THE INTERNATIONAL HANDBOOK ON INNOVATION

Edited By

Larisa V Shavinina, Universite du Quebec en Outaouais, Canada

Description

The International Handbook on Innovation is the most comprehensive and authoritative account available of what innovation is, how it is measured, how it is developed, how it is managed, and how it affects individuals, companies, societies, and the world as a whole. Leading specialists from around the world, responsible for much of the current research in the field, analyze the multidisciplinary and multifaceted nature of innovation, its types and levels, its criteria, its development, its management, its specificity in various domains and contexts, and societal demands on it. They consider innovation from the viewpoints of psychology, management science, business, technology, sociology, philosophy, economics, history, education, art, and public policy. With contributions from over 90 distinguished authors covering 17 nations, readers will obtain expert insight into the latest research and future developments in the field of innovation. The Handbook will present many facets of innovation including its nature, its development, its measurement, its management, and its social, cultural, and historical context. The breadth of this work will allow the reader to acquire a comprehensive and panoramic picture of the nature of innovation within a single handbook. The reader will develop an accurate sense of what spurs potentially creative and innovative people and companies toward their extraordinary achievements and exceptional performances. The handbook can be used as a reference source for those who would like information about a particular topic, or from cover to cover either as a sourcebook or as a textbook in a course dealing with innovation. Anyone interested in knowing the wide range of issues regarding innovation will want to read this handbook.

Audience

Researchers, practitioners and students in the fields of psychology, management science, business, technology, sociology, philosophy, economics, history, education, art, and public policy.

Contents

Dedication. Preface. Introduction. Understanding innovation: introduction to some important issues (L.V. Shavinina). The Nature of Innovation. The neurophysiological basis of innovation (L.R. Vandervert). On the nature of individual innovation (L.V. Shavinina, K.L. Seeratan). Models of innovation (D. Marinova, J. Phillipmore). Evolutionary models of innovation and the Meno problem (T. Nickles). The three-ring conception of giftedness: its implications for understanding the nature of innovation (J.S. Renzulli). Innovation and strategic reflexivity: an evolutionary approach applied to services (J. Sundbo). The nature and dynamics of discontinuous and disruptive innovations from a learning and knowledge management perspective (E.G. Carayannis et al.). Profitable product innovation: the critical success factors (R.G. Cooper). Types of innovation (R.J. Sternberg et al.). Problem generation and innovation (R. Root-Bernstein). The role of flexibility in innovation (A.S. Georgsdottir et al.). The effect of mood on creativity in the innovative process (G. Kaufmann). Case studies of innovation: ordinary thinking, extraordinary outcomes (R.W. Weisberg). Innovation and evolution: managing tensions within and between the domains of theory and practice (J.R. Bailey, C.M. Ford). E-creativity and e-innovation (Keng Siau). Individual Differences in Innovative Ability. The art of innovation: polymaths and university of the creative process (R.

Root-Bernstein). Development of Innovation Across the Life Span. Young inventors (N. Colangelo et al.). Exceptional creativity across the life span: the emergence and manifestation of creative genius (D.K. Simonton). Innovations by the frail elderly (T. Heinzen, N. Vail). Assessment of Innovation. The measurement of innovativeness (R.E. Goldsmith, G.R. Foxall). Development of Innovation. Developing high potentials for innovation in young people through the schoolwide enrichment model (S.M. Reis, J.S. Renzulli). Towards a logic of innovation (G.F. Smith). The development of innovative ideas through creativity training (M.M. Clapham). Intuitive tools for innovative thinking (R. Root-Bernstein, M. Root-Bernstein). Stimulating innovation (R.N. Kostoff). Developing innovative ideas through high intellectual and creative educational multimedia technologies (L.V. Shavinina, E.A. Ponomarev). Innovations in Different Domains. Dimensions of scientific innovation (G. Holton). Do radical discoveries require ontological shifts? (M.T.H. Chi, R.G.M. Hausmann). Understanding scientific innovation: the case of Nobel Laureates (L.V. Shavinina). Innovation in the Social Sciences: Herbert A. Simon and the birth of a research tradition (S. Dasgupta). Poetic innovation (G. Swede). Directions for innovation in music education: integrating conceptions of musical giftedness into general educational practice and enhancing innovation on the part of musically gifted students (L. Scripp, R.F. Subotnik). Determinants of technological innovation: current research trends and future prospects (V. Souitaris). Innovation in financial services infrastructure (P. Nightingale). Innovation in integrated electronics and related technologies: experiences with industrial-sponsored large scale multidisciplinary programs and single investigator programs in a research university (R.J. Gutmann). Basic Approaches to the Understanding of Innovation in Social Context. The barriers approach to innovation (A. Hadjimanolis). Knowledge management processes and work group innovation (J.L. Farr et al.). Creativity and innovation = competitiveness? When, how, and why (E.G. Carayannis, E. Gonzales). Innovation tensions: chaos, structure, and managed chaos (R. Nag et al.). Involvement in innovation: the role of identity (N. King). Manager's recognition of employees' creative ideas: a social-cognitive model (Jing Zhou, R.W. Woodman). Venture Capital's role in innovation: issues, research and stakeholder interests (J. Callahan, S. Muegge). Innovations in Social Institutions. Encouraging innovation in small firms through externally generated knowledge (E. Major, M. Cordey-Hayes). Linking knowledge, networking and innovation processes: a conceptual model (J. Swan et al.). Managing innovation in multitechnology firms (A. Prencipe). Innovation processes in transnational corporations (O. Gassmann, M. von Zedtwitz). An analysis of research and innovative activities of universities in the United States (Yukio Miyata). Incubating and networking technology commercialization centers among emerging, developing, and mature technopoles worldwide (D. Gibson, P. Conceicao). Science Parks: a triumph of hype over experience? (J. Phillimore, R. Joseph). Innovation Management. Challenges in innovation management (J. Bessant). Managing technological innovation in business organizations (R. Katz). Towards a constructivist approach of technological innovation management (V. Boly et al.). Promoters and champions in innovations: development of a research paradigm (J. Hauschildt). Innovation and Leadership. Innovation and leadership (J.P. Deschamps). Innovation and Marketing. Innovation and market research (P. Trott). Marketing and the development of innovative new products (R.W. Veryzer). Innovation Around the World: Examples of Country Efforts, Policies, Practices and Issues. Innovation process in Hungary (A. Inzelt). Innovation under constraints: the case of Singapore (Hung-Kei Tang, Khim-Teck Yeo). Continuous innovation in Japan: the power of tacit knowledge (Ikujiro Nonaka et al.). Innovation in Korea (Sunyang Chung). Regional innovations and the economic competitiveness in India (K. Mehra). Innovation process in Switzerland (B. Wilhelm). Systems of innovation and competence building across diversity: learning from the Portuguese path in the European context (P. Conceicao). M. Heitor). The Taiwan innovation

system (Chiung-Wen Hsu, Hsing-Hsiung Chen). Innovation in the upstream oil and gas sector: a strategic sector of Canada's economy (A.J. Persaud et al.). The national German innovation system: its development in different governmental and territorial structures (H. Grupp et al.). Frankenstein futures? German and British biotechnology compared (R. Harding). Innovations of the Future. Future innovations in Science and Technology (J.F. Coates). The future of innovation research (T. Rickards). Conclusion (L.R. Vandervert).

About the Authors

Mohi Ahmed is a visiting researcher at the Graduate School of International Corporate Strategy of Hitotsubashi University, Tokyo, working in conjunction with Professor Nonaka.

Susan G. Assouline is the Belin-Blank Center's Associate Director and Clinical Supervisor. She received her B.S. in general science with a teaching endorsement, her Ed.S. in School Psychology, and her Ph.D. in Psychological and Quantitative Foundations, all from The University of Iowa. She has an appointment as a Clinical Associate Professor in School Psychology. She is especially interested in identification of academic talent in elementary students and is co-author of the book *Developing Mathematical Talent: A Guide for Challenging and Educating Gifted Students* (Prufrock Press). Also, she is co-editor with Nicholas Colangelo of the series *Talent Development: Proceedings from the Wallace Research Symposia on Giftedness and Talent Development*, and co-developer of *The Iowa Acceleration Scale*.

James Bailey is an Associate Professor of social and organizational theory at George Washington University. Professor Bailey's scholarship examines how the nature and experience of change are manifested in crucial tensions between opposing values and how practitioners understand and adapt their competencies to environmental demands. His research has appeared in such outlets as *Organizational Science*, *Journal of International Business Studies*, and *Journal of Applied Behavioral Science*. Has worked extensively as a consultant on issues relating to conflict management, skill development and organizational change. In 2000 he was named the Associate Editor of the *Academy of Management Learning and Education*.

Clar M. Baldus is the administrator for Rural Schools Programs and Inventiveness Programs at the Belin-Blank Center and the Sate Coordinator of Invent Iowa. Her research has been guided by a passion for art, interest in creative processes, and commitment to talent development. Before joining the Belin-Blank Center, Dr Baldus was a resource specialist and assessment facilitator for elementary gifted and talented students. Her extensive, 25 years of teaching experience at the secondary, postsecondary, and professional development levels has also included working with students in the areas of art, creativity, and gifted education.

John Bessant is Professor of Innovation Management at Cranfield University and before that was Director of the Centre for Research in Innovation Management at the University of Brighton in the U.K. Originally a chemical engineer, he has been active in the field of research and consultancy in technology and innovation management for over 25 years. His areas of special interest include organizational development for innovation, inter-firm learning and enabling the emergence of agile enterprises. He is the author of 12 books (the latest—2001—J. Tidd, J. Bessant & K. Pavitt, *Managing Innovation* published by John Wiley) and many articles on the topic and has lectured and consulted widely on the topic around the world.

Vincent Boly is Professor of Innovation at Ecole Supérieure en Génie des Systèmes Industriels of Nancy, France. His research and teaching interests span the field of new product design, metrology and integration concepts. Before returning to University, Dr Boly worked as a consultant with major international companies as well as SMEs. He was a member of the board of a High Tech SME after being involved in its launch. Dr Boly is invited Professor at Quebec University in Trois Rivières.

John Callahan is cross-appointed in both the Department of Systems and Computer Engineering and the School of Business at Carleton University, Ottawa, Canada. He teaches graduate courses and supervises graduate research in telecommunications and product development management in Engineering, and in R&D management in the Sprott School of Business. He has published in journals such as *Management Science*, *Research Policy*, *IEEE Transactions on Engineering Management*, *Technovation* and *R&D Management*. Dr Callahan graduated from Carleton University with a B.Sc. (Hons.) in Mathematics and Physics. He then did an M.A. in Applied Mathematics and a Ph.D. in Industrial Engineering at the University of Toronto.

Elias G. Carayannis is an Associate Professor at the Management Science Department and Director of Research on Science, Technology, Innovation and Entrepreneurship of the European Union Center, School of Business and Public Management, George Washington University. He also co-founded the Environmental Studies Center and the Social and Organizational Learning Studies Center at the School. Dr Carayannis has published in *Research Policy*, *Journal of Engineering and Technology Management*, *International Journal of Technology Management, Technovation*, *Journal of Technology Transfer*, *R&D Management*, and others. He has consulted for the World Bank, USAID, NSF SBIR, NIST ATP, Sandia National Laboratories, the General Electric Corporate Training & Development Center, Cowen & Co, and others.

Hsing-Hsiung Chen received a B.Sc. in Electrical Engineering from the National Taiwan Institute of Technology in 1987, and an M.S. degree from the National Tsing Hua University in 1989. He then joined the Strategic Planning Department (SPD) of Electronic Research & Service Organization (ERSO), Industrial Technology Research Institute (ITRI), where he worked his way up from a Planning Engineer, Deputy Manager, to the Department Manager. In 2000, he transferred to the Industrial Economics & Knowledge Center (IEK), ITRI, where he currently serves as Deputy Director of Integrated Research Division. Mr Chen received his second M.S. degree in Information Management from the National Taiwan University in 2001 and is pursuing his Ph.D. in Management Science at the National Chiao Tung University.

Micheline Chi is a Senior Scientist at the Learning Research and Development Center and a Professor at the Department of Psychology, University of Pittsburgh. Her research interests include learning from tutoring, learning from collaboration, understanding emergent processes, and conceptual change.

Sunyang Chung is a Director of the Institute for Technological Innovation (ITI) and Professor of Technology Management at the School of Business Administration, Sejong University, Seoul, Korea. He received a Ph.D degree from the University of Stuttgart, Germany. He carried out several research projects at the Fraunhofer-Institute for Systems and Innovation Research (FhG-ISI) in Karlsruhe, Germany. He had worked about 13 years at the Science and Technology Policy Institute (STEPI), Korea. His research areas are technology management and policy, regional innovation strategies, environmental management and policy, and the integration of the South and North Korean innovation systems. He has published several books in Korea and Germany and has written over 50 articles in Korean and International journals.

Maria Clapham is an Associate Professor of Psychology at Drake University. She received her doctorate in Industrial and Organizational Psychology from Iowa State University. Her research interests include employee assessment and development, bias in assessment procedures, and factors that predict and affect creative performance. She has published numerous articles in professional journals such as the *Journal of Occupational and Organizational Psychology*, *Creativity Research Journal*, *Educational and Psychological Measurement*, and *Journal of Managerial Issues*.

Joseph F. Coates is Head of Joseph F. Coates, Consulting Futurist, Inc., also President Emeritus of Coates & Jarratt, Inc., a future research organization that he founded in 1979 and managed until May 2001. He consulted with 45 of the Fortune 100 companies, numerous smaller firms, trade, professional, and public interest groups, and all levels of government. Joe lectures to many groups each year about trends and future developments. He is the co-author of *2025: Scenarios of U.S. and Global Society Reshaped by Science and Technology* (Oakhill Press, 1997), *Futurework* (Jossey-Bass, 1990), *What Futurists Believe* (World Future Society, 1989), and *Issues Management: How Can You Plan, Organize, and Manage for the Future* (Lomond, 1986), and is the author of over 300 articles, chapters, papers, and other publications.

Nicholas Colangelo is the Myron and Jacqueline Blank Professor of Gifted Education and the Director of The Connie Belin & Jacqueline N. Blank International Center for Gifted Education and Talent Development. He has published extensively on the counseling and social-emotional needs of gifted students. He is co-author of the *Iowa Inventiveness Inventory* and the *Iowa Acceleration Scale*. He was presented with the Distinguished Scholar Award in 1991 by the National Association of Gifted Children. He is the senior editor of the *Handbook of Gifted Education* (3rd ed.).

Pedro Conceição is Assistant Professor at the Instituto Superior Tecnico in Lisbon, Portugal, at the Center for Innovation, Technology and Policy Research, <http://in3.dem.ist.utl.pt/>, and a Senior Research Fellow at the IC2 Institute, The University of Texas at Austin, USA. He is currently with the United Nations Development Program.

Robert G. Cooper is President of the Product Development Institute Inc., Professor of Marketing at the School of Business, McMaster University in Hamilton, Ontario, Canada, and ISBM Distinguished Research Fellow at Penn State University's Smeal College of Business Administration. Dr Cooper is the father of the *Stage-Gate*TM

process, now widely used by leading firms around the world to drive new products to market. He is a thought-leader in the field of product innovation management, having published more than 90 articles and also written six books on the topic, including the best-seller, *Winning at New Products: Accelerating the Process from Idea to Launch*.

Martyn Cordey-Hayes is an Emeritus Professor at Cranfield University in the U.K. Previously he was Director of the Innovation and Technology Assessment Unit and Head of the International Ecotechnology Research Centre, Cranfield University.

Kevin G. Corley is an Assistant Professor of organizational behavior in the College of Business at the University of Illinois, Urbana-Champaign. His research interests focus on organizational change, especially as it pertains to issues of organizational identity, image, reputation, and learning. His research has recently appeared in the *Academy of Management Journal*, the *Academy of Management Review*, *Journal of Organizational Change Management*, and *Corporate Reputation Review*.

Laurie J. Croft is the administrator for Professional Development at the Belin-Blank Center, teaches and coordinates workshops for pre-service and in-service educators about various aspects of gifted education, as well as about the Advanced Placement Program. Formerly a teacher at the University of Tulsa School for Gifted Children, she supervises practicum experiences for educators of the gifted.

Subrata Dasgupta studies creativity, especially as it is manifested in science, technology, design, intellectual history, and art. He is presently Director, Institute of Cognitive Science, and holder of the Eminent Scholar Chair in Computer Science at the University of Louisiana at Lafayette, where he also has professorial appointments in the Department of History and the Center for Advanced Computer Studies. His most recent books include *Creativity in Invention and Design* (Cambridge, 1994), *Technology and Creativity* (Oxford, 1996), and *Jagadis Chandra Bose and the Indian Response to Western Science* (Oxford, 1999).

Jean Philippe Deschamps teaches technology and innovation management to executives at IMD in Lausanne (Switzerland). Prior to joining IMD, in 1996, he was a corporate vice-president at Arthur D. Little and the founder and Chairman of the firm's technology and innovation management practice. He has 30 years of international consulting and lecturing experience with a great variety of industries, and co-authored *Product Juggernauts—How Companies Mobilize to Generate Streams of Market Winners*, published in 1995 by the Harvard Business School Press. He graduated from HEC (Paris), INSEAD in Fontainebleau, and the Harvard Business School.

Iciar Domingue-Lacasa has a M.A. in economics from the University Complutense in Madrid, Spain. In 1996–1998 she was a postdoctoral fellow in international economics at the University of Mannheim, Germany. In 1998–1999 Lacasa worked at Boston Consulting Group in Munich. Since 2000 she has been a research fellow at the Fraunhofer Institute for Systems and Innovation Research (ISI) in Karlsruhe, Germany.

James L. Farr is Professor of Psychology at The Pennsylvania State University. He is the Editor of *Human Performance* and a former President of the Society for Industrial and Organizational Psychology. His research interests are in work group innovation, performance measurement and management, older workers, and work motivation.

Cameron Ford's interests are in the areas of organizational creativity, innovation, and new venture creation. His research has appeared in journals such as the *Academy of Management Review*, *Journal of Management*, *Journal of Applied Behavioral Science*, *IEEE Transactions on Engineering Management*, and *Journal of Organizational Change Management*. He has also published numerous book chapters related to creativity, edited the book *Creative Action in Organizations*, and has an edited book tentatively titled *The Handbook of Organizational Creativity* scheduled for publication in 2003. He is on the editorial boards of *Academy of Management Learning and Education*, *Journal of Creative Behavior* and *Creativity and Innovation Management*.

Gordon Foxall is a Distinguished Research Professor at Cardiff University. His chief research interests lie in psychological theories of consumer choice and consumer innovativeness and their relationships to marketing management and strategy. He has published some 16 books and over 250 articles and papers on these and related themes. His undergraduate work was at the University of Salford, and he is also a graduate of the Universities of

Birmingham (Ph.D. industrial economics and business studies) and Strathclyde (Ph.D. psychology). In addition, he holds a higher doctorate of the University of Birmingham (DSocSc).

Monika Friedrich-Nishio studied industrial engineering and management at Karlsruhe University, Germany, and graduated in informatics in 1999. Since 2000 she has been with the section System Dynamics and Innovation of the Institute of Economic Policy Research, Faculty of Economics, Karlsruhe University. With a Humboldt scholarship she was with the Institute of Innovation Research, Hitotsubashi University, Tokyo, from July to November, 2002.

Oliver Gassmann is Professor at the University of St Gallen, Switzerland, and Director of the Institute for Technology Management. In 1996–2002 he was Vice President responsible for Corporate Research and Strategic Technology Management at Schindler Corporation. He holds a Masters degree in economics and business administration from the University of Hohenheim-Stuttgart and a Ph.D. degree in business administration from the University of St Gallen. He is a member of several boards, such as the Board for Science and Research of Economiesuisse, the Comité Stratégique Euresearch, and the Editorial Board of the *R&D Management Journal*. His research focuses on international R&D and strategic innovation management. He has published five books and over 40 papers in the area of technology and innovation management.

Asta S. Georgsdottir is currently completing her doctoral studies at the University of Paris 5, France. She received her B.A. degree in Psychology from the University of Iceland, Reykjavik, and her D.E.A. (Master) degree from the University of Paris 5, France. Her research focuses on cognitive flexibility, with an emphasis on individual differences, and the development of cognitive flexibility in children and adolescents.

Isaac Getz is a Professor of Creativity and Innovation Management at the ESCP-EAP European School of Management, Paris, France. He was a Visiting Professor at Cornell and Stanford Universities and at the University of Massachusetts. Dr Getz's current research focuses on emotion, metaphor, creativity, and idea management. He is editor of a book *Organizational Creativity* (Vuibert, 2002) and co-author of another book *Your Ideas Change Everything* (Editions d'Organisation, 2003).

David V. Gibson is Director, Research and Global Programs, and The Nadya Kozmetsky Scott Centennial Fellow, IC² (Innovation, Creativity, Capital) Institute (www.ic2.org), The University of Texas at Austin. In 1983, he earned his Ph.D. from Stanford in organizational behavior and communication theory. He is a consultant to businesses and governments worldwide. His research and papers have been translated into Mandarin, Japanese, Korean, Russian, Spanish, Italian, French, German, Finnish, and Portuguese.

Dennis A. Gioia is Professor of Organizational Behavior in the Department of Management and Organization at the Smeal College of Business Administration, Penn State University. His current theory and research interests focus on organizational identity, image, reputation, learning, and sensemaking. His work has appeared in most of the major journals in the field, and he has co-edited two books: *The Thinking Organization* and *Creative Action in Organizations*. Prior to his academic career he worked for Boeing Aerospace at Kennedy Space Center during the Apollo lunar program and served as vehicle recall coordinator for Ford Motor Company.

Ronald E. Goldsmith is the Richard M. Baker Professor of Marketing at the Florida State University. He has published approximately 150 journal articles and conference papers as well as a book, *Consumer Psychology for Marketing*. His articles have appeared in the *Journal of the Academy of Marketing Science*, *Journal of Business Research*, *Service Industries Journal*, and others. He is currently the North American Editor of the *Service Industries Journal*.

Edgar Gonzalez holds an M.S. and M.D. degree from the London School of Economics, U.K. In Colombia he served as General Director of the Health Services Development Department in the Ministry of Health, Health Advisor to the President of the Republic, and founding Director of the Health Services Management Program at the National School of Public Management. He also worked as a consultant for the Pan-American Health Organization, World Health Organization, United Nations, and Multilateral Development Banks in the fields of public health and social and economic development.

Hariolf Grupp is a Professor of Systems Dynamics and Innovation and Director of the Institute for Economic Policy Research (IWW) in the Economics Faculty at the Karlsruhe Technical University. He graduated from Heidelberg University with Ph.D. in physics and mathematics. Since 1985 he has been at the Fraunhofer Institute for Systems and Innovation Research (ISI) and has been a Deputy Director of this institute since 1996.

Ronald J. Gutmann is a Professor of Electrical Engineering at Rensselaer Polytechnic Institute, where he is active in teaching and research activities in semiconductor devices and integrated circuit interconnect technology. He has authored approximately 300 technical papers in these and related fields and is a Fellow of IEEE for contributions in microwave semiconductor technology. He has co-authored three books in IC interconnect technology: *Chemical-Mechanical Planarization of Microelectronics Materials* (Wiley, 1997), *Copper — Fundamentals for Microelectronic Applications* (Wiley, 2000) and *Chemical-Mechanical Polishing of Low Dielectric Constant Polymers and Organosilicate Glasses* (Kluwer, 2002).

Athanasios Hadjimanolis obtained his first degree in Chemistry from the University of Athens (Greece). He then obtained the certificate and diploma of the Chartered Institute of Marketing (U.K.) and received his MBA and Ph.D. from Brunel University in London (U.K.). He has published several papers in international journals like *Research Policy* and *Technovation*. He has worked for many years in an industrial firm as a division head. He also teaches at the Business School at Intercollege in Nicosia, Cyprus. He is a member of the Chartered Institute of Marketing (U.K.) and other professional associations.

Rebecca Harding is a Senior Fellow of London Business School and the Chief Economist of The Work Foundation. Up until March 2002 she was a Senior Lecturer at the Science Policy Research Unit at the University of Sussex and a Research Associate of the Institute for Public Policy Research in London. Her work has focused on all areas of entrepreneurship and innovation management, including science-based entrepreneurship and international comparisons of venture capital structures and policy. She has published extensively in this area and has acted in an advisory capacity to the U.K., Danish and German regional governments on innovation, venture capital and entrepreneurship. Recently she was appointed as Research Director for the Entrepreneurial Working Party and she is on the Advisory Board of Inner City 100.

Jürgen Hauschildt is a Professor of Business Administration at the University of Kiel and Director of the Institute for Research in Innovation Management. Since 1999 he has been Managing Director of the 'Studienkolleg BWL' at Kiel University, responsible for education of technical and chemical engineers in business administration. Dr Hauschildt also coordinated the research program 'Theory of Innovation Management' sponsored by the German Science Foundation. He has published in the areas of organisation theory, financial management, controlling, financial statement analysis, decision theory, innovation management, and crisis management.

Robert Hausmann is a doctoral candidate in the cognitive program at the University of Pittsburgh. His current research interests include collaborative learning and collaborative scientific discovery.

Thomas E. Heinzen studies creativity among a variety of unlikely populations, provides clinical services to elderly individuals and their families, and writes extensively on creativity and aging. He is the author of six books and numerous scientific articles. He earned his Ph.D. at the State University of New York at Albany, studied the New York State workforce while affiliated with the Rockefeller College of Public Affairs and Policy, and now serves as Associate Professor of Psychology at William Paterson State University of New Jersey.

Manuel Heitor is Professor at the Instituto Superior Tecnico in Lisbon, Portugal, Director of the Center for Innovation, Technology and Policy Research, <http://in3.dem.ist.utl.pt/>, and a Senior Research Fellow at the IC2 Institute, The University of Texas at Austin, USA.

Gerald Holton is Mallinckrodt Professor of Physics and Professor of History of Science, Emeritus, at Harvard University. He is the author of several books, including *Thematic Origins of Scientific Thought, Science and Anti-Science*, *The Advancement of Science*, and *Einstein, History and Other Passions* (all from Harvard University Press). His honors include The George Sarton Medal, The Millikan Medal, election to the presidency of the History of Science Society, and the selection as Jefferson Lecturer.

Chiung-Wen Hsu received her B.S. in Industrial Management from the National Taiwan Institute of Technology in 1983 and continued graduate studies in Management Science at the National Chiao Tung University. After receiving her M.S. in 1985, she joined the Industrial Technology Research Institute's (ITRI) Offices of Planning where she worked as a researcher. While working for ITRI, she entered the Ph.D. program in Management Science at the National Chiao Tung University in 1989, and received her Ph.D. in 1994. Dr Hsu has been teaching at the National Tsing Hua University since 1994. In 2000, she transferred to the Industrial Economics & Knowledge Center, ITRI, where she currently serves as a research manager. Most of her research work has been in the area of technology transfer, project management, and industrial technology policy.

Damien Ihrig earned his B.A. in Developmental Psychology and Russian History from the University of Iowa in 1996. He worked from 1992 to 1996 as a research assistant in the Childrens' Cognitive Research Laboratory coordinating research for Dr Jodie Plumert. He then coordinated research activities for 2 years in the Traumatic Brain Injury Laboratory for Dr Jeffrey Max, a child psychiatrist at the University of Iowa Hospitals and Clinics. He earned his M.A. in Educational Measurement and Applied Statistics from the University of Iowa in May of 2000. His responsibilities at the Belin-Blank Center include administrating the Belin-Blank Exceptional Student Talent Search, a nationwide above-level testing program for academically talented youth; coordinating research activities; and directing the evaluation of Belin-Blank Center student and teacher programs.

Annamária Inzelt is a Founding Director of IKU Innovation Research Centre (1991) and Founding Co-Director of the Centre for Innovation Policy Research and Education for Central and Eastern Europe, Budapest, Hungary (1999). She is a member of several international organisations and has organised some international conferences. Dr Inzelt is author and editor of several books, chapters and articles and regularly participates in international research projects. Her main research interests are: systems of innovations, the role of internationalisation in technology upgrading and research and development, knowledge flows through mobility and migration.

Richard Joseph is an Associate Professor of Telecommunications Management in the Murdoch Business School, Murdoch University, Perth, Western Australia. He has over 20 years of experience in both government and academia, having worked as a science and technology policy advisor for various Australian government departments in Canberra. He has also worked for the OECD in Paris. He has provided advice to the United Nations Development Program and Australian and New South Wales Governments on science and technology parks.

Ralph Katz is a Professor of Management at Northeastern University's College of Business Administration and Principal Research Associate at MIT's Sloan School of Management. He has published numerous articles in leading professional journals and several books, the most recent of which is entitled *The Human Side of Managing Technological Innovation*. In 1981, Dr Katz received the National Academy of Management's 'New Concept Award' for that year's most outstanding contribution in organizational behavior. He was also the 1990 and 1991 recipient of the Academy of Management TIM Division's 'Best Paper' Awards. Dr Katz serves on several journal editorial boards and was the R&D/Innovation and Entrepreneurship Departmental Editor of *Management Science* for the past 10 years.

James C. Kaufman is Assistant Professor at California State University, San Bernardino where he is also the director of the Learning Research Institute. He received his Ph.D. from Yale, and worked as an Associate Research Scientist at Educational Testing Service for two years. He is the Associate Editor of the journal *Research in the Schools*. He is the author of *The Evolution of Intelligence* (with R. Sternberg) and *The Creativity Conundrum* (with R. Sternberg & J. Pretz), as well as the forthcoming *Gender Differences in Mathematics* (with Ann Gallagher) and *Faces of the Muse: Creativity in Different Domains* (with John Baer). Kaufman is interested in many aspects of creativity, including different domains, measurement, its relationship to mental illness, and its relationship with other constructs such as motivation and academic achievement.

Geir Kaufmann is Professor of Psychology at the Norwegian School of Economics and Business Administration. His major research interests are in the field of the psychology of problem-solving and behavioral decision-making, with a special focus on the creativity aspect of these processes. Dr Kaufmann has published a large number of scientific articles and books in these fields. Currently his main interest is in the relationship between affect and problem-solving, and he is engaged in developing and testing a model of the effects of mood on creative problem-solving.

