinea and the coral reefs of Australia and considers the threats to these areas from global warming.

The Venus Theory

- *Production company:* Talent House
- *Released:* 2004
- *Synopsis:* A Finish documentary, this hour-long film explains the science behind the claims about global warming and considers whether Earth could experience a runaway greenhouse effect like that of its sister planet Venus.

Wake Up, Freak Out: Then Get a Grip

- *Production company:* RCA
- *Released:* 2008
- *Synopsis:* This short animation explains the positive feedback mechanisms that could accelerate global warming and lead to irreversible, calamitous climate change.

Water Planet

- *Production company:* Tree Media
- *Released:* 2005
- *Synopsis:* In this short documentary, actor Leonardo DiCaprio explains the dangers to the world's freshwater supply from pollution, wasteful use, and the desertification caused by climate change.

Waterworld

- *Production company:* Universal Pictures
- *Released:* 1995
- *Synopsis:* In this futuristic drama, the ice caps have melted and Earth is covered by the oceans. A mutant sailor sets out with a woman and mysterious girl in search of a rumored island as bandits in an oil tanker try to waylay them.

We Are All Smith Islanders: Global Warming in Maryland, Virginia, and D.C.

- *Production company:* MDP Productions
- *Released:* 2004
- *Synopsis:* This documentary follows the watermen of Smith Island in the Chesapeake Bay who are losing the ability to make a living because of damage from global warming, and it considers clean-energy solutions that might reduce the human contribution to the problem.

Weather Report

- *Production company:* Sienna Films
- *Released:* 2008
- *Synopsis:* This thirty-five-minute documentary previews the worldwide effects of climate change by depicting current environmental alterations in India, Kenya, and the Canadian Arctic and by interviewing local residents who are taking measures to adapt.

Time Line

- 4.5 billion years ago

Earth forms

- 65 million years ago

A 10-kilometer-diameter asteroid produces a 180-kilometer-diameter crater on the Yucatán Peninsula. The impact is believed to have penetrated the earth's crust, spewing dust and debris into the atmosphere, causing huge fires and acid rain, increasing already active volcanic eruptions, and setting off tsunamis and storms with high winds. These environmental disasters would have caused most of the species then living, including the dinosaurs, to become extinct.

- 5.1-5.8 million years ago

The Pliocene Epoch: A cooling period leads to the Ice Age.

- 1.8 million years ago to11,000 years ago

The Pleistocene Epoch: Glaciation leads to the Ice Age. Modern humans evolve.

- 11,000 years ago

The Holocene Epoch: The Ice Age ends. Human beings begin to impact the biosphere.

- 9th-13th centuries

The Medieval Warm Period: Temperatures in the Northern Hemisphere, particularly in the North Atlantic region, are warmer than in previous years.

- 15th-19th centuries

The Little Ice Age: Temperatures in the Northern Hemisphere, particularly in the North Atlantic Region, are cooler than during the prior Medieval Warm Period.

- 1643-1653

Europe experiences its severest winters since the Ice Age.

- 1665-1666

Very hot summers in London exacerbate the last plague epidemic.

- 1690

Siberia experiences extreme heat, probably due to southerly winds. At this time, Europe is abnormally cold.

- 1718-1719

Great heat and drought affect most of Europe during the summers of these years.

- June 8, 1783-February 7, 1784

The Laki fissure eruption in Iceland produces the largest lava flow in historical time, with major climatic effects. Benjamin Franklin speculates on its connection to a cold winter in Paris the following year.

- 1798

Thomas Robert Malthus publishes *An Essay on the Principle of Population, As It Affects the Future Improvement of Society*, in which he proposes that population growth will outpace food production, with devastating consequences. The book sets off a public flurry and a debate among intellectuals.

- April 5, 1815

The dramatic explosion of Tambora, 400 kilometers east of Java, the largest volcanic event in modern history, produces atmospheric and climatic effects for the next two years. Frosts occur every month in New England during 1816, the Year Without a Summer.

- 1825

Joseph Fourier postulates that Earth's atmosphere acts "like the glass of a hot-house," dispensing high-energy (ultraviolet) radiation but retaining low-energy (infrared) radiation.

- 1845

Moist, southerly winds and a hot summer provide the perfect growing conditions for the potato blight fungus, resulting in the Irish Potato Famine.

- 1852

Louis Agassiz receives the Cuvier Prize from the French Academy of Sciences. Agassiz originated the concept of a great Ice Age, a period when, amid a series of catastrophes, vast sheets of ice covered much of the earth.

- 1859

Using spectrophotometry, John Tyndall discovers that certain gases, such as water vapor and carbon dioxide (CO_2), have the power to absorb ultraviolet rays.

- August 26, 1883

A cataclysmic eruption of Krakatoa, an island in Indonesia, is heard 4,777 kilometers away. Many die as pyroclastic flows race over pumice rafts floating on the surface of the sea; many more die from a tsunami.

- 1887-1896

Droughts drive out many early settlers of the Great Plains.

- 1895

Svante August Arrhenius, sometimes called the father of climate change, creates the first mathematical model that proves how even small amounts of carbon dioxide in the atmosphere can increase global temperatures.

- May 8, 1902

Mount Pelée, on the northern end of the island of Martinique in the Caribbean, sends violent pyroclastic flows into the city of St. Pierre, killing all but 2 of the 30,000 inhabitants.

- 1910-1915

The first in a series of recurring droughts affects the Sahel region of Africa.

- 1923

English physicist Gilbert Walker discovers the Southern Oscillation, which in the 1960's is linked to El Niño.

- December, 1930

The DuPont Corporation introduces Freon, a nontoxic, nonflammable, chlorofluorocarbon chemical used as a refrigerant. In later years, Freon is shown to harm the earth's ozone shield, creating a potential environmental hazard.

- 1933-1936

Extensive droughts in the southern Great Plains destroy many farms, creating the Dust Bowl, in the worst drought in more than three hundred years in the United States. Between 15,000 and 20,000 die.

- 1938

Guy Stewart Callendar, an English physicist, speculates that increasing carbon dioxide levels are the probable cause for a warming trend in North America and Northern Europe that meteorologists began to observe in the 1880's. He is the first person to assemble a large amount of data from several scientific sources in order to predict significant temperature change from anthropogenic carbon dioxide.

- 1939

American soil conservationist Hugh Hammond Bennett publishes *Soil Conservation*, in which he describes how temperature, wind speed, humidity, and the amount and duration of precipitation affect soil erosion.

- September 8, 1943

On "Black Wednesday," Los Angeles, California, experiences a new and more severe type of air pollution, causing eye irritation, decreased visibility, and plant damage. The episode demonstrates for the first time the extent of the health dangers posed by the area's smog.

- 1951

Rachel Carson, often called the mother of the modern environmental movement, publishes *The Sea Around Us*. One of the book's chapters, "The Global Thermostat," describes how the ocean dominates the world's climate and predicts that a tidal effect will recur around the year 2400, causing global warming.

- December 4-8, 1952

A lethal smog blankets the city of London, causing the death of almost 12,000 residents, asphyxiating cattle and other animals, and creating other health problems. The disaster results in the implementation of strict clean-air legislation throughout the United Kingdom.

• 1957
Oceanographer Roger Revelle and geochemist Hans Seuss propose the concept of the greenhouse effect, describing how it would eventually result in global warming.

• June 23, 1961
The Antarctic Treaty System enters into force. The system protects the continent and provides free access to Antarctica for research scientists, enabling them to conduct research that will improve the understanding of climate change.

• 1963
The U.S. Congress adopts the Clean Air Act, which mandates reductions in various atmospheric pollutants. The act is subsequently amended in 1970, 1977, and 1990, with increasingly stringent standards imposed over time.

• May, 1967
Meteorologists Syukuro Manabe and Richard Wetherald publish an article in the *Journal of Atmospheric Studies* describing the results of greenhouse, or global, warming. They conclude that atmospheric temperatures are much more sensitive to carbon dioxide and ozone content than previous studies had indicated. In particular, they predict an increase of about 2° Celsius for the average temperature if the amount of carbon dioxide in the atmosphere is doubled.

• 1968-1973
The Sahel region of Africa suffers a drought that extends the size of the Sahara Desert, ruins the economies of sixteen countries, and causes widespread famine and emigration. This desertification is the result of large-scale climatic change, intense population pressure, and poor land management.

• February 2, 1971
The Ramsar Convention, the first international treaty on environmental conservation, is signed by eighteen nations. The convention initially seeks to conserve wetlands, but its provisions are subsequently expanded to consider the importance of wetlands in global climate change.

• 1972
A team of scientists at the Massachusetts Institute of Technology develops a computer model, World3, containing a complex set of differential equations which models the environmental impacts of human population growth and the global economy. Their book describing this model, *The Limits to Growth*, issues a dire warning about biological productivity, environmental degradation, increasing population growth, and economic activity.

• June 5-16, 1972
The United Nations Conference on the Human Environment, the first global conference on the environment, is held in Stockholm, Sweden. The meeting, which will later be known as the Stockholm Conference, solidifies public opinion regarding the need to address environmental concerns while making the global community more acutely aware of climate change.

• 1974
American automakers introduce the catalytic converter, a device that uses chemical reactions to reduce air pollution from automobile exhaust gases. Although the device helps decrease carbon monoxide, unburned hydrocarbon, and nitrogen oxide emissions, it does not reduce all automobile pollutants.

• June, 1974
F. Sherwood Rowland and Mario J. Molino, physical chemists at the University of California, Irvine, publish an article in *Nature* demonstrating that chlorofluorocarbon gases may be destroying the earth's ozone layer. Their research will earn them and partner Paul J. Crutzen the 1995 Nobel Prize in Chemistry.