Nigel King has a Ph.D. in psychology from the University of Sheffield, and is currently Reader in Psychology at the University of Huddersfield, U.K. He has published widely in the area of creativity, innovation and change in organisations, including the recent book *Managing Innovation and Change: A Critical Guide for Organisations* (with Neil Anderson). His research has mostly been in health care settings, and he is Director of the Primary Care Research Group at Huddersfield. He has a strong interest in the use of qualitative methods in work and organisational psychology, especially those from a phenomenological perspective.

Ronald Neil Kostoff received a Ph.D. in Aerospace and Mechanical Sciences from Princeton University in 1967. He worked at Bell Labs, Department of Energy, and Office of Naval Research. He invented and patented (1995) the Database Tomography process, a computer-based textual data mining approach that extracts relational

information from large text databases. He is listed in *Who's Who in America*, 56th Edition (2002), *Who's Who in America, Science and Engineering*, 6th Edition (2002), and *2000 Outstanding Intellectuals of the 21st Century*, First Edition (2001). He has published many papers on technical, evaluation, and text mining topics, and has edited three journal special issues since 1994 (*Evaluation Review* (February, 1994), *Scientometrics* (July, 1996), *Journal of Technology Transfer* (Fall, 1997)).

Uma Kumar is a Professor of Management Science and Director of the Research Centre for Technology Management at the Eric Sprott School of Business, Carleton University. Her research is in the area of Management of Technology including forecasting and monitoring technology, efficiency in new product development through e-commerce, quality in R&D, managing R&D internationally, R&D and innovation policy, and performance metrics in e-commerce. Dr Kumar has published over 60 articles in journals and refereed proceedings. Her seven papers have won best-paper awards at prestigious conferences. Twice, she has won the Scholarly Achievement Award at Carleton University. Dr Kumar is the recipient of a number of research grants from SSHRC and NSERC.

Vinod Kumar is the Director of the Eric Sprott School of Business at Carleton University where he is also a Professor of Technology and Operations Management and the Head of the Manufacturing Systems Centre. His research is in enterprise system adoption and implementation, e-commerce technology strategy, supply chain management, improving performance of production and operation systems, manufacturing flexibility, technology transfer, quality in R&D, and innovation management in the defence and high-tech sector. Dr Kumar has published more than 75 articles in refereed journals and proceedings. He has won several Best Paper Awards in prestigious conferences. At Carleton University, Dr Kumar has also obtained the Scholarly Achievement Award twice and University Research Achievement Award twice.

Todd I. Lubart is a Professor of Psychology at the University of Paris 5, France. His research focuses on creativity, with emphases on individual differences, the development of creativity, and the role of emotion in creativity. Dr Lubart has been a visiting scholar at the Paris School of Management (ESCP). He is co-author of *Defying the Crowd: Cultivating Creativity in a Culture of Conformity* (Free Press, 1995).

Edward Major completed his Ph.D. in innovation and small firms at the Innovation and Technology Assessment Unit at Cranfield University in 2000. He is currently a Business Analyst with Bedfordshire Police Force in the U.K. and a Part-Time Lecturer in Strategy and Small Business Management at Middlesex University, also in the U.K.

Dora Marinova is the Head of the Institute for Sustainability and Technology Policy at Murdoch University, Perth, Western Australia where she has been working in the last 12 years and is currently a Senior Lecturer. She completed her Ph.D. in Bulgaria in the field of innovation theory. Dr Marinova's research interests include innovation, science and technology policy, environmental policy, Eastern Europe and technology transfer. She has published over 50 refereed journal articles and book chapters, and has been involved with more than 15 contract reports for government and industry. She is also a Fellow of the Modeling and Simulation Society of Australia and New Zealand.

Kavita Mehra has a Ph.D. in plant tissue culture from Delhi University and is a research scientist at National Institute of Science Technology and Development Studies (NISTABS), CSIR, India. Her research focuses on issues related to innovations, innovation networks and commercialization of technologies. Dr Mehra has dealt with these issues across various sectors and technologies such as plant tissue culture, floriculture, sericulture, dairy and information technology. Also worked on the concepts and methodologies of Action Research and for that, has been a visiting faculty outside India. She has published several papers in international Journals and contributed chapters in books edited by internationally recognized authors. The editorship of a special issue of an international journal '*AI & Society*' (Springer Press) on Enterprise Innovations is there to her credit.

Yukio Miyata is a Professor at the Department of Economics, Osaka Prefecture University, Osaka, Japan. After obtaining his B.A. degree in Economics from Osaka University in 1983 and B.S. degree in Materials Engineering from the University of Washington, Seattle, in 1987, he obtained an M.S. degree in Engineering and Policy in 1989 and Ph.D. in Economics in 1994, both from Washington University, St Louis. His current research interest is economic and policy analysis of technological innovations. He is particularly interested in inter-organizational collaboration for R&D. His publications include papers in *Technovation* and *Japan and the World Economy*, and three books in Japanese.

Laure Morel is a Researcher at Ecole Nationale Supérieure en Génie des Systèmes Industriels in Nancy, France. She works on constructivism knowledge management and organizational learning, and conducts research in the chemical and food industries.

Steven Muegge is completing an M.Eng. degree in Telecommunications Technology Management at Carleton University. He has eight years of telecommunications industry experience in various managerial and technical roles. His responsibilities have spanned all phases of product development, from concept definition to customer deployment, including management of hardware, software, and systems products. He has published at the International Intersociety Electronics and Photonic Packaging Conference (InterPACK) and is the inventor of a U.S. patent. Steven graduated from McMaster University with a B.Eng. in Engineering Physics, with concentrations in optical communications and solid-state devices. He is a certified Project Management Professional (PMP).

Rajiv Nag is a Doctoral Candidate in the Department of Management and Organization at the Smeal College of Business Administration, Penn State University. His current research interests focus on organizational knowledge, managerial cognition, and strategic management. Prior to commencing his doctoral studies, Rajiv worked in areas of marketing and manpower development with Fiat SpA and Leo Burnett Inc.

Thomas Nickles, Professor and Chair of the Philosophy Department at the University of Nevada, Reno, specializes in history and philosophy of science and technology. He has published numerous articles on scientific explanation, reduction of theories and of problems, problem-solving, heuristic appraisal, and innovation. He is editor of *Scientific Discovery, Logic, and Rationality* and *Scientific Discovery: Case Studies* (both Reidel, 1980) and of *Thomas Kuhn* (Cambridge University Press, 2003).

Paul Nightingale is a Senior Research Fellow in the Complex Product Systems Innovation Centre at the Science Policy Research Unit (SPRU), University of Sussex, U.K. Originally a chemist, he has industrial experience managing R&D projects for a large blue-chip firm. His Ph.D. research analyzed the introduction of computer simulation technologies in R&D processes. His research interests include IT project management in financial services, the relationship between scientific research and technical change, and innovation in instrumentation technologies. He has written on banking innovation, the introduction of genetics technologies, the role of science in society, and aerospace project management. He publishes in *Research Policy* and *Industrial and Corporate Change*.

Ikujiro Nonaka is a Professor at the Graduate School of International Corporate Strategy of Hitotsubashi University in Tokyo. He is also the Xerox Distinguished Professor in Knowledge at the Haas School of Business, University of California at Berkeley, and Visiting Dean and Professor at the Centre for Knowledge and Innovation Research of Helsinki School of Economics and Business Administration, Finland.

A. Jai Persaud is a senior policy advisor with Natural Resources Canada (NRCan), Corporate Policy and Portfolio Coordination Branch. He previously held several positions including Senior Economist and Head, Industry and Supply Analysis, with the Energy Policy Branch, Energy Sector, NRCan; the National Energy Board; the Bureau of Competition Policy; and the Alberta Energy Utilities Board. Mr Persaud has held several key assignments, including his most recent involvement with the high-profile Canada Transportation Act Review, and has undertaken significant research in the area of energy. He holds a B.A. and an M.A. in economics from the University of Calgary and an M.B.A. from the University of Ottawa. He is a Ph.D. candidate in the Sprott School of Business, Carleton University in the area of technology management.

John Phillimore has worked for the past 10 years at the Institute for Sustainability and Technology Policy at Murdoch University, Perth, Western Australia, where he is a Senior Lecturer. He has a Ph.D. from the Science Policy Research Unit at the University of Sussex, U.K. He has worked as an advisor to the Minister for Technology and the Minister for Housing, Local Government and Regional Development in the Western Australian State Government. His research interests include innovation and industry policy, research policy, vocational training policy, environmental policy, and the future of social democracy.

Evgueni Ponomarev is at the Department of Physics, University of Ottawa, Canada. His current research interests include organizational learning and development, innovation technology management, and R&D management.

Andrea Prencipe is Associate Professor of Economics and Management of Innovation, Università G. D'Annunzio, Italy and a Research Fellow at the CoPS Innovation Centre in SPRU—Science and Technology Policy Research Unit, University of Sussex, U.K. His qualifications include a Ph.D. in Technology and Corporate Strategy (SPRU), an M.A. in Innovation Management (S. Anna School of Advanced Studies, Pisa, Italy), an M.Sc. in Technology Innovation Management (SPRU), and a B.A. in Economics and Business (University G. d'Annunzio). His research interests include the co-ordination and division of innovative labour in multitechnology industries and organizational memory in project-based organisations. He has published in journals such as *Administrative Science Quarterly*, *Industrial and Corporate Change*, and *Research Policy*.

Jean E. Pretz is a doctoral candidate in the Psychology Department at Yale University. She received a B.A. in psychology and music from Wittenberg University, Springfield, Ohio, and an M.S. and M.Phil. from Yale University. She has received awards from the American Psychological Association, the American Psychological Foundation, and the American Psychological Society Student Caucus for her research on intuition and insight in problem solving. Her research interests include creativity, expertise, and transfer in problem-solving.

Sally M. Reis is a Professor and the Department Head of the Educational Psychology Department at the University of Connecticut where she also serves as Principal Investigator of the National Research Center on the Gifted and Talented. She was a teacher for 15 years, 11 of which were spent working with gifted students on the elementary, junior, and high school levels. She has authored more than 130 articles, nine books, 40 book chapters, and numerous monographs and technical reports. Her research interests are related to special populations of gifted and talented students, including: students with learning disabilities, gifted females and diverse groups of talented students.

Jean Renaud is Assistant Professor of Concurrent Engineering at Ecole Supérieure en Génie des Systèmes Industriels in Nancy, France. His research focuses on knowledge capitalization. Dr Renaud currently serves as innovation expert to French firms, and he heads a National Association on Project Management.

Joseph Renzulli is the Raymond and Lynn Neag Distinguished Professor of Educational Psychology at the University of Connecticut, where he also serves as Director of the National Research Center on the Gifted and Talented. His research has focused on the identification and development of creativity and giftedness in young people, and on organizational models and curricular strategies for differentiated learning environments and total school improvement. A focus of his work has been on applying the pedagogy of gifted education to the improvement of learning for all students.

Tudor Rickards is Professor of Creativity and Organisational Change at Manchester Business School. He is also head of the Organisation Behaviour group at MBS. His earlier career included posts in a medical school, and as a technical professional within an industrial Research at Development Laboratory. He has published extensively on creativity, innovation, and change management. He has won numerous awards for teaching in these areas, and has been Alex Osborn visiting professor for creativity at the State University of New York, Buffalo. He is founder of the Creativity and Innovation Management journal, and co-founder of the European Association for Creativity and Innovation. His latest book is *Creativity and the Management of Change*, published by Blackwell.

Maxine Robertson is a Lecturer in Organizational Behavior at Warwick Business School, University of Warwick, U.K. She has a Ph.D. in Organization Studies from Warwick Business School. She is a member of the Innovation, Knowledge and Organizational Networking (IKON) Research Centre in Warwick Business School. Her main research interests are the management of knowledge workers and knowledge intensive firms, knowledge management and innovation. She has published extensively in all of these areas.

Michele Root-Bernstein is author or co-author of three books, the most recent being *Sparks of Genius, The Thirteen Thinking Tools of the World's Most Creative People* (1999), a close look at creative imagination across the arts and sciences. As an independent scholar and writer, with a Ph.D. in History from Princeton University, she has published articles and essays in a diverse array of scholarly and literary journals and has taught in elementary, secondary and university classrooms. In addition, she has consulted on creative process and transdisciplinary schooling for educational institutions and museums across the United States and abroad.

Robert Root-Bernstein is the author or co-author of four books, including *Discovering* (1989) and, with Michele Root-Bernstein, of *Sparks of Genius, The Thirteen Thinking Tools of the World's Most Creative People* (1999), both of which explore the nature of creative thinking. He earned his Ph.D. in History of Science at Princeton

University, received a MacArthur Fellowship while doing post-doctoral research at the Salk Institute for Biological Studies in 1981, and is currently a Professor of Physiology at Michigan State University. In addition to his academic studies, he has also consulted widely for the pharmaceutical and biotech industries and has several patents himself.

Keigo Sasaki is an Assistant Professor of business administration at Yokohama City University, Japan.

Harry Scarbrough is a Professor in Warwick Business School and is Director of the ESRC's Evolution of Business Knowledge research program in the U.K. Previously he was Research Director at the University of Leicester Management Centre. Dr Scarbrough's current interests include the influence of social networks on innovation, the transfer of learning between projects, and management practices for the evaluation of human capital within firms.

Larry Scripp has conducted extensive research in art and education at the Harvard Graduate School of Education's Project Zero and has published many articles about children's musical development, computers and education, and the acquisition of music literacy skills. He has also become a nationally known educator and researcher through his work for Harvard Project Zero's Arts PROPEL project, the Leonard Bernstein Center for Education Through the Arts, and his formative role in creating The Research Center for Learning Through Music and the National Music-in-Education Consortium at the New England Conservatory. In addition he is a founding director for the Conservatory Lab Charter School in Boston and is currently chair of the new Music-in-Education Program at New England Conservatory.

Kavita L. Seeratan has a Masters Degree in Human Development and Applied Developmental Psychology, obtained from the University of Toronto. She also has an Honours Bachelors Degree with a Specialist in Psychological Research and is currently pursuing her Doctoral studies at the University of Toronto. She works as a Research Associate at the University of Toronto's Adaptive Technology and Resource Centre and is Director of Research and Development for the Learning Disabilities Resource Community Project. Kavita is also currently involved as a key member in a project development team aimed at the development, testing and application of a new Meaning Equivalence Instructional Methodology (MEIM) geared at the assessment of deep comprehension.

Larisa V. Shavinina is a Professor at the Department of Administrative Sciences in the University of Québec en Outaouais, Hull, Canada. Her research program includes such projects as Psychological Foundations of Innovation, Innovations in Silicon Valley North, Innovation Leadership, Innovation and Knowledge Management, and Innovation Education. Originally focusing on psychology of high abilities (i.e. talent, giftedness, creativity), Dr Shavinina's research has expanded to encompass innovation. She is engaged in research aimed at unifying the field of innovation, that is, to merge psychological, management, and business perspectives together. Her publications have appeared in the *Review of General Psychology*, *New Ideas in Psychology*, *Creativity Research Journal*, and others. She co-edited *CyberEducation* and *Beyond Knowledge*.

Keng Siau is Associate Professor of Management Information Systems at the University of Nebraska-Lincoln. He is Editor-in-Chief of the *Journal of Database Management* and Editor of the *Advanced Topics in Database Research* book series. He received his Ph.D. degree from the University of British Columbia where he majored in Management Information Systems and minored in Cognitive Psychology. His Master and Bachelor Degrees are in Computer and Information Sciences from the National University of Singapore. Dr Siau has edited 7 books and written 15 book chapters. In addition, he is the author of over 45 refereed journal articles and over 60 refereed conference papers. His journal papers have appeared in such journals as *Journal of Creative Behavior*, *Management Information Systems Quarterly*, *Communications of the ACM*, *IEEE Computer*, *Information Systems*, *DATABASE*, *IEEE Transactions*, *Journal of Computer Information Systems*, *Journal of Database Management*, *Journal of Information Technology*, and *International Journal of Human-Computer Studies*.

Dean Keith Simonton is Professor of Psychology at the University of California, Davis. He published more than 250 articles and chapters plus eight books, including *Genius, Creativity, and Leadership*, *Scientific Genius*, *Greatness*, *Genius and Creativity*, *Great Psychologists*, and *Origins of Genius*, which received the William James Book Award from the American Psychological Association. Other honors include the Sir Francis Galton Award for Outstanding Contributions to the Study of Creativity, the Rudolf Arnheim Award for Outstanding Contributions to Psychology and the Arts, and others. He served as President of the International Association of Empirical Aesthetics from 1998 to 2000. His research focuses on the cognitive, personality, developmental, and socio-cultural factors behind exceptional creativity, leadership, genius, talent, and aesthetics.

Hock-Peng Sin is currently a graduate student in industrial and organizational psychology at Pennsylvania State University. His research interests include performance appraisal and management, work group effectiveness, work motivation, as well as levels and temporal issues in organizational research.

Gerald F. Smith is a Professor in the Department of Management at the University of Northern Iowa, where he teaches managerial decision-making and problem-solving. Dr Smith studies and writes about critical thinking, problem-solving, creativity, and other topics related to higher-order thinking, especially in practical, real-world, contexts.

Vangelis Souitaris is a lecturer and research coordinator at the Entrepreneurship Centre of Imperial College, London, U.K. He is a Chemical Engineer with an M.B.A. from Cardiff University, and a Ph.D. in Technological Innovation Management from Bradford University. His research is on technology and innovation management and entrepreneurship. He has published in such journals as *Research Policy*, *R&D Management*, *Technovation*, *International Journal of Innovation Management*, and *British Journal of Management*.

Robert J. Sternberg is IBM Professor of Psychology and Education in the Department of Psychology at Yale University and Director of the Center for the Psychology of Abilities, Competencies, and Expertise. He is 2003 President of the American Psychological Association.

Rena F. Subotnik is Director of the Center for Gifted Education Policy funded by the American Psychological Foundation. The Center's mission is to generate public awareness, advocacy, clinical applications, and cutting-edge research ideas that will enhance the achievement and performance of children and adolescents with special gifts and talents in all domains (including the academic disciplines, the performing arts, sports, and the professions). She is author of *Genius Revisited: High IQ Children Grown Up* and co-editor of *Beyond Terman: Contemporary Longitudinal Studies of Giftedness; Talent, Remarkable Women: Perspectives on Female Talent Development*, and the 2nd edition of the *International Handbook of Research on Giftedness and Talent*. Dr Subotnik is the 2002 Distinguished Scholar of the National Association for Gifted Children.

Jon Sundbo is a Professor of Business Administration specializing in innovation and technology management at Department of Social Sciences, Roskilde University, Denmark. He is also a Director of the Center for Service Studies, coordinator of the Department's research in the area of Innovation and Change Processes in Service and Manufacturing, Director of the University's Ph.D. program Society, Business and Globalization. Dr Sundbo has been doing research on innovation, service management and the development of the service sector, human resources management and organization. He has published articles on innovation, entrepreneurship, service and management and has published several books, including *The Theory of Innovation* and *The Strategic Management of Innovation*.

Jacky Swan is Professor in Organizational Behavior at Warwick Business School, University of Warwick. She completed her Ph.D. in Psychology. She is founding member of IKON—research Centre in Innovation, Knowledge, and Organizational Networks—and conducts her research in related areas. Professor Swan's current interests are in linking innovation and networking to processes of managing knowledge. She has been responsible for a number of U.K. Research Council projects in innovation and is currently working on a study of managing knowledge in project-based environments. She has published widely, including articles in *Organization Studies*, *Organization*, *Human Relations*, and is co-author of *Managing Knowledge Work* (Palgrave, 2002).

George Swede is Chair of the Department of Psychology at Ryerson University in Toronto, Canada. He has published two books and a number of papers on the psychology of art and creativity. Furthermore, he has published 30 collections of poetry, six poetry anthologies as editor, one book of literary criticism, as well as poems, short stories and articles in over 125 different periodicals around the world. His work has also appeared on radio and television in six countries and has been translated into 15 languages.

Hung-Kei Tang obtained his B.S. and M.S. degrees in electronics engineering from Queen's University in Canada and University College in London, U.K., respectively. After practising as an engineer and manager in Canada, Hong Kong, the Netherlands and Singapore, he returned to academia. He obtained his Ph.D. in innovation management from the Nanyang Technological University in Singapore where he is currently an Associate Professor. He has more than 60 academic publications. He is the Chairman of the IEEE Engineering Management Society in Singapore.

Paul Tesluk is an Associate Professor in Management and Organization at University of Maryland, Robert H. Smith School of Business. His research interests include the implementation and utilization of technology in the workplace, design and implementation of high-involvement workplace systems, work team performance, and employee and managerial development.

Paul Trott is a Principal Lecturer, Business School, University of Portsmouth. He holds a Ph.D. from Cranfield University. He is author of many reports and publications in the area of innovation management. His book *Managing Innovation and New Product Development* published by Financial Times Management is now in its second edition.

Nancy Vail has focused her career on human resources in the United States Office of Personnel Management while earning graduate degrees at the University of California, Davis and the University of Florida, Gainesville. Her interest in aging is complemented by further studies in clinical psychology at William Paterson State University of New Jersey.

Larry Vandervert is a theoretician, writing in psychology and the neurosciences for the last two decades. He co-founded The Society for Chaos Theory and the Life Sciences in 1991. In the past two decades he has authored many articles on a brain-based theory and epistemology. Dr Vandervert proposes that the true fundamentals of science must eventually be stated in terms of brain algorithms. In recent years, Dr Vandervert has published a series of papers that describe how he believes that mathematics arises from collaborative functions of brain areas. He believes that mechanisms in the brain that generate and manipulate patterns are responsible for both the discovery of mathematics and the processes that lead to innovation.

Robert W. Veryzer is an Associate Professor in the Lally School of Management and Technology at Rensselaer Polytechnic Institute, Troy, New York. His work experience includes product planning and product management positions with *Fortune 500* firms as well as design and new product development consulting. He holds an M.B.A. from Michigan State University and a Ph.D. in consumer research and marketing from the University of Florida. His research focuses on product design, new product development, radical innovation, and various aspects of consumer behavior. Dr Veryzer's articles appear in leading professional journals, and he is co-author of *Radical Innovation: How Mature Firms Outsmart Upstarts* (Harvard Business School Press, 2000).

Robert Weisberg is Professor of Psychology at Temple University. He received a Ph.D. in psychology from Princeton University, and his areas of interest are problem-solving and creative thinking. He has published papers investigating cognitive mechanisms underlying problem-solving, and has published papers and books examining cognitive processes underlying creative thinking. His current work in problem-solving is investigating mechanisms underlying 'insight'. He is also carrying out research in creative thinking, which focuses on case studies of major creative advances, using historical 'data' to draw conclusions concerning cognitive processes involved in creative thinking.

John Wetter is Manager of e-Services Business Unit at the Xerox Corporation He is also a Doctoral Candidate at the GWU SBPM MSII Program. He leads a specialized group focused on consulting to major corporations regarding their document management needs. He developed and implemented a number of service offerings, including Digital Fulfillment, Financial Transaction Health Care and Digital Imaging Management. Prior to his current position, he managed Globalization & Localization Services for Software Development as Vice President-General Manager. Other positions held during his career were Manufacturing Manager, Materials Manager, Sales & Marketing, and Production Control Manager.

Beate E. Wilhelm, Ph.D., is Managing Director of z-link, Zurich, a non-profit institution at the interface between higher education, industry, and government in the Greater Zurich Area. Previously, she was a member of the executive board of z-link. She has many years of experience as consultant and scientist in promoting strategic innovation processes to develop regional economies. Dr Wilhelm also worked at the University of St Gallen, Switzerland, and at the Fraunhofer-Institute for Production Technology and Automation, Department of Business Organization, Germany. She is founder member and member of the board of the Swiss Association for Studies in Science, Technology, and Society. Her main research interests include knowledge production, knowledge- and technology transfer, strategic innovation processes, regional innovation policy, and self-organization.

Richard W. Woodman is the Fouraker Professor of Business and Professor of Management at Texas A&M University where he teaches organizational behavior, organizational change, and research methodology. He served

as Head of the Department of Management from 1993 to 1997. His research interests focus on organizational change and organizational creativity. His current research and writing explore the role of the organization in individual change, the relationship between processes of creativity and organizational change, and reoccurring patterns in the failure of change programs. Woodman is co-editor of the JAI Press annual series, *Research in Organizational Change and Development*; his co-authored text, *Organizational Behavior*, is in its 9th edition.

Khim-Teck Yeo obtained his Ph.D. in Project Management from the University of Manchester. He has been a visiting scholar at the Sloan School of Management, MIT and visiting professor in Industrial Engineering at the University of Washington. His main academic interests are in project, systems and technology management. He has published widely in these fields with over 120 papers in international journals and conference proceedings. He serves on the Editorial Board of the *International Journal of Project Management*. He was the founding President of the Project Management Institute (PMI), Singapore Chapter. He is currently an Associate Professor in Nanyang Technological University, Singapore, and Director of the Centre for Project Management Advancement.

Maximilian von Zedtwitz is Professor of Technology Management at IMD—International Institute for Management Development, Lausanne, Switzerland. He holds Ph.D. and M.B.A. degrees from the University of St Gallen, and M.Sc. and B.Sc. degrees from ETH Zurich. He was a research associate at the Institute for Technology Management in Switzerland, and a Visiting Fellow at the Graduate School of Arts and Sciences at Harvard University in Cambridge, Massachusetts. He joined IMD in summer 2000 to teach international innovation strategy, R&D management, and technology-based incubation. He has published two books and more than 40 papers on international innovation management and R&D. He won the 1998 RADMA prize for the best paper in the *R&D Management Journal*.

Jing Zhou is Associate Professor and Mays Fellow in the Management Department at the Mays Business School at Texas A&M University. Her current research interests focus on personal and contextual factors that promote or inhibit employee creativity and innovation. She has published widely in top journals in the field, such as *Academy of Management Journal*, *Journal of Applied Psychology*, *Journal of Management*, and *Personnel Psychology*. She currently serves on the editorial boards of *Journal of Applied Psychology* and *Journal of Management*.

Preface

There is no doubt that innovations were, are, and will be extremely important for the individual and society. One way to understand the history of human culture is via its inventions and discoveries. All human cultural development builds on the amazing technological, scientific, educational, and moral achievements of the human mind. Today, people increasingly realize that innovations are even more critical than in the past. Thus, industrial competition is increasingly harsh and companies must continuously bring innovative products and services to the global market. To survive, companies need creative and inventive employees whose novel ideas are, to a certain extent, a necessity for the companies' continued existence and future success. Consequently, modern society desperately requires highly able citizens who can produce innovative solutions to current challenges and contribute new ideas that aid in the development and growth of the market for a particular product or service. People of exceptionally innovative ability thus remain an extremely important source of innovation and renewal. Hence, the new millennium is characterized by the need for innovative minds. Contemporary society, without doubt, is highly reliant on innovations. The future will be synonymous with innovation, since it will need an extremely high saturation of innovations in all areas of human endeavour. Despite the quite evident importance of innovations in the life of any societal 'organism', one should acknowledge that the phenomenon of innovation is far from well understood. Because of this, a handbook on innovation is an exceptionally timely endeavour.

The field of innovation is lively on many fronts. For the most part, it is studied today by many different disciplines as one of their components. However, contemporary demands on innovative ideas, solutions, products, and services mark an imperative of a special unified, multifaceted and multidimensional discipline: science of innovation. It was a combination of my interest in the topic of innovation with my perception of the field as needing unification that encouraged me to initiate the present project. I came to believe that the time was ripe for an *International Handbook on Innovation*—a volume that would help guide research in innovation during at least the next decade and, therefore, would advance the field.

The purpose of the handbook is multifold: (a) to pose critical questions and issues that need to be addressed by research in a given subfield of innovation; (b) to review and evaluate recent contributions in the field; (c) to present new approaches to understanding innovation; and (d) to indicate lines of inquiry that have been, and are, likely to continue to be valuable to pursue. This handbook does not provide the kind of literature reviews usually found in textbooks. The conventional understanding of handbook—as a compendium of review chapters suggesting a guide to practice—seems to be very restricted in the context of the field of innovation. The 'handbook' title suggests a guide to practice only in cases where the body of knowledge is understood to be complete and more or less unchanging. For example, 'Handbook of Mathematical Formulae', or 'Handbook of Motorcycle Repair'. However, the study of innovation is a body of knowledge under dynamic theoretical development, and so I prefer to use the 'International Handbook on Innovation' instead of the 'International Handbook of Innovation'. I hope readers will find the present chapters lively and provocative, stimulating greater interest in the science of innovation.

The handbook covers a wide range of topics in innovation. The handbook offers a broad analysis of what innovation is, how it is developed, how it is managed, how it is assessed, and how it affects individuals, groups, organizations, societies, and the world as a whole. The handbook will therefore serve as an authoritative resource on many aspects of theory, research, and practice of innovation. In short, the handbook can be considered as the first serious attempt to unify the field of innovation and, consequently, as the beginning of unified science of innovation. I hope that readers of this handbook will view it as serving that function.

The target international audience for this handbook is broad and includes a wide range of specialists—both researchers and practitioners—in the areas of psychology, management and business science, education, art, economics, technology, administration, and policy-making. Non-specialists will also be interested readers of this handbook, and it will be useful in a wide range of graduate courses as supplementary reading. Because the coverage of the handbook is so broad, it can be read as a reference or an as-needed basis for those who would like information about a particular topic, or from cover to cover either as a sourcebook or as a textbook in a course

dealing with innovation. In short, anyone interested in knowing the wide range of issues regarding innovation will want to read this handbook.

The handbook hopes to accomplish at least four things for readers. First, the reader will obtain expert insight into the latest research in the field of innovation. Indeed, some of the world's leading specialists agreed to contribute to this handbook. Second, the handbook will present many facets of innovation including its nature, its development, its measurement, its management, and its social, cultural, and historical context (most books are devoted to only one of these facets). This breadth will allow the reader to acquire a comprehensive and panoramic picture of the nature of innovation within a single handbook. Third, based on this picture, the reader will develop an accurate sense of what spurs potentially creative and innovative people and companies toward their extraordinary achievements and exceptional performances. Fourth, and perhaps most importantly, the reader will be able to apply the ideas and findings in this handbook to critically consider how best to foster their own innovative abilities and innovative performance in their organization.