• 1977-1978
The western United States experiences a drought.

• March 17, 1978
The U.S. Consumer Product Safety Commission, Environmental Protection Agency, and Food and Drug Administration ban chlorofluorocarbons in aerosol sprays because these chemicals are harmful to Earth's protective ozone layer.

- September 17, 1978

The National Climate Program Act is signed into law. The act creates an interagency program that conducts climate research, provides climate information, and supports policy decisions in the United States.

- November, 1979

The Geneva Convention on Long-Range Transboundary Air Pollution is signed into law. One of the oldest international environmental treaties, the convention addresses air pollution, including greenhouse gas emissions, and creates procedures for gathering and accessing data.

- May 18, 1980

Mount St. Helens in Washington State erupts with a directed blast to the north, moving pyroclastic flows at velocities of 100 to 300 meters per second—nearly the speed of sound.

- June, 1980

Luis Alvarez and others at the University of California at Berkeley publish an article in *Science* presenting the hypothesis that an asteroid impact caused the extinction of the dinosaurs.

- 1982

English climatologist Hubert Horace Lamb publishes his most influential work, *Climate, History, and the Modern World*, which provides the first scientific explanation of how climate works and fluctuates and lays out a research program for studying historical climate change.

- June, 1982-August, 1983

A destructive El Niño episode is held responsible for more than 2,000 deaths and $13 billion in damages and introduces the public to this Pacific Ocean weather phenomenon.

- May 16, 1985

A group of scientists from the British Antarctic Survey publish a research paper based on several years of measurements of the stratospheric ozone above Halley Bay in Antarctica. The researchers note that the total amount of ozone in early spring decreased by almost 50 percent during the previous ten years. Their discovery spurs many other scientists to study the "ozone hole" above Antarctica and ultimately link ozone depletion to increased concentrations of atmospheric chlorofluorocarbons.

- September, 1987

Twenty-four countries sign the Montreal Protocol, a United Nations agreement to phase out substances which damage the earth's ozone layer—the atmospheric shield which protects the planet's inhabitants from dangerous ultraviolet rays.

- November, 1988

The World Meteorological Organization and the United Nations Environment Programme create the Intergovernmental Panel on Climate Change (IPCC). The panel is charged with studying climate change and analyzing its effects on human beings and the environment.

- 1990

The IPCC predicts that greenhouse gases and carbon dioxide emissions produced by human activity could raise world temperatures by 0.28° Celsius each decade.

- June 29, 1990

Representatives of ninety-three nations meet in London and agree to ban production of most ozone-destroying chemicals by the end of the twentieth century.

- June 12-15, 1991

Mount Pinatubo in the Philippines erupts after having been dormant for four hundred years. The eruption kills more than seven hundred people and injects aerosols into the stratosphere that will affect both the earth's ozone layer and global temperatures.

- June 3-14, 1992

The United Nations Conference on Environment and Development is held in Rio de Janeiro, Brazil. Also known as the Earth Summit, the conference produces the United Nations Framework Convention on Climate Change, an international treaty that aims to stabilize greenhouse gas emissions at a level that might prevent dangerous disruption of Earth's climate.

• June 14, 1992
Agenda 21, a comprehensive plan of action to address global carbon emissions, is adopted by 179 nations participating in the Earth Summit in Rio de Janeiro. The plan mandates cooperation at the global, national, and local levels to reduce emissions in industrialized nations and to slow the rate of emission increase in developing countries. Conference participants also create the Rio Declaration on Environment and Development, a series of principles that support Agenda 21 by elucidating the rights and responsibilities of states.

• August 22-26, 1992
Hurricane Andrew strikes southern Florida, leaving fifty dead and $26 billion in damage.

• October 24, 1992
The U.S. Energy Policy Act of 1992 is signed into law. Title XVI of the act establishes mechanisms for monitoring and addressing climate change and global warming.

• April-October, 1993
Heavy rains and unusually high snowmelt cause midwestern rivers to begin rising in the spring. In the summer, unremitting rainfall leads to record flooding on the Missouri and Mississippi Rivers, as well as many major tributaries. The floods are responsible for fifty-two deaths and more than $18 million in damage.

• December 29, 1993
The Convention on Biological Diversity enters into force. The convention aims to conserve the Earth's biological resources, which are threatened by climate change.

• March 21, 1994
The United Nations Framework Convention on Climate Change, the first comprehensive global agreement seeking to control the atmospheric factors which cause global warming, enters into force. The convention establishes a process through which pollution control agreements, such as the Kyoto Protocol, can be created.

• June 17, 1994
The United Nations Convention to Combat Desertification in Those Countries Experiencing Serious Drought and/or Desertification, Particularly in Africa, is adopted by 193 countries. The convention mandates a new approach to combating desertification.

• August, 1994
A severe heat wave and drought parches Japan. Blocks of ice are placed in subway stations so riders can cool their heads.

• 1995
The IPCC predicts carbon dioxide and greenhouse gas emissions will raise Earth's temperatures between 0.8 and 3.3° Celsius within one hundred years.

• March 28-April 7, 1995
The Berlin Mandate is negotiated, establishing a series of international meetings that ultimately will lead to the Kyoto Protocol to the United Nations Framework on Climate Change.

• June-October, 1997
A severe drought in Indonesia, exacerbated by El Niño conditions, delays the autumn monsoon season by two months. In the summer, industrial and subsistence farmers seek to take advantage of this delay; they burn more than the usual amount of land in order to clear it for crops and to increase their profits. These human-caused forest fires rage through the country from June through October, burning millions of hectares, including rain forests. The fires also create smoke that covers Indonesia, Malaysia, Singapore, Thailand, Vietnam, and the Philippines for several months, harming both humans and animals.

• July 25, 1997
The U.S. Senate by a vote of 95-0 adopts the Byrd-Hagel Resolution, declaring that the United States should not agree to limit its greenhouse gas emissions unless developing nations, including China and India, are also required to limit theirs.

• December 1-11, 1997
Representatives of more than 150 nations meet in Kyoto, Japan, to negotiate a protocol committing signatory nations to reduce their production of greenhouse gases over the next fifteen years. A section of this newly created Kyoto Protocol allows countries to collaborate on emissions-reducing projects and to trade and purchase emissions credits.

• January 14, 1998
The Protocol on Antarctic Environmental Protection enters into force. The protocol aims to enhance cooperation among many of the world's countries in order to protect the environment and resources of Antarctica.

• July, 1998
A heat wave hits the southwestern and northeastern United States. Daytime temperatures in Texas hit 43° Celsius, with forty-one days of highs above 38°, causing huge crop losses and 144 deaths.

• July, 1998
Worldwide, July is determined to be the hottest month in history to date.

• August, 1998
India reaches 51° Celsius, causing 3,000 people to die in the nation's worst heat wave in fifty years.

• August, 1998
Record heat in Germany produces severe smog. Cars lacking antipollution devices are banned.

• September 16-29, 1998
Hurricane Georges, with winds exceeding 209 kilometers per hour, strikes in the Caribbean and then the Gulf Coast, leaving 400 people dead.

• October 27, 1998
Hurricane Mitch hits Central America, killing more than eleven thousand people.

• November 11, 1998
The United States signs the Kyoto Protocol; however, in subsequent years, Congress does not ratify the agreement.

• 1999
A major drought strikes the southeastern United States, the Atlantic coast, and New England.

• October 12, 1999
The world's six billionth person is born.

• November 17, 1999
The Scientific Ice Expeditions program, which analyzed decades of data from Arctic Sea ice, reports a significant reduction in the thickness of the ice during the last decade—evidence that the Arctic climate is warming.

• December 22, 1999
The World Meteorological Organization reports that the 1990's were the warmest decade since instrumental measurement started in the 1860's.

• February 23, 2000
The National Climate Data Center reports that Earth has warmed at a rate of 2.2° Celsius in the past twenty-five years—a faster rise than originally predicted.

• May 22, 2000
The U.S. National Oceanic and Atmospheric Administration (NOAA) declares that January through April, 2000, was the warmest period in recorded history.

• August 30, 2000
The World Wildlife Fund reports that one-third of the world's habitat will be lost or dramatically changed due to global warming.

• February 19, 2001
The IPCC reports that the least adaptable and poorest regions of the world will be the most severely impacted by climate change.

• March 26, 2001
Leaders of the European Union write President George W. Bush, seeking his commitment to implement the Kyoto Protocol.

• March 28, 2001
Christine Todd Whitman, head of the Environmental Protection Agency, announces that the United States will not implement the Kyoto Protocol. The announcement draws scorn from environmentalists, scientists, and leaders of many other nations.

• September, 2001
The Greenhouse Gas Protocol, designed to help corporations account for and report greenhouse gas emissions, is published. The protocol, revised in March, 2004, will become more widely used than other similar accounting systems.

• September 4, 2001
Researchers from the National Aeronautics and Space Administration (NASA) report that parts of the Northern Hemisphere have become much greener during the past twenty-one years as a result of rising temperatures. While the data confirm that Russia and Canada will have a longer growing season in which to produce more crops, NASA scientists say the study also indicates an increase in atmospheric carbon dioxide and other greenhouse gases.

• October 4-9, 2001
Hurricane Iris kills thirty-one people and destroys $150 million worth of property in Belize.

• 2002
A severe, long-term drought begins in Australia. Urban areas begin to feel its effects by 2006, as major cities pass heavy restrictions on water usage and Perth constructs a desalination plant.

• February 12, 2002
President George W. Bush proposes a plan that will set goals for the reduction of greenhouse gases based on America's economic growth, while providing companies with incentives to comply with these goals. The plan contrasts with the Kyoto Protocol, which sets tougher mandatory reductions.

• March 19, 2002
British researchers report that an Arctic ice shelf weighing 500 billion tons broke apart in less than a month—the largest single ice shelf retreat in the past thirty years. Scientists describe the speed of the collapse as "staggering."

• May 28, 2002
The U.S. Climate Action Report 2002 is submitted, marking the first time that the Bush administration acknowledges that global warming is influenced by human beings' behavior. The report also acknowledges that unchecked global warming will seriously harm America's environment.

• May 31, 2002
The European Union ratifies the Kyoto Protocol.

• September 4, 2002
Agenda 21 is reaffirmed *(see June 14, 1992)*.

• September 16, 2002
NOAA reports that the average temperature in the United States from June through August, 2002, was 23.3° Celsius, the hottest summer since the Dust Bowl droughts of 1934 and 1936.

• November 7, 2002
In an article in *Nature*, a team of British scientists reports that the wildfires which devastated Indonesia and other parts of Southeast Asia in 1997 released as much as 2.6 billion metric tons of carbon, mostly in the form of carbon dioxide, into the atmosphere—as much carbon as the entire planet's biosphere removes from it in a year.

• July-August, 2003
A heat wave grips all of Europe, especially France, Italy, Spain, and Portugal; as many as 40,000 die from heat-related causes, and drought and wildfires follow.

• September 18, 2003
Hurricane Isabel, a Category 5 storm, makes landfall south of Cape Hatteras, North Carolina, leaving fifty-three dead and property damage of $3.37 million.

• October 21-November 4, 2003
Hot Santa Ana winds fuel at least twelve wildfires stretching from San Diego County north to the sub-

urbs of Los Angeles. Twenty-two people are killed, including fourteen in the 1,137-square-kilometer Cedar Fire—the largest individual blaze in California history. At least 3,450 homes are destroyed.

- 2004

Four Category 5 storms—Charley, Frances, Ivan, and Jeanne—make landfall in the United States, the most in a hurricane season since 1963.

- January 2, 2004

In a report published in *Science*, a team of NASA scientists and other researchers concludes that year-to-year changes in concentration of carbon dioxide and methane can be linked to fire activity associated with the El Niño-La Niña cycle.

- May 28, 2004

The film *The Day After Tomorrow*, a fictional depiction of the advent of a modern ice age, is released, reflecting popular concerns about global warming.

- December 26, 2004

A massive tsunami strikes eleven nations bordering the Indian Ocean, leaving at least 212,000 people dead and almost 43,000 missing.

- February 16, 2005

The Kyoto Protocol enters into force. The protocol sets out clear targets for reducing greenhouse gas emissions, balances national economic development plans with emissions reductions, and sets up free market mechanisms to achieve the targets set by intergovernmental negotiations.

- August 25-September 2, 2005

Hurricane Katrina kills 1,500-2,000 people in Louisiana, Mississippi, Alabama, and Florida and leaves hundreds missing; property damage is estimated at $75 billion. The levees protecting New Orleans are breached, and the city is completely flooded. Two other powerful hurricanes, Rita and Wilma, hit the Gulf Coast shortly afterward.

- December, 2005

In Tehran, Iran, businesses and schools close because of severe smog conditions. Hundreds of people are taken to the hospital.

- December 21, 2005

The administration of California governor Arnold Schwarzenegger begins the lengthy process of obtaining a waiver from the U.S. Environmental Protection Agency to implement standards for state vehicle greenhouse gas emissions which are more stringent than those mandated by federal legislation. Thirteen other states eventually adopt California's tougher emissions standards.

- August, 2006

Former vice president Al Gore publishes *An Inconvenient Truth* and releases a popular film of the same name in which he emphasizes the need to stop global warming in order to prevent the destruction of Earth's natural resources and the accompanying loss of biodiversity.

- October 12, 2007

Gore and the IPCC are awarded the Nobel Peace Prize.

- October 20-November 9, 2007

Flames whipped by Santa Ana winds engulf large portions of Southern California, forcing the evacuation of more than 500,000 people. More than a dozen wildfires burn 1,200 homes and businesses and set fire to about 1,000 square kilometers.

- December 3-14, 2007

Participants in the United Nations Climate Change Conference in Bali, Indonesia, establish a time line for future negotiations aimed at reducing global warming.

- February 7, 2008

The Center for Biological Diversity petitions the U.S. Fish and Wildlife Service to protect the Pacific walrus under the federal Endangered Species Act, arguing that the marine mammal is threatened by global warming and the growth of oil and gas development in its habitat. When the service refuses to process the petition, the center files suit to compel the federal agency to consider its request.

- May 14, 2008

The U.S. Department of the Interior lists the polar bear as a threatened species under the Endangered

Species Act based on evidence that the bear's sea ice habitat is shrinking and will likely continue to shrink during the next several decades.

- March 29-April 8, 2009

Delegates from 182 countries meet in Bonn, Germany, to begin negotiating a successor treaty to the Kyoto Protocol. Additional negotiating sessions will be held in Bonn on June 1-12 and August 10-14; in Bangkok, Thailand, on September 28-October 9; and in Barcelona, Spain, on November 2-6. The negotiators' efforts will culminate in the United Nations Climate Change Conference in Copenhagen, Denmark, on December 7-18.

- May 18, 2009

A federal judge in Anchorage, Alaska, requires the U.S. Fish and Wildlife Service to consider if the Pacific walrus should be protected under the Endangered Species Act. The requirement is part of a settlement between the agency and the Center for Biological Diversity, which is seeking protection for the marine mammal. Under the agreement, the service must make an initial finding on the center's petition for protection by September 10, 2009, and in 2010 must decide if the walrus should be listed as an endangered species.

- May 19, 2009

President Barack Obama announces a plan to raise fuel-economy standards to an industry average of 35.5 miles per gallon in 2016, an increase of more than 8 miles per gallon per vehicle. He estimates these standards will save 1.8 billion barrels of oil over the lifetime of vehicles sold in the next five years.

- May 21, 2009

By a vote of 33-25, the House Energy and Commerce Committee passes the Waxman-Markey climate and energy bill, also known as the American Clean Energy and Security Act—the first time a serious climate-change bill has progressed this far in the legislative process. The bill aims to cut greenhouse gas emissions by roughly 17 percent below 2005 levels by 2020, and by about 80 percent by 2050, while promoting renewable energy and energy efficiency.

- June 16, 2009

NOAA releases a new study, *Global Climate Change Impacts in the United States*, which confirms previous evidence that the global temperature changes in recent decades are created by human activity. Among its findings, the report predicts that heat waves will occur more frequently and will be more intense in the future, increasing threats to human health, transportation, energy, crops, and livestock. The study also predicts the warming climate will increase the number of wildfires and insect infestations, as well as leading to increased rainfall and flooding.

- December 7-18, 2009

The United Nations Climate Change Conference is held in Copenhagen, Denmark.

Glossary

abatement cost: cost incurred when reducing a nuisance such as pollution
accretion: the final process of planetary formation, in which smaller objects are pulled into the nascent planet
***acqua alta*:** flooding; Italian for "high water"
ad hominem argument: an attempt to discredit an idea by discrediting the person espousing it
adaptation: the process through which entities adjust in response to external circumstances
additive processes: human activities that build or enhance Earth's surface topography
aerobic: occurring in or requiring the presence of oxygen
aerodynamic: designed to minimize drag from the air
aerosols: minute particles or droplets of liquid suspended in Earth's atmosphere
afforestation: the creation of new forests on previously unforested land
agricultural drought: lack of sufficient soil moisture for crop growth, leading to partial or total loss of yield
agricultural revolution: the advent, about ten thousand years ago, of human domestication and cultivation of plants and animals and the reorganization of social and economic structures that resulted
ahermatypic corals: non-reef-forming corals
air parcel: a theoretical, house-sized volume of air that remains intact as it moves from place to place
air pollution: anthropogenic or natural degradation of air quality
air quality: atmospheric purity, as measured by the relative concentrations of contaminants, toxins, and other potentially harmful trace elements
Air Quality Index (AQI): a numerical index used to report air pollution and hazard levels to the public
aircraft emissions: gases and particulate matter expelled from aircraft engines
albedo: the fraction of radiation reflected by a surface
algae: a class of predominantly aquatic plants and plantlike organisms
algal bloom: a sudden explosion in the algae population in a given body of water or a localized portion of a body of water; blooms deplete oxygen, killing fish, and they can be caused by chemical fertilizers or other nutrients carried in runoff water
alluviation: soil erosion that results in the filling of watercourses or harbors
alpine glaciers: large masses of ice found in valleys, on plateaus, and attached to mountains
alternative energy or fuels: fuels and other energy resources that are renewable, nonpolluting, or both and have the potential to replace fossil fuels and other traditional energy resources
anaerobic: occurring in, or requiring, the absence of oxygen
anecdotal evidence: isolated instances illegitimately used to establish a logical principle or general rule
Annex A: an annex to the Kyoto Protocol listing the six GHGs covered by the agreement: CO_2, methane, nitrous oxide, hydrofluorocarbons, perfluorocarbons, and sulfur hexafluoride
Annex B: an annex to the Kyoto Protocol that specifies the GHG reduction targets for Annex I nations and establishes a credit trading system to help them reach those targets
Annex I: an annex to the United Nations Framework Convention on Climate Change that lists the industrialized nations that are parties to the convention; these nations are committed to achieving significant GHG emissions reductions by a certain date, while developing-nation parties are not listed in Annex I and are not committed to achieving such reductions
annular mode: a pattern of change in atmospheric circulation biases that corresponds to changes in the midlatitude westerlies
anomaly: a phenomenon that is outside the realm of normal, predictable occurences in a given context or a datum that fails to fit easily into the data set of which it is a part
anthropocentric: treating human beings and human concerns as the primary source of value
anthropogenic: caused by human activity

anthropogeomorphology: changes to the surface of the Earth brought about intentionally or unintentionally by humans

aqueduct: a human-made channel or pipe that carries water for consumption or industrial or agricultural use

aquifer: a layer of sand, gravel, or permeable rock containing water

Arab oil embargo: a 1973 action by Middle Eastern oil-producing states to stop exporting oil to the United States and other supporters of Israel

archaeological record: the human-made objects and residues of the past that are used to reconstruct history

arid climate: a dry climate in which rainfall is so sparse as to make agriculture difficult or impossible without irrigation

assigned amount units: the GHG emission allowances of Annex I parties

asthenosphere: the ductile layer of the Earth, beneath the lithosphere, defined by mechanical behavior; although solid, it deforms horizontally over tens of millions of years

astronomical forcing: climatic change triggered by changes in solar luminosity, variation in the Earth's orbit, and bolide impact