There are many people to thank for helping this handbook come to fruition. Most important are the authors: I thank them for their willingness to undertake the difficult and challenging task of contributing chapters. I am particularly grateful to Professor Marina A. Kholodnaya, my former Ph.D. supervisor, who to a great extent 'made' me a researcher, developing my perception of scientific problems. She continually inspires me to undertake innovative endeavors. I am also grateful to my editors at Elsevier Science—Gerhard Boomgaarten and Geraldine Billingham, Publishing Editors, Lesley Roberts, Marketing Editor, and Debbie Raven, Senior Administrative Editor—who provided just the right blend of freedom, encouragement, and guidance needed for successful completion of this project.

I also wish to acknowledge my debt of gratitude to my parents, Anna Shavinina and Vladimir Shavinin, who aroused a passionate intellectual curiosity in me. Finally, I owe my biggest debt of gratitude to my husband, Evgueni Ponomarev, and our four-year-old son, Alexander. In countless ways, Evgueni has been a true colleague, critic, and friend throughout the four years of the project. He provided the moral, financial, and technical support, and—more importantly—the time I needed to complete this project. He did so by performing a number of great tasks, from cooking and administering PC problems when I worked at nights, to assuming the lion's share (and the lioness's, too) of child care for our Alexander, who was born during the course of this project. Very simply, this is his handbook, too.

I especially wish to thank Alexander, whose entry into the world taught me more about innovation and the need for it than has any other single event in my life. He demonstrates everyday that innovation is constantly possible. I sincerely hope that today's children from around the world will grow up to be innovative individuals—in both professional and daily life.

Larisa V. Shavinina

Understanding Innovation: Introduction to Some Important Issues

Larisa V. Shavinina

Département des Sciences Administratives, Université du Québec en Outaouais, Canada

Abstract: This introduction provides an overview of the multidisciplinary and multi-faceted research on innovation presented in the following chapters of this handbook. The main contents of each chapter are summarized, and approaches taken by chapter authors are described.

Keywords: Innovation; Creativity; Approaches to understanding innovation; Management; Business science.

Introduction

Most scholars and decision-makers will agree that innovations are necessary for individuals, groups, and society as a whole. There is also a consensus that human beings must advance in their study of innovation in greater detail. But there are a relatively small number of individuals around the world who study innovation. My goal in bringing them together in this handbook is to present a comprehensive picture of contemporary innovation research by integrating the quite diverse findings obtained by scholars from highly specialized and frequently remote disciplines, and to outline directions for further research, thus advancing the field. In choosing chapter authors, I was particularly interested in those new models, theories, and approaches, which they proposed. My deepest belief is that any handbook on any scientific topic should not only report the current findings in the field, but must also advance that field by presenting challenging new ideas. In one way or another each chapter in the handbook adds something new to our existing edifice of knowledge about innovation. This is the main merit of this handbook, which is international in scope, reflecting American, Canadian, Asian, European, and global perspectives. The chapter authors take a number of different approaches, both empirical and theoretical, reflecting a variety of possible perspectives and research methods aimed at understanding innovation. These range from case studies and autobiographical and biographical methods to experimental methods. I will briefly describe these approaches below. The handbook is divided into XV parts. The first part provides a general introduction to the work. Parts II to

XIV, consisting of 69 chapters, represent distinctive, although sometimes overlapping, approaches to understanding innovation. The final part of the handbook integrates these approaches.

Part I comprises just the present chapter, Chapter 1, which sets the stage for understanding innovation. This chapter describes the various approaches used by authors of this handbook in understanding innovation and briefly summarizes the main contents of each chapter.

Part II of the handbook describes work aimed at the understanding the multifaceted nature of innovation, its basic mechanisms and its various facets. This part presents neurophysiological, psychological, philosophical, sociological, economic, management and business science perspectives on innovation. This part comprises 15 chapters.

In Chapter 1 of Part II, *The Neurophysiological Basis of Innovation*, Larry Vandervert describes for a broad audience how the repetitive processes of working memory are modeled in the brain's cerebellum. He argues that when these models are subsequently fed back to working memory they are experienced as new, more efficient concepts and ways of doing things. As this process is repeated, the resulting degree of generalization (abstraction) increases. When multiple pairs of models are learned in working memory, they may give rise to sudden experiences of insight and intuition. To illustrate the working memory/cerebellar process of innovation, Vandervert walks the reader through three of Albert Einstein's classic subjective accounts of discovery. This is the only chapter in the handbook, which sheds light on the neuropsychology

logical nature of innovation. The neuropsychological foundations of innovation is a promising new direction in research on innovation.

Chapter 2, *On the Nature of Individual Innovation*, by Larisa V. Shavinina and Kavita L. Seeratan, introduces a fascinating theme, which also will be discussed in other chapters of the handbook from various angles. The theme is why some individuals are exceptionally able to generate new ideas, which lead to innovation. The chapter presents a new psychological conception of individual innovation. According to the conception, individual innovation is a result of a specific organization of an individual's cognitive experience. This organization is, in turn, a result of the protracted inner process of the actualization, growth, and enrichment of one's own cognitive resources and their construction into an unrepeatable cognitive experience during accelerated mental development. The direction of this process is determined by specific forms of the organization of the individual cognitive experience (i.e. conceptual structures, knowledge base, and mental space). The unique structure of the mind, which makes possible the creative ideas leading to innovation, is being formed on the basis of this process. The uniqueness of innovators' minds expresses itself in objective representations of reality; that is, in their unique intellectual picture of the world. This means that innovators see, understand, and interpret the world around them by constructing an individual intellectual picture of events, actions, situations, ideas, problems, any aspects of reality in a way that is different from other people.

In contrast to one of the psychological understandings of innovation presented in Chapter 2, Dora Marinova and John Phillimore's *Models of Innovation*, Chapter 3, reviews a number of models developed by economists, management and business scholars, sociologists, geographers, and political scientists that are used to explain the nature of innovation. Their overview includes six generations of models: the black box model, the linear model, the interactive model, the systems model, the evolutionary models, and the innovative milieu model. The authors view innovation mainly as a process leading to generating new products. Marinova and Phillimore analyze each model, its explanatory power and related concepts, and draw further research directions. A comprehensive review of the six models of innovation provides readers with a panoramic picture of the evolution of researchers' views on the nature of innovation.

In Chapter 4, *Evolutionary Models of Innovation and the Meno Problem*, Thomas Nickles proposes a philosophical view of innovation. He presents universal Darwinism as a new approach to understand innovation. According to this approach, innovation is the product of blind variation plus selective retention (BV + SR) and is thus a kind of adaptation, that is, a selective-adaptive process. In Nickles' view, accepting

BV + SR enables human beings to recognize sources of innovation other than new ideas of creative and talented individuals. He, however, points out that the human design model is not entirely wrong, but it turns out to be based on previous applications of BV + SR.

Chapter 5, *Three-Ring Conception of Giftedness: Its Implications for Understanding the Nature of Innovation*, by Joseph S. Renzulli, is the chapter where an author was given an explicit assignment; in this case, to apply his well-known conception of giftedness toward achieving an understanding of innovation. According to the conception, giftedness that leads to innovation emerges from the interaction and overlap of three clusters of traits; high ability in a particular domain, task commitment, and creativity, and occurs in certain individuals, at certain times, under certain conditions. This is another psychological attempt to address the intriguing issue about where innovation 'comes from'. Renzulli's Three-Ring Conception of Giftedness focuses on creative/innovative productivity, which differs from academic giftedness, and is thus appropriate for understanding forces leading to the appearance of innovators.

In Chapter 6, *Innovation and Strategic Reflexivity*, Jon Sundbo presents a strategic innovation theory, which explains activities that lead to innovations in firms. His theory, in which strategic reflexivity is the core concept, is based on evolutionary theory. According to the theory, market conditions and internal resources are the drivers of the innovation process. Firms manage their innovation process and market position through the strategy. Reflexivity is considered as a process during which managerial staff and employees define their strategy. Sundbo presents case studies of innovation in service firms, which support his strategic innovation theory.

Chapter 7, *The Nature and Dynamics of Discontinuous and Disruptive Innovations from a Learning and Knowledge Management Perspective*, by Elias G. Carayannis, Edgar Gonzalez and John Wetter, discusses the nature and dynamics of innovation as a socio-technical phenomenon. Specifically, these authors analyze the evolutionary and revolutionary dimensions of innovation, that is, discontinuous and disruptive types of innovation, respectively. They claim, and provide evidence to support that claim, that the key to organizational competence for generating and leveraging discontinuous—and especially disruptive—innovations is in the individual and organizational capacity for higher-order learning and for managing the stock and flow of knowledge. This chapter is the first in the Handbook to introduce important topics of organizational learning and knowledge management and their growing role in the emergence of innovation. This role is so significant that it is generally recognized today that we live in a society, which is largely based upon a knowledge-based economy.

In Chapter 8, *Profitable Product Innovation: The Critical Success Factors*, Robert G. Cooper analyzes the critical success factors that underlie new product performance, relying upon his and other's research into hundreds of new product launches, probing the question: 'what distinguishes the best from the rest?' Ten common denominators or factors appear to drive new product success, profitability and time-to-market. The chapter outlines these ten critical success factors, and notes the management implications of each.

Chapter 9, *Types of Innovations*, by Robert J. Sternberg, Jean E. Pretz and James C. Kaufman, describes various innovative forms, each representing a different kind of creative contribution. Based on Sternberg's propulsion model of creative contributions, the authors present the following eight types of innovation: replication, redefinition, forward incrementation, advance forward incrementation, redirection, reconstruction, reinitiation, and integration. For example, a conceptual replication is a minimal innovation, simply repeating with minor variations an idea that already exists (e.g. when Mercury puts the 'Mercury' label on what is essentially an already-existing Ford car). Forward incrementations represent next steps forward in a line of progression (e.g. the 2001 version of a 2000 Ford car). Redirections represent a totally different direction for products that diverges from the existing line of progress (e.g. electric cars). The authors discuss these types of innovations and the circumstances under which they are likely to be more or less successful.

In Chapter 10, *Problem Generation and Innovation*, Robert Root-Bernstein further extends our understanding of innovation. Following Albert Einstein and many other innovators in the sciences and engineering, Root-Bernstein argues that problem generation or problem-raising is far more critical to innovation than problem solution, involving not just a thorough grasp of what is known (epistemology), but of what is not known (nepistemology). The key thesis of nepistemology states that we must know what we do not know before we can effectively solve any problem. People are creative and innovative only when they need to do something that cannot yet be done. Root-Bernstein explores strategies used by successful innovators to generate productive problems.

In Chapter 11, *The Role of Flexibility in Innovation*, Asta S. Georgsdottir, Todd I. Lubart and Isaac Getz, define flexibility as the ability to change, emphasizing that innovation encompasses different types of change. Innovation is essentially a science about change, so it is not surprising that 'innovation' is frequently considered synonymous with 'organizational change'. The authors analyze different types of flexibility, particularly concentrating on adaptive flexibility (the ability to change as a function of task requirements) and spontaneous flexibility (the tendency to change for intrinsic reasons, to try out a variety of methods). The

issue of how these types of flexibility are important at different stages in the innovation process is also considered.

In Chapter 12, *The Effect of Mood On Creativity in the Innovative Process*, Geir Kaufmann focuses on creativity aspects of innovation, discussing a recent stream of new research on the importance of mood and affect in the process of creativity. He addresses the issue of the effect of mood states on creative problem-solving as part of the process of innovation. Kaufmann criticizes the dominant opinion that there exists a positive causal link between positive mood and creativity. He analyzes research findings, which demonstrate that under certain conditions positive mood may in fact impair creativity, while negative and neutral moods may facilitate searching for creative solutions to existing problems. Finally, Kaufmann presents a new theory of mood and creative problem-solving and provides data supporting it.

Chapter 13, *Case Studies of Innovation: Ordinary Thinking, Extraordinary Outcomes*, by Robert W. Weisberg, presents another approach to understanding the nature of innovation. He challenges the existing view that innovation is the result of extraordinary thought processes, such as Wertheimer's productive (as opposed to reproductive) and Guilford's divergent (as opposed to convergent) thinking. Weisberg asserts that innovation is the result of the use of ordinary thinking process; creative thinking is simply ordinary thinking that has produced an extraordinary outcome. The author uses quasi-experimental quantitative methods to examine case studies of innovators in the arts and science to support his approach. A sampling of case studies includes Picasso's development of his painting *Guernica*, Edison's electric light, Mozart's compositions, and the Beatles' stylistic innovations.

In Chapter 14, *Innovation and Evolution in the Domains of Theory and Practice*, James R. Bailey and Cameron M. Ford claim that innovation appears when individuals produce novel solutions, and members of the relevant domain adopt it as a valuable variation of current practice. The authors assert that at the individual level, creative or innovative actions are adoptive responses to tensions between the person and situation. In domains such as the arts or sciences, person-situation tensions are best resolved by favoring novelty, whereas in domains such as business, the same tensions are best resolved by favoring value. Bailey and Ford employ a neo-evolutionary view of creativity to propose that these within domains tensions create intractable tensions between domains.

Chapter 15, *E-Creativity and E-Innovation*, by Keng Siau, is about developments in the field of artificial intelligence, which provide researchers another means of analyzing the creative process. The author reviews germane work and discusses the existing approaches to e-creativity and their application for understanding e-innovation. He concludes that we can build creative

programs, which have the potential to shape the future of innovation.

Although many of the above-mentioned chapters consider individual differences in innovation to some extent, Part III of the Handbook, *Individual Differences in Innovative Ability*, concentrates directly on this issue. This Part consists of one chapter, *The Art of Innovation: Polymaths and Universality of the Creative Process*, by Robert Root-Bernstein, that discusses individual differences in innovative ability, which are caused by human innovative thinking. The author takes an interesting approach to the topic: he focuses on polymaths, that is, those innovative artists who have made scientific discoveries, innovative scientists who have made artistic contributions, and those who bridge both sets of disciplines without claiming allegiance to one the other. Root-Bernstein argues that examples of such scientists and artists are unexpectedly common. He concludes that it is precisely those polymaths, that is, those people who incorporate modes of thinking belonging to many cognitive domains that are those most likely to become innovators. Root-Bernstein's analysis of the most innovative polymaths leads him inevitably to the consideration of sciences–arts interactions from the viewpoint of their mutual contribution to innovation.

Part IV of the Handbook, *Development of Innovation Across the Life Span*, is aimed at understanding innovation mainly from the viewpoint of developmental psychology. It thus reflects developmental perspectives on innovation, showing how it develops in individuals from early years through late adulthood and until the end of the personal life. The developmental approaches to innovation explain many of the individual differences in innovation caused by the specificity of human development.

Chapter 1, *Young Inventors*, by Nicholas Colangelo, Susan Assouline, Laurie Croft, Clar Baldus, and Damien Ihrig, analyzes a special kind of innovation in children and adolescents, namely inventiveness. The authors briefly review the history of the study of young inventors. They further describe research on the young inventors who were part of the Invent Iowa program and who have been evaluated as meritorious inventors at local and regional invention competitions qualifying for the State of Iowa Invention Convention. This research revealed a wide range of important findings regarding perceptions of young inventors about the inventiveness process, their attitudes toward school, toward students, and an analysis of their inventions. It is interesting to note that boys and girls have equally strong interest and equal participation in inventiveness programs.

In Chapter 2, *Exceptional Creativity Across the Life Span: The Emergence and Manifestation of Creative Genius*, Dean Keith Simonton connects major innovations in the arts and sciences to the output of creative geniuses. He addresses the two main questions: “How

do great innovators appear?”; and “How does their creativity manifest itself?”. Considering the first question, Simonton analyzes the early experiences that contribute to the development of extraordinary creative potential. Those factors include family background, education, and professional training. In order to address the second question, Simonton focuses on the typical career trajectory of great innovators. He discusses the ages at which geniuses tend to produce their first great work, their best work, and their last great work.

Chapter 3, *Innovations by the Frail Elderly*, by Tomas Heinzen and Nancy Vail, presents an exceptional approach to understanding innovation. The authors point out that the study of extreme, unusual, or unlikely populations represents one seldom-used yet insightful research strategy. In their opinion, non-normative populations can provide insights about innovation that may generalize to larger populations. One such population that appears to be unlikely to demonstrate significant innovation is the frail elderly. The nine innovation principles presented in this chapter are abstracted from research, naturalistic observation, and clinical experience of the ‘pre-hospice’ population of frail elderly people living in nursing homes. Heinzen and Vail’s principles state that ‘the impetus for innovation may be external, unpleasant, and unwelcome’; ‘innovation does not require a ‘creative personality’; ordinary personalities in extraordinary circumstances will innovate’; ‘both frustration and suffering can inspire innovation’; ‘frustration will not lead to innovation unless it is sufficiently annoying to force new ways of thinking about a problem’; ‘innovative behavior is both externally and internally self-rewarding’. ‘changing ourselves represents one form of innovation’. Analyzing situation-driven and personality-driven kinds of innovation, Heinzen and Vail conclude that maximal probability of innovation is the product of the interaction between external stressors such as necessity, desperation, and perceived threat combined with internal capabilities such as habit, preparation, and motivation.

I would like to note that one of the aims of the handbook is to extend the existing understanding of innovation. For the most part, within the psychological science, the term ‘innovation’ is perceived as referring specifically to ‘innovative ideas’. Within the business and management science, the concept of ‘innovation’ is highly associated with ‘new product development’ or ‘innovation management’. I believe, however, that ‘innovative behavior’, ‘innovation in daily life’, and other similar phenomena should be explored, and this is another focus of the Handbook. In this light the Heinzen and Vail chapter definitely extends our understanding of innovation, pointing out a new promising direction in research on innovation.

Part V of the Handbook, *Assessment of Innovation*, comprises just one chapter about the measurement of

innovation. In this chapter, Ronald E. Goldsmith and Gordon R. Foxall analyze the assessment issues from a marketing perspective. Innovativeness refers to individual differences in how people react to innovations and accounts for much of their success or failure. Their conceptualization of innovativeness includes global, consumer, and domain-specific levels of innovativeness. Goldsmith and Foxall present many of the current perspectives on innovativeness and describe a variety of measures that reflect them.

Taking into account today's ever increasing demand for innovative ideas, solutions, products, services, and the commensurate demand on the creative, gifted, and talented individuals able to produce them, Part VI of the Handbook, *Development of Innovation*, consists of chapters with clear educational implications. Their authors analyze a variety of psychological methods, creativity techniques, and educational strategies best suited for the development of human abilities to innovate. The term education is broadly interpreted in the context of this Handbook. It refers to: (a) school and university education for innovation devoted to the development of students' innovative abilities, innovative behavior, and innovative attitude to the world around them; (b) organizational learning; (c) creativity and innovation training; and (d) teaching of innovation. This Part discusses what should be done to encourage the appropriate development of innovative abilities in children and adults, and how this can be accomplished within and outside of traditional education frameworks.

Chapter 1, *Developing High Potentials for Innovation in Young People Through the Schoolwide Enrichment Model*, by Sally M. Reis and Joseph S. Renzulli, presents the Schoolwide Enrichment Model (SEM), developed during 20 years of research in programs for gifted students, which enables each school to develop unique programs for talent development and creative productivity based upon local resources, student demographics, and school dynamics as well as upon faculty strengths and creativity. The major goal of SEM is to promote challenging and enjoyable high-end learning across a wide range of school types, levels, and demographic differences. The idea is to create a repertoire of enrichment opportunities and services that challenge all students. Any individual student does better in a school when all students appreciate creativity and innovation. SEM is one of the excellent ways to develop the creative potential of students within a traditional educational setting and inspire in them a spirit of innovation, inquiry, entrepreneurship, and a sense of power to effect change.

In Chapter 2, *Towards a Logic of Innovation*, Gerald F. Smith asserts that though it is affected by the organizational and social context, and by the individual's personality and motivation, the generation of innovative ideas depends to a considerable degree on

consciously controlled mental activities. His chapter discusses how an aspiring innovator can utilize specific mental activities and exercises in order to improve the prospects for successful idea generation. Smith points out that traces of such logic can be found in the many idea generation methods that have been proposed, but rarely tested, in the creativity literature. He also analyzes the logic of scientific discovery, another component of such logic that has been the target of philosophical and psychological development for the past half century. In Smith's view, the final and most promising stream of research is recent work that tries to develop useful prescriptions for innovation through the analysis of past cases of innovative activity. The most significant of these efforts is TRIZ, the theory of inventive problem-solving developed by Genrich Altshuller.

Chapter 3, *The Development of Innovative Ideas through Creativity Training*, by Maria M. Clapham, examines the effectiveness of various creativity training programs in enhancing innovation. In order to develop innovative thinking and to increase human ability to generate new ideas, creativity training programs of various types have become widespread in educational and business settings. Clapham provides an overview of various types of creativity training programs, which vary widely in methodology and scope, and analyzes recent research findings regarding their effectiveness for stimulating the development of innovative ideas.

In Chapter 4, *Intuitive Tools for Innovative Thinking*, Robert Root-Bernstein and Michele Root-Bernstein consider the role of intuitive thinking skills in the appearance of great innovations in the arts and sciences. The authors identified 13 non-verbal, non-mathematical, non-logical thinking tools that innovative individuals in a wide variety of disciplines say they use and discuss these tools in detail. The tools are: observing, imaging, abstracting, recognizing and forming patterns, analogizing, body thinking, empathizing, dimensional thinking, modeling, playing, transforming and synthesizing. R. Root-Bernstein and M. Root-Bernstein conclude that private, unarticulated insights generated by means of these tools are then translated in an explicitly secondary step into verbal, mathematical and other modes of public communication. Educational efforts to promote creative thinking must thus recognize and exercise intuitional thinking skills and directly address the process of translating idiosyncratic subjective thought into objectified public forms of discourse.

Chapter 5, *Stimulating Innovation*, by Ronald N. Kostoff, describes how innovation can be increased through the discovery by cross-discipline knowledge transfer. The author's approach entails two complementary components: one literature-based, the other workshop-based. The literature-based component identifies the science and technology disciplines related to

the central theme of interest, the experts in these disciplines, and promising candidate concepts for innovative solutions. These outputs define the agenda and participants for the workshop-based component. An example of this approach is presented for the theme of Autonomous Flying Systems.

In Chapter 6, *Developing Innovative Ideas Through High Intellectual and Creative Educational Multimedia Technologies*, Larisa V. Shavinina and Evgueni A. Ponomarev examine how human innovative abilities can be increased by the means of contemporary educational multimedia technologies. They analyze innovations in instructional technology and their implications for developing an individual's intellectual and creative abilities. The authors present high intellectual and creative educational multimedia technologies (HICEMTs) as a special kind of psycho-educational multimedia technology, which are aimed at the development of people's innovative abilities. They argue that a real goal of education should be seen not in knowledge transfer, but in the development of the individual intellectual and creative potential.

Part VII of the Handbook, *Innovations in Different Domains*, is aimed at understanding domain-specific innovations. One of the facets of the uniqueness of the Handbook and its fresh perspectives should be seen in analyzing the specificity of innovation(s) in various areas like science, art, education, management, business, technology, finance, and so on. In other words, the chapter authors reflect a domain-specific view of innovation, considering scientific innovations, technological and industrial innovations, financial innovations, innovations in education, and so on. In this regard, the Handbook addresses the exceptionally important question: Does the uniqueness of each domain predetermine the specific mechanisms of innovation within it?

Chapter 1, *Dimensions of Scientific Innovation*, by Gerald Holton, concentrates on scientific innovation of geniuses. The author describes essential but largely hidden mechanisms of scientific innovation as they manifest themselves in works of Johannes Kepler, Henri Poincare, Enrico Fermi, and the discoverers of high-temperature superconductivity.

In Chapter 2, *Do Radical Discoveries Require Ontological Shifts?* Michelene T. H. Chi and Robert G. M. Hausmann claim that many great revolutionary discoveries in science may have occurred because the scientists have undertaken an ontological shift. That is, the scientists re-conceptualized or re-represented the problem (i.e. the phenomenon to which she/he is seeking an explanation) from the perspective of one ontology or ontological category to another ontology. Examples of the highest level of ontological categories are entities, processes, and mental states. Chi and Hausmann explain what this re-representation or shifting across ontological categories entails, and why it is unusual to undertake, therefore shedding light on

the low frequency of exceptionally revolutionary scientific discoveries. The authors discuss examples from contemporary science and the history of science, which provide evidence in favor of their radical ontological change hypothesis.

Chapter 3, *Understanding Scientific Innovation: The Case of Nobel Laureates*, by Larisa V. Shavinina, addresses an important issue in understanding scientific innovation, namely: 'Why are Nobel Laureates so capable of innovation?' The author demonstrates that scientific innovation of Nobel laureates is determined in part by specific preferences, feelings, and beliefs, which constitute a whole field of unexplored or weakly explored scientific phenomena. These phenomena constitute Nobel Laureates' extracognitive intelligence that accounts for their exceptionally developed tacit knowledge, which, in turn, significantly contributes to the emergence of scientific discoveries. Based on autobiographical and biographical accounts of Nobel laureates, Shavinina describes all of these phenomena in detail and shows that they predict scientific productivity of the highest level resulting into innovations and, as such, displaying an outstanding talent of Nobel caliber.

In Chapter 4, *Innovation in the Social Sciences: Herbert A. Simon and the Birth of a Research Tradition*, Subrata Dasgupta describes the cognitive-social-historical process of innovation in the realm of the social sciences. In his view, innovation presumes creativity but creativity does not necessarily result in innovation. The latter involves both the cognitive process of creation and the social-historical process by which the created product is assimilated into a milieu. Dasgupta analyzes how the American polymath Herbert A. Simon (1916–2001) was led to a particular model of human decision making which in turn gave birth to a radically new research tradition—the cognitive tradition or, more simply, cognitivism—first in organization theory and economics, and then in other domains of the human sciences. For his seminal role in the creation of this research tradition, Simon was awarded the 1978 Nobel Prize for Economic Science. In Dasgupta's view, the emergence of a research tradition in any science signifies a major innovation in that science.

In Chapter 5, *Poetic Innovation*, George Swede points out that every artist wants his or her work to be considered innovative, in both historical and contemporary terms. A psychologist, poet and editor of poetry periodicals and anthologies, the author discusses how and why poets strive towards these goals. His results can also be applicable to other kinds of artistic innovation. Swede's analysis is based upon the findings of psychological research on poets and their poetry, literary theory, and upon his own rich poetic and editorial experience.

Chapter 6, *Dual Directions for Innovation in Music: Integrating Conceptions of Musical Giftedness into*

General Educational Practice and Enhancing Innovation on the Part of Musically Gifted Students, by Larry Scripp and Rena F. Subotnik, discusses what should be done for systemic and sustainable innovation in public school music education. Scripp and Subotnik's analysis of innovations in music education lead them to propose a five-step course of action, potentially resulting into future innovations. These steps are: reconcile perspectives regarding the purpose of music education, establish a framework for comprehensive, interdisciplinary programs intended to benefit all children, prepare advanced college-conservatory students to contribute to the development and sustainability of innovative programs as 'artist-teacher-scholars', form networks of college-conservatory, arts organization, and public school partnerships, and, finally, explore and promote new conceptions of giftedness that result from the implementation of innovative forms of comprehensive, interdisciplinary music education.

In Chapter 7, *Determinants of Technological Innovation: Current State of the Art, Modern Research Trends, and Future Prospects*, Vangelis Souitaris reviews various methodologies used to identify the distinctive characteristics of innovative firms in the field of technology, that is, determinants of technological innovation. He discusses a wide range of issues, including the diverse nature and non-standardized definition and measurement of innovation, non-standardized measurements of the determinants, interrelated variables, different characteristics of firms, and, finally, different economic regions where the surveys take place. The author also presents a portfolio model, which synthesizes the existing research results and may be used for country- or industry-specific studies.

As follows from its title, Chapter 8, *Innovation in Financial Services Infrastructure*, by Paul Nightingale, is a thorough review of the state of research on innovations in the financial services infrastructure. Despite their evident importance to the world economy, both innovations in services in general and in financial infrastructure in particular are essentially neglected topics within the academic innovation literature. Nightingale discusses how external infrastructure technologies between institutions improve market liquidity by increasing the reach of markets. The author also analyzes internal infrastructure technologies within institutions, which are used to coordinate the profitable allocation of resources. The heavy regulation of the financial industry, the software intensity of modern infrastructure technologies, the way in which they have multiple users and their increasing complexity create extra uncertainties in their design and development. All of these cause very different patterns of innovation in financial services infrastructure than is observed in traditional consumer goods.

In Chapter 9, *Innovation in Integrated Electronics and Related Technologies: Experiences with Large-*

Scale Multidisciplinary Programs and Single Investigator Programs in a Research University, Ronald J. Gutmann overviews advances in university research innovation in integrated electronics via his own many decades involvement in the field. The author distinguishes between discontinuous (or radical) and continuous (or incremental) university knowledge-based innovations. He discusses the impact of the Semiconductor Research Corporation (SRC) initiated in 1981, SEMATECH initiated in 1988 and the Microelectronics Advanced Research Corporation (MARCO) initiated in 1998 on the development of innovations in integrated electronics.

Parts VIII–XIII are about innovations in social context, broadly defined. The importance of social context in the development and implementation of innovations is widely recognized by innovation scholars. The aim of these Parts is to overview research in this direction. They comprise chapters on innovation in different group contexts, for example, companies, universities, and countries. They thus discuss innovation at the group, organizational, regional, national, and international levels. A wide range of topics such as the impact of innovation on organizational members, innovation management, innovation leadership, and national innovation systems is under consideration.

Part VIII, *Basic Approaches to the Understanding of Innovation in Social Context*, contains seven chapters. Chapter 1, *The Barriers Approach to Innovation*, by Athanasios Hadjimanolis, is a comprehensive review on the various types of barriers to innovation, including internal (i.e. strategy-related) barriers and external (e.g. market-related) barriers. The author analyzes the nature of barriers, critically examines their various classifications, discusses their impact on the innovation process, considers theoretical explanations of barriers, and overviews the existing empirical studies. He further describes the specificity of barriers in different social contexts. For instance, barriers have a particular impact in small firm innovation and in small countries. Finally, the chapter presents a set of suggestions regarding how to overcome barriers.