Atlantic Multidecadal Oscillation: a pattern of cyclical increases and decreases in Atlantic sea temperatures that last for decades

atmosphere: the envelope of gases surrounding a planet

atmospheric chemistry: the chemical composition of and reactions occurring within an atmosphere

aurora: glow released by gases in the upper atmosphere when they are bombarded by charged solar particles

barrier island: an island that runs parallel to a nearby coastline and that protects the coastline from storm surges

base year: a year that is used to set baseline measurements of emissions or other phenomena in order to compare future variations or to determine target levels

baseline: a selected norm from which phenomena deviate

bayou: a small, often intermittent, branch of a river

behavioral economics: the study of the combined economic and psychological principles affecting human behavior and decision making

biocentric: treating all living things as equal in value and as more important than nonliving things

biodiesel: plant-derived oil that can be used to power diesel engines

biodiversity: the total variation within and among all species of life in a given area, ecosystem, or context

biofuels: energy sources derived from recently dead organisms, most commonly plants

biomass: plant and other organic materials that can be used as fuel

biome: a major biological community adapted to a particular climate or area

biosecurity: measures required or taken to protect organisms from risk or danger

biosphere: the totality of Earth's living organisms and ecological zones

biotechnology: techniques and devices that use living organisms to achieve human goals

bloggers: people who publish information or commentary in regularly updated journals or columns on the World Wide Web

brackish: of water, having an intermediate level of salinity, between 5 and 35 parts per thousand

brine rejection: expulsion of salt from freezing seawater, increasing the salinity of the liquid seawater and decreasing the salinity of the forming sea ice

calcium carbonate: a compound of carbon and calcium that forms part of the bodies of small marine organisms, in which carbon may be sequestered

calving: the separation of a large portion of ice from a glacier or ice shelf, creating an iceberg

canopy: the upper layers of vegetation or uppermost levels of a forest where energy, water, and greenhouse gases are actively exchanged between ecosystems and the atmosphere

cap and trade: a system in which a limit is set on the total permissible emissions of a pollutant or class of pollutants and permits to emit a specific amount of pollution are distributed; those permits are then treated as commodities that may be sold or traded

capitalism: an economic system in which the means of production are privately owned and operated with the goal of increasing wealth

capture: to secure and contain harmful substances or contaminants

carbon budget: the total amount of CO_2 emissions that can be sustained, given a target atmospheric CO_2 concentration, and the way in which those emissions are apportioned

carbon-capture-and-storage (CCS) systems: processes that remove CO_2 from combustion products and sequester it—typically in underground storage

carbon cycle: the set of processes through which carbon atoms circulate among Earth's atmosphere, terrestrial biosphere, oceans, and sediments

carbon dioxide (CO_2): a greenhouse gas produced by burning fossil fuels, respiration, and other natural and anthropogenic processes

carbon dioxide equivalent (CO_2e): an expression of a given quantity of GHG's contribution to the greenhouse effect as a function of the amount of CO_2 that would have the same effect

carbon fixation: the conversion of CO_2 into organic molecules through such processes as photosynthesis or calcification and the sequestration of those molecules within living systems

carbon footprint: a measurement of the annual GHG emissions attributable to a specific entity, meant to express the detrimental effects of that entity's actions on the environment

carbon neutrality: the quality of neither subtracting from nor adding to the amount of carbon in the atmosphere

carbon sequestration: removing CO_2 from the atmosphere and storing it, or the carbon atoms within it, somewhere else

carbon sink: an entity that absorbs and stores carbon, thereby removing CO_2 from the atmosphere

carbon tax: a tax on activities that directly or indirectly produce CO_2 emissions

carrying capacity: the maximum population that can be supported indefinitely with the available resources and services of a given ecosystem

catalytic converters: devices that reduce vehicular carbon monoxide exhaust by converting it into carbon dioxide

certified emissions reduction (CER): a unit of GHG reduction, equivalent to 1 metric ton of CO_2e in emissions reduced through the clean development mechanism; CERs may be used to fulfil Annex I nations' obligations under the Kyoto Protocol and may be traded as commodities between nations

chinook/foehn wind: a warm, dry wind that blows on the eastern side of the Rocky Mountains or the Alps

chlorofluorocarbons (CFCs): compounds of chlorine, fluorine, and carbon, popularly known by the trade name Freons

Clean Air Acts: a set of federal laws, passed between 1963 and 1990, that form the basis for the United States' air pollution control efforts

clean development mechanism: a mechanism of the Kyoto Protocol wherein Annex I countries sponsor GHG reduction projects in developing nations in order to earn certified emissions reductions, which they can use to fulfill their treaty obligations or sell to other countries that are in need of credits

climate: long-term, average, regional or global weather patterns

climate canaries: the first victims of world climate change, whose plight serves as an early warning to others

climate change: a lasting, significant change in the average weather of a given area

climate change scenario: a projected set of changes in average weather patterns based on a hypothetical set of changes in meteorological and climatological inputs; used to predict the most likely results of various possible occurrences

climate control: the relatively permanent factors that govern the general climate of a region

climate feedback loops: self-reinforcing and self-negating processes that accelerate or retard climatic trends

climate fluctuations: changes in the statistical distributions used to describe climate states

climate impact: the effects of climate and climate change on the socioeconomic well-being of an area

climate impact statement: an empirical case study designed to help predict future climate impacts

climate normals: averages of a climatic variable for a uniform period of thirty years

climatic envelope: the range of temperatures, precipitation, and other climatic parameters to which a given species has adapted

climatic oscillation: a fluctuation of a climatic variable in which the variable tends to move gradually and smoothly between successive maxima and minima

climatic precession: cycle of variations in the Earth-Sun distance at summer solstice

climatic trend: a climatic change characterized by a smooth, monotonic increase or decrease of the average value in the period of record

climatic variable: a specific, measurable quantity related to climate, such as annual rainfall, night-time temperature, or average humidity

cloud condensation nuclei: atmospheric particles such as dust that can form the centers of water droplets, increasing cloud cover

Coase theorem: assertion that when property rights are properly defined, people are forced to pay for the negative externalities they impose on others and market transactions will produce efficient outcomes

coefficient of performance: a standard measurement of energy efficiency

combustion: the burning of fuels to produce energy

commodity: anything that has commensurable value and can be exchanged

community: a group of people who live and interact within a specific geographic or social sphere

complex interdependence: a situation in which intensive interconnections between transnational actors necessitate cooperation among those actors

compressed air: air that is forced into a small space under high pressure

condensation: the transformation of a substance from its gaseous to its liquid state

congestion charge: a tax levied for driving in the urban core of a large city

conservation: the perpetuation through sustainable use of renewable resources and the development and wise utilization of nonrenewable resources

conservation tillage: practices designed to leave stubble and other crop residues on the land surface to reduce soil erosion and surface runoff

conspiracy: a secret effort by a group to achieve a (usually illegitimate) purpose

conspiracy theory: a theory that some event was engineered by a covert group or that seemingly unrelated entities are secretly working in the service of a common agenda

contiguous zone: area between 22.2 and 44.4 kilometers from a nation's coastline within which the nation enjoys partial but not full sovereignty

continental crust: the uppermost layer of the Earth, granitic in composition, with a density of about 2.7 metric tons per cubic meter

continents: large sections of a planetary surface that are above water and composed largely of low-density rock

convection: motion in a fluid (or atmosphere) that results in the transport and mixing of the fluid's physical properties, such as heat

coral: a colony-forming cnidarian organism that excretes a calcium carbonate exoskeleton

coral atoll: an island or islet composed of a lagoon encircled wholly or partly by a coral reef

coral bleaching: whitening of coral that occurs when it expels a single-celled, symbiotic algae as a result of environmental stress

Coriolis effect: the deflection of moving objects caused by Earth's rotation

cosmic rays: energetic particles bombarding Earth's atmosphere

cosmogenic isotope: an isotope produced when a cosmic ray strikes the nucleus of an atom

coupled atmosphere-ocean models: computer simulations of alterations in and interactions between Earth's atmosphere and oceans

cover crops: domesticated plants grown to cover the land surface for the purpose of managing soil fertility, soil quality, water, weeds, pests, diseases, diversity, or wildlife

crisis: a potential turning point to the worse in a difficult situation

criteria air pollutant: an air pollutant for which acceptable levels of exposure can be determined and ambient air quality standards have been set

crust: the upper portion of the Earth's surface—about 7 to 10 kilometers thick in the oceans and about 25 to 70 kilometers thick on the continents

cryosphere: the portion of the Earth's surface that is composed of frozen water, including snow, glaciers, ice caps, and ice sheets

cyclone: a storm system that rotates about a low pressure area

dangerous climate change: a shift in which a meteorological event that had been occurring only once every one hundred years begins to occur once every ten years

dead zones: areas of deepwater oxygen depletion, in which fish cannot survive, caused by surface algal blooms or disruption of thermohaline circulation

decay constant: a measure of how radioactive an isotope is, determined with a Geiger counter

deforestation: the process by which areas are stripped of forests and tree cover, exposing the underlying soil to erosive forces

delta: a network of distributaries flowing through deposited sediments at the mouth of a river

desalination: removal of soluble salts from water, usually to make it potable or suitable for irrigation

desert: an arid ecosystem in which water resources are unusally scarce

desert climate: a hot climate characterized by extremely low and sometimes deficit amounts of precipitation

desertification: the gradual transformation of habitable land into desert by climate change or destructive land use

detritus: the residue left behind by decay or disintegration

developing nations: poor, incompletely industrialized, primarily agricultural or island nations

dew point: the temperature at which water vapor condenses into liquid water

direct action: nonconventional, confrontational political activity, including protests, demonstrations, and civil disobedience

disability-adjusted life years (DALYs): a time-based quantitative measure of the burden of disease in a population that combines years of life lost to premature mortality and years of life lost to poor health or disability

disaster: a drastic disruption in the functioning of a system

discount rate: the present economic cost of preventing future harms, expressed as a percentage of the future economic cost of allowing those harms to occur

distillation: use of evaporation and condensation to remove solutes from a liquid

distributary: a branch of a river that removes water from the main river, especially near or in a delta

dormancy: the portion of the year during which no growth occurs

drag: friction caused by air as an object passes through it

drainage basin: an area bounded by a continuous and topographically higher divide where water from precipitation drains downhill into a body of water

drought: an extended period of months or years when a region experiences a deficiency in its water supply

dune mobility index: a measure of potential sand mobility as a function of the ratio of the annual percentage of the time the wind is above the sand transport threshold and the effective annual rainfall

Dust Veil Index: a numerical index that quantifies the impact of a volcanic eruption's release of dust and aerosols

dystopia: a fictional world in which living conditions are extremely bad; the opposite of a utopia

easterlies: the prevailing winds in the low latitudes, including the trade winds

ecological niche: the relational position of a species in an ecosystem with respect to all other species, resources, and physical and chemical factors affecting life and reproduction within that ecosystem

economic interdependency: a state of affairs in which the economic processes of a group of nations are mutually dependent

ecosystem: all living organisms within an area, as well as the nonliving area's environment, understood as a coherent functioning unit

ecosystem services: all living and nonliving aspects of an ecosystem that function to sustain life within the ecosystem

ecotage: ecologically motivated sabotage

ecoterrorism: acts of violence against anti-environmental interests, designed to protect the environment from harm

El Niño: weather phenomenon that sends an influx of nutrient-poor, warm water into the normally cold, nutrient-rich surface waters off the coast of Ecuador and Peru

El Niño-Southern Oscillation (ENSO): the combined and related phenomena of El Niño effects in the Pacific Ocean and shifts in sea-level air pressures between the eastern and western Pacific

electric cars: automobiles run completely on electricity, without the need to burn fuels

emission charge: a fixed-rate tax calculated per unit of emissions

emission credits: purchasable shares in an emission-reducing project that are used to measure attempts by an entity to offset its GHG emissions

emission reduction unit (ERU): a unit of credit used to measure the amount of GHG emissions reduced by a joint implementation project under the Kyoto Protocol

emission scenario: a set of posited conditions and events, involving climatic conditions and pollutant emissions, that is used to project future climate change

emissions: gases and particulates released into the atmosphere

emissions trading: a practice in which the right to pollute is turned into an exchangeable commodity, motivating polluters to reduce their emissions so they can profit by selling their rights to others

emissivity: a measure of the ability to radiate absorbed energy

empirical: based on experiential observation

endangered species: a species that is in danger of extinction throughout all or a significant portion of its habitat range

energy: the capacity to do work

energy balance: the equilibrium state of all energy entering and leaving a system, such as the Earth

energy efficiency: the proportion of expended energy that drives work, as opposed to the proportion that is dissipated as waste heat

energy from waste: energy produced from waste materials and substances

energy independence: the ability of a nation to generate energy sufficient for its needs domestically, without relying on foreign imports

energy-intensive: using an unusually large amount of energy, usually in the service of industrial processes

energy resources: the raw materials necessary to produce energy, such as fossil fuels, a waterfall, or a region that enjoys abundant sunlight

enhanced greenhouse effect: increased retention of heat in the atmosphere resulting from anthropogenic atmospheric gases

environmental refugees: people forced to leave their homes by climate change or other environmental disasters

environmental terrorism: violent acts intended to harm the environment or deprive people of environmental benefits or resources

equilibrium: a condition in which all directly competing forces in a system are balanced, resulting in the stability of the system

erosion: the removal or wearing down of solids by wind or water

ethanol: ethyl alcohol, a product of fermentation that can be used as a biofuel

ethics: the application of moral philosophy or principles to real-world decision making

eukaryote: an advanced cell, containing a nucleus and other membrane-bound organelles

evangelical: pertaining to proselytizing Protestants who emphasize individual salvation through faith and place what they consider scriptural authority above church tradition

evaporation: the transformation of a substance from its liquid to its gaseous state

evapotranspiration: the set of processes through which water on surfaces or in plants is lost to the atmosphere

exclusive economic zone (EEZ): a zone extending from a nation's coast up to 370, or even 650, kilometers that is considered that nation's sole legal preserve to regulate and exploit economically

exotic species: a species found in an area where it is not native

extinction: the total disappearance of a species from the Earth

extinction event: an unusually large number of extinctions occurring in a relatively short period of time

extraction: removal of a resource from its natural location

extratropical cyclone: a cyclone originating and subsisting outside the tropics

extreme ultraviolet radiation (EUV): electromagnetic radiation with wavelengths between 10 nanometers and 120 nanometers

extreme weather events: major, potentially damaging weather occurrences, such as hurricanes, snowstorms, or floods

fallacy: a false belief or an argument that looks superficially convincing but is based on logical errors

falsifiability: the ability of a scientific theory to be tested experimentally and disproved with data

feedback: a process in which a change to a system renders that system either more or less susceptible to further changes; positive feedback accelerates changes to and destabilizes the system, whereas negative feedback decelerates changes to and stabilizes the system

fermentation: the biochemical generation of energy from organic compounds in the absence of oxygen

fertilization: a process that increases plant growth, either intentionally through the addition of nutrients to soil or unintentionally through an increase in atmospheric CO_2 concentration

filtration: separation or removal of contaminants from emissions

firn: the intermediary stage between snow and ice

fission, nuclear: the splitting of a heavy nucleus (such as in a uranium atom), accompanied by the release of a relatively large amount of energy

flexible-fuel engine: a motor vehicle engine that is capable of burning more than one type of fuel

flood: the overflowing of a body of water, causing some water to leave it and pour onto land

flux: a shift or flow of energy or matter from one location to another

foehn: *see* chinook/foehn wind

forebulge: an elevated area just beyond the area depressed by an ice sheet

forest clearing: destruction of forests in order to create land suitable for human habitation or use

fossil fuels: carbon-based fuels derived from decayed plants and animals under geologic pressure over millions of years

freedom of the seas: the principle that, outside the water adjoining nations' shorelines, all nations have the right of free passage and use of the ocean's resources

Freon: trade name for CFCs made by DuPont chemical company

Fresnel lenses: small plastic sheets with very small, patterned, concentric circles stamped or milled into them that concentrate sunlight

fuel: an energy source that is burned to release energy

fuel alternative: an energy source that does not require burning and may be used in place of fossil fuels

fusion, nuclear: the combination of two light nuclei to produce a heavier nucleus

gasoline: a fuel, refined from oil, that is used to power automobile and other engines

generator: a mechanical device whose rotational movement around magnets produces an electrical current

geoengineering: the intentional production of large-scale changes to the Earth in order to promote human welfare

geomagnetic storm: magnetic activity caused when charged particles from solar flares strike Earth's magnetic field

geomorphology: the form and shape of Earth's surface features

geostrophic current: a current driven by horizontal gradients in pressure that are balanced by the Coriolis effect

geothermal energy: energy from heat stored in or generated by the Earth

glacial fluctuations: advances and retreats of glaciers in response to warming and cooling of the climate

glacial ice: ice created by the compression of snow into glaciers

glacial isostatic adjustments: vertical motions of Earth's crust to restore it to preglacial elevations

glaciation: the advance of a continental ice sheet

glacier: a mass of ice that flows downhill, usually within the confines of a former stream valley

global climate change: change in Earth's temperature and precipitation patterns over time

global cooling: lowering of the Earth's atmospheric and oceanic temperatures over time

global dimming: a reduction in the amount of sunlight reaching the surface of the Earth

global radiative equilibrium: the state of balance between solar radiation reaching Earth and radiation returned to space

global warming: increase of Earth's atmospheric and oceanic temperatures over time

global warming potential: the climatic impact of a given mass of greenhouse gas, measured as a function of the impact of the same mass of carbon dioxide

globalization: the worldwide expansion and consequent transformation of socioeconomic interrelationships

gradient: the differential between two values, such as temperatures or salinity levels

Great Climate Shift: a sudden shift of global climate in 1977, ending thirty years of global cooling and beginning a period of global warming

green politics: a political orientation founded upon environmental concerns

Green Revolution: a dramatic increase in global food production brought about by the development of new strains of wheat, rice, and corn around 1960

greenhouse effect: a phenomenon in which atmospheric gases act like glass in a greenhouse, allowing ultraviolet solar radiation to reach the ground but trapping infrared terrestrial radiation and heating the planet

greenhouse gases (GHGs): atmospheric gases that trap heat within a planetary system, preventing it from escaping into space

greening: process of becoming more environmentally conscious or responsible, as in the greening of industry

greenwashing: the exploitation and appropriation of environmental concerns and issues by corporations, government agencies, and political operatives to advance self-interested agendas

groundwater: water stored beneath the land's surface

groundwater table: the upper surface of the underground zone that is saturated with water

growing season: the portion of the year during which photosynthesis occurs in a given location