In Chapter 2, *Knowledge Management Processes and Work Group Innovation*, James L. Farr, Hock-Peng Sin, and Paul E. Tesluk present a dynamic model of work group innovation. The model integrates recent advances in taxonomies of work group processes and stages of the innovation process with a focus on the temporal nature of innovation. This model identifies transition and action phases with each of two major stages of innovation: a creativity stage and an innovation implementation stage. The transition phases both involve primarily planning and evaluation tasks that guide later goal accomplishment. The action phases involve primarily in acts that directly contribute to goal accomplishment. Within the creativity stage, the transition phase consists of interpretation of issues and problem identification and the action phase consists of

idea generation. Within the innovation implementation stage, the transition phase consists of the evaluation of the generated ideas as possible solutions and selection of the one(s) to implement and the action phase consists of the application of the idea(s) to the problem.

Chapter 3, *Innovation and Creativity = Competitiveness? When, How, and Why*, by Elias G. Carayannis and Edgar Gonzales, describes the circumstances within which creativity and innovation occur in organizations. Using empirical findings from public and private companies, the authors discuss how and why creativity triggers innovation and vice versa, and the resulting implications for competitiveness. Carayannis and Gonzales analyze the existing literature on the topic and field interviews on the practice and implications of creativity and innovation from the perspective of competitiveness.

In Chapter 4, *Innovation Tensions: Chaos, Structure, and Managed Chaos*, Rajiv Nag, Kevin G. Corley, and Dennis A. Gioia presents a framework for understanding the tensions that underlie an organization's ability to manage innovation effectively in the face of a turbulent competition. These tensions are: (1) the fundamental tension between the desire for structure and need for creative chaos, and (2) the on-going tension between technology-push and market-pull approaches to innovation. The authors discuss the nature and boundaries of these tensions and characterize them as four distinct 'innovation contexts'. Nag, Corley, and Gioia present a case study of one high-technology organization as an example that supports their approach. The authors examine the notion of 'managed chaos', a concept that helps understand the role of innovation in the maintenance and change of an organization's identity.

Chapter 5, *Innovation and Identity*, by Nigel King, continues the theme of identity and innovation within an organizational context. The author specifically focuses on how innovation processes shape people's work-related identities. King further argues that the concept of identity is useful for considering the relationship of the person to the organization in the context of innovation. He analyzes the potential contributions of Social Identity Theory and Constructivist/Constructionist accounts of identity to the field of innovation. The author also presents findings from case studies of innovations in the British health service to demonstrate the value of an interpretive approach to innovation and identity.

In Chapter 6, *Manager's Recognition of Employees' Creative Ideas: A Social-Cognitive Model*, Jing Zhou and Richard W. Woodman concentrate on organizational creativity as a basis for the appearance of innovation. They employ a social-cognitive approach to explaining the conditions under which a manager is likely to consider rewarding and/or implementing an employee's idea. The recognition and support of

employee creative ideas is a critical facet in organizational creativity. Zhou and Woodman present a model, according to which the manager's 'creativity schema' determines recognition of creative ideas in the organizational context. In the authors' view, the creativity schema is influenced by personal traits of the manager, by aspects of the manager's relationship with the employee, and by a number of organizational influences. Finally, Zhou and Woodman describe implications of the social-cognitive approach for innovation research and business practice.

Chapter 7, *Venture Capital's Role in Innovation: Research Methods and Stakeholder Interests*, by John Callahan and Steven Muegge, is a comprehensive review of how venture capital contributes to innovation. The important role of venture capital in innovation is widely recognized by innovation research literature. Callahan and Muegge begin with the history and current state of venture capital. They describe the process of venture capital financing and how it relates to the innovation process. The authors then review the research literature related to venture capital investment decision-making, the venture capital-entrepreneur relationship, and the fostering of innovation by venture capital. Finally, using a stakeholder perspective, Callahan and Muegge emphasize the value of current research for different stakeholders and call for more qualitative, longitudinal research that contributes better stories and richer data on variable interrelationships.

In Part IX, *Innovations in Social Institutions*, chapter authors analyze innovations along a broad spectrum of social institutions, including small and medium-size firms, multitechnology companies, transnational corporations, universities, network forms of organizations, and technopoles.

Chapter 1, *Encouraging Innovation in Small Firms through Externally Generated Knowledge*, by Edward Major and Martyn Cordey-Hayes, continues the topic of knowledge management previously addressed in the two other chapters. Specifically, Major and Cordey-Hayes analyze the conveyance of externally generated knowledge to small firms. The authors emphasize that successful innovation requires firms to draw on multiple sources of knowledge. Many small firms take little note of external sources, thus restricting their potential innovative base. Major and Cordey-Hayes present the concepts of knowledge translation and the knowledge translation gap to illustrate why so many small firms fail to access externally generated knowledge. The authors' findings from research into U.K. small firms and national innovation schemes demonstrate how intermediary organizations can be used to bridge the knowledge translation gap. Finally, they discuss implications for government innovation policy for intermediaries and for small firms.

In Chapter 2, *Linking Knowledge, Networking and Innovation Processes: A Conceptual Model*, Jacqueline Swan, Harry Scarbrough, and Maxine Robertson

present a model that relates specific kinds of networking to episodes of innovation, that is, invention, diffusion, and implementation and to knowledge transformation processes. The operation of the model is illustrated through three longitudinal case studies, each focusing on a different innovation episode. The authors' thorough review of the relevant literature demonstrates that the need for innovation is frequently cited as a major reason for the emergence of network forms of organization. Through networks, it is assumed, knowledge needed for innovation is transferred more easily. However, Swan, Scarbrough, and Robertson point out that relatively little research has addressed the links between networks and the development and utilization of knowledge during processes of innovation. Research that does exist tends to focus on networks, in the structural sense, as channels for the communication of knowledge, which is seen as relatively unchanging. This research provides a useful starting point but tends to be rather static in its treatment of networks and knowledge flows during innovation. It also tends to emphasize the diffusion episode of the innovation process. In contrast, there is relatively little research on the relations between networking, as a dynamic process, and the development of innovation. The authors' model provides a more dynamic account of the links between networking and innovation processes.

Chapter 3, *Innovation in Multitechnology Firms*, by Andrea Prencipe, is about the generation of innovations in companies specializing on complex multitechnology products. He identifies two major dimensions of capabilities of such companies: synchronic systems integration and diachronic systems integration. Within each of these two dimensions, multitechnology companies maintain absorptive capabilities to monitor and identify technological opportunity from external sources and generative capabilities to introduce innovations at the architectural and component levels. Prencipe concentrates on company's generative capabilities and shows that these capabilities enable a company to frame a particular problem, enact an innovative vision, and solve the problem by developing new manufacturing processes. The author concludes that frame-enact-solve is the primary feature of a company's generative capability. Prencipe presents the case study that support his approach.

In Chapter 4, *Innovation Processes in Transnational Corporations*, Oliver Gassmann and Maximilian von Zedtwitz describe innovation in transnational business settings. The authors identify two phases in innovation process: (1) a pre-project phase fostering creativity and effectiveness, and (2) a discipline-focused phase ensuring efficiency of implementation. Such differentiation enables transnational companies to replicate and scale innovation efforts more easily in remote locations, exploiting both economies of scale and of scope. The distinctive features of these phases are different,

however: a few companies mentioned by Gassmann and von Zedtwitz have consistent and differentiated techniques to manage and lead the overall innovation effort specific to each phase.

Chapter 5, *An Analysis of Research and Innovative Activities of Universities in the United States*, by Yukio Miyata, examines how American universities contribute to innovation through their research and collaboration with industry. Universities are an important component of the national innovation system: they supply highly qualified personnel and advanced scientific and technological knowledge to public and private industry. Therefore, the state of innovative activities in universities should be an essential topic in innovation research. In light of the leading role of American science, it is especially interesting to analyze innovative efforts in the American universities. Miyata shows that American universities with a high quality of research tend to be productive in generating academic publications and research results that are close to commercialization. However, license revenue results from a small number of 'hit' inventions that are often in the field of medical research. It is difficult for universities to finance their research by license revenue, so the role of the central government is critical to maintain research quality.

In Chapter 6, *Incubating and Networking Technology Commercialization Centers among Emerging, Developing, and Mature Technopoles Worldwide*, David Gibson and Pedro Conceição discuss the development of innovations at the regional and global levels. Technopoles (Greek for technology and city state) refer to regions of accelerated wealth and job creation through knowledge creation and technology use. Innovation is considered as the adoption of 'new' knowledge that is perceived as new by the user. The access to knowledge and the ability to learn and put knowledge to work is essential to regional economic development and for globalization today. The authors present the conceptual framework for leveraging knowledge through Internet and web-based networks, face-to-face communication, and training programs. The aim is to accelerate regional economic development through globally linked Technology Commercialization Centers (TCCs).

Chapter 7, *Science Parks: A Triumph of Hype over Experience?* by John Phillimore and Richard Joseph, considers the role of science parks in innovation. For example, such parks can serve as technology and/or business incubators thus fostering the growth of start-ups. Phillimore and Joseph emphasize that there is a disjuncture between the critical assessment of the academic literature about most science parks and their growing number worldwide. The authors analyze the skepticism frequently expressed about science parks in the literature and how it contrasts with their continued international popularity. Phillimore and Joseph also discuss possible new directions for science parks.

Part X, *Innovation Management*, is devoted to one of the most central topics within innovation research, that is, how innovation processes should be managed. Today academic and professional journals publish more articles on innovation management than on any other innovation topic. This fact alone highlights an important role of innovation management. Four chapters included in this Part are aimed at the analysis of various aspects of this role.

Chapter 1, *Challenges in Innovation Management*, by John Bessant, reviews the question of managing innovation and particularly looks at some of the key challenges, which must be addressed if company plans to manage innovation successfully. A need to understand innovation, to build an innovation culture, and to extend participation in innovation process, as well as continuous learning are among these challenges.

In Chapter 2, *Managing Technological Innovation in Business Organizations*, Ralph Katz was given an ‘assignment’ to consider technological innovations and innovation management issues in technological companies. The author thus analyzes the patterns of innovation that usually take place within an industry and how such patterns affect a company’s ability to manage its streams of innovative projects along technological cycles.

In Chapter 3, *Towards a Constructivist Approach of Technological Innovation Management*, Vincent Boly, Laure Morel, and Jean Renaud describe a constructivist approach to the understanding of technological innovation management. The key aspects of this approach include the development of a value-oriented strategy and a systemic vision of innovation management through its three levels: strategy, piloting, and sparking. The authors present findings from technological innovation survey in French small and medium size enterprises (SMEs), which support the constructivist approach to technological innovation management.

Chapter 4, *Promoters and Champions in Innovations: Development of a Research Paradigm*, by Jürgen Hauschildt, considers a typology of those individuals within an organizational context who enthusiastically support innovations. The success of innovations depends to a great extent on the activities of such ‘champions’ or ‘promoters’. The author analyzes 30 years of research in this direction. Hauschildt concludes that three types of champions or promoters are necessary for successful development of innovations. First, innovations need a technical expert who acts as ‘promotor by expertise’. Second, innovations need top management’s sponsorship by a ‘power promoter’. Third, innovations need boundary-spanning skills of a ‘process promoter’. The size of a company and the diversification of its products, as well as the complexity and newness of innovation, considerably influence this ‘troika’ model.

Part XI, *Innovation Leadership*, comprises just one chapter, ‘Innovation and Leadership’, by Jean Philippe

Deschamps. This chapter is about innovation leaders, those critical senior executives which top management sees as the linchpins of its innovation process and the ‘evangelists’ of an innovation and entrepreneurship culture. The author begins with a well-accepted list of generic leadership imperatives as they relate to innovation. He further describes the common traits of innovation leaders in terms of personal profiles and behavioral attributes. Finally, Deschamps discusses the beliefs and management philosophy on innovation leadership adopted by some innovative companies and their CEOs and CTOs.

Part XII, *Innovation and Marketing*, presents a marketing perspective on innovation. This Part includes two chapters. In Chapter 1, *Innovation and Market Research*, Paul Trott examines the debate about the use of market research in the development of innovative products and discusses the extent to which market research is justified. The author points out that market research can provide a valuable contribution to the development of innovative products. Trott presents the conceptual framework, which should help product and brand managers to consider when and under what circumstances market research is most effective.

Chapter 2, *Marketing and the Development of Innovative New Products*, by Robert W. Veryzer, further develops the market-based view of innovation. Specifically, he analyzes innovation from the perspective of marketing concerns and challenges. The author highlights the critical value of market vision for companies, that is, the ability to bridge technological capability and market need and opportunity. Veryzer emphasizes that market vision is particularly important for high innovation products because they typically involve a significant degree of uncertainty about exactly how an emerging technology may be formulated into a usable product and what the final product application will be. He presents the conceptual framework that can help to clarify the innovation and adoption context with respect to the marketing challenge(s). Marketing thus provides a necessary and useful function in helping to shape an innovative idea into a product offering that meets the needs and desires of the people who are intended to use it.

Part XIII, *Innovation Around the World: Examples of Country Efforts, Policies, Practices and Issues*, discusses innovation practices and innovation policy issues in different countries. The 11 chapters included in this Part are essentially about national innovation systems and describe the unique paths of various states to innovation. It is beyond the scope of this Handbook to include chapters about innovations in all, or even in most, nations. The solution therefore was the following: first, to describe innovations in a few countries whose systems of innovation are unique, or which include unique and useful aspects; and second, to describe innovation systems which are representative of several or many other countries. For example, in

Chapter 1, *Innovation Process in Hungary*, Annamária Inzelt discusses innovations in Hungary, the country, which is, to a significant degree, representative of other post-socialist countries, all of which are characterized by transition economy. Inzelt based her chapter on the analysis of findings of the Hungarian innovation survey and concludes that the level of innovation in the Hungarian economy is low. For instance, Hungarian companies are aware of the importance of developing new products and accessing new markets, but in practice they mainly do this within the limited Hungarian context. The author largely attributes this low level of innovation to the financial stringency imposed by the economic transition process.

In Chapter 2, *Innovation under Constraints: The Case of Singapore*, Hung-Kei Tang and Khim-Teck Yeo examine the specificity of innovation in Singapore, a young nation that has achieved outstanding infrastructural innovations. The authors point out that the real challenge of innovation lies not only in identifying opportunities and committing to action, but also in identifying and mitigating the internal and external constraints that impede the process of innovation. Using four case studies, Tang and Yeo explore how constraints of different types can give rise to innovation as well as cause innovation efforts to fail. The Singaporean government has recognized the need for a better environment for innovation and entrepreneurship and has embarked on several strategic initiatives aimed at fostering that environment.

Chapter 3, *Continuous Innovation in Japan: The Power of Tacit Knowledge*, by Ikujiro Nonaka, Keigo Sasaki, and Mohi Ahmed, describes how Japanese companies innovate. Management practices of the knowledge-creating Japanese corporations had attracted a great deal of attention worldwide. The authors consider the issue of what the basic pattern of innovation is in the knowledge-creating business organizations. Specifically, Nonaka, Sasaki, and Ahmed analyze the basic pattern of innovation at Nippon Roche. They conclude that learning and rule-breaking alone are not enough for continuous innovation. Rather, individuals as well as organizations need to possess tacit knowledge.

In Chapter 4, *Innovation in Korea*, Sunyang Chung reviews the Korean national innovation system. Korea is an innovative and dynamic country. It has implemented a relatively competent national innovation system in three decades. Korea has invested a lot of resources in order to enhance the efficiency of its national innovation system and increase the innovation capabilities of major innovation actors. The author concludes that the dynamic development of the Korean economy within the context of global economy is connected to its efficient national innovation system.

Chapter 5, *Regional Innovations and the Economic Competitiveness in India*, by Kavita Mehra, examines

the innovation process in India. The study of innovation in India is particularly interesting, given that country's dual position as both a developing nation, and one with an ancient, and rich, civilization. Mehra describes the case studies of regional innovations from diverse locations in India, which are very typical to those regions and bound to local culture, knowledge, and resources. She points out that India has a vast storehouse of knowledge in various fields, particularly in tacit form. For this reason the tacit knowledge based innovations are one of the main kinds of innovations in India. These innovations are territorially specific ones, because of their embodiments in individuals, in their social and cultural context. The author concludes that this is exactly what allows developing nations to retain their identity, and preserve local art and craft as the national heritage in the era of globalization.

In Chapter 6, *Innovation Process in Switzerland*, Beate Wilhelm analyzes the national innovation system in one of the most economically advanced countries in the world. She emphasizes that the primary role of Swiss innovation and technology policy is to foster the utilization of scientific knowledge via organized technology transfer from universities to industries. Despite the robust health of the Swiss economy, Wilhelm concludes that the national innovation system needs improvement. Specifically, the existing innovation policy must be developed in order to better coordinate science, industry, government and societal demands.

Chapter 7, *Systems of Innovation and Competence Building across Diversity: Learning from the Portuguese Path into the European context*, by Pedro Conceição and Manuel Heitor, considers the current Portuguese path towards an innovative society. It focus on Portugal within a European scene, considering a context increasingly characterized by uncertainty and diversified environments, which are particularly influenced by social and institutional factors. The authors present a conceptual framework that helps to understand the contemporary demands for being innovative. The concepts of learning society, knowledge accumulation, competence building, and systems of innovation are main components of this framework. Finally, Conceição and Heitor propose suggestions aimed at the further development of innovation policy in Portugal.

In Chapter 8, *Innovation in Taiwan*, Chiung-Wen Hsu and Hsing-Hsiung Chen examine the Taiwan innovation system, which contributes to a great extent to its accelerated technology-based industrial development. The authors consider the most representative characteristics of the Taiwan innovation system, including: (1) the Technology Development Program of the Ministry of Economic Affairs planning the industry innovation policy; (2) the research and development and technology diffusion strategy of the Industrial Technology Research Institutes; (3) the Hsinchu Science-Based Industrial Park's method of

technology commercialization; and (4) the recruitment of overseas experts and cultivation of talents. Hsu and Chen show the Taiwan innovation system ‘in action’ on the example of the successful development of the Taiwan integrated circuit industry.

Chapter 9, *Innovation in the Upstream Oil and Gas Sector: A Strategic Sector of Canada’s Economy*, by A. Jai Persaud, Vinod Kumar, and Uma Kumar, is about the Canadian innovation system and innovations in oil and gas industry. The authors discuss the main facets of Canada’s innovation agenda aimed at the advanced economic development. The government of Canada is interested in making Canada a highly innovative economy. Persaud, V. Kumar, and U. Kumar consider the Canadian innovation strategy and related policy issues. The authors focus on the oil and gas sector of Canada’s economy—its strategic sector—and analyze the key aspects of innovation in this sector. Innovations in the oil and gas industry can make greater contributions to sustainable development and play a crucial role in reducing greenhouse gas emissions.

Chapter 10, *The National German Innovation System: Its Development in Different Governmental and Territorial Structures*, by Hariolf Grupp, Icíar Domínguez Lacasa, and Monika Friedrich-Nishio, is about innovation system in the united Germany. Germany existed as one country from 1871 to 1945. It existed as a large array of individual states before that period and was divided into West and East from the Second World War to 1990, with extremely different innovation policies. Since then, it was reunited again. Nevertheless, there are many indications of a national innovation system through all these periods, government structures and territorial changes.

In Chapter 11, *Frankenstein Futures? German and British Biotechnology Compared*, Rebecca Harding analyzes biotechnology policies in the U.K. and Germany. She compares and contrasts the market based biotechnology policies of the U.K. with the regionally engineered biotechnology policies of Germany in the light of the national and regional systems of innovation. The author demonstrates that innovation systems generally and regional innovation systems in particular are still useful concepts in explaining the clustering of biotechnology. Harding shows that German biotechnology policy has been particularly successful in

stimulating rapid catch-up with U.K. and global levels of research.

Part XIV, *Innovations of the Future*, consists of two chapters. *Future Innovations in Science and Technology*, by Joseph F. Coates, describes future innovations in genetics, brain science, information technology, nanotechnology, materials science, space technology, energy, and transportation. A scientist and futurist, the author presents a 25-year look into the future, considering scientific developments and their practical technological applications. He concludes that a general result of future innovations will be continuing enhancement of the quality of human life, leading to unprecedented richness, on a worldwide scale.

In Chapter 2, *The Future of Innovation Research*, Tudor Rickards presents his view of future advances in the field of innovation. He identifies a few research directions in which the main developments should be expected. Rickards also describes challenges, which will be faced by innovation scholars, and discusses the multifaceted impact of innovation research on practice.

Part XV, *Conclusion*, contains a single chapter, *Research on Innovation at the Beginning of the 21st Century: What Do We Know About It?* by Larry R. Vandervert, which serves to integrate the other chapters in the Handbook. This chapter points out common as well as unique features of the various accounts of innovation and suggests directions in which future research, practice, and policy might lead us.

The chapters of this Handbook therefore demonstrate that the phenomenon of innovation is inherently multidimensional, multifaceted, interdisciplinary, personally demanding, socially consequential, cross-cultural, and frequently surprising. As a result, understanding the scientific principles that underlie innovation requires a variety of research approaches. Authors presented a wide range of approaches to understanding the nature of innovation at the individual, group, organizational, societal, and global levels. This Handbook thus provides what is perhaps the most comprehensive account available of what innovation is, how it is developed, how it is managed, how it is measured, and how it affects individuals, companies, societies, and the world as a whole.

The Neurophysiological Basis of Innovation

Larry R. Vandervert

American Nonlinear Systems, USA

Abstract: It is proposed that: (a) the recursive processes of working memory (online consciousness) are modeled in cognitive control processes of the cerebellum; and (b) when these new, more efficient control processes are subsequently fed back to working memory, they are learned in a manner that facilitates innovation. Walking through this cerebellar-working memory sequence, Einstein's experiential accounts of discovery are examined. Methods of encouraging innovation are outlined. It is concluded that innovation is a recursive neurophysiological process that constantly reduces conceptual thought to patterns, thus constantly opening new and more efficient design spaces.

Keywords: Einstein; Cerebellum; Design space; Innovation; Mathematics; Mental models; Working memory.

Introduction

Many scholars and researchers have described the close parallels between biological evolution on the one hand and the processes that govern innovation on the other (e.g. Ziman, 2000). This broad-based literature leaves little doubt that innovation is an integral part of overall biological and socio-cultural evolution. But what, precisely, is the primary evolutionary mechanism behind innovation? Why is human innovation so prolific? And why does the pace of innovation seem to be accelerating? The purpose of this chapter is to describe neurophysiological processes going on in the human brain that can address these questions. Understanding how the human brain extends itself into the production of new ideas and technologies will help build a basic science of innovation. Such a basic science will perhaps permit us to unleash more of the seemingly limitless potential of innovation.

An attempt will be made to keep the jargon of neurophysiology at a minimum. Technical terms will be used only in a manner that will likely be understood by readers from a broad variety of disciplinary backgrounds.

The Neurophysiology of Mathematical Discovery Represents a Generalized Model for All Innovation

Recently, I described a theory of how mathematical discovery arises through the collaboration of working memory and *patterns* generated in the cerebellum

(Vandervert, in press).¹ In the present chapter I provide: (a) a description of how the brain processes that lead to mathematical discovery represent a general neurophy-

¹ Historically, mathematics has been defined first as geometry, and, later, as number. With the advent of high-speed computers, however, mathematics is seen in a new, more fundamental light. We realize now that mathematics is actually all about *patterns*:

Mathematics is the science of patterns. The mathematician seeks patterns in number, in space, in science, in computers, and in imagination. Mathematical theories explain the *relations* (italics added) among patterns; functions and maps, operators and morphisms bind one type of pattern to another to yield lasting mathematical structures. Applications of mathematics use these patterns to 'explain' and predict natural phenomena that fit the patterns (Steen, p. 616).

See also Devlin (1994).

Today, we understand that the core of mathematics is about *relations* (functions and maps, operators and morphisms) among patterns that, ultimately, fit *all* real-world phenomena. Mathematics, as we know it, consists of patterns among phenomena in terms of scientific operations upon which there is social agreement (scientific validity). It is a thesis of this chapter that the cerebellar models of movement, perception, and thought are coded in functions, mappings, operators and morphisms pertinent to all processes taking place in the cerebral cortex. Thus it is proposed that innovation in all fields can be modeled after the brain processes that lead to mathematical innovation.

biological model for *all* innovation; and (b) a walk-through of three of Einstein's classic experiential accounts of discovery that corroborates the neurophysiological model.

Why the Cerebellum and Working Memory?

During the course of repetitive bodily movement, a person becomes able to move more quickly and precisely. These increases in efficiency are the result of control models that are learned in the cerebellum and subsequently fed back to motor areas of the cerebral cortex. In this chapter, three interrelated arguments are presented. First, it is proposed that in the same way that cerebellar models for bodily movement are learned and fed back to the cerebral cortex, models for working memory processes are learned in the cerebellum and fed back to working memory, making its visuospatial, speech, and central executive functions significantly more efficient (see Desmond & Fiez, 1998; Doya, 1999; Ito, 1993, 1997; Leiner, Leiner & Dow, 1986, 1989 for the extension of cerebellar modeling to thought processes). Second, because the components of working memory contain the attribute of conscious awareness (Baddeley, 1992; Baddeley & Andrade, 1998; Baddeley & Hitch, 1974; Teasdale, Dritschel, Taylor, Proctor, Lloyd, Nimmo-Smith & Baddeley, 1995), it is argued that the newer, high-efficiency *patterns* of the cerebellar models learned in working memory provide the experiential basis for innovation. Finally, it is the contention of this chapter that the experience of innovative discovery is the result of the action of multiple paired cerebellar models (see Haruno, Wolpert & Kawato, 1999 for a description of such models).

Three general theoretical premises constitute the working memory/cerebellar theory of innovation.

- (1) Innovation is a process of evolutionary adaptation.
- (2) The selective advantages of innovation arise from efficiencies that accrue through the reciprocal learning relationship between working memory (i.e. the visuospatial sketchpad, the speech loop, and the central executive) and the perceptual-cognitive functions of the cerebellum.
- (3) The working memory/cerebellar processes that lead to mathematical innovation represent the generalized model of innovation (Vandervert, in press). Thus the neurophysiological model of mathematical innovation can serve as the fundamental model for the brain processes that lead to innovation in all fields.

The Plan of this Chapter

Working Memory

First, the components of working memory will be examined. Since the concept of working memory is widely understood and resources on the topic are easily obtained, only a brief account that relates its compo-

nents to selected areas of the cerebral cortex and cerebellum will be described.

The Cognitive Functions of the Cerebellum

Next, a review of findings from newer research on the cognitive functions of the cerebellum will be presented. Because much of the research on the cognitive functions of the cerebellum tends to be relatively new and is spread over many sub-areas of investigation, a more lengthy discussion will be presented.

A Demonstration of the Generalized Model of Innovation: Einstein's Experiential Accounts of Mathematical Discovery

Finally, the interaction of working memory and the cognitive functions of the cerebellum will be illustrated within the framework of three of Albert Einstein's classic experiential accounts of mathematical discovery. While the neurophysiological 'walk through' of Einstein's subjective accounts is admittedly tentative, it is an attempt to both round out and demonstrate the generalized model of innovation that is suggested by the behavioral studies of working memory, and the neurophysiological studies of the collaborative cognitive functions of the cerebellum and working memory.

Working Memory: The Ongoing Stream of Cognitive Consciousness

According to Baddeley (1992) the term 'working memory' refers to processes in the brain that provide temporary storage and manipulation of the information necessary for such complex cognitive tasks as language comprehension, learning, and reasoning. Working memory may be characterized as our 'on-line' cognitive consciousness (e.g. Baddeley & Andrade, 1998). Working memory may be thought of as 'working consciousness'. It will be important to keep this latter conception of working memory in mind when we examine Einstein's experiential accounts of mathematical discovery.

When our attention is on a particular stream of verbal and/or visuospatial consciousness, such as when I am writing this sentence, or when it is being read, the essential conscious, cognitive framework is working memory. Working memory consists of three interacting components: a central executive and two subsidiary slave systems—a visuospatial sketchpad and a phonological (speech) loop. To maintain information in a conscious, on-line state in the central executive, the visuospatial sketchpad and the speech loop are in a continual process of repetitive rehearsal and updating. We can use the above-mentioned writing of a sentence to conveniently illustrate the on-line, repetitive interplay of the three components of working memory. First, *attentional control* of the action of writing (or reading) the sentence is carried on by working memory's central executive functions. Attentional functions of the central executive supervise, schedule

and integrate information from different sources. The *visuospatial sketchpad* and the *phonological loop* are short-term memory stores/rehearsal processes for maintaining, respectively, visuospatial images and speech information that is needed for the on-line composition (or deciphering, if reading) of the sentence. Because the sketchpad and speech loop are *short-term memory* stores/rehearsal processes, they are within the ongoing grasp of consciousness, but additional and updating information continually enters working memory via the attentional functions of the central executive.

The Evolutionary Birth of Human Working Memory and its Collaboration with the Cognitive Functions of Cerebellum

The relationships among the three components of working memory are both phylogenetically and ontogenetically dynamic and interactive. Mandler (1988, 1992a, 1992b) proposed how image-schemas (conceptual primitives) drive the ontological development of language. Following in the vein of Mandler's description of the development of language from image-schemas, I proposed that image-schemas and language evolved in a yoked fashion due to the following two-part, compounding selective advantage: (a) their visuo-linguistic advantage as state variables for cognitive simulation and communication of possible future states of events in working memory; and (b) new, higher efficiency advantages in movement, thought and communication as a result of their being modeled in the cerebellum, and then being fed back to working memory (Vandervert, 1997). I believe that this is the substantial account of the evolutionary selection toward the constantly improving, reciprocal relationships among working memory's central executive, visuospatial sketchpad, and phonological (speech) loop.

There are three highly supportive lines of evidence that the activity of working memory is indeed modeled in the cerebellum. First, Ito (1993, 1997) points out that, at the neurological level, movements and thoughts are identical control objects:

In thought, ideas and concepts are manipulated just as limbs are in movements. There would be no distinction between movement and thought once encoded in the neuronal circuitry of the brain; therefore, both movement and thought can be controlled with the same neural mechanisms [namely, those of the cerebellum] (1993, p. 449).

Thus, the control of the components of working memory in solving problems is not different from the control of hands and feet in solving problems. And, as the use of the components is repeated, the cerebellum acts to make the manipulations smoother, faster, and more efficient. Second, as will be seen below in the sections on the cognitive functions of the cerebellum,

there is abundant evidence that *patterning* representing both visual and linguistic aspects of cognition is learned in the cerebellum (see, e.g. Desmond & Fiez, 1998; Houk & Wise, 1995). Third, it has recently been found that the cerebellum continually updates its models of variations in cognitive activity (Imamizu, Miyauchi, Tamada, Sasaki, Takino, Pütz, Yoshioka & Kawato, 2000). This newer evidence is critical to the argument here because, to be of selective advantage to the rapidly changing, online nature of working memory, the infusion of parallel, rapidly updated cerebellar models is required.

Working Memory and Associated Brain Areas

Functions of working memory can be related to brain areas. Before proceeding to this description it is important to note that the distribution of working memory functions across brain areas is likely quite complex. For example, there is strong evidence that storage and rehearsal functions involve differing brain areas (Awh, Jonides, Smith, Schumacher, Koeppe & Katz, 1996). Figure 1 is a simplified illustration of key brain areas involved in working memory:

- (a) The central executive functions can be tentatively thought of as spread over the SMA (supplementary motor area—long associated with 'will' or intentionality (e.g. Deecke, Kornhuber, Lang, Lang & Schreiber, 1985), Brodmann area 9, with overlappings in Broca's area (Brodmann areas 44/45), lateral and inferior parietal areas (Brodmann areas 39/40), and, I will argue below, the cerebellum (Desmond & Fiez, 1998; Fiez, Raife, Balota, Schwarz, Raichle & Peterson, 1996).
- (b) The phonological loop involves at least Brodmann areas 44/45, and the cerebellum (Desmond & Fiez, 1998).
- (c) The visuospatial sketchpad most likely involves, Brodmann areas 40/18/19 (Fiez, Raife, Balota, Schwarz, Raichle & Peterson, 1996).

In brief summary of this section, the brain areas described above and shown in Fig. 1 are those most fundamentally associated with working memory and, I believe, with the production of mathematical discovery and innovation. The next section describes the cognitive functions of the cerebellum in learning and feeding adaptive control models to the cognitive processes of working memory.

The New Perception of the Cerebellum: The Cognitive Functions of the Cerebellum

Research and Theory on the Cerebellum: A Fast Computational System for Patterns of Both Movement and Thought

Understandings of the cerebellum have moved far beyond the earlier, more traditional idea that its functions are limited to motor control (e.g. Kornhuber,

Figure 1. (A) Brodmann areas; (B) simplified connections among Brodmann areas, and between Brodmann areas and the cerebellum.

1974). A number of newer and converging lines of research and theory suggest that the cerebellum provides a fast computational system for the *patterning* of both motor and *cognitive* processes that take place in the cerebral cortex (Desmond & Fiez, 1998; Doya, 1999; Houk & Wise, 1995; Ito, 1993, 1993; Leiner & Leiner, 1997; Leiner, Leiner & Dow, 1986, 1989). This

newer knowledge about the cognitive control functions of the cerebellum was the thrust of Schmahmann's (1997) volume, *The Cerebellum and Cognition*. More recently, research on the cognitive functions of the cerebellum has been increasing at an accelerating rate. Table 1 contains a collection of chapter and paper summaries of such research that is particularly relevant

Table 1. Newer research and theory supporting cognitive control functions of the cerebellum.

to the purposes of this chapter. It can be seen in the right-hand column of Table 1, that the cerebellum is now understood to be a builder of *models* that govern the rapid manipulation of both motor and cognitive activities (including language and working memory).

The Recent Evolution of the Relationship Between the Cerebellum and the Cerebral Cortex: Expansion Toward the Control of Cognitive Functions

Before proceeding to specific cognitive modeling functions of the cerebellum, it will be helpful to briefly sketch the recent evolution of the cerebellum in its relation to the cerebral cortex. Leiner, Leiner & Dow (1986, 1989) proposed that the massive three- to fourfold increase in the size of the cerebellum (and not in the basal ganglia which concurrently enlarged at a very low rate) in humans arose in conjunction with parallel increases in size and cognitive complexity of the cerebral cortex:

A detailed examination of cerebellar circuitry suggests that its phylogenetically newest parts may serve as a fast information processing adjunct of the association cortex and could assist this cortex in the

performance of a variety of manipulative skills, including the skill that is characteristic of anthropoid apes and humans: the skillful manipulation of ideas (1986, p. 444).

Ito (1984, 1993, 1997) anticipated and later elaborated on Leiner, Leiner and Dow’s work by proposing *how* neurophysiological processes that take place in the cerebellum can apply equally well to both movements and mental processes:

This view may be justified in view of the common features of movement and thought as control objects . . . The cerebellum may be viewed in this way as a multipurpose learning machine which assists all kinds of neural control, autonomic, motor or mental (verbal or nonverbal) (1993, p. 449).

The cerebellum is now conceived as learning machine, as Ito put it, that facilitates the neural control of all information flows in the cerebral cortex.

Thus, the selective advantage of the greatly enlarging cerebellum was that its computing capacities were being harnessed as an ‘operating system’ (determining the which, when and where of information flows)

for the evolving yoked complexities of movement, language, and thought—including, of course, operating system control of the visuospatial sketchpad and speech loop of working memory. Leiner & Leiner (1997) have described the computing capacity of neural connections between the cerebellum and the cerebral cortex (some 40 million nerve tracts) in some detail. The details of this enormous amount of cerebellar connectivity with the cerebral cortex are beyond the scope of this article, but see Leiner & Leiner (1997, pp. 542–547) and Leiner, Leiner & Dow (1989). It is significant to recognize here that the influence of the cerebellum in the spatial and temporal control in the *internal* world of the brain rivals the influence of the nerve tracts of the visual system on the perceived spatial and temporal dimensions of the *external* world. It will be important to recall this idea, later in this chapter, when we examine Einstein's internal world.

The Neurophysiological Basis of Innovation

In this section we will examine how the interplay between the cerebellum and the cerebral cortex leads to innovation.

Cerebellar Models

Biological *feedback* loops are relatively slow, and, therefore, rapid and coordinated movement and thought patterns cannot be smoothly or competitively executed through feedback control alone (e.g. Kawato, 1999; Kawato & Gomi, 1992). For example, the movements and thoughts of professional athletes would be disastrously handicapped if dependent only on feedback information. However, the cerebellum has evolved rapid control of such movements and thoughts by way of internal *feedforward models* that are acquired through learning (Ito, 1984, 1993, 1997; Leiner, Leiner & Dow, 1986, 1989).² As one learns to

² According to the *computational* scheme for *mental models* set for originally by Craik (1943) and extensively elaborated by Johnson-Laird (1983), thought processes construct mental models that are imitative, small-scale computational representations of the external world that retain the external world's relation-structure. Craik described how the preserved relation-structure of the model is computationally parallel to that which it imitates:

A calculating machine, an anti-aircraft 'predictor', and Kelvin's tidal predictor all show the same ability. In all of these latter cases, the physical process, which it is desired to predict, is *imitated* (relation-structure is preserved) by some mechanical device or model which is cheaper, quicker, or more convenient in operation (1943, p. 52).

Thus, the similarity of the relation-structure of the model captures the fundamentals of operation of that which it imitates, but makes the operations faster and cheaper, and in the case of cerebellar models, 'neurologically cheaper and simpler'. This abstractive-imitative modeling advantage, it is proposed, is precisely what takes place between working memory and the cerebellum.

play basketball or play the piano, for example, movement and thought strategies become smoother, quicker, and more efficiently executed.

More important to the premises of this chapter, cerebellar models also greatly increase the efficiency of purely *conceptual thought* (Doya, 1999; Ito, 1993, 1997; Leiner & Leiner, 1997; Leiner, Leiner & Dow, 1986, 1989). Leiner, Leiner & Dow (1989) described the processing of conceptual thought related to novel situations:

In confronting a novel situation, the individual may need to carry out some preliminary mental processing before action can be taken, such as processing to estimate the potential consequences of the action before deciding whether to act or to refrain from acting. In such decision-generating processes, the prefrontal cortex is activated. This cortex, via its connections with the cerebellum, could use cerebellar preprogramming [e.g. learned cerebellar models that involve rapid strategies of search, planning, pattern recognition, and induction] to manipulate conceptual data rapidly. As a result, a quick decision could be made. This could be communicated to the motor areas, including the supplementary motor areas (p. 448).

The foregoing account of innovative problem-solving clearly involves the visuospatial sketchpad, speech loop and central executive functions of working memory. But how, exactly, does such 'faster-than-real-time' cerebellar preprogramming lead to innovation?

Cerebellar Models are Dynamics Models

Cerebellar feedforward models are neural representations of the dynamics of movement and thought (Ito, 1993, 1997). A dynamics model learns the *dynamics* of control objects (e.g. hands, legs, or the components of working memory) instead of a specific motor command for a movement or a specific cognitive control for the manipulation of conceptual information (Ito, 1993, 1997; Kawato, 1999; Kawato & Gomi, 1992). This means that a dynamics model is a set of control instructions that *generalizes* to a broad variety of situations that could potentially occur in the state-space in which it was originally learned. This capacity for generalization, along with the speed advantage, permits a great flexibility of movement and thought, and it is why cerebellar dynamics models have powerful selective advantage when, as described above, the individual confronts novelty. The capacity for generalization that is inherent in dynamics models of the cerebellum is the key to innovation. But this is only the beginning of the story.

Manipulation of Thought: Unconscious Generalization

In the process of learning, the cerebellum acquires two types of feedforward dynamics models, namely, dynamics models and *inverse* dynamics models. Dynamics (g) models are neural representations of the transformation from motor commands to movement and thought patterns in behavior and cognitive processing. However, the inverse dynamics (1/g, i.e. motor dynamics inversely equal to g) models are defined as neural representations of the transformation from the movement and thought patterns to the motor commands required to achieve them (see Ito, 1997, p. 481; Kawato & Gomi, 1992, pp. 445–446). In everyday language, this means that dynamics models are associated with rapid, skilled movement/thought while under conscious control, while cerebellar inverse dynamics models permit the motor cortex to be bypassed, thus allowing rapid, skilled movement/thought to take place at an unconscious level.

Ito (1997) provided an example of the respective operation of dynamics and inverse dynamics models that is highly pertinent to the learning of models of working memory activity by the cerebellum:

According to the psychological concept of a mental model (Johnson-Laird, 1983) [see footnote 2], thought may be viewed as a process of manipulating a mental model formed in the parietolateral association cortex (see Fig. 1) by commands from the prefrontal association cortex. A cerebellar microcomplex may be connected to neuronal circuits involved in thought [notably language processing] and may represent a *dynamics or an inverse dynamics model of a mental model* (italics added). In other words, a mental model might be transferred from the parietolateral association cortex to the cerebellar microcomplex during repetition of thought. By analogy to voluntary movement, one may speculate that formation of a dynamics model in the cerebellum would enable us to think correctly [and rapidly] in a feedforward manner, i.e. without the need to check the outcome of the thought. . . . However, an inverse dynamics model in the cerebellum would enable us to think automatically without conscious effort (p. 483).

The inverse dynamics model helps explain how generalizations can be formed outside a person's conscious awareness. This is one of the reasons that innovative insight may seem to leap out of 'nowhere'.

The Cerebellar/Working Memory Basis of Innovation: Details

In this section I describe in more detail: (1) how the resulting new cerebellar patterns of operation are learned in working memory; and (2) why innovative discovery (actually the discovery of new cerebellar

patterns in working memory) is often experienced as intuition or insight.

Detail: How Cerebellar Patterning ('Innovation') is Learned in Working Memory

What is the neurophysiological basis, in working memory, of 'seeing' (in the visuospatial sketchpad), 'hearing' (in the speech loop), and 'making decisions about' (in the central executive) innovative versions of conceptual information? Houk & Wise (1995) propose that the output from the cerebellum guides the frontal cortex by training its cortical networks toward more efficient use of problem spaces. I propose that the experience of innovation arises as cerebellar commands are executed toward broadened generalization in the conceptual thought of working memory (see also Vandervert, in press). Houk & Wise describe these cerebellum-initiated changes in the frontal cortex (and other modules of the cerebral cortex) as follows:

On the one hand, these alterations [arriving from the cerebellum] would serve to modify the collective computations being performed by the cortical network on a moment-to-moment basis. On the other hand, the same alterations would promote changes in the weights of the Hebbian synapses on pyramidal neurons, that, in the long run, would move the network's attractors closer to the points being forced by cerebellar and basal ganglia modifications. As a consequence, the frontal cortex would become trained to perform, in a highly efficient and automatic fashion, those particular functions being forced on it by its subcortical [cerebellar and basal ganglia] inputs (1995, p. 106).

The above training of the frontal cortex may involve the input of new efficiencies and generalization from either *within* a cerebellar dynamics space or *between* cerebellar dynamics spaces (see Haruno, Wolpert & Kawato, 1999). This would account for the fact that innovations may occur either within the narrow scope of a single technology or from diverse interdisciplinary efforts.

The alteration of cortical networks toward the experience of new ideas or technology may be experienced as an innovative insight, just as is, for example, an innovative hand movement that more efficiently renders a drawing, makes a signal, or throws a Frisbee. Since such alteration is a continuous updating process in working memory, innovation is a feature of learning that occurs regularly in everyone. What makes an innovation an 'important' innovation, or a deeply experienced 'insight' is a matter of its cultural or organizational context, and its degree of generalization.

Detail: The Dynamics of Dynamics Models are Compounded: The Deepening of Generalization

There is a rather profound corollary to the foregoing principle of dynamics learning in working memory. Once a new model of the cerebellar mental model is learned in working memory and given its new, more generalized expression, the newer expression in the neural networks of the cerebral cortex, under continued recursive processing in working memory, *itself* yields even more generalized dynamics—a deeper insight. Redrafting in writing, art or model-making is an example of this compounded recursive process. This ever-new level of realized generalization is one of the reasons, perhaps the most important reason, that ‘yesterday’s’ writing often appears to somehow be ‘sub-standard’.

Within the working memory/cerebellar theory of innovation, this ‘model-of-a-mental-model loop’ produces an ever-deepening level of generalization or abstraction. These new levels of generalization may be accomplished either by the individual who produced the initial level of abstraction or by importing generalized information from others that could be further ‘reduced’ in its recipient new ‘host’. I believe that this conceptually simple, selective mechanism is why the history of innovation is the story of continual refinement and an ever-deepening level of abstraction. It is an epistemological question as to how far this model-of-a-mental-model process may continue into the realm of abstraction. (See Constant (2000) for a discussion of recursive innovative processes at the socio-cultural level.)

Einstein’s Experiential Accounts of Mathematical Innovation: The Generalized Case for All Innovation

In preparation for the examination of Einstein’s subjective account of mathematical innovation, I will layout a summary diagram showing the hypothesized flow of information in terms of the collaborative contributions of recursive control patterns of working memory and the cerebellum. This articulated flow of brain functions provides a neurophysiological basis upon which to follow the mental steps to mathematical innovation as described by Einstein. In this way, we may assume for a moment that Einstein was perhaps describing actual, operationally specifiable milestones (within the general experimental framework of working memory developed by Baddeley and his colleagues, as it is influenced by the cognitive functions of the cerebellum) that constitute the gestation and birth, as it were, of mathematical axioms. Indeed, for Einstein, such a general assumption was the key to understanding how pure thought is directly connected to the axioms of science and mathematics (see Holton, 1979). Einstein took great pains on many occasions to tell us that the internal world of thought processes is

the epistemological nidus of axiomatic knowledge (Einstein, 1949, 1956; Holton, 1979).³

A General Structure for the Analysis of Einstein’s Experiential Account

Figure 2 is a summary illustration of the flow of information between working memory and the cerebellum that will be used to study Einstein’s experiential account.

While the mental processes that lead to the cognition of mathematical axioms are ultimately dependent upon the world of sensory experience, and such discovery must be verified in terms of tests in relation to the sensory world, the focus in Fig. 2 is upon events taking

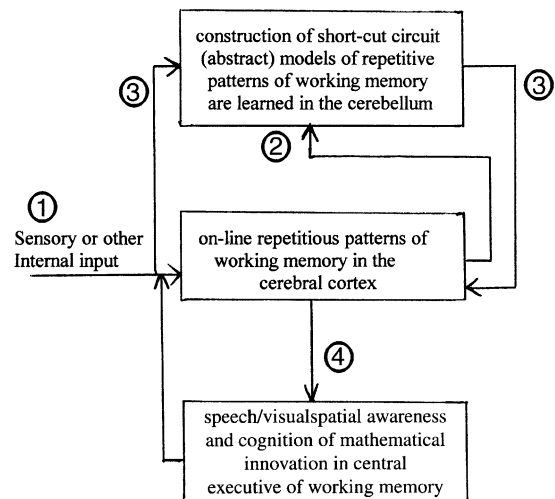

Figure 2. Flow between working memory functions of the cerebral cortex and their mapping representation in the cerebellum. Routing sequence: (1) sensory and/or other internal brain processes utilized by working memory; (2) mapping of patterns of working memory learned in the cerebellum; (3) upon elicitation by sensory, perceptual-motor, or other internal input, mappings fed forward from the cerebellum to facilitate smooth and rapid working memory processing, (4) awareness/cognition of innovation in the central executive. Since all innovations are based upon the cerebellar categorization and generation of patterns, mathematical discovery can serve at the basic model for all innovations (see footnote 1). Compare flow with simplified flows in brain areas illustrated in Fig. 1B.

³ Similarly, it is the epistemological contention behind the theory of innovation presented in this chapter that the *patterns* that constitute mathematics (see footnote 1) arise from the reference frame of bodily movement in relation to perceptual-cognitive processing (Vandervert, 1993, 1997, 1999, 2001). This position does not deny the existence of a real world ‘out there’, but proposes that mathematics is based on patterns that are constructed in the brain as it adapts to its environment. See also the epistemological position on mathematics espoused by Lakoff & Núñez (1997, 2000).

place *within* the brain. Houk & Wise (1995, pp. 105–106) have presented an excellent overarching picture of brain functions that supports the processing plan proposed here. See especially their concluding section titled, ‘The Search for Intelligent Behavior’. It is important to note that Fig. 2 obviously does not represent an entire account of brain areas that may have a bearing on innovation. Such a detailed, full account is beyond the purposes of this chapter.

In Fig. 2, recursive patterns of the activity of working memory are learned in the cerebellum. Short-cut mappings (generalizations or ‘abstractions’) of these patterns are subsequently fed back to working memory’s central executive to facilitate more efficient on-line processing of conceptual thought as described in the previous section (Ito, 1993, 1997).

Bringing Cerebellar Models to Awareness Within Mental Models Employed by Working Memory: Cognizing Abstract Predictive Mappings

Baddeley (1993, 1998, especially chapters 6 and 18) has suggested that the central executive manages and comprehends available information by ‘running’ it within the predictive *mental model* frameworks proposed by Johnson-Laird (1983) (see footnote 2). According to Johnson-Laird, thought processes construct mental models that are *computational* representations of the external world. The selective advantage of such mental models is that they permit an organism to predict probable future states that may be critical to its survival (Vandervert, 1997). At the same time, Ito (1993, 1997) and Kawato & Gomi (1992) propose that the short-cut mappings generated in the cerebellum are also predictive mental models of the Johnson-Laird type. (See Ito (1997) on the subject of dynamics and inverse dynamics cerebellar models in the earlier section on the cognitive functions of the cerebellum.) In the brain-internal dialogue depicted in Fig. 2, then, the mental models employed by working memory and the cerebellum are computationally compatible predictive models. They would, of course, have to be compatible if cerebellar models were to act as short-cut circuits for movement and thought patterning (see Ito, 1997).

Thus within the flow depicted in Fig. 2, it is hypothesized that: (a) the *patterning* basis for mathematical innovation is contained in models generated by the cerebellum; and (b) the central executive has the capacities to bring these patterns to conscious awareness. We will now examine Einstein’s experiential accounts of mathematical innovation within the foregoing perspective.

Einstein’s Inner World

There are three classic sources that contribute to Einstein’s subjective account of mathematical discovery: (a) Einstein’s responses to Hadamard’s (1945) study of invention/discovery in the mathematical field;

(b) Einstein’s (1949) comments on the nature of thinking that appeared in his ‘Autobiographical Notes’; and (c) his model of the construction of axioms that appeared in a 1952 letter to Maurice Solovine (Einstein, 1956). (A thorough theoretical and epistemological discussion of the letter to Maurice Solovine appears in Holton (1979).) The above sources extend over several years and provide an excellent sampling of Einstein’s persistent views on the workings of his own experiential world. All three of the reports contain a great deal on how the structure of his thoughts evolved, and are therefore especially amenable to analysis in terms of the structure of processing depicted in Fig. 2.

A View of the Central Executive

Although we could begin with any one of the three sources on Einstein’s experiential world, we will begin with the earliest account. This is perhaps our best chance to view the operation of the central executive of Einstein’s working memory. The account was in response to a question in Hadamard’s (1945) survey of the habits and mental methods of mathematicians. The specific question read as follows:

It would be very helpful for the purpose of psychological investigation to know what internal or mental images, what kind of ‘internal world’ mathematicians make use of; whether they are motor, auditory, visual, or mixed, depending on the subject they are studying (Hadamard, 1945, Appendix I, p. 140).

Einstein answered this question in the following structured manner:

(A) The words or the language, as they are written or spoken, do not seem to play any role in my mechanism of thought. The psychical entities which seem to serve as elements in thought are certain signs and more or less clear images which can be ‘voluntarily’ reproduced and combined.

There is, of course, a certain connection between those elements and relevant logical concepts. It is also clear that the desire to arrive finally at logically connected concepts is the emotional basis of this rather vague play with the above mentioned elements. But taken from a psychological viewpoint, this combinatory play seems to be the essential feature in productive thought—before there is any connection with logical construction in words or other kinds of signs which can be communicated to others.

(B) The above mentioned elements are, in my case, of visual and some of muscular type. Conventional words or other signs have to be sought laboriously only in a secondary stage, when the

mentioned associative play is sufficiently established and can be reproduced at will.

- (C) According to what has been said, the play with the mentioned elements is aimed to be analogous to certain logical connections one is searching for (Appendix II, pp. 142–143).

Einstein says that, in the process of mathematical discovery, he consciously ('voluntarily') plays with combinations of psychical elements, but that they are not words or language as they are written or spoken. Because the search he describes was under voluntary control, it appears that Einstein was talking about ongoing awareness in the (his) central executive. However, because conventional words and other signs had to be 'sought for laboriously only in a *secondary stage*' (italics added), it sounds as if the essential combinatorial play Einstein describes is a process of 'decoding' less conventionalized sources of information (and not simply retrieval processing). What might be the origin of such less conventionalized sources of information? Within the framework of this chapter, the only source of this type of information would be cerebellar inverse dynamics models of thought patterns that Einstein had repeated many times as he mulled over problems of mathematics. That is, these are perhaps cerebellar models emerging into the consciousness of Einstein's central executive. Recall Houk & Wise's (1995) description of how cerebellar patterns are learned in the frontal cortex.

But we need to know more about the *structure* of the 'signs and more or less clear images' (psychical entities) he mentions. The next source will greatly clarify that picture.

Visualizing Automaticity in the Visuospatial Sketchpad: Decoding Cerebellar Models

In his 1949 'Autobiographical Notes' Einstein focuses on the psychical elements and processing structure of his internal world. He offers a visual record of the combinatorial play and structure that brings forth an ordering element. This ordering element provides the logical connections that he mentioned 'searching for' in his above response to Hadamard. Einstein referred to the process that unlocks the ordering element of combinatorial play as 'thinking':

What, precisely, is 'thinking?' When, at the reception of sense-impressions, memory-pictures emerge, this is not yet 'thinking'. And when such pictures form series, each member of which calls forth another, this too is not yet 'thinking'. When, however, a certain picture turns up in many such series, then—precisely through such return—it becomes an *ordering element* for such series, in that it connects series which in themselves are unconnected. Such an element becomes an instrument, a concept. I think that the transition from free association or 'dreaming' to thinking is charac-

terized by the more or less dominating role which the 'concept' plays in it. It is by no means necessary that a concept must be connected with a sensorily cognizable and reproducible sign (word); but when this is the case thinking becomes by means of that fact communicable (Einstein, 1949, p. 7).

In his picture series, each picture calling forth another picture, and, as well, in the certain picture that turns up in many series, Einstein reveals the automaticity that underlies what he is referring to as axiomatic-level 'thinking'. (See Ito's (1997) comments on the automaticity of inverse dynamics models in the section on the cognitive functions of the cerebellum. See also Kihlstrom (1987) on automaticity in the cognitive unconscious.) The automatic flow of various series of memory pictures Einstein describes fits the computational architecture of *linked* multiple pairs of forward (predictive) and inverse (controller) models (Haruno, Wolpert & Kawato, 1999; Kawato, 1999). Within this architecture, a large number of separate but interconnected pairs of forward and inverse models cover a range of learning and control contexts. The paired models govern both conscious learning and unconscious control aspects related to various environment contexts, e.g. manipulation of physical objects, manipulation of language communication, and manipulation of working memory processes. A responsibility predictor function (forward model of a pair) automatically calls forth its context-appropriate inverse controller model. *In the case where working memory is mulling over several contexts, the responsibility predictor function would result in the calling forth of a series of inverse models and their visuospatial (and central executive and phonological) content (images or 'pictures')*. Thus the paired model computational architecture of the cerebellum appears to be a good candidate for the control of the automatic, each-picture-calling-forth-another portion of Einstein's description. I believe this is the selective strategy by which working memory forms new mathematical concepts (Vandervert, in press). But, we have not yet explained the crucial appearance of the ordering element that Einstein mentions.

The Axiomatic Ordering Element: The Working Memory/Cerebellar Confabulation of Intuition and Insight

Our final report from Einstein helps clarify *how* the ordering element, which would be an axiom in mathematical discovery, is 'constructed'. In a 1952 letter to his good friend Maurice Solovine (Einstein, 1956), Einstein described a complete diagrammatic model of the discovery of axioms. In the model, discovery begins with immediate sensory experience (E). Then, in the next step, Einstein shows an *intuitive leap* to axioms (A). In the letter he described the situation as follows:

A are the axioms from which we draw consequences. Psychologically the A are based upon the E. There is, however, no logical path from E to A, but only an intuitive (psychological) connection, which is always subject to 'revocation' (p. 121).

Einstein went on to say that once axioms were intuitively conceptualized, logical assertions could be deduced, and that, finally, these assertions could be tested against experience. The idea that axioms could *only* be arrived at by an intuitive leap was Einstein's most persistent epistemological belief.

Einstein suggested that we prepare ourselves for the intuitive leap to axioms (concepts or ordering principles) by focusing our attention on "certain repeatedly recurring complexes of sense impressions" and "relating to them a concept" (Einstein, 1954, p. 291). This focus of attention (on the part of the central executive functions of working memory), I believe, is the basis of the confabulation and appearance of the ordering principle or 'certain picture' mentioned above in Einstein's (1949) classic description of 'thinking'.

But why would this new, common picture that Einstein mentions begin to turn up in many series? This new, common picture seems to be the key to intuitive discovery, and I think it is an expression of the *dynamics* principle described earlier in this chapter. That is, I believe that this picture is the result of *generalization* from a newly generated level of abstraction that has originated in the cerebellum (recall the recursive model-of-a-mental-model principle described earlier).

The Cerebellar Trigger of Intuition

Why would the new picture appear *suddenly*, and *how* would it give new conceptual order to the several series? First, the appearance of the new picture would occur among many series as Einstein describes it, because the responsibility predictor functions of the several series (of multiple paired models) had simultaneously responded (via the neural computation of responsibility estimates)⁴ to a newly generated level of abstraction as a *novel* control object. That is, since the new generalization had been recognized as a new control object by the series of multiple paired models, they would, depending on the coherence of their several contexts, simultaneously generalize their prediction and control *to* it. Such simultaneous generalized prediction and control would result in a new 'picture' in the visuospatial sketchpad that would appear 'suddenly' (either through simultaneous acquisition or through rapid recursion) in the many series mentioned by Einstein. Second, this new picture would be a synthesis based upon joint generalization in the

several impacted series of multiple paired models, and thus it would serve as an ordering element for otherwise unconnected series. When such simultaneous generalization among collections of multiple paired models occurs in working memory, it would be experienced as *insight* or *intuition*.⁵

Encouraging the Production of Innovation

The neurophysiological process that leads to innovation works pretty much the same way in all people, although, due to a variety of learning and genetic predispositions, the emergence of innovation is perhaps not experienced to the same degree of clarity or of productivity. The main point is that everyone is born with, and carries throughout life, the neurophysiological 'apparatus' of innovation. And, like other cognition involving the cerebellum and working memory, this apparatus is highly educable.

The most fundamental product of the interplay between working memory and the cerebellum appears to be its boundless capacity for the deepening of abstraction. And, we can conclude from the earlier discussion of the subjective reports of Albert Einstein that the abstraction of pattern is the fundamental building block of innovation. Root-Bernstein and Root-Bernstein (chap. 5, 1999) have convincingly shown that abstraction is a product of a recursive 'play' involving some problem in art, science, poetry and so on. These authors show that when abstraction is achieved in this way, it is inevitably tied to discovery and innovation. Of course, in regard to the working memory/cerebellar theory of innovation, such recursive play is exactly what leads to the transfer of working memory information to the cerebellum for pattern abstraction, and then back to working memory where it may be consciously experienced. The reason that pattern abstraction produces something new is that an abstraction moves the system (physiological or mental) toward the fundamental rules, designs, and laws that connect collections of movements and thoughts. Abstractions thereby make new connections among disciplines and among topics within disciplines. Indeed, the deepest level of abstraction, which history seems to show we are neurophysiologically destined to achieve, may eventually lead humans to a verifiable grand 'theory of everything'.

Steps That Will Encourage Abstraction and Innovation

Root-Bernstein and Root-Bernstein (chap. 5, 1999) provide several classic examples, beginning with the art of Picasso, which illustrate how pattern abstraction

⁴ Haruno, Wolpert & Kawato (1999) provide equations for the computation of the functions of each component of the multiple paired model architecture.