Gulf Stream: the warm current originating in the Gulf of Mexico that travels along the U.S. east coast before turning east to cross the Atlantic Ocean

gyre: a massive ocean-circulation system that flows in a circular pattern around the center of an ocean basin

habitat: the area normally inhabited by a particular species

Hadley circulation: an atmospheric circulation pattern in which a warm, moist air ascends near the equator, flows poleward, descends as dry air in subtropical regions, and returns toward the equator

half-life: the time needed for half of a quantity of a radioactive isotope to decay

halocarbons: a general family of compounds that includes chlorofluorocarbons, hydrochlorofluorocarbons, hydrofluorocarbons, and other molecules in which carbon bonds with halogen atoms

halocline: a gradient of sea salinity, usually vertical

halon: a compound containing bromine, carbon, chlorine, and fluorine

hazardous: poisonous, corrosive, flammable, explosive, radioactive, or otherwise dangerous to human health

heat: the energy, associated with molecular and submolecular motion, that flows from bodies with higher temperatures to bodies with lower temperatures

heat flow: the rate at which thermal energy flows through a surface

heat wave: an extended period of abnormally high temperatures

herbicides: substances or preparations for killing plants

hermatypic corals: reef-forming corals

high-level waste: extremely radioactive fission products and transuranic elements such as plutonium

Holocene: the current interglacial, which began 11,700 years ago

Hubbert's peak: the point at which the rate of production or extraction of an energy resource ceases to increase and begins to decrease

hurricane: a cyclone originating in the tropics
hybrid vehicles: automobiles that run on more than one power source, such as electric batteries and fuel-burning engines
hydroelectric power: electricity generated by moving water in turbines
hydrogen engines: engines that run either on hydrogen-oxidizing fuel cells or on hydrogen combustion
hydrologic cycle: the continuous circulation of solid, liquid, and gaseous water among the oceans, atmosphere, and continents
hydrologic drought: significantly below average water levels in lakes, rivers, reservoirs, and aquifers

ice age: a period during which sea ice and glaciers cover a significant fraction of Earth's surface
ice cap: a domed body of ice covering a highland; smaller than an ice sheet
ice cores: cylindrical samples of ice taken from glaciers or ice caps that provide proxy data relating to past atmospheric compositions
ice sheet: a mass of ice covering a large area of land; larger than an ice cap
ice shelf: a floating body of ice extending from a coast and often attached to an ice sheet
igneous rocks: rocks formed by the crystallization of magma or lava
incinerator: a facility used to burn waste until it is reduced to ash
indigenous: native to a given place
indirect aerosol effect: formation of water droplets in clouds caused by particulate matter
individualization of responsibility: placing responsibility for climate change on individuals rather than on businesses, corporations, or the government
industrial: related to large-scale manufacturing or energy production
Industrial Revolution: the eighteenth and nineteenth century mechanization of mining, manufacturing, and agriculture that transformed national economies
industrialization: development and dissemination of mechanical, mass-production technologies
inefficiency: preventable waste in the use or distribution of resources
infiltration: the process of water on the Earth's surface entering soil
infrared radiation: heat energy transmitted as longwave electromagnetic radiation
inner core: the innermost layer of the Earth, extending from 5,150 kilometers to 6,370 kilometers below the ground and composed mostly of solid iron
insolation: radiant energy received by the Earth from the Sun, or the process of receiving such energy
instability: a state in which one or more normally constant, essential features of a system are in flux
integrated gasification combined cycle (IGCC) systems: electric power generation technology that converts coal to combustible gas before burning it
Inter-Tropical Convergence Zone (ITCZ): a meandering zone of convergence of the northeast and southeast trade winds adjacent to the equator
intercropping: the cultivation of two or more crops simultaneously on the same field
intergenerational equity: relative equality of treatment between present and future generations, including the obligation of present generations to preserve limited resources for the future
interglacial: the warm period between glaciations
Intergovernmental Panel on Climate Change (IPCC): a group of scientists charged by the United Nations to compile data on past, present, and likely future changes in Earth's climate
internal combustion engines: engines that burn fuel in a chamber to generate force
international waters: ocean waters lying beyond the full or partial jurisdiction of any nation and considered open to all nations for all legitimate, nonbelligerent purposes
invasive species: a species whose population grows out of control and negatively affects other species
irrigation canal: a human-made channel or pipe that carries water for consumption or industrial or agricultural use
isotopes: variants of an element that are chemically identical but have different atomic mass numbers and vary in radioactivity

joint development: a system in which Annex I countries can earn certified emissions reduction credits by working on clean development mechanism projects in economically transitional nations, generally one of the former Soviet or Balkan nations

junk science: faulty science that attacks established scientific findings or advances poorly supported theories for a practical goal

Köppen climate classification system: a system for classifying climate based mainly on average temperature and precipitation

Kyoto Protocol: a 1997 international treaty in which industrialized signatories made legally binding commitments to reduce their GHG emissions

La Niña: an ocean-circulation pattern that cools the Pacific Ocean west of Peru, affecting world weather

laissez-faire economic policy: an antiregulation policy that allows markets to operate free of government interference

land management: the oversight and planning of land use and development

land reclamation: modification of unsuitable land to restore it or otherwise make it useful for human projects

land rehabilitation: restoration of land that has suffered environmental degradation

landfill: a site where municipal or industrial wastes are buried in the ground

lapse rate: the rate at which an atmospheric variable changes as altitude increases

late heavy bombardment: a period, about 3.9 to 4.0 billion years ago, when Earth was pummeled by debris from space at one thousand times the normal rate, heating the atmosphere and melting the crust

latent heat: the heat released or absorbed by a change of state, such as condensation or evaporation

latent heat flux: the flux of thermal energy from land surface to the atmosphere that is associated with the evaporation and transpiration of water from ecosystems

latitude: the distance of a point on Earth from the equator, measured in degrees of the planet's curvature

leakage: the shortfall in targeted greenhouse gas emissions reduction caused by industries relocating to jurisdictions with weaker regulation

legal standing: eligibility to bring a civil lawsuit in a specific case, usually as a result of suffering damages

levee: a natural or human-made raised bank along a river

limnetic zone: the upper layers of open ocean through which light penetrates and which thus support photosynthesis by planktonic organisms

lithium-ion batteries: long-lasting, lightweight batteries made from lithium

lithosphere: the solid part of the Earth, comprising Earth's crust and the rigid part of its upper mantle

litigation: disputes in court between parties regarding the meaning and execution of laws

Little Ice Age: a time of drastic global cooling from about 1300 to 1900 that resulted in famines, population migration, glacier expansion, and significant environmental changes

loess: deposits of very fine grained, wind-blown material often associated with glacial deposits

longitude: the distance of a point on Earth from the prime meridian, measured in degrees of the planet's curvature

low Earth orbit (LEO): an orbit situated between 160 kilometers and 1,600 kilometers above Earth's surface

luminosity of Sun: the total energy output of the Sun every second, measured in watts

magma: molten rock and suspended crystals below the Earth's surface

magnetic field: the flow patterns of magnetism that surround a celestial body as a result of an electro-dynamo effect

mainstream media (MSM): an often derogatory term for major journalistic media outlets, including major television networks and newspapers

mantle: the layer of the Earth beneath the crust, peridotite in composition, with a density of about 3,400 kilograms per cubic meter

marine isotope stage: half of a glacial cycle, as identified in the oxygen isotope data from ocean cores; advances are given even numbers, and retreats are given odd numbers

market benefits: positive effects of a given climate policy on production and trade, including prevention or mitigation of damages

mass balance: the difference between the accumulation of snow and the ablation of ice on a given glacial formation

Maunder Minimum: a period from about 1645 to about 1715 when very few sunspots were observed

maximum achievable control technology (MACT) standards: standards designed to limit air pollution from stationary sources (usually heavy industries)

media: all available mass-distributed information sources, from news outlets to books and films

media bias: valuations made or endorsed by mass mediated information sources that are supposed to strive for objectivity

Medieval Warm Period: a time period from around 800 to 1250 when European and possibly global temperatures were generally warming

megacity: an urban area with a total population in excess of 10 million people

megadrought: a drought lasting for years, decades, or centuries, often leading to permanent changes in ecosystems and human societies

megalopolis: a megacity that sprawls over a large area, rather than being concentrated spatially in the manner of traditional cities

meteorological drought: prolonged deficiency of precipitation in an area, as compared to the historical average

methane (CH_4): a gas, the primary component of natural gas, whose greenhouse effect is considerably stronger than that of CO_2

methane hydrates: small bubbles of natural gas trapped in a crystalline ice matrix

microalgae: photosynthetic microorganisms similar to plants

migration: the movement of people and other entities from place to place

Milanković cycles: recurring time periods during which the shape of the Earth's orbit, the tilt of its axis, and the occurrence of its furthest distance from the Sun all change

millennium development goals (MDGs): a set of objectives for economic development adopted by the United Nations in 2000

model: a simplified representation of a complex system used to determine causal relationships and predict future outcomes within the system

monsoon: a seasonal shift in prevailing wind, often associated with significant rainfall

Montreal Protocol: a 1987 international agreement to phase out the manufacture and use of ozone-depleting chemicals

mortality and morbidity: statistics on death and illness in population groups

multiproxy reconstruction: a method of estimating prehistoric climate conditions using a combination of proxy indicators

municipal solid waste (MSW): the trash, refuse, and garbage thrown away from homes and commercial establishments

national action plan: formal plan submitted by a national government to take measures to limit or mitigate the nation's contribution to climate change