⁵ Einstein's example appears to involve mostly the central executive and visuospatial sketchpad of working memory. However, the same effects of multiple paired models, if arising in the other components or combinations of components of working memory, would lead to insight and intuition, although appearing in differing experiential form.

leading to innovation develops. To encourage the development of abstractions, in both children and adults, they offer the following advice:

Abstracting. . . is a process beginning with reality and using some tool (a personally-chosen, repetitive technique) to pare away the excess to reveal a critical, often surprising, essence. . . . Use one of the abstraction sequences discussed in this chapter—Picasso's *Bulls*, for example, or 'Observations on a Water-Worn Stone'—as a guide. Choose your subject and your abstracting tool; think about them realistically; play around with their various properties or characteristics; get at what might be most essential; then consider and reconsider your results from a distance of time and space. Say your abstraction, mime it, sing it, write it in prose, write it in poetry, extract a concept or metaphor. Practice with artwork, or, if you are scientifically inclined, practice with simple experiments or mathematical concepts. If you are a dancer, replicate the real movements of real people or of animals, then try to find the essence characterizing that personality or that species. Describe in music the distillation of birdness or windness or a carousel. Find the minimum vocabulary to convey a maximum amount of sense and sensibility (p. 90).

One can see the interplay of the components of working memory and its associative executive areas of the cerebral cortex on the one hand, and cerebellar model making on the other running all through the Root-Bernstein's approach to abstracting. Of course, their approach can also be looked upon as a guide to the improvement of the process of thinking in general. I will clarify this point in a moment.

I believe that the how-to-develop-an-abstraction plan that Root-Bernstein and Root-Bernstein have suggested is good, solid advice for systematically encouraging cerebellar/working memory processes toward generalization and innovation. And, as they say, it would be increasingly effective as it were carried out over longer periods of time. If we were to disassemble and examine Root-Bernstein's recommendations as we did Einstein's experiential account of 'thinking' in the previous section, we would find that they both make use of the same cerebellar/working memory processes. In other words, processes very much like the abstract processes Root-Bernstein and Root-Bernstein describe are iterated automatically in the mind of, for example, an Einstein or a Picasso. The key to highly productive innovation would seem to be an approach that keeps a person (or an organization) at tasks that are contexted in such 'play' for an extended period of time.

Discussion

Dasgupta (1996) argued that innovation is a lawful process that can be seen running across individual

innovators and across innovations in different disciplines. And, he says, the study of innovation can therefore be carried out in a scientific manner.

As a part of such a science, I have described how the recursive collaboration of working memory (online consciousness) and the cognitive functions of the cerebellum constitutes the primary evolutionary mechanism behind innovation. The repetitive activities of the visuospatial loop, speech loop, and central executive control processes of working memory are constantly reduced to new and more efficient spatio-temporal patterning in the cerebellum. These control patterns are subsequently fed back to working memory where neural networks constantly learn the new and ever more efficient control instructions for conceptual thought. Human innovation is prolific and its pace has accelerated, because constantly increasing levels of generalization are produced by the reciprocal relationship between the cerebellum and working memory. This process makes its appearance as ever-new levels and combinations of design space in working memory. (See Stankiewicz (2000) for a discussion of design space as implied here.)

Highly reduced patterning involving collections of multiple paired cerebellar models becomes the basis for the discovery of mathematical knowledge when it is learned in the neural networks of working memory. This cerebellar-working memory sequence of mathematical discovery was examined by way of three of Einstein's classic experiential accounts of mathematical discovery. The neurophysiology of the discovery of mathematics constitutes the general process of innovation in all fields and accounts for their unique subjective experiences of insight and intuition.

The transparency between mathematical discovery and innovation in other fields can be seen most clearly in technological innovation. This transparency becomes increasingly evident as technology has become increasingly electronic as in computing, communication and telepresence. At this advanced level of technological development, mathematics can be literally 'reverse engineered' from technology. In other words, mathematics is embodied in technology, just as it is embodied in the neurophysiological operation of the human mind. This is the essential theoretical-epistemological basis of cybernetics, as defined by Wiener (1948): "the entire field of control and communication theory, whether in the machine or in the animal" (p. 19).

Acknowledgements

I would like to thank Marc Nagel for his help in securing the illustration of the Brodmann brain areas that appears in Fig. 1. The illustration was kindly provided by Hermann Strohmaier, Director of the Korbinian Brodmann Museum, Hauptstr. 43, 78355 Hohenfels, Germany.

On the Nature of Individual Innovation

Larisa V. Shavinina¹ and Kavita L. Seeratan²

¹ *Département des Sciences Administratives, Université du Québec en Outaouais, Canada*

² *Department of Human Development and Applied Psychology, University of Toronto, Canada*

Abstract: In this chapter a new conception of individual innovation, seeking to explain its very nature, will be presented. Individual innovation refers to innovation at the level of an individual. This conception ventures to explore an issue of exceptional importance necessary for a scientific understanding of the inner essence of innovation, namely: why innovative ideas emerge in human minds. To successfully grasp this issue, we believe that mainly developmental and cognitive mechanisms must be taken into account. The internal structure of individual innovation is presented at five levels: (1) developmental foundation of innovation; (2) its cognitive basis; (3) its intellectual manifestations; (4) its metacognitive manifestations; and (5) its extracognitive manifestations.

Keywords: Innovation; Individual innovation; Giftedness; Talent; Creativity; Cognitive experience.

Introduction

A growing body of literature suggests that innovation originates from within the individual, that is, from his or her new idea(s) (Amabile, 1988, 1996; King, 1990, this volume; Simonton, this volume). Various definitions, models, and theories of creativity and innovation include the ‘generation of new ideas’ as one of their components (Bailey & Ford, this volume; Clapham, this volume; Dugapata, this volume; Lubart, 2001–2002; Runco & Pritzker, 1999; Sternberg, 1999; Sternberg et al., this volume). For instance, many innovation scholars—including us—would agree with Kanter (1983) who states that innovation is the generation, acceptance, and implementation of new ideas, processes, products, or services. In this chapter, we focus on individual innovation, that is, innovation which appears at the individual level and which is mainly responsible for the generation of new ideas. In spite of advances in innovation research, determined mostly by studies of business scholars and management science specialists (Christensen, 1997; Katz, 1997; Leonard-Barton, 1995; Tidd, Bessant & Pavitt, 1997; Tushman & O’Reilly, 1997; Van de Ven et al., 1999), we do not know for certain why it is that some individuals are exceptionally able to generate new ideas and others not. An important goal of this chapter is to try to shed some light on this important issue by presenting a new conceptual framework for understanding individual innovation.

Individual innovation begins from the generation of new ideas, which is eventually externally manifested in the extraordinary innovative achievements we see in any field of human activity. According to our conception, individual innovation is a result of a specific organization of an individual’s cognitive experience which functions as a carrier of all the manifestations of individual innovation (i.e. its traits and characteristics). Cognitive experience expresses itself in a specific type of the representations of reality (i.e. how an individual sees, understands, and interprets the world around), that is, in an individual’s intellectual picture of the world.

The essence of individual innovation rests in the uniqueness of the individual’s intellectual picture of the world. In other words, innovators’ unique view, understanding, and interpretation of what is going on in the surrounding reality are keys for the scientific understanding of individual innovation.

In our view, the internal structure of individual innovation is presented at five levels: (1) a developmental foundation for innovation; (2) the cognitive basis of innovation; (3) the level of intellectual manifestations of innovation; (4) the level of metacognitive manifestations of innovation; and (5) the level of extracognitive manifestations of innovation. Below we consider each of them in detail.

Before beginning a presentation of our conception of individual innovation, it is important to note three

things. First, from our point of view, individual innovation belongs to a general construct of high abilities, which includes creativity, exceptional intelligence, giftedness, and talent. Thus, in this chapter we do not draw a distinction between individual innovation and creativity, talent, and giftedness. In our view, innovators are gifted, creative, and talented individuals.

Second, it should be emphasized that in this chapter we deal especially with individual innovation, which differs from the general understanding of innovation (e.g. Kanter's definition). Specifically, our chapter addresses the issue of *why* new ideas—from which any innovation begins—appear in the minds of only certain individuals. In this light, a range of questions arises such as: What is exceptional about the personalities of those people who are able to generate new ideas leading to innovations? Do they have extraordinary minds? Is their exceptionality a result of a combination of their unique minds and personalities? In order to successfully address these questions, one should recognize—as we have—that those individuals who are able to generate new ideas resulting into innovations (i.e. innovators) are gifted, creative, and talented.

Finally, since many chapters in this handbook provide comprehensive reviews of the existing literature on innovation appropriate in the context of our chapter (see, for example, Chi et al., this volume; Georgsdottir et al., this volume; Kaufmann, this volume; Root-Bernstein, this volume; Simonton, this volume; to mention just a few), we do not include our own literature review in this chapter.

A New Conception of Individual Innovation

Cognitive Experience as a Psychological Basis of Individual Innovation

As we previously mentioned, the nature of individual innovation is still an area of innovation research that has been left relatively unexplored. Although the traits, characteristics, features, properties, and qualities of innovation and innovative people (i.e. their external manifestations in any real activity) have been the subject of scientific research, the psychological basis (or psychological carrier) of these manifestations has not been investigated (Kholodnaya, 2002; Shavinina & Kholodnaya, 1996). Attempts to understand the nature of any psychological phenomenon based solely on listing and describing its external manifestations, including its characteristics, traits, features, qualities, and properties, are inadequate. Contradictions and crises in psychology testify to this (Vekker, 1981).

There is a need for a new direction for research that considers individual innovation as the sum of its two important aspects: its external manifestations and its

psychological basis. Consequently, there is a need to re-examine the question of the nature of individual innovation. Researchers should not simply answer the question 'What is individual innovation?' by merely listing its characteristics and traits (i.e. its external manifestations). Rather, they should answer the question: 'What is the carrier (a basis) of the characteristics and traits associated with individual innovation?' (Shavinina & Kholodnaya, 1996).

From this fundamentally changed viewpoint, scientists should study an individual's mental or cognitive experience—more precisely, the specificity of its structural organization. We assert that the individual cognitive experience is the psychological basis of individual innovation or the psychological carrier of its manifestations (Shavinina & Kholodnaya, 1996). Mental or cognitive experience is defined as a system of the available psychological mechanisms, which forms a basis for the human cognitive attitude towards the world and predetermines the specificity of his or her intellectual activity (Kholodnaya, 2002). Cognitive experience—that is the cognitive level in the structural organization of individual innovation—is formed by conceptual structures (i.e. conceptual thinking), knowledge base, and subjective mental space (Kholodnaya, 2002). These are all forms of the organization of the cognitive experience.

The importance of *conceptual structures* is determined by scientific findings, which indicate that conceptual thinking is the integrated cognitive formation, that is, a form of the integrated functioning of human intelligence (Kholodnaya, 2002). The more conceptual thinking is a form of the integrated work of intelligence, the better organization of an individual's intellectual activity will be. That means that intelligence will function perfectly (Kholodnaya, 1983; Vekker, 1981; Vygotsky, 1978). Chi & Hausmann (this volume) discuss the importance of conceptual structures in the context of their approach to understanding scientific innovation.

The *knowledge base* is the second form in the organization of the cognitive experience. Many researchers emphasize the role of the knowledge base in the development of an individual's intellectual resources as crucial (Bjorklund & Schneider, 1996; Chi & Ceci, 1987; Chi, Feltovich & Glaser, 1981; Kholodnaya, 2002; Pressley, Borkowski & Schneider, 1987; Rabinowitz & Glaser, 1985; Schneider, 1993; Shavinina & Kholodnaya, 1996; Shore & Kanevsky, 1993; Sternberg, 1985). Thus, the quantity and quality of specialized knowledge play a critical part in highly intellectual performance and in the process of acquiring new knowledge (Bjorklund & Schneider, 1996). For example, productive problem-solving cannot occur without relevant prior knowledge (Chi & Ceci, 1987). The knowledge base can facilitate the use of particular strategies, generalize strategy use to related domains, or even diminish the need for strategy activation

(Schneider, 1993). It was demonstrated that intellectually gifted people are distinguished by an adequate, well-structured, well-functioning, and elaborate knowledge base, which is easily accessible for actualization at any time (Kholodnaya, 1997; Rabinowitz & Glaser, 1985). Moreover, this rich knowledge base can sometimes compensate for overall lack of general cognitive abilities (Pressley et al., 1987; Schneider, 1993).

Conceptual structures and the knowledge base generate subjective mental space, the third form in the organization of cognitive experience. Individual differences in flexibility, differentiation, integration, and hierarchical structure of the mental space influence a persons' cognitive attitude to the world and, therefore, predetermine his or her intellectual and creative abilities, which lead to new ideas resulting into innovation. A more detailed review of the influence of flexibility on innovation can be found in the chapter by Georgsdottir et al. (this volume).

Cognitive experience expresses itself in a specific type of the objective representations of reality—that is, how an individual sees, understands, and interprets what is going on in the surrounding reality and in the world around him or her. Kholodnaya's (2002) investigations of the nature of individual intelligence have demonstrated that one of the basic phenomena (i.e. a proto-phenomenon) of an individual's intellectual life and his or her experience as a whole is his or her representations. Many psychologists have viewed representations to be important in understanding the essence of intelligence, intellectual giftedness, and innovation (Bamberger, 1986; Chi et al., this volume; Chi, Feltovich & Glaser, 1981; Klix, 1988; Oatley, 1978; Piaget, 1969). For example, Kholodnaya (1990) found that the main function of human intelligence lies in the construction of adequate representations of the world around.

In modern cognitive psychology, the expert–novice research paradigm also gives credence to the importance of the phenomenon of representations in the understanding of the nature of human intellectual abilities (Chi et al., 1981; Chi, Glaser & Rees, 1982; Kanevsky, 1990; Schneider, 1993; Shore & Kanevsky, 1993; Sternberg & Powell, 1983). For example, Chi et al. (1981) demonstrated that the main difference between experts and novices in physics has to do with their problem representations. They found that experts classified problems according to underlying principles and rules, but that novices tended to use superficial meanings of words and diagrams in their own classification of the same problems.

Therefore, cognitive experience manifests itself in the specific types of representations. This means that intelligent persons—and particularly innovators, who are intellectually gifted, creative, and talented—see, understand, and interpret the world around them by constructing an individual intellectual picture of events, actions, situations, ideas, problems, any aspects

of reality in a way that is different from other people. Because of that, their individual intellectual picture of the world (i.e. world view) is a unique one (Kholodnaya, 2002; Shavinina & Kholodnaya, 1996). One aspect of this uniqueness is connected with their objectivization of cognition, that is, they see, understand, and interpret everything in a very objective manner. Robert Root-Bernstein in his chapter, *The Art of Innovation* (this volume), emphasizes that sometimes perceiving the world differently is the key to making discoveries. Contributors to this handbook also highlight the importance of changing perspective for new ideas to appear (Chi et al., this volume; Georgsdottir et al., this volume).

It is important to note that scholars in the field of innovation point out that innovation does not necessarily imply acceptance and implementation of only objectively new ideas. Ideas can also be subjectively new ones—new only for some individuals or companies, but not for the rest of the world. As individual innovation deals mainly with the generation of new ideas, our conception of individual innovation emphasizes *objectively* new ideas, because the very essence of innovators—which, in our view, are intellectually gifted individuals—resides in their ability to see the world from an objective point of view. Kaufmann (this volume) also points out that novelty of ideas must be objective, and not only subjectively novel to its originator. Kholodnaya's (1990) understanding of human intelligence as the mechanism for structuring specific representations of reality—representations connected with the reproduction of 'objective' knowledge—suggests that the degree of development of the ability for the objectivization of cognition determines one's intellectual and creative productivity. She showed that one of the distinguishing features of gifted individuals' representations of reality is their objective character. In this respect the most important conclusion is that:

... the significance of *intellectually gifted individuals* in society should be seen not only in that they solve problems well and create new knowledge, but mainly in the fact that they have *the ability to create an intellectual (objective) picture of the world*, i.e. they can see the world as it was, as it is, and as it will be in its reality (Kholodnaya, 1990, p. 128; italics added).

The same is true in the case of innovators. Let us consider, for example, Albert Einstein, whose scientific innovations have been undeniable for decades. A countless number of people who came along before him tried to understand the fundamental questions of time, space, and relativity. However, the fact is that only Einstein was able to propose specialized and generalized theories of relativity—the monumental

achievements of the human mind of the 20th century. In our view, it was possible because Einstein saw the world—with its fundamental questions of time, space, gravity, and relativity—in its objective reality. That is—in accordance with Kholodnaya's (1990, p. 128) quotation—he saw the world as it was, as it is, and as it will be in its reality. Einstein's case as an innovator is especially compelling, because his ability to objectivize cognition was extremely pronounced (Shavinina, 1996).¹ Based on our study of Einstein, R. B. Woodward, Jean Piaget, and V. I. Vernadsky, we suggested that scientific innovations (i.e. new discoveries) are probably generated in the world of objectivization. In other words, the highly productive work of gifted, creative, and talented scientists—that is, their numerous discoveries and inventions—are made possible by their ability to objectivize cognition. Being active on a number of fronts and making important advances (i.e. formulating objectively new fundamental laws, rules, novel ideas, etc.) can be

considered a result of their objectivization of cognition. It should be noted that despite its importance to the understanding of individual innovation, the phenomenon of the objectivization of cognition with regards to innovators has been, thus far, a relatively unexplored topic. Although we have begun to investigate this topic in the case of our studies of Einstein and other innovators in science (Shavinina, 1996), further research is needed in this direction.

We suggest that the ability to objectivize cognition is important not only for innovators in science but the same is true for innovators working in business settings (we will call them 'business innovators'). Why are some companies' employees able to generate ideas resulting into new products or services and others not? In our view, business innovators are able to objectively see either hidden consumers' needs, or potential developments in these needs, or changes in technology, or something else. Of course, everyone agrees that innovation in contemporary companies is a team sport, an endeavor of many players. Modern companies have Research & Development departments, marketing channels, and so on for successful development of new ideas and their transformation into new and profitable products. This is essentially what allows one to call innovation a 'team sport'. But one cannot deny that new ideas appear in the minds of certain individuals. It may be surprising that innovation is not a very frequent event in today's companies, in spite of its quite evident importance. In our view, one main reason is that companies do not have enough intellectual and creative employees and senior executives with the ability to objectivize cognition, that is, to objectively see every aspect of their business activity. In this light the study of the objectivization of cognition of business innovators—who are responsible for initial ideas for successful new products in today's companies—is a promising research direction for innovation scholars within management schools.

The whole structural organization of an individual's cognitive experience (i.e. its conceptual structures, knowledge base, and subjective mental space) determines innovators' unique intellectual picture of the world. As our previously mentioned study of Einstein and other Nobel laureates (Shavinina, 1996) demonstrated, the objectivization of cognition is one of the important aspects of this uniqueness. Our comparative experimental study of the individual cognitive experience of the 'gifted' high school students in physics and mathematics and those high school students who were not identified as 'gifted' (i.e. 'average') allowed us to shed light on other aspects of the unique intellectual picture of the world of gifted, creative, and talented people (Shavinina & Kholodnaya, 1996). In comparison with 'average' students, 'gifted' students' representations of the reality as a whole consisted of a predominance of categorical (generalized) cognition. The 'gifted' groups' representations of the future

¹ This is very clearly shown in his life ideal: "The *cognition of the world in its unity and its rational comprehension*" (as cited in Kuznetsov, 1979, p. 326; free translation from Russian, italics added). Being very young, Einstein wanted to go beyond various personal everyday problems to active work on *superpersonal* rational ideas, which take place in the *superpersonal world*, beyond the world of daily interests. Later, his desire to achieve objective and superpersonal cognition of the world became very strong. He was interested in general laws of the universe, nature, and existence. He wrote:

The most important level in the development of a person like me is reached then, when the *basic interest of life goes beyond the temporary and personal, and concentrates more and more on the desire to understand mentally the nature of the world* (as cited in Kuznetsov, 1979, p. 326; free translation from Russian, italics added).

Indeed, all Einstein's scientific activity was at the highest level of abstractness. His great theories are evidence of this. No doubt, such a level of abstraction was dependent on Einstein's ability to objectivize cognition. Probably only in the world of objectivization was it possible for Einstein to go beyond the known facts, principles, laws, and so on to the new constructive theories, which could adequately explain unknown phenomena of the universe and nature and move against the prevailing concepts in theoretical physics. As a whole, Einstein's productive work on the frontier problems of physics in 1905 depended on his ability to objectivize cognition. It is not therefore surprising that he preferred "to work alone and out of the academic mainstream" (Miller, 1988, p. 171), because only in the world of objectivization can scientists interact directly with their subject (i.e. experimental findings, ideas arising from their thoughts, and so on) to the maximum degree. As a result, Einstein was able to add fresh and unusual, objectively new ideas from his thought experiments to the information available, in order to formulate his innovative view of physical theory (Shavinina, 1996).

focused on the differentiation of the ‘vision’ of future events. ‘Gifted’ students were also distinguished by more complex and rich conceptual representations (i.e. their representations are quite unfolded and a clearly articulated phenomena; Shavinina & Kholodnaya, 1996). Accordingly, the cognitive mechanisms of the construction of these representations play a key role in the organization of the experience of the gifted. These mechanisms are responsible for the construction of more categorical, differentiated, integrated and conceptually complex individual intellectual picture of the world. As innovators are gifted, creative, and talented individuals, then we can suggest, on the basis of these experimental findings, that their cognitive experience is a differentiated and integrated phenomenon. Correspondingly, their representations are generalized, categorical, conceptually rich, and complex. This allows innovators to have a unique intellectual picture of the world, which expresses itself in their exceptional performance and achievements (e.g. in their ability to generate new ideas).

Thus far, a few determinants, which constitute the uniqueness of an individual’s intellectual picture of the world, have been discussed. These are: (1) innovators’ objectivization of cognition; (2) their generalized, categorical, conceptually rich, and complex representations; and (3) their differentiated and integrated cognitive experience.

So far, the basis of individual innovation (i.e. an individual’s cognitive experience) was considered. In other words, the psychological carrier of its various manifestations (i.e. traits, characteristics, features, and properties) was described. We now briefly look at the three levels of the manifestations of individual innovation.

Manifestations of Individual Innovation

The first level is the *level of intellectual and creative abilities* and it is composed of intellectual productivity, individual specificity of intellectual activity, and creativity (Kholodnaya, 2002; Shavinina & Kholodnaya, 1996). *Intellectual productivity* includes three types of the properties of human intelligence: *level properties*, *combination properties*, and *process properties*. In other words, all properties of human intelligence identified by psychological science were categorized into these three types (Kholodnaya, 1990, 2002).

Level properties characterize the achieved level of intellectual functioning—both verbal and non-verbal. These properties form a basis for such cognitive processes as rate of perception, capacity of short- and long-term memory, attention, vocabulary, and so on. Typical examples of the level properties of intelligence are those intellectual properties assessed by the Wechsler intelligence scales.

Combination properties characterize the ability to decipher various links, connections, and relations between different concepts or combination of concepts. In general, it is the ability to combine the components of experience in various ways (spatial, verbal, etc.). These intelligence properties are measured by tests of verbal analogies or the Raven Progressive Matrices Test, as well as reading comprehension tests and the so-called sorting tests.

Process properties characterize the elementary processes of information processing, as well as operations and strategies of intellectual activity. Piaget’s theory describes such properties of intelligence. Standardized intelligence tests may be used to measure process properties of intelligence (e.g. the Wechsler intelligence scales, the Stanford–Binet Intelligence Test, the Raven Progressive Matrices Test, and others).

Individual specificity of intellectual activity is the second component in the level of intellectual and creative abilities. This component manifests itself in the cognitive styles of an individual. Cognitive styles provide valuable information about individual differences in the functioning of human cognitive processes. For example, originally introduced by Kagan et al. (1964), reflectivity-impulsivity cognitive style displays individual differences in the speed and accuracy with which people propose and formulate hypotheses and make decisions under conditions of uncertainty. Today’s reality, in the fast-paced business world, is that a company’s employees and managerial staff must be able to propose and formulate new hypotheses and ideas and make informed, critical, high-staked decisions under conditions of uncertainty. Our experimental studies showed that intellectually gifted high school students are distinguished by a reflective cognitive style (Shavinina & Kholodnaya, 1996). Results from our administration of the Kagan’s Matching Familiar Figures (MFF) test also demonstrated that gifted students made fewer errors in the situation of multiple choices. From the viewpoint of basic cognitive mechanisms, it means that the gifted accurately analyzes visual space up to the moment of making decisions, that is, they are more careful in evaluating alternatives, hence making few errors. Average students, however, presumably hurry their evaluation thereby making more mistakes. The active character of visual scanning by the gifted indicates, in particular, a capacity to delay or inhibit a solution in MFF test performance containing response uncertainty, and also a capacity to differentiate unimportant and essential features of the external stimulus. When we assert that innovators are exceptionally able to generate new ideas, this also implies—in accordance with our conception—that they are able to carefully evaluate those ideas as well as the possible alternatives. This example of the reflectivity-impulsivity cognitive style demonstrates its significance for understanding individual innovation. Other cognitive styles (e.g. cognitive

complexity-simplicity) are equally important, since they shed light on the manifestations of the cognitive experience, which, as we propose, is a basis of individual innovation.

Creativity refers to the originality, fluency, and flexibility of thinking, and to the ability to generate original and appropriate ideas (Georgsdottir et al., this volume; Kholodnaya, 2002; Lubart, 2001–2002; Runco & Pritzker, 1999; Shavinina & Kholodnaya, 1996). Although creativity manifestations seem to be the most appropriate in the context of our chapter, we will not consider them in detail here, because there is a vast body of literature on this topic. In contrast to what many innovation researchers assert, a real novelty of our conception resides in our emphasis that the originality, fluency, and flexibility of thinking are not the basis of individual innovation. As we discussed previously, the real basis of individual innovation is an individual's cognitive or mental experience, which serves as a psychological carrier of all manifestations of individual innovation, including the creative ones. That is, the originality, fluency, and flexibility are derivatives from the individual cognitive experience. For example, flexibility, differentiation, and integration of an individual's mental space determine one's own creative abilities. The individual mental space is one of the above-mentioned forms in the structural organization of one's own cognitive experience.

The second level of the manifestations of individual innovation is formed by *metacognitive abilities* (i.e. metacognitive awareness and regulatory processes). Metacognitive awareness refers to: (a) a system of knowledge about the basic manifestations of intellectual activity in general and about one's own individual cognitive possibilities; (b) the ability to evaluate the 'strong' and 'weak' aspects of his or her own intellectual functioning, including the ability to compensate for one's own weaknesses and rely on strengths; and (c) the ability to manage his or her mental work using various stimulation methods. Regulatory processes include planning, guiding, monitoring, and coordinating one's own cognitive processes (Kholodnaya, 1990; Shavinina & Kholodnaya, 1996).

According to many psychological accounts, metacognitive abilities are critical for the productive functioning of the human mind (Brown, 1978, 1987; Butterfield, 1986; Campione & Brown, 1978; Flavell, 1976; Sternberg, 1985). Knowledge about one's own intellectual creative abilities and the whole cognitive set-up, evaluating their efficiency, advantages and limitations, as well as planning, monitoring, and executive control are among important human abilities (Brown, 1978, 1987; Flavell, 1976; Pressley et al., 1987; Shavinina & Kholodnaya, 1996; Shore & Kanevsky, 1993; Sternberg, 1985). Moreover, research showed that less intelligent persons are characterized by a more superficial metacognitive understanding of

their own cognitive systems and of how the functioning of these systems depends upon the environment. It is also found that less intelligent people use executive processes that are not as complete and flexible for controlling their thinking (Butterfield, 1986).

Finally, the third level of the manifestations of individual innovation is presented by specific preferences, beliefs, and feelings, which can be referred to as *extracognitive abilities* (Kholodnaya, 2002; Shavinina, 1994). All of these abilities characterize the mental work of innovators. A special chapter in this volume by Shavinina analyzes this issue.

So far, we considered the second, third, fourth, and fifth levels in the internal structure of individual innovation. In the next section we are going to discuss its developmental foundation. Specifically, we will address the issue of what might happen in the individual development of certain people, which might eventually make them more open to innovations and consequently able to generate new ideas.

Developmental Foundation of Individual Innovation

Deschamps' (this volume) research on innovation leadership shows that innovation leaders are extremely fascinated and receptive to new ideas proposed by their colleagues and subordinates, which may potentially lead to new products or services. In our opinion, innovation leaders are open to innovation due to their sensitivity to everything new. Martindale (1999) noted that many creative and innovative people—in any field of human endeavor—point out that sensitivity is one of the essential characteristics of their personalities. We think that sensitivity as a personality characteristic has its roots in the specificity of the individual development of these people, particularly in their advanced development during childhood. In other words, if one wishes to know why it is that some individuals in, say, today's companies are able to produce new ideas resulting into innovative products and services or are open to supporting innovation in others (as in the case of innovation leaders), then one should look at their advanced childhood development.

We define advanced development as the development, which leads to the significant expression of an individual's potential—in the forms of innovation, giftedness, exceptional creativity, or extraordinary intelligence—and results in any socially valuable human achievement or performance (e.g. in new ideas leading to new products and/or services). According to our conception, the essence of advanced development in gifted, creative, and talented children—many of which will grow into adult innovators—can be seen in the specificity of a child's age. In the individual development—including cognitive, intellectual, emotional, personality, psychomotor, and social

aspects—of a child, there are certain age periods of heightened sensitivity, which are known as *sensitive periods*. The underlying mechanism of the advanced development in the gifted, creative, and talented that actualizes their potentially high abilities can be seen in sensitive periods.