National Ambient Air Quality Standards (NAAQS): standards established by the EPA that limit acceptable outdoor air pollution levels throughout the United States

natural climate cycles: alternating global warming and cooling patterns that occur for non-anthropogenic reasons

natural succession: changes in the types of plants that grow in an area over time, starting with grasses and moving through shrubs to trees

Navier-Stokes equation: an equation describing the flow of air (or any other fluid)

negative externality: a situation in which market prices do not reflect the full social costs of some behavior

neoliberalism: school of economic thought that stresses the importance of free markets and minimal government intervention in economic matters

niche: the role of a species within its ecosystem

nissology: the study of islands

nonmarket benefits: positive effects of a given policy on health, social and psychological welfare, and other attributes that are not primarily economic

nonrenewable resource: a resource that, once consumed, cannot be reproduced

North Atlantic drift: a current that diverges from the Gulf Stream, moving warm water northward to areas where it will cool and sink

ocean-atmosphere coupling: the interaction between the sea surface and the lower atmosphere that drives many patterns and changes in Earth's weather systems

ocean basins: large sections of an earthlike planet's surface that have low elevations and higher-density rocks

oceanic rise: linear mountain chains on the ocean floors in which lithosphere is formed by crystallization of magma or volcanism

offsetting: the practice of supporting GHG-reducing efforts elsewhere in order to mitigate the effects of one's own emissions

oil embargo: a refusal on the part of oil-producing nations to sell oil to other nations

oil shale: a fine-grained, sedimentary rock rich in oil, gas, and solid tarlike substances

orbital eccentricity: cyclically variant deformities in a planet's orbit

organic matter: carbon-containing compounds produced by life processes

orographic: triggered by or pertaining to topographic features

orographic barrier: a mountain or a hilly area that acts as a control on the climate on either side

orographic precipitation: precipitation caused by changes in topography that drive air higher, where it cools and condenses

outer core: a liquid layer of the Earth, extending from the base of the mantle at a depth of 2,900 kilometers down to the inner core, at a depth of 5,150 kilometers, and composed mostly of molten iron

ozone: a highly reactive molecule consisting of three oxygen atoms

ozone hole: an area of diminished ozone in the ozone layer

ozone layer: a stratospheric region containing relatively high concentrations of ozone that prevents much potentially harmful ultraviolet solar radiation from reaching Earth's surface

Pacific Decadal Oscillation (PDO): a cycle of decadal changes in Pacific sea surface temperatures between warm and cool modes in the eastern Pacific

paleoclimates: climates of the past for which there are no records of direct, scientifically accurate measurements

paleoclimatology: the study of past climates

palynology: the study of relict pollen from ancient pollen traps

parameterization: the approximation of processes

Pareto optimum: a situation in which it is impossible to improve any individual's condition without worsening that of another individual

particulate matter: small particles, such as fly ash and soot, such as are emitted during the combustion of a carbon-based fuel

parties: countries that have ratified a given international agreement and are bound by its provisions

passive vacuum technology: a method that utilizes gravity and atmospheric pressure, rather than pumps, to create a vacuum, enabling evaporation to occur at lower temperatures, requiring less energy

pathogens: viruses, bacteria, protozoa, or other chemical or biological agents that can infect a human host to produce disease

peak oil: the point at which oil availability and production reaches its zenith, before the Earth's oil resources begin either to dwindle or to become prohibitively expensive to exploit

permafrost: soil, sediment, rock, or other solid ground that has been frozen for at least two years

pesticides: chemical preparations that kill pests, including unwanted animals, fungi, and plants

pests: any of a class of relatively small organisms that damage structures or crops, spread disease, or are otherwise detrimental to human health or endeavors

petrochemical industries: businesses that refine crude oil to create raw materials needed in the manufacture of most chemicals, from fertilizers and pesticides to plastics, synthetic fibers, and medicines

pH: a measure on a fixed scale of the acidity or alkalinity of a solution

photosynthesis: the physiological process in plants that uses carbon dioxide and water to convert solar energy into chemical energy

photovoltaics: devices and technologies that transform sunlight into electricity

plate tectonics: the mechanisms responsible for creating movement in large sections of a planet's surface

Pleistocene epoch: an epoch within the geologic timescale that ended 11,700 years ago

polders: Dutch land areas reclaimed from sea or marsh

policy: the broad set of principles guiding governmental actions and legislation in a specific arena, such as energy or foreign affairs

post-glacial rebound: a rise in the elevation of a land mass after a glacier on top of it melts

power: a source of energy; also, the rate over time at which work is done

Power Dissipation Index: a measure of the total annual energy output of all hurricanes in a region

preadaptation: the ability of a species to move into a new ecosystem or to assume a new niche as a result of adaptations it already possesses

precautionary principle: a policy rule that one should act to prevent severe harm, even if the likelihood of that harm occurring is unknown or potentially low

precipitation: the condensation of atmospheric water vapor that deposits hail, mist, rain, sleet, or snow on the Earth's surface

preservation: keeping a natural area, as nearly as possible, pristine, unaltered, and uncontaminated by human influence

primary air pollutants: harmful substances that are emitted directly into the atmosphere

primary production: the conversion of CO_2 into organic compounds, primarily by photosynthesis

primordial isotope: an isotope that has been present on Earth since the planet formed 4.5 billion years ago

processing: changing a resource into a marketable commodity by milling, refining, and so on

prokaryote: a primitive cell (bacterium) lacking a nucleus and other membrane-bound organelles

prototype: a trial model of a product that a manufacturer is considering mass-producing

proxies: tree rings, fossils, and other artifacts that provide indirect evidence of past climatic conditions

pseudoscience: scientific-sounding claims that are either scientifically false or so poorly supported by evidence that they should not be taken seriously

quantified emission limitation and reduction commitments (QELRCs): the specific GHG reduction targets agreed to by the industrialized parties to the Kyoto Protocol

radiative forcing: a change in the planetary balance between incoming and outgoing radiation that increases or decreases the planet's overall energy balance

radiometric dating: an analytical technique using radioactive isotopes to determine the age of rocks and minerals

rain forest: a tropical area dominated by evergreen trees whose leaves form a continuous canopy and that receives at least 254 centimeters of rain per year

rain shadow: the region on the lee side of a mountain where precipitation is noticeably less than on the windward side

reef: a marine feature lying below the water's surface; often formed by biological activity, as by corals

reforestation: the replacement of forest lost to anthropogenic or natural influences

regenerative braking: process that uses the friction caused by applying a car's brakes to produce energy to help power the vehicle

removal units (RMUs): emission reduction units generated under land use, land-use change, and forestry projects

renewable resource: a resource that can be reproduced, such as a crop, or that renews itself, such as tidal or solar energy

replicability: the ability of an experiment or observation to be repeated and confirmed

reserves: the estimated amount of a nonrenewable resource remaining to be consumed

reservoir: 1) a body of water that forms behind a dam; 2) an object that accumulates, stores, and releases a substance in a box model

resources: entities that—whether renewable or nonrenewable—are finite in amount and usable to achieve human ends

respiration: the physiological process that breaks down organic compounds to obtain energy and that releases CO_2 as a by-product
reverse osmosis: forced passage of a liquid through a membrane to remove solutes
risk: the likelihood of a negative event occurring
runoff: precipitated water flowing over land toward water bodies, including the land surface material dislodged and carried by it

Saffir-Simpson scale: a scale that ranks hurricanes from Category 1 through Category 5, based on their sustained wind velocity
salinity: the concentration of salts in water
salinization: accumulation of soluble salts, as in soil or liquid
saltwater intrusion: process along a coastline in which salt water flows inland into a freshwater aquifer
savanna: grassland with scattered trees characteristic of tropical areas with seasonal rainfall on the order of 50 centimeters per year
scenario: a posited set of conditions used to project the likely consequences of those conditions
scrubbers: liquids that remove pollutants from emissions
sea ice: frozen ocean water
sea level: the theoretical level of the surface of the ocean, halfway between high and low tide
sea-level equivalent (SLE): the change in global average sea level that would occur if a given amount of water or ice were added to or removed from the oceans
secondary air pollutants: harmful substances that result from the reaction of primary air pollutants with principal atmospheric components
sediment: 1) particulate matter that is transported by water and eventually deposited, forming layers on a surface; 2) the layers so formed
sediment load: non-dissolved organic or inorganic particles carried by water
semiarid climates: climates of low annual precipitation (250-500 millimeters)
sensible heat flux: the flux of thermal energy that is associated with a rise in temperature
sequestration: isolation of a substance, such as carbon, in a place or form that prevents it from interacting with or contaminating the atmosphere
signatories: nations that have signed but not yet ratified an international agreement and are thus not yet bound by its provisions
sink: an entity capable of storing a substance and removing it from environmental circulation
smog: the noticeable brown haze created by vehicular and industrial emissions and other fossil emissions; especially prevalent in large cities
snow line: altitude below which snow does not accumulate
snowpack: accumulated snow in mountainous areas that melts during warmer months
socioeconomic drought: a drought severe enough to cause disruption to human societies and economies
soil: the loosely packed mineral and organic substances in which plant life grows on the surface of the Earth
solar irradiance: energy received from the Sun
Southern Oscillation: an oscillation in air pressure between the eastern and western tropical Pacific Ocean; the oscillation is associated with El Niño- and La Niña-related changes in sea surface temperature, and it influences the strength of the Pacific trade winds
stable air: air that resists convectional mixing and uplifting and in which precipitation is unlikely to occur
stoma: a pore in the leaf and stem epidermis of a plant that is used for gas exchange
storm surge: high water associated with a storm, especially that caused by wind action
stratosphere: the atmospheric region just above the tropopause that extends up to about 50 kilometers
subduction: the movement of one lithospheric plate below another
sublimation: the conversion of a solid directly into a gas, bypassing its liquid state
subsidence: land sinkage due to compaction of underlying material
subtractive processes: human activities that reduce Earth's surface topography
subtropical anticyclonic belts: a series of high-pressure belts situated at latitudes 30° north and south of the equator
subtropics: a climate zone found just poleward of the tropics
summer monsoon: a summertime influx over a

continent of unstable, rain-bearing air from over the ocean

sunspots: dark spots on the surface of the Sun caused by solar magnetic activity

surface water: water found on land in such bodies as ponds, lakes, streams, rivers, wetlands, and inland seas

sustainability: the ability of an environmental or environmentally dependent system to continue indefinitely without exhausting the means of its reproduction

sustainable development: the growth of population, industry, and agriculture in a fashion that does not deplete global resources

tar sands: sands containing highly viscous, asphalt-like oil that can be extracted by mixing the sands with hot water or steam

temperature: a numerical measurement on a fixed scale of the molecular and submolecular kinetic energy of a body

territorial waters: the seas within 22 kilometers of a national coast that are considered a nation's exclusive jurisdiction

thermal expansion: a heat-induced increase in the volume of a liquid or gas

thermodynamic disequilibrium: a state of instability in the energy distribution of a system

thermohaline circulation: the rising and sinking of ocean water—caused by differences in density due to differences in temperature and salinity—that drives the world's currents

thermosteric sea-level change: variability in sea level due to changes in water temperature

threatened species: a species likely to become endangered within the foreseeable future

tipping point: the point at which the transition from one state in a system to another becomes inevitable

tornado: a narrowly focused, funnel-shaped, violent windstorm

total equivalent warming impact: a measurement, in mass of CO_2 equivalent, of the global warming potential of an entire system

trade winds: easterly surface winds in the tropics

tragedy of the commons: the perverse collective outcome of self-interested behavior in the absence of property rights

transpiration: the process through which water evaporates from the aerial parts of plants, especially leaves

tree lines: elevations that separate areas of tree growth and areas with no trees

tree rings: layers of new growth added to trees in annual cycles that vary in thickness based on climatic conditions in the years they were formed

tree spiking: hammering a metal or ceramic spike into a tree to discourage logging

tropical climates: climates generally found in equatorial or tropical regions that exhibit high temperatures and precipitation year-round

tropics: a climate zone found close to the equator that lacks a winter season

tropopause: the transition region between the troposphere and the stratosphere

troposphere: the lowest layer of the atmosphere—in which storms and almost all clouds occur—extending from the ground up to between 8 and 15 kilometers high

turbine: an enclosed vessel containing rotating parts turned by the passage of a fluid, such as water or air

United Nations Framework Convention on Climate Change (UNFCCC): a 1992 international agreement creating the overall context for future agreements designed to reduce GHG emissions

unstable air: air that is readily susceptible to convectional mixing and uplifting, which often results in precipitation

upwelling: a rising of warm water to the surface, displacing colder water

urban heat island: an urban region that is significantly warmer than the surrounding rural areas

urbanization: the process of spatial concentration of the human population in cities

varve: an annual layer in a sediment, usually the result of seasonal variation in inputs

viscosity: a measure of how easily a material flows

volatile organic compounds: substances with carbon backbones that evaporate or vaporize easily at room temperature

volcano: a usually mountainous rift in Earth's crust caused by magma erupting through fissures onto the planet's surface

Walker circulation: an atmospheric circulation pattern in the Pacific and elsewhere in which hot, moist air rises, travels eastward, cools and dries, descends, and returns westward

water basin: an area of land where all surface or groundwater flows in the same direction

water rights: the rights of legal entities to contested water supplies

water table: the upper level of groundwater

watershed: the area of land drained by a river and all of its tributary streams

weather: the set of atmospheric conditions obtaining at a given time and place

weathering: a chemical process in which atmospheric carbon dioxide is converted to carbonates through reactions with water and silicate minerals

west coast marine climate: a mild, annually moist climate found along the western coasts of continents

westerlies: the prevailing winds in the midlatitudes, resulting from a combination of vertical circulation patterns in the atmosphere and the rotation of the Earth

wildfire: spontaneously ignited, naturally occurring fire

wildland/urban interface: a region where residential housing is embedded within, or abuts, a wild or nearly wild environment

winter monsoon: a wintertime, large-scale wind system that extends cool, dry, stable air from a continental interior over a large area

zero-emission automobiles: motor vehicles that do not produce toxic pollutants

zooxanthellae: photosynthetic organisms that live in symbiosis with corals and other organisms, providing up to 90 percent of a coral's energy requirements

General Bibliography

This bibliography includes a sampling of works on the scientific, policy, political, and cultural debates relating to global warming, as well as general and focused studies in climatology and related sciences. Readers seeking more narrowly focused sources are encouraged to consult the annotated lists of further reading accompanying the relevant essays in this set.

Web Sites

Listed below are more than one hundred Web sites that are current as of 2009. In addition to political entities and sources of objective scientific information, this list includes the sites of advocacy groups that seek selectively to interpret such data for polemic purposes. These groups are an important component of the discussion surrounding global warming, but readers are advised to evaluate carefully and independently all sites listed here. Furthermore, although every effort has been made to ensure the accuracy of universal resource locators (URLs), Web sites are continually being updated and there may be changes to the site address listed. A subject or keyword search through any of the major search engines will help locate a new address if the URLs listed below have been changed.

Abbey, Edward, 359
Abdullah, 905
Absolute zero, 546
Abu Simbel temple, 1095
Accelerator mass spectrometry, 294
Acid, 42, 820-822; freshwater, 284; oceans, 320, 780-781, 786, 821, 832, 928, 999; rain, 23, 42, 70, 215, 284, 448, 821, 964, 1035; soil, 676, 820
Acqua alta, 1055
Action plans; international, 13-15, 956, 1025, 1093; local, 209; national, 203, 841, 1021, 1051; state, 1052
Activism, 239-240, 400-403, 459-461, 524-525
Ad Hoc Group on the Berlin Mandate, 135
Adams, Mark, 910
Adaptation, 627, 695
Adaptation Fund, 767, 1021
Adiabatic processes, 5-6, 985
Advanced Technology Microwave Sounder, 722
Advancement of Sound Science Center, 7
Advertising, 853
Aeronomy of Ice in the Mesosphere, 763
Aerosols, 7-11, 98, 811; carbonaceous, 10, 183-185, 811; cloud condensation nuclei, 69; global dimming, 498; natural, 27; propellants, 198, 205, 216; radiative forcing, 326; salt, 8; secondary organic, 1058; sulfate, 28, 228, 679, 811, 832, 962-964; volcanic, 28, 960
Africa, 708, 896-897, 948-950, 1029
African Humid Period, 896
Agassiz, Louis, 3, 11-13, 48, 483, 490, 807, 1103
Agenda 21, 13-15, 336, 1022, 1031
Agricultural revolution, 391, 855, 1017
Agriculture, 15-18; animal husbandry, 16, 57-59; Bangladesh, 120; biofuel crops, 141, 144, 405, 465; carbon dioxide fertilization, 172; carbon 4 plants, 177; composting, 264-266; drought, 322; effects of climate change, 695; environmental effects, 305; forestry and, 18-19; history, 689; industrial, 137, 891; land clearing, 31, 58, 71, 445; liming, 676; livestock, 899; nitrogen and, 759-761; productivity, 973; research, 273-275; soil, 941; waste, 387; water use, 457, 731, 930
Agroforestry, 18-19, 995
Ahmadinejad, Mahmoud, 629
Air conditioning, 19-22, 571, 742
Air pollution, 8, 447-449; anthropogenic, 22-26, 102, 183-185; California, 159; carbon monoxide, 179; emissions standards, 187, 374-376, 890; global dimming, 498; history, 30-33; legislation, 22, 214-217; measurement, 33-37; natural, 26-30, 179; from oceans, 29; ozone, 804; particulate, 24, 27, 37, 810-811; prevention, 114, 187-188, 253, 463; transboundary, 283-286
Air Pollution Control Act (1955), 1051
Air pressure, 564; high, 107, 288, 706, 739; low, 107, 288, 624, 706, 739
Air quality; pollutants, 22-26, 30-33, 326; rural, 889-891; standards, 33-37
Air Quality Act (1967), 1051
Air Quality Index, 34
Air travel, 37-40, 175
Aircraft, 277
Akasofu, Syun-Ichi, 1103
Akkadian Empire, 211
Alainga, Pitseolak, 82
Alaska, 82; oil, 793
Albania, 343-344
Albedo, 100, 109, 778, 968; aerosols, 183, 679; clouds, 289, 499, 565, 599, 715, 1004; feedback, 40-42, 81, 768; ice, 4, 84, 223, 291, 301, 373, 664, 1008; land use and, 16, 58, 68, 306, 899; precipitation and, 356; volcanoes and, 441
Alberta, Canada, 160
AlbuquerqueGreen, 209
Alexander the Great, 72
Algae, 141, 143, 310-312, 387, 467, 813, 928; blooms, 256, 693, 788, 822
Alkalinity, 42-43, 820-822
Alkanes, 1058
Alkenes, 1058
Allègre, Claude, 1103
Allergens, 92, 737
Alleroed oscillation, 43
Alley, Richard B., 1103
Alliance of Small Island States, 43-45, 632
Allocation of resources. *See* Resource allocation
Alps, Swiss, 247
Alternative Fuels Act (1988), 398

Aluminum, 294
Amazon rain forest, 45-48, 147, 412; history, 425