Research demonstrates that human development is not a smooth process. Instead, it contains certain stages or periods, that is, it is ‘periodical’ in its essence (Ananiev, 1957; Case, 1984a, 1984b; Fischer & Pipp, 1984; Flavell, 1984; Vygotsky, 1956, 1972). For example, Piagetian stages of cognitive development reflect different ways in which the child processes information and interacts with the environment and also highlights specific age ranges within which these stages are likely to occur. Investigations into sensitive periods, in developmental psychology especially, indicate a periodical nature of human development (Bateson, 1983; Bateson & Hinde, 1987; Bornstein, 1987a, 1987b; Colombo, 1982; Gottlieb, 1988; Leites, 1960, 1971, 1978; Lewis, 1988; Oyama, 1979). Psychologists working in the field of high abilities also point out the periodical essence of gifted development (Feldman, 1986a, 1986b; Leites, 1985, 1988, 1996; Morelock, 1992; Shavinina, 1997, 1999; Silverman, 1997). For example, Feldman (1986a) sees giftedness as the “movement through the stages that leads to performance superior to that of most others” (p. 302). The Columbus Group’s approach to the understanding of giftedness as asynchronous development and Bamberger’s (1986) findings on ‘midlife crisis’ also provide strong evidence for the ‘periodical’ nature of development of the gifted, creative, and talented.

The Concepts of Sensitive Periods and Sensitivity

Sensitive periods are defined here as special periods during human development when individuals show great openness to everything in the world around them. Specifically, *sensitivity* involves an individual’s idiosyncratic, personal, and heightened responsiveness to everything going on around him or her (Leites, 1971, 1996; Shavinina, 1997, 1999; Vygotsky, 1956, 1972). Such definitions of sensitivity and sensitive periods might seem rather general; however, they appear to be expedient on the contemporary level of the study of these phenomena in innovators, where the research, specific to the gifted, creative, and talented, is restricted.

The literature provides clear indications that age sensitivity takes a certain place in the advanced development of the gifted, creative, and talented (Feldman, 1986b; Jellen & Verduin, 1986; Leites, 1960, 1971, 1996; Kholodnaya, 1993; Piechowski,

1979, 1986, 1991; Shavinina, 1997; Silverman, 1994, 1995, 1997). For instance, Feldman (1986b) incorporated unusual sensitivity into his theory of prodigy phenomenon, in the “individual psychological qualities” component. Sensitivity is also one of the important elements in Jellen & Verduin’s (1986) conception of giftedness. Leites (1971) concluded that the child’s sensitivity and sensitive periods are critical phenomena in the development of prodigies. Piechowski (1991) considered sensitivity to be an individual’s heightened response to selective sensory or intellectual experiences—asserting that unusual sensitivity reveals the potential for high levels of development, especially for self-actualization and moral vigor (Piechowski, 1979, 1986). Sternberg (1986a) viewed “sensitivity to external feedback” as one of the metacomponents of his theory of intellectual giftedness. Kholodnaya (1993) considered child prodigies as the result of the specific development of a child during the early years.

Shavinina (1997) distinguished cognitive (i.e. sensitivity to any new information), emotional (i.e. sensitivity to one’s own inner world and to the inner words of other people), and social kinds of sensitivity, which intersect with one another, forming mixed kinds of sensitivity. Leites (1971) emphasized that each child’s age is characterized by one or numerous kinds of sensitivity. Vulnerability, fragility, empathy, and moral and social responsiveness are among some of the manifestations of sensitivity (Shavinina, 1999; Silverman, 1994, 1997). Cognitive sensitivity is extremely important in a child’s development in general and in the advanced development of the gifted in particular. Thus, the first years of a child’s life are characterized by the ease and stability of knowledge acquisition and of the development of many abilities, skills, and habits (for example, linguistic abilities; Leites, 1996). Shavinina (1999) suggested that because of cognitive sensitivity, children’s knowledge acquisition is very quick; it may take place even from the very first experience.

The Characterization of Sensitive Periods in Gifted Children, Future Innovators

An individual’s sensitivity is not a constant—it varies in the course of development. At some points in the personal development the child is characterized by heightened sensitivity and these special age periods are called *sensitive periods*. At other points in his or her development the child’s sensitivity is low or even absent (Leites, 1971). There are exceptionally favorable inner conditions (i.e. conditions provided by the process of child development itself) and extraordinary possibilities for cognitive and intellectual development

during sensitive periods. Vygotsky (1956, 1972) specifically emphasized this issue. Introducing the concept of sensitive periods, he characterized their essence in the following way:

during these periods, certain influences have a big impact on the entire course of individual development by provoking one or another deep changes. During other periods, the same influences might have no effect or even an opposite impact on child development. Sensitive periods coincide fully with (. . .) the optimal times for learning (Vygotsky, 1956, p. 278).

Surprisingly, in light of Vygotsky's great impact on contemporary developmental theory, his view about sensitive periods appears never to have been translated into English, although it remains an important part of his developmental theory. Following Vygotsky, a general tendency in Russian psychology is to consider sensitive periods as an exceptionally productive time for learning (Leites, 1960, 1971, 1996; Shavinina, 1997, 1999) because they present extremely favorable internal conditions for mental development (Leites, 1985, 1988). In this respect, all human development—even in infancy—is characterized by individual periods of heightened sensitivity.

The years over which a child acquires language are one of the best-known examples of sensitive periods (Leites, 1996). Over a very short period of time, young children easily learn different forms and constructions of languages, but it becomes increasingly more difficult to do this in later years. It is fascinating and seems paradoxical that at a time when, for example, children are learning and speaking foreign languages with relative ease in the appropriate environment, adults who have a more developed mind—and therefore seem to be able to easily manage any linguistic difficulties—cannot do as well. Everyday life provides many examples of the difficulty with which adults learn and speak foreign languages. It seems clear that a certain age or age range—early childhood—is best suited for the specific mental activities involved in language acquisition. It appears that sensitive periods during childhood prepare and temporarily conserve favorable inner possibilities for advanced development. Elaborating further Vygotsky's ideas of sensitive periods, Zaporozhets (1964) asserted that “each period of a child's development has its age sensitivity, and because of that learning is more successful in the early years than in the elder ones” (p. 678). This is a key to the explanation of fast knowledge acquisition by gifted children that in turn leads to their advanced development. Cases of gifted, creative, and talented children at

sensitive periods support this assertion.² Taken together, the theoretical and empirical findings demonstrate that the changes of a child's age bring unique determinants of the advanced development: sensitive periods. Sensitive periods mean a qualitatively new strengthening of the possibilities for mental growth, which appear during the early childhood years. The strengthening of such possibilities leads to the general heightening of a child's cognitive resources.

Sensitive Periods: Developmental Losses and Individual Acquisitions

Favorable possibilities for individual development granted by these sensitive periods will weaken at a slow or fast rate—this is reality (Leites, 1971). Thus, the following question arises: can sensitive periods experienced by a child be predictors of his or her intellectually creative productivity in adulthood, which may eventually lead to innovation? We believe that the answer to this question will be ‘yes’ only if two important requirements are fulfilled during childhood. First, all *developmental* capacities (i.e. new abilities, habits, skills, qualities, traits, etc. acquired during a certain sensitive period) should be transformed into stable *individual* acquisitions. Second, these acquired

² For example, Alexander expressed his unusual abilities at a very early age. He started to read very well and to calculate before he was four years old. His interest in numbers probably indicated the first sensitive period. The boy continually demanded that all adults around him set up simple arithmetical tasks for him; he was hungry for them. In this period, he also liked to write various numbers. The number seven (7) was especially attractive for him: he wrote it everywhere in different forms and sizes painted in various colors. This ‘digital’ period eventually came to the end.

Just after his fourth birthday, Alexander entered a new sensitive period—the ‘geographical’ one. He read a lot about continents, countries, cities, seas, mountains, and rivers. All his questions to adults concerned only geographical issues. He asked his parents to buy geography books for him and he looked for related articles in newspapers. He watched TV programs that concerned travels around the globe and meteorological news (in this case, he could always see a map of his country). As a result, Alexander's acquired knowledge of geography was impressive. However, his new sensitive period did not consist only of the acquisition of new knowledge about geography. All of Alexander's cognitive activity was directed toward achieving one clear goal: to make a map of the world. All his time was devoted to this task. He prepared the map, conveying shapes and names of geographical objects (i.e. continents, countries, etc.) with amazing accuracy. Such an activity certainly required his artistic skills in drawing and painting, which were significantly developed during this period. In a few months, Alexander's second sensitive period—the geographical—was almost over (Shavinina, 1999).

individual capacities should, in turn, be transformed into unique cognitive experiences (Shavinina, 1999).

Although all stages of childhood can be distinguished by the heightened sensitivity (as compared to that of adults), sensitive periods have their own 'life story'. Sensitive periods emerge, exist, and even disappear during a child's development (Leites, 1971). What is important is what remains in the child at the end of sensitive period(s), as he or she grows older and favorable opportunities for advanced development weaken. It is important to note that although the favorable possibilities opened up by sensitive periods allow a child to advance significantly in his or her development by acquiring new and valuable knowledge, skills, and habits, he or she can also lose these acquisitions when a sensitive period ends. That seeming paradox is at the crux of, and is a real problem of, sensitive periods. Because of that Leites (1985, 1988, 1996) differentiates between *developmental* and *individual* aspects of sensitive periods.

If, at the end of a sensitive period a child loses almost all the exceptional capacities that he or she acquired during the given period, then one can assert that these capacities were mainly a *developmental* phenomenon (i.e. *developmental* capacities that disappear with age). This is key to understanding why so many gifted individuals who demonstrated exceptional abilities in childhood become ordinary adults who do not display extraordinary talents or outstanding creativity. Gifted children lose their unique abilities and talents in the process of their own individual development (Shavinina, 1999).

At the same time, sensitive periods are a true foundation for powerful *individual* gains. If new extraordinary capacities acquired during a certain sensitive period remain in the developing child after this period, then one can assert that these capacities have been transformed into *individual* acquisitions. Only in this case one can suppose, to a significant extent, that the child has the potential to be an intellectually creative adult, potential innovator.³

³ In this context it is expedient to further consider the case of Alexander in detail. When Alexander was a five and a half, a seven-year-old girl began to live temporarily in their family. She was admitted to school and a new educational period started for Alexander. The children did exercises together, solved mathematical tasks, and learned poems by heart. Alexander started kindergarten. His teacher was impressed both by Alexander's mental development and by his ability to draw and paint. The accuracy of the presentation of even the smallest details was a distinguishing characteristic of his paintings. When he was seven, Alexander successfully passed all examinations and was admitted directly from the kindergarten into the fourth-grade class for 11-year-old pupils. All of his school grades were 'excellent'. At that time, the third

The Nature of Advanced Development in Today's Gifted Children, Tomorrow's Innovators

Our analysis of the gifted at sensitive periods demonstrated the following tendency: their sensitive periods usually are linked sequentially or in chains (although the periods may overlap; Shavinina, 1999). This means that gifted children are always at sensitive period(s). In other words, the gifted's sensitivity does not disappear completely. In contrast to the previously mentioned opinion that sensitive periods emerge, exist, and disappear during childhood development (Leites, 1971, 1985, 1988), the chain of sensitive periods in gifted development testifies to the lasting sensitivity of gifted children. Research supports this conclusion. Thus, Silverman (1993) pointed out that "extraordinary levels of sensitivity and compassion do not disappear with maturity. A capacity for rich, intense emotions remains in the personality throughout the lifespan" (p. 642). Probably, this depends on the kind of sensitivity (i.e. cognitive, emotional, or social). Maybe emotional sensitivity, more than any other kind, remains in the individual during his or her life, whereas cognitive sensitivity changes periodically (but certainly it does not disappear in the gifted). Such characteristics of the gifted as sensitivity to a new experience and openness of mind—which are mentioned by many contributors to this volume as essential traits of innovators—can be regarded as evidence of this tendency of cognitive sensitivity. Perhaps the availability of cognitive sensitivity throughout the life span determines the exceptional mental abilities of an individual (Shavinina, 1999). Furthermore, if sensitivity remains in gifted children for a long time, then it is quite reasonable to state that new capacities acquired during a certain sensitive period will also remain in the gifted for a long time. These capacities are fortified and

sensitive period started, which can be called an 'ornithological' period (Shavinina, 1999).

At the age of seven, Alexander read three volumes of Brem's book for university students, *The Life of Animals*. This was the beginning of his interest in zoology; birds were especially attractive to him. The essence of a new sensitive period consisted of his writing (or, more precisely, creating) a book about birds. Alexander wrote down the summary of the corresponding chapters of Brem's volumes and made many illustrations for them. He also used two lengthy articles about birds that he found. The scale of his work was impressive: the manuscript ran more than 300 pages with more than 100 drawings. The text was divided into chapters, and all chapters were interconnected with an internal integrity. Alexander had an extensive vocabulary. His linguistic abilities were manifested in the absence of mistakes in the writing of his manuscript, which included many foreign words and biological terms. Alexander continued to read a lot, preferring scientific literature. He often used an encyclopedia and a dictionary of foreign words.

developed later, and finally they are transformed into true *individual* acquisitions that have a potential to remain in the person throughout the life span. In this case one can predict to a certain extent the transition of a gifted child into a talented adult innovator who will be able to excel intellectually and creatively.⁴

Moreover, the revealed chain of sensitive periods in the development of gifted children indicates a natural *overlapping* of age sensitivity. But to demonstrate that children may be continually in sensitive period(s) does not appear to be enough to explain truly advanced development. The overlapping of sensitivities is one of the keys to discerning the inner nature of advanced development. Such an *overlapping* of age sensitivities means that a child's sensitivity originates from different (i.e. previous, current, and subsequent) childhood periods.⁵ Furthermore, the overlapping of a child's sensitivity predetermines *duplication* and even *multiple strengthening* of the foundations for the rapid intellec-

⁴ In this context the example of Alexander should be considered briefly once again. At 14 and a half, Alexander graduated from high school with excellent grades. He was equally successful at the Department of Biology at Moscow State University and became a distinguished ornithologist. He participated in many expeditions, mainly to the north, related to the investigations of various birds. As an adult, he was characterized by the ability to work very hard, an intense interest in learning, the ability to draw well (especially birds), high ability in learning foreign languages, and an extremely clear and detailed memory. He was a competent, respected, and high-achieving scientist. Alexander's colleagues wrote: "He was distinguished by a combination of abstract thinking with deep knowledge of ecology and birds that he had learned during his numerous expeditions. He had strong will, excellent memory, and was able to work hard. He was also able to read in many European languages including Scandinavian languages; he was perfect in English. Alexander was an excellent scientist, untiring, purposeful, persistent. He could make an instant draft of a bird or landscape. He had an unlimited ability to work. He created his own scientific school" (Leites, 1996, p. 156).

What is remarkable is the complete coincidence between the description of 43-year-old Alexander, the talented scientist (by his colleagues) and the description of Alexander, the exceptionally gifted child (by the psychologist) (Leites, 1996, 1996). Alexander's life shows that his *developmental* capacities (i.e. those new capacities acquired during sensitive periods in childhood) were indeed transformed into powerful *individual* abilities that remained throughout the life span. In turn, Alexander, the profoundly gifted child, evolved naturally into Alexander, the highly creative researcher.

⁵ The description of Alexander's childhood summers supports this assertion. At that time, he had at least two sensitive periods: the 'bird' period and the 'butterfly' period. His interest in birds can be considered as three distinct, yet overlapping, periods: the first (his intense interest at age seven), second (his summertime interest in the observation of birds), and third (his renewed intense interest, developing as a variation of his previous interest). A new—and partially concurrent—sensitive period was that of his interest in butterflies.

tually creative growth that results into advanced development of the gifted. The phenomenon of the overlapping of age sensitivity of gifted children also testifies to the above-mentioned fact that they are always in sensitive periods. In this instance the likelihood of the transformation of all *developmental* capacities into the *individual* abilities is getting significantly high. Being permanently in sensitive periods also implies the actualization of the gifted's immense cognitive potential and acceleration of their mental development. The latter implies rapid accumulation of the gifted's cognitive resources and the construction of those resources into the unique cognitive experience that continues to enrich itself in the process of the further accelerated development governed mainly by heightened cognitive sensitivity⁶ (Shavinina & Kholodnaya, 1996). Their unique cognitive experience means their unrepeatable intellectual picture of the world. All the above written concerning sensitive periods demonstrates that they are not a factor, condition, characteristic, feature, or trait in a child's development. They should be understood as an inner mechanism of advanced development of the gifted, creative, and talented.

Sensitive periods, therefore, constitute a developmental foundation of individual innovation in that that they provide a basis for an extremely accelerated mental development in childhood. This intellectual acceleration leads to fast actualization and development of one's own mental potential and its transformation into the unique cognitive experience that, in turn, forms a cognitive basis of individual innovation.

Summing Up

This chapter presented a new conception of individual innovation, which explains: (1) its developmental foundation; (2) its cognitive basis; (3) its intellectual manifestations; (4) its metacognitive manifestations; and (5) its extracognitive manifestations. The developmental foundation, the cognitive basis, and intellectual, metacognitive, and extracognitive manifestations constitute the first, second, third, fourth, and fifth levels, respectively, of the internal structure of individual innovation.

⁶ The case of Alexander is quite appropriate again. Thus, although his 'ornithological' sensitive period was very long, his cognitive experience was different in each stage of childhood. For example, his initial drawings of birds were based on verbal descriptions from books because Alexander's first ornithological knowledge was from books, whereas his 'summer' drawings were based on his personal experience of natural observations. As mentioned above, at that time, his knowledge of birds reached a new level. Because of this, one can assert that Alexander had, in fact, a few 'ornithological' sensitive periods. These periods can be considered as previous, current, and subsequent sensitive periods sometimes simultaneously.

The developmental foundation of individual innovation is connected with the advanced childhood development of innovators that manifests itself in their accelerated mental growth, beyond which there are periods of heightened cognitive sensitivity. Specifically, during the childhood years, certain 'temporary states'—or sensitive periods—emerge at each age stage, providing significant opportunities for advanced development. Sensitive periods accelerate a child's mental development through the actualization of his or her intellectual potential and the growth of the individual's cognitive resources resulting in the appearance of a unique cognitive experience. Such accelerated development further facilitates rapid and deep knowledge acquisition, intellectual functioning, and the creation of something new and original. This leads to advanced development of future innovators. In turn, cognitive experience expresses itself in the unrepeatably intellectual picture of the world of innovators and is responsible for their exceptional achievements and performance (e.g. generation of new ideas).

In our view, individual innovation is not a 'gift', chance event, or a consequence of socialization. Individual innovation is a result of a specific organization of an individual's cognitive experience. This organization is, in turn, a result of the protracted inner process of the actualization, growth, and enrichment of one's own cognitive resources and their construction into an unrepeatably cognitive experience during accelerated mental development. The direction of this process is determined by specific forms of the organization of a person's cognitive experience (i.e. conceptual structures, knowledge base, and mental space). The unique structure of the mind, which makes possible the creative ideas leading to innovation, is being formed on the basis of this process. The uniqueness of innovators' minds expresses itself in specific, objective representations of reality—that is, in their unique intellectual picture of the world—which can manifest itself in a wide range of intellectual, metacognitive, and extracognitive manifestations.

Models of Innovation

Dora Marinova and John Phillimore

Institute for Sustainability and Technology Policy, Murdoch University, Australia

Abstract: This chapter presents a historical examination of models used to explain innovation. It focuses on the attempts to describe innovation as a process generating new products and methods and outline the activities involved. The purpose of these models is to explain how all parties come together to generate commercially viable technologies. The overview includes six generations of models, namely black box, linear, interactive, systems, evolutionary models and innovative milieux. Each of them is explained by addressing the following issues: conceptualization background, the model itself and its elements, explanatory power, related models and concepts, and further research directions.

Keywords: Innovation; Black box; Linear; Interactive; Systems; Evolutionary models; Innovative milieux.

Introduction

Technological change and innovation have become important factors in economic and policy debates. The qualitative nature of socioeconomic changes induced by innovation (in the form of new products, technologies, outputs, activities, actors, institutions and organizations, among others) also translates into quantitative measures, such as increased company turnover, profits, market shares, exports and GDP. While many people are aware of this phenomenon, our understanding of the process of technological innovation is still quite limited.

Since the 1960s, an ever-increasing number of researchers have tried to put together pictures of the process of generation of new products and production methods and outline the activities involved in this. Efforts to explain technological change have come from a variety of disciplines, including economics, management, sociology, geography and political science. The main aim of these models of innovation is to explain how all parties come together to generate commercially viable technologies. Four decades later, we can ascertain that there are a number of process characteristics, which we have come to understand. Nevertheless, the complete phenomenon is still covered under a veil of mystery, intuition and intelligent decisions in situations of risk, uncertainty and lack of information.

The main purpose of this chapter is to review the innovation models developed so far and in doing so

outline their explanatory powers and weaknesses. The focus is on technological innovation, as distinct from social, educational or organizational innovations, for example. The models examine innovation as a creative process engaging a variety of activities, participants and interactions¹ the outcome of which is a technological product or process.

This overview includes six generations of models, namely the black box model; linear models; interactive models; system models, including networks and linkages; technology learning and evolutionary models; and innovative milieux. After a brief explanation of the historical background, each generation of models is examined separately with references to the main related theoretical developments and publications. The concluding section of this chapter draws together the progress made so far in our understanding and description of innovation. Having done this, we also recognize the challenging task of capturing a snapshot of a phenomenon, which in each specific occurrence

¹ The innovation models discussed in this chapter specifically refer to innovation by firms. As pointed out by Beije (1998), this modelling activity does not concern individuals or not-for-profit organizations. Also not included are models representing the impact that innovation has on the economy and society (e.g. economic growth, comparative advantages or technology gap models). Nor does the chapter differentiate innovation by sector (see Pavitt, 1984) or by 'importance' or 'spread' of technological impact (see Freeman, 1982, 1984).

involves qualitatively different features, and where the exceptions constitute the rules.

Generations of Models

In the early 1990s, Rothwell (1992) described five generations of innovation models: technology push; need pull; coupling model (with feedback loops); integrated model (with simultaneous links between R&D, prototyping and manufacturing) and systems integration/networking model (with emphasis on strategic linkages between firms). The approach taken in this overview reflects a similar chronology; however, it extends Rothwell's typology. The sections to follow cover six generations of innovation models, namely:

- (1) First generation—the black box model;
- (2) Second generation—linear models (including technology push and need pull);
- (3) Third generation—interactive models (including coupling and integrated models);
- (4) Fourth generation—systems models (including networking and national systems of innovation);
- (5) Fifth generation—evolutionary models; and
- (6) Sixth generation—innovative milieux.

Each of them is explained by addressing the following issues: conceptualization background, the model itself and its elements, explanatory power, related models and concepts and further research directions.

The Black Box

Background

Irrespective of the widely acknowledged importance of resource allocation in all spheres of human activity, the economics of science, research and development and innovation has remained for decades an underdeveloped field of enquiry (David, 1994). The first attempt to incorporate technological progress in the economic equation was the influential mid-1950s production function study of Solow (1957) who analysed U.S. total factor productivity during the period from 1909 to 1949. His approach was that the component of economic growth, which changes in capital and labour could not explain, is due to technological advances. He concluded that about 90% of the per capita output could be attributed to technological change. This apparent invisibility of what happens when you invest in science and technology gave rise to the so-called black box innovation model.

The Model

According to Rosenberg (1982), economists have treated technological phenomena as events transpiring inside a black box. Although they have recognized their importance, "the economics profession has adhered rather strictly to a self-imposed ordinance not to inquire too seriously into what transpires inside that box" (Rosenberg, 1982, p. vii).

The black box model, borrowed from cybernetics,² states that the innovation process itself is not important and that the only things that count are its inputs and outputs. For example, money invested in R&D (input into the black box) will generate, as a rule of thumb, new technological products (outputs) but economists do not need to analyse the actual mechanisms of transformation.

Explanatory Power

The model places innovation as an important economic activity for firms. Although it does not explain research and development characteristics, it draws attention to the fact that "firms and industries that spend relatively large amounts on R&D may tend to have managements that are relatively progressive and forward looking" (Mansfield, 1995, p. 259). The black box coupled with the appropriate and timely management activities makes certain firms more successful than others.

Related Models and Concepts

The black box model of innovation arose along with, and sits neatly alongside, sociological theories of science that emphasized the importance of scientific autonomy and independence as essential for the flourishing of science (Merton, 1973). The threat to scientific freedoms under Nazism and communism, coupled with the astonishing successes of scientific and technological projects in the West (such as radar, the Manhattan project and nuclear energy), led to a strong belief in the power of science to produce radical technologies, if the scientific enterprise was given sufficient resources and 'space' with which it could be free to set its own methodologies and, to a large extent, its own goals. In such a climate, the fact that the actual innovation process was effectively a 'black box' was neither surprising nor particularly of concern; rather, it could be seen as a protective cover within which scientific inquiry could flourish. 'All' that was required was innovative outcomes in return for the input of resources. While this idea of 'big science' arose in the government funding of science, it translated easily into the management of innovation in large corporations, with the establishment and growth of corporate research laboratories, many of which became internationally renowned for their innovations, but whose inner workings were only partially understood by corporate management.

Further Research

The black box model and the reluctance of economists and other researchers to address the link between science, technology and industrial development were major factors in the lack of public policy encouraging innovation. The reliance on market mechanisms to

² A black box is any apparatus whose internal design is unknown.

support technological developments demonstrated the perception of a large number of economic analysts and policy-makers that there was little need to understand how innovation actually works.

The black box model also generally refers to the research and development component of innovation and/or has a tendency to equate the two. However, non-R&D activities, such as marketing, manufacturing start-up, tooling and plant construction, are crucially important for the introduction of new products and processes. The need to open the black box and explore its interior gave rise to a number of other models which are discussed in the sections to follow.

Linear Models

Background

The 1960s and 1970s witnessed the opening of the black box of innovation with researchers becoming interested in the specific processes that generate new technologies and the learning involved in technological change. The expectations were that understanding innovation would also open the road to formulating policies, which would stimulate R&D and consequently the development of new products and processes. Innovation started to be perceived as a step-by-step process, as a sequence of activities that lead to the technologies being adopted by the markets.

The Model

The first linear description of innovation was by the so-called ‘technology push’ model, which was closely related to the ‘science push’ model of science policy advocated by Vannevar Bush in his groundbreaking *Science: The Endless Frontier* report. According to the report, “discoveries in basic science lead eventually to technological developments which result in a flow of new products and processes to the market place” (Rothwell & Zegveld, 1985, p. 49). The step sequence is as follows:

Basic Science ⇒ Applied Science and Engineering
⇒ Manufacturing ⇒ Marketing ⇒ Sales.

The stages of the model may differ slightly (see, for example, Beije, 1998 or Feldman, 1994), but the focus is on technological newness as a driving force for innovation.

The ‘technology push’ model is also associated with the name and theoretical work of Schumpeter who studied the role of the entrepreneur as the person taking the risk and overcoming the barriers in order to extract the monopolistic benefits from the introduction of new ideas (Coombs et al., 1987).

The linear ‘need pull’ (or ‘market-driven’) model was developed not long afterwards in recognition of the importance of the marketplace and the demands of potential consumers of technology. It states that the causes of innovation are existing demands so that

the step sequence becomes as follows (Rothwell & Zegveld, 1985):

⇒ Market Place ⇒ Technology Development
⇒ Manufacturing ⇒ Sales.

The main exponent of demand-led innovation is considered to be Schmookler who studied patterns in patents and investments (Coombs et al., 1987; Hall, 1994). His conclusion was that fluctuations in investments can be explained better by external events (e.g. demand) than by trends in inventive activities.

Explanatory Power

The 1960s and 1970s witnessed an enormous amount of research on success factors for innovation. The technology-push/need-pull dichotomy was used to explain not only a wide range of successfully introduced new technologies but also numerous cases of failure (see the description of some projects in Coombs et al., 1987).

Policy-makers around the world have also adopted much of the simplistic linear ‘technology push’ model because of its clear message and economic rationale (i.e. market failure as the main justification for public investment in research and development). However, funding R&D without supporting other innovation related areas often leads to disillusionment with research and criticism that researchers do not deliver the outputs that have been promised or expected.

Related Models and Concepts

A related concept to the linear model of innovation is the so-called ‘barriers to innovation’ or factors which impede the adoption of new technologies (see Hadji-manolis, this volume). Similarly, a lot of research has been conducted into defining the factors for successful innovation (Cooper, this volume; Freeman, 1982), such as understanding user needs, attention to marketing and publicity, good communications and the existence of key individuals within the firm. Any deficiencies or weak links in the causal chain could cause innovations or technologies to fail in the marketplace. Both barriers and success factors can be broadly classified as belonging to the push or pull side of the innovation process.

Further Research

Although very clear and easy to understand, the linear models have always been too much of a deviation from reality. They were soon replaced by more sophisticated concepts in theory but in practice they have developed firm ground in the way research is financed and in the outcomes expected by funding bodies and corporate management. The question of what comes first—technology or need—has turned out to be a chicken and egg question, and that field of research has remained relatively quiet.

Interactive Models

Background

Both linear models were regarded as an extremely simplified picture of the generally complex interactions between science, technology and the market. There was a need for deeper understanding and a more thorough description of all the aspects and actors of the innovation process. The sequential nature of innovation has begun to be questioned and the process subdivided into separate stages, each of them interacting with the others.

The Model

According to Rothwell and Zegveld (1985, p. 50), “(t)he overall pattern of the innovation process can be thought of as a complex net of communication paths, both intra-organizational and extra-organizational, linking together the various in-house functions and linking the firm to the broader scientific and technological community and to the marketplace”. The stages are as follows (Rothwell, 1983):

By permission of The British Library.

Beiji (1998) stresses that in such an interactive model, innovation is no longer the end product of a final stage of activity but can occur at various places throughout the process. It can also be circular (iterative) rather than sequential. An example of this was the ‘chain-link’ model suggested by Kline & Rosenberg (1986) which includes feedbacks and loops allowing potential innovators to seek existing inter- and intra-firm knowledge as well as carry out or commission additional research to resolve any problems arising from the market-design-production-distribution process.

Explanatory Power

The main power of the model is the explanation of the variety of interactions necessary for the success of innovation. Further studies expanded the number of boxes and provided insight into the iterative nature of innovation. According to Dodgson & Bessant (1996), the acceptance of the interactive model is now widespread. The original simple model has been extended in numerous variants to describe more players and organizations or to make it specific to a certain situation.

Related Models and Concepts

The interactive model drew the attention of researchers to the lag between new technological ideas and economic outcomes. Issues such as whether the innovation cycle is becoming shorter became a field of intensive research.

Another derivative of this model were the ‘technological gap’ studies that explored deficiencies in firms’ competences (Dodgson & Bessant, 1996) in relation to the various components and interactions required to make innovation happen.

Further Research

The interactive model was an attempt to bring together the technology-push and market-pull approaches into a comprehensive model of innovation. As a result, it provided a more complete and nuanced approach to the issue of the factors and players involved in innovation. However, it still did not explain what drives the engine of innovation and why some companies are better at doing it than others. Nor did it provide an answer as to how organizations learn or what is the role of their operational environment.

System Models

Background

The complexity of innovation requires interactions not only from a wide spectrum of agents within the firm but also from cooperation amongst firms. The well-established hierarchical mechanisms seem to break and in many cases are being replaced by new entities, which cross between organizational boundaries as well as market entities. Marceau (1992) calls this phenomenon ‘permeability’ of firms while Sako (1992) describes it as the existence of dynamic, industrial, strategic or innovation networks. The main focus of this approach is on innovation as a system, which includes emphasis on interactions, inter-connectedness and synergies.

The Model

The system model argues that firms that do not have large resources to develop innovation in-house, can benefit from establishing relationships with a network of other firms and organizations. Hobday (1991) summarizes the following advantages of such an organization for innovation:

- groups of small firms can maintain leading edge technologies by using the support of the other organizations within the network;
- skill accumulation and collective learning occurs within the network and benefits all participants;
- the network promotes flows of key individuals between firms;

- skills can be combined and re-combined to overcome bottlenecks;
- innovation time and costs can be reduced;
- the network provides entry into the industry for small innovative firms;
- individual firms within the network operate with high flexibility and in low cost ways, including small overheads.

The most well-known system model is the so-called national systems of innovation (e.g. Freeman, 1991; Lundvall, 1992; Nelson, 1993, 2000). It deals with the diversity in approaches to innovation in countries around the globe which differ in size, level of economic development, historical traditions or level of concern about specific policy problems (e.g. education or global warming). According to one study, this is reflected in the way the main actors in the innovation process (firms, public and private research organizations, government and other public institutions) interact and the forms, quality and intensity of these interactions (OECD, 1999, p. 22). A national system of innovation is defined as a set of institutions, which jointly and individually contribute to the development and diffusion of new technologies and provide a framework for the implementation of government policies influencing the innovation process (Metcalfe, 1995). The most important feature of this set is its interconnectedness, the way the various elements interact.

Explanatory Power

The main power of this model is in explaining the place and role of small firms in innovation and how they can survive the competition and pressures from large companies. The synergistic effect of the innovation networks explains their capacity to produce positive sum effects for all the participants (DeBresson & Amesse, 1991; Freeman, 1991). They are also flexible and can adapt more easily to the changing requirements coming from various clients and markets. They are better equipped to deal with technological risk and uncertainty. The systems facilitate communications (Tisdell, 1995), the flow of information and transfer of formal and tacit knowledge.

The national systems of innovation concept explains the differences between countries and the various role governments play. It highlights specific patterns of scientific, technological and industrial specialization, institutional profiles and structures and, most importantly, how different countries learn, “since innovation is—by definition—novelty in the capabilities and knowledges which make up technology” (Smith, 1998, p. 25). The concept is also not confined to the level of the nation state and can be applied worldwide or to regions and localities.

Related Models and Concepts

Related concepts are innovation chains (Marceau, 1992) and complexes (Gann, 1991, 2000). Chains refer to the relationships between core manufacturers and their suppliers and distributors (Dodgson, 1993). Complexes integrate not only firms but publicly funded institutions and specific industry-based research organizations (examples of this are the military or construction industry complexes).

Strategic networks (or alliances) is another related concept (Jarillo, 1988; Sako, 1992) which refers to long-term, purposeful arrangements between for-profit organizations in order to gain competitive advantage over players outside the network or alliance.

A particular case of networks is the regional network (Dodgson, 1993) in which geographic location has prime importance. In addition to physical proximity, regions share similar culture, industrial mix, economic and administrative homogeneity as well as political and governance environment, which can promote distinctive styles and modes of innovation within regions (Cooke, 1998). Regional systems of innovation are closely linked to the concept of innovative milieu, which is discussed further below.

Further Research

The potential of networks in promoting innovation compared to that of large firms is not always clearly understood. Networks are generally very dynamic, and there is not much evidence of how long they last. Their competitive advantages may be easily lost if (or when) some firms become larger, quit the network and/or take over other firms. Trust building is a crucial component in the networked innovation, and the ways to achieve and sustain this are not always clear. The mechanisms of simultaneous cooperation and competition within the network (be it in different areas or on different projects) also require further investigation and understanding.

Edquist (1997) lists nine characteristics of the systems models, which, as well as describing the approach, shed light on its weaknesses and the need for further conceptualization. They are: (1) innovations and learning are at the centre of the model; (2) it offers a holistic and interdisciplinary approach; (3) a historical perspective is natural; (4) there are differences between systems and there is no optimality; (5) it emphasizes interdependence and non-linearity; (6) it encompasses product technologies and organizational innovations; (7) it points to the central role of institutions; (8) there is a place for various kinds of ambiguities and diffusion of concepts; and (9) it provides a broad conceptual framework rather than formal theories.

Another aspect of networking which requires further investigation is the role of government, proactive policies and the regulatory environment in creating

favorable conditions for such linkages and interactions. For example, a special case of facilitating networking could be public encouragement of cooperation in the development of environmental technologies.

Evolutionary Models

Background

According to Saviotti (1996, p. 29), the need for an evolutionary approach in economics was proposed on the basis of a number of failures in neoclassical economics, including its inability to deal with dynamic qualitative changes, which are internal features of technological innovation. Hodgson (1993) argues that the mechanical metaphor adopted in orthodox economic thinking has weak explanatory power, as economics and innovation are products of living creatures. Hence, the biological metaphor is more useful and parallels can be made with the Darwinian evolution of species (more explanation on this approach is provided in the reviews by Nelson, 1995; Dosi & Nelson, 1994). More recently, evolutionary studies of technological change have combined fundamentals not only from biology, but also from equilibrium thermodynamics, organizational theory and heterodox approaches in economics.

The Model

Saviotti (1996) explains the key concepts in an evolutionary approach to innovation as being the following:

- Generation of variety—innovations are seen as equivalent to mutations. They continuously generate new products, processes and forms and contribute to increased variety. Not all mutations (new technological developments) are successful, but the ones, which are often replace older products and processes consequently making them extinct.
- Selection—selection processes act together with variety-generating mechanisms. The outcome is the ‘survival’ (which could also be interpreted as introduction or maintenance) of some products, technologies and firms as a result of their adaptation to the environment in which they operate, and the demise of others.
- Reproduction and inheritance—firms are perceived as producing organizations and inheritance is expressed in the continuity in which organizations make decisions, develop products and generally do their business. Firms are learning entities but any developed expertise is difficult to inherit or transfer to other firms.
- Fitness and adaptation—Darwin’s ‘survival of the fittest’ principle is represented by the propensity of an economic unit to be successful in a given environment.

- Population perspective—variation is an essential component for an evolutionary process. Hence, not only average values but also variances in the population of firms/products should be analyzed.
- Elementary interactions³—these include mainly competition (between products or firms) and are the most studied interaction in economics. More recently, collaboration has also become a recognized type of interaction.
- External environment—a key element in the evolutionary approach. It traditionally covers the socioeconomic (including regulatory) environment in which technologies are developed. It is determined by mechanisms such as patent regimes, market structures, standards and regulations. More recently (in the case of the green or ecologically friendly technologies) it has also started to include the link with the natural environment.

Nelson & Winter (1982) were the first to translate the conceptual evolutionary model into a computer simulation model describing business behaviour on the basis of the so-called ‘routines’ or regular and predictable behavioural patterns and habits of firms. This model was initially applied to data used by Solow (1957) who studied U.S. productivity. Nelson and Winter were successful in demonstrating that ‘realistic’ firm behaviour could account for macroeconomic outcomes at least as well as Solow’s growth modelling production function. With the further advance of computer technologies, the 1980s and 1990s witnessed further interest in evolutionary modeling (e.g. Kwasnicki, 2000).

Explanatory Power

The evolutionary model challenged the central concept of economic theory, which traditionally focused on market equilibrium and complete information. This new approach explains that innovation by definition involves change, and decisions are made not merely on price. They evolve from historical context, social conventions and relationships between people and organizations. Metcalfe (1995, p. 26) concludes that in a “fundamental sense, innovations and information asymmetries are one and the same phenomenon”. In other words, imperfections are necessary conditions for technical change to occur in a market economy.

The uncertainty and imperfect information inherently associated with the innovation process is a departure from the ‘rational individual’ concept in neoclassical economics. The evolutionary model

³ In biology, elementary interactions between species include competition (for a common resource in short supply), commensalisms (one species stimulate the growth of the other) and predation (one species inhibits the growth of the other).

stresses ‘bounded rationality’ (Dosi & Egibi, 1991) and the value of diversity (Dowrick, 1995). It also shows how, under meaningful economic values of certain parameters, such as technological opportunities, and established decision-making rules, firms can be dynamic self-organized systems (Dosi & Orsenigo, 1994).

The selection process and the importance of the surrounding environment shed light on the processes of failure of generally fit technologies and the success of technologies which are considered inferior (e.g. MS-DOS computer operation system or VHS videorecording system). According to Tisdell (1995, p. 128), “a fit technique... may fail to be selected because its surrounding environment at the time of its occurrence is unfavourable”.

According to Bryant & Wells (1998), the evolutionary school of thought is likely to become very influential in policy considerations. Since World War II, governments have consistently funded outcome oriented research. What the evolutionary model emphasizes is that the process is as (if not more) important as the results from R&D. For example, a 1996 OECD report recommends governments to increase the population of innovative firms as a main policy goal rather than correcting market failure (OECD, 1996).

The evolutionary model also points out that outcomes are to a large degree determined by the evolutionary process, be it at the level of company or country. Shedding light on how decisions are made and how the various participants interact to produce innovations, is a major explanatory feature of this model. Therefore governments should be urged to create conditions conducive to the process of innovation by shaping relationships, encouraging learning, and balancing competition with cooperation. The model has less normative power, and is less focused on the implications for innovation strategy at the level of the firm beyond the need for firms to protect diversity and a range of competencies (of people, product ranges, technologies, etc.).

Related Models and Concepts

Related to the evolutionary model are a number of generalizations, which appeared in the 1970s and 1980s. They refer to technological imperatives (Rosenberg, 1976), innovation avenues (Sahal, 1981), technological trajectories (e.g. Biondi & Galli, 1992; Pavitt et al., 1989), technological (Dosi, 1982, 1988) and technoeconomic paradigms (Freeman & Perez, 1988; Perez, 1983). The main argument is that during a particular time period we witness certain regularities in the development of technologies (represented by the nature of the applied principles and practical solutions), but they are often hindered by the delays with which institutions adapt to the new potential of these technologies.

Further Research

In addition to explanatory power, an extremely important aspect of any model is its predictive potential. If a model is a relatively accurate representation of reality, the traditional scientific approach expects it to also deliver forecasts and predictions of future parameter values. The evolutionary model in general lacks such a capacity as it describes constant change, and hence, its parameters are always in flux. Nevertheless, there is some degree of predictability if we can explain the mechanisms supporting the continuity of the old and the introduction of the new and if we can characterize the turning points in between.

Innovative Milieux

Background

Since the 1970s, a large body of literature has developed dealing with aspects of the growth of regional clusters of innovation and high technology (Feldman, 1994; Keeble & Wilkinson, 2000). The importance of geographical location for knowledge generation gave rise to the innovative milieux explanatory model. The concept is the main contribution by geographers, regional economists and urban planners to a field, which traditionally has been studied by economists and sociologists. The real-estate rule of: ‘Location! Location! Location!’ started to attract attention to the natural, social and built environment surrounding establishments where technologies are developed. The model includes networking and linkages but goes beyond that to emphasize the importance of quality-of-life factors.

The Model

The innovative milieu model states that “innovation stems from a creative combination of generic know-how and specific competencies” and “territorial organization is an essential component of the process of techno-economic creation” (Bramanti & Ratti, 1997, p. 5). According to Longhi & Keeble (2000, p. 27), “the innovation process is not spaceless. On the contrary, innovation seems to be an intrinsically territorial, localized phenomenon, which is highly dependent on resources which are location specific, linked to specific places and impossible to reproduce elsewhere”.

An early description of innovative milieux by Camagni (1991) lists the following components:

- a productive system, e.g. innovative firm;
- active territorial relationships, e.g. inter-firm and inter-organizational interactions fostering innovation;
- different territorial socio-economic actors, e.g. local private or public institutions supporting innovation;
- a specific culture and representation process;
- dynamic local collective learning process.

Camagni & Capello (2000) emphasize that the interactions creating the innovative milieu are not necessarily based on market mechanisms but include movement and exchange of goods, services, information, people and ideas among others. They are not always formalized in cooperative agreements or any other contracts. Major features of such an environment are the ease of contact and trust between partners, which reduce uncertainty in the development of new technologies and prove to be a source of exchange of tacit knowledge.

In addition to the components of a productive working environment, more recently other factors have started to impact on the capacity of locations to generate innovative firms. They relate to the social, cultural and natural characteristics of the place, such as proximity to recreational sites, climate and air quality, quality of life for family members, including children, to mention a few. The high density of links is also being expressed in relation to interactions with the local community (Willoughby, 1995).

Explanatory Power

The innovation milieu concept helps explain the success of small and medium-sized enterprises, which in general lack the resources to maintain aggressive R&D strategies and operate at the cutting edge of technologies. The existing supporting network compensates for that and provides an operational “microcosm in which all those elements which are traditionally considered as the sources of economic development and change within the firm operate as if they were *in vitro*” (Camagni & Capello, 2000, p. 120).

The model also explains why certain localities give birth to a large number of small innovative firms, which are situated in close proximity and share a similar cultural and business ethos. It also highlights the fact that different localities have different patterns and paths in knowledge development and transfer of high technology.

Related Models and Concepts

Porter’s (1990) analysis of groups of firms located in geographic proximity is often referred to as ‘innovation clusters’. According to the OECD (1999), the concept of clusters is closely linked to firms networking but it goes beyond that as it captures all forms of knowledge sharing and exchange within a specific locality. Many clusters have developed over extended periods of time and have deep historical roots. Often they are also linked to the particular natural, human and other resources available in the region.

Other closely related concepts are ‘the learning region’ (e.g. Florida, 1995; Kirat & Lung, 1999; Macleod, 1996; Simmie, 1977) and ‘collective learning’ (Keeble, 2000; Lawson, 2000). They stress that learning is the most important feature of any economy

and successful regions provide particular combinations of institutions and organizations to encourage knowledge development within the community and learning by local firms through conscious and unconscious mechanisms.

Further Research

The innovative milieu model has not so far addressed the links between innovation and ecology. It is still predominantly anthropocentric, and innovators rarely address the issues of harmony with the natural environment. Nevertheless, there is increasing evidence that the development of technologies is not a means of its own but a mechanism to achieve broader goals. An example of this is the Finnish environmental cluster research program (Honkasalo, 2000), which covers projects encouraging cooperation between entrepreneurs who utilize the natural environment for eco-business and promotes innovative enterprises specializing in environmental technologies. The interest in the locality will hopefully result in increased consideration of issues such as ecologically sustainable development and social justice.

Conclusion

What becomes apparent from this overview of the six generations of innovation models is that the more we study innovation, the more we realize how complex a process it is and how difficult it is to ‘master’ it, whether at a corporate or government policy level. Hence while all the models discussed here stem at least in part from an interest on how innovation occurs in the firm, the explanatory factors have broadened out markedly. Innovation models have moved from a concentration on factors wholly or to a greater or lesser degree within the control of the firm (i.e. R&D management, marketing, financial resources, etc.) to factors external to the firm, so that networks of firms, government institutions and policies, and even culture and geography, have become relatively more important. The models studied here provide the basics of an explanation of the innovation phenomenon. Nevertheless, they leave a lot of questions unanswered. Every model is intrinsically a simplification of reality and as a rule omits the myriad details which make every innovation case so unique in its success or failure.

Evolutionary Models of Innovation and the Meno Problem

Thomas Nickles

Philosophy Department, University of Nevada, Reno, USA

Abstract: ‘Universal Darwinism’ is an innovation paradigm superior to the intelligent design and romantic paradigms. All innovation, including new knowledge, is the product of blind variation plus selective retention (BV + SR) and is thus a kind of adaptation. Yet many methodologists continue to regard BV + SR as a limited model of innovative problem-solving. I show how this clash can be (partially) resolved by exploring (1) the roots of the problem of innovation in Plato’s Meno paradox and (2) the implications of the ‘No Free Lunch’ theorems. The BV + SR paradigm recognizes sources of innovation other than novel ideas of creative individuals.

Keywords: Creativity; Innovation; Universal Darwinism; Universal evolution; Evolutionary epistemology; Design; Adaptation; ‘No free lunch’ theorems; Meno paradox.

Introduction

Popular accounts of innovation in the sciences and the arts appeal to special powers of creative individuals. Da Vinci, Newton, Mozart, Einstein, Picasso, and perhaps also Napoleon, Thomas Edison, and Henry Ford, are said to be geniuses able to see into the future or into the deep-structure of the universe, to have special powers of intuition that transcend those achievable by mastery of one’s subject area. In one way or another, these intellectual heroes possess clairvoyance, prescience, or foreknowledge. In this chapter I reject all such accounts as nonexplanatory, question-begging, or even regressive in the sense that invoking them makes the explanation problem harder rather than easier. What we are left with on a thoroughly naturalistic account is the ordinary abilities of human beings (cf. Weisberg, this volume). To be sure, we humans vary tremendously, both in our natural abilities and in the expertise that we bring to various domains; but none of us have supernatural powers. None of us are gods, and not even the brightest of innovators can foresee or control the future implications of their work with guaranteed accuracy.

In avoiding the supernatural, my account agrees with others in this Handbook. However, my emphasis will be less on especially creative individuals (that is, on ‘great men and their ideas’) and more on general processes that constitute sources of innovation. I do not

deny that exceptional people exist, but here I am interested in the question: What are the implications of ‘going natural?’ Even the more sophisticated studies of canonical innovators tend to overplay the degree to which they knew enough about what they were doing to preplan their actions in accurate detail. Building on the work of Donald Campbell, Daniel Dennett, and others, I shall try to get to the bottom of the innovation issues in cognitive and epistemological terms.¹ Although I propound nothing worth calling a general *theory* or general *method* of innovation, I claim that the subject can be interestingly addressed at a general level. This will require thinking about innovation in a rather abstract way.

If I am successful, the overall result will be a framework, with some usable constraints, for thinking about genuine innovation of any kind—namely an evolutionary framework of a broadly Darwinian type. The major implication is that blind variation plus selective retention—an evolutionary process—plays an

¹ See the references at the end of the chapter to Campbell and Dennett as well as to Richard Dawkins, Gerald Edelman, Henry Plotkin, Aharon Kantorovich, Gary Cziko, Dean Keith Simonton (who has a chapter in the present Handbook), and William Calvin. These authors are, of course, not responsible for the particular twist that I give to the BV + SR model of innovation.

essential role (although not the only role) in all innovative inquiry. This in turn implies that, at least to a first approximation, all innovation, all design, and, indeed, all knowledge can be construed as adaptation; and, contrariwise, in a broad sense, all adaptation can be construed as design or knowledge and, when new, as innovation. Insofar as a design is *fully* the product of intelligent planning, its production is routine, not novel, although the plan itself may of course be original and hence itself the product of prior trial and error.

Learning theories and, by extension, theories of innovation are sometimes classified into three types. *Providential* theories ultimately appeal to divine providence or some other transcendent process as the source of new knowledge or design, for example, a doctrine of innate a priori knowledge or a special capacity of clairvoyance. *Instructionist* theories claim that the world directly instructs the knowing agent by imposing its form on the receptive mind. The classical model is the signet ring impressing its pattern in wax. During the modern period we get the simple empiricist view that we can read the truth directly off nature, by passive induction, without any need for interpretive trial and error. One version of the modern view is British empiricist philosopher David Hume's psychological theory of learning or habit acquisition through mere repetition of an environmental contingency. Hume simply took for granted that the agent unproblematically *notices* the repetitive pattern.

Finally, *selectionist* theories postulate some sort of variation and selection process or iterative trial and error. In this chapter I defend the third approach, and I reject providential theories on the ground that they are question begging and viciously regressive. I shall not have space to critique instructionist theories (but see Campbell, 1974; Cziko, 1995).

At its core, Darwinian evolution consists of three mechanisms: a mechanism of blind or undirected variation, a mechanism of selection, and a mechanism of transmission or heredity, in short, BV + SR. Darwin appreciated that whenever these mechanisms operate in a reasonably stable environment with selection pressures, evolution of the species in question *will* occur. He elaborated a mechanism of natural selection but was ignorant of the precise mechanisms of variation and transmission. Although not a mathematician, Darwin thought statistically, in a qualitative sort of way, and thereby introduced populational thinking into biology more clearly than anyone had before. Moreover, his theory in effect introduced a new kind of control system into our thinking about natural processes, a kind of feedback mechanism of a subtle, indirect sort (one that is purely eliminative, with death or reproductive failure as the 'teacher'), operating over a distributed population of agents or processors responding only to their local conditions (Cziko, 2000, ch. 1 *et passim*). We should not consider evolution (and

BV + SR in general) as a mechanistic theory of a Newtonian kind.

It is no secret that evolutionary mechanisms can produce remarkably novel design. Indeed, biological evolution is surely the most innovative process that we know. What other process has produced anything as innovative and original as the biological world in all its amazing complexity and variety? This fact alone makes Darwinian evolution worthy of serious attention from students of creativity and innovation. What is it that enables such a blind- and dumb-looking process, one that completely lacks creative individuals in the human sense, to produce so much innovative design? Can we 'reverse engineer' this process and put it to human use? Have we already done that implicitly? While evolutionary processes are fascinating producers of innovation, I want to defend a stronger claim: they are the *only* truly innovative processes that we currently know!

I believe that an evolutionary process is implied by a thoroughly naturalistic treatment of innovation. At least there is no alternative account in sight at the present time, with the possible exception of self-organizing systems as a partial explanation. Yet many people interested in innovation find the selectionist model of learning and innovation highly counterintuitive. At the end of the chapter I shall reply to a few of the more frequent objections to the evolutionary model of innovation. Meanwhile, I shall maintain that, *since* it is the only innovative process that we really know and understand, we need to reconceive innovation, including learning and research. To a first approximation, we should conceive of all genuine innovation, including new knowledge, as a kind of adaptation.² And we should view all genuine design or fit as the product of an evolutionary process. This grand generalization of Darwinian evolution is often called 'universal Darwinism'. The label is convenient, but it misleadingly suggests too close a tie to Darwinian *biological* evolution. Accordingly, I shall often call it 'the BV + SR model of innovation' or 'Campbell's thesis'. I now motivate this generalization of the innovation problem and solution from an unexpected philosophical angle, namely, Plato's paradox of the *Meno*.

² Although this is a broadly biological conception of innovation and learning, I mean only that they are underlain by BV + SR processes, not necessarily strictly Darwinian biological processes. Still, my thesis can be viewed as an extension of the adaptationist paradigm in evolutionary theory. I do not commit myself slavishly to adaptation as the only possible origin for innovation (given such things as genetic drift and the possibility of self-organizing systems); hence my 'to a first approximation'. However, I believe that adaptation is the most important factor. And if a physical system in effect explores a phase space and hits on a stable, self-organized state or falls into an attractor basin, that is rather like blind search and selection, although it will not be iterative unless the state is self-reproducing or is shaken out of its basin with the possibility of finding an even deeper basin.

Innovation, the Meno Paradox, and Darwinian Evolution

The Meno paradox presents us with the problem of how successful inquiry is possible. The paradox denies that inquiry is possible and hence denies that we can learn anything new. By two plausible extensions, the Meno problem can also be interpreted as: (1) the problem of how human innovation is possible; and (2) the problem of how novel design anywhere can emerge, whether or not that design is accomplished by the deliberate, conscious activity of intelligent agents. Indeed, taking a cue from Plotkin (1993) and Dennett (1995) as well as Campbell, I claim that all knowledge can be treated as a form of design and, conversely, that all adaptive design can be construed as a form of knowledge. The issues are too complex to defend in detail here, but I hope to make them at least intelligible.

The paradox, formulated in Plato's dialogue *Meno*, 80d-e, has the logical form of a dilemma. In its original form the problem is to show how successful inquiry is possible, that is, how is it possible to gain new knowledge. Meno (the character in dialogue with Socrates) concludes that it is not possible. For either you already know the answer (or problem solution) that you seek or you do not. If you do, you cannot really inquire, for you already have the answer. But if you do not know the answer, then you also cannot inquire, since you would not *recognize* the answer even should you stumble upon it accidentally. Ability to recognize is the key, and you have to know an item already in order to recognize it.

To many readers, the paradox is nettlesome word-play, to others an unnecessary abstraction. There is a bit of verbal confusion, to be sure; but in my view the paradox presents us with *the* core problem of innovation; and its solution possesses practical importance as well as intellectual interest.

As usual, there are two 'horns' to the dilemma. If you already know that magnetic monopoles exist, then you cannot genuinely inquire into whether or not they exist; and so you impale yourself on the first horn of the dilemma. This is true whether you had previously learned that alleged fact by empirical investigation, by reading a text, or by direct revelation by Providence. However, if you have no idea whether monopoles exist and even what exactly they are and what would count as detecting them, then you impale yourself on the second horn, since you would not recognize one even should you 'stumble upon it' accidentally. To change the example: Had Aristotle asked what makes salt flash yellow when tossed into the fire, and a twentieth-century quantum theory textbook had fallen out of the sky at his feet, he would have been incapable of recognizing that the text provides the answer to his question (namely in terms of electron state transitions

of sodium ions, which flash the familiar sodium yellow, as first proposed by Niels Bohr).

The Aristotle illustration is extreme. We all know that inquiry *is* possible, as is innovation. What, then, is the solution to the paradox? I take up this question more fully in Section 5, but to anticipate: As far as I know, the only viable solution involves an element of trial and error, that is, a process of blind variation plus selective retention (BV + SR). Of course, pure, blind or 'random' trial and error that simply discards all problem solutions that are imperfect, by some pre-established standard, is very inefficient. But things are very different if the standard of comparison is greater fitness relative to other members of an extant population, if the fitter individuals have a greater chance of selection, and if the retention mechanism involves transmission, with variation, to a new generation such that we get iterated 'cycles' of BV + SR. In that case we get gradual evolution. Darwin was the first to recognize this, and he further recognized that a BV + SR process, when it is in place, does not merely make evolution *possible*, it makes it (nominally) *necessary*, assuming a reasonably stable environment with selection pressures. As long as these conditions remain in place, there is no stopping evolution!

My claim is that human inquiry in the various sciences and the arts frequently satisfies the conditions that make evolution and hence innovation almost inevitable. So we have passed from puzzlement about whether and how innovation is possible at all to understanding why, under a variety of situations, it is inevitable—virtually necessary.

Although it is not news that human innovation is possible, the BV + SR model once again raises the question whether we can improve our innovative techniques by reverse engineering biological evolution, whether we can distill out the secret to its innovative powers, and 'bottle' it for our own use. 'Simulation of the evolutionary process is tantamount to a mechanization of the scientific method', wrote Lawrence J. Fogel, one of the founders of the field of evolutionary computing.³

This chapter and two companion pieces (Nickles, 2003 and forthcoming) can be viewed as an exploration of Fogel's claim. I believe that there is some truth in it. However, this does not mean that biological BV + SR is immediately applicable as a powerful scientific method (let alone as 'the' scientific method), for several reasons. One is that there are many kinds of BV + SR processes besides the biological family of evolutionary processes discovered by Darwin. Another is that the more powerful processes are highly domain-specific. It turns out that you cannot reliably or knowingly use a powerful method unless you already know a great deal

³ L. J. Fogel (1999, p. 44), quoted by Jacob (2001, p. 3).

about the subject domain. So there remains this much truth in the Meno paradox. Roughly speaking, it takes knowledge to get knowledge, a claim that obviously raises ‘ultimate origins’ problems analogous to those faced by biological evolution. It also raises questions about how explicit that knowledge has to be and whether biological or mechanical processes can ‘know’ in this sense. I shall not be able to pursue such large questions in this chapter.

It was Darwin who first found the entrance to the vast space of BV + SR mechanisms and the new sort of control theory that accompanies them. In appreciating the potential of BV + SR to generate novel design, Darwin and Alfred Russel Wallace achieved the extraordinary but controversial insight that here is a process capable of producing more design (or at least apparent design) from less and hence a process that is genuinely creative. Still more controversial was Darwin’s insight that, ironically, the only previously known way of explaining design—the *intelligent design model*—actually explains no truly *innovative* design at all; and that, hence, the *evolutionary model* replaces it as the only game in town! Late nineteenth-century Darwin sympathizers such as Thomas Henry Huxley and William James already realized, to some degree, that there is no reason to restrict the evolutionary process to biology and to Darwin’s specific mechanisms—that bodies of knowledge claims and cultural practices may also be considered designs, designs that at one time were innovative and adaptive. Darwinian *biological* evolution is only one of many possible instances of BV + SR.

Now whether and how we can create more from less is precisely the knowledge problem of the *Meno*. Restated in our terms, the Darwinian claim is therefore that the intelligent design model does not really solve the Meno problem after all; only evolutionary models do. If this is correct, then, given the absence of viable alternatives, we can say that it is only within the last century and a half that we have been able to solve the Meno and hence learned the secret of inquiry, the key to innovation. Interestingly, even the young Darwin of 1838 had some notion of the relevance of his emerging ideas about evolution to the Meno problem. In response to a reference to Plato’s doctrine of innate ideas owing to the soul’s journey between lives, Darwin wrote in one of his notebooks ‘read monkeys for preexistence (of the soul)’.⁴

In our time, Donald Campbell and several other investigators (see Note 1) have revived and defended a *universal* evolutionary or selection theory—the claim that, ultimately, *all* innovative design is produced by

one or another variation-plus-selection-plus-transmission process.⁵ This is the aforementioned ‘universal Darwinism’. Meanwhile, scientists such as Nils Jerne⁶ and Macfarlane Burnet, founders of the ‘clonal selection theory’ of antibody formation in immunological theory have fruitfully applied generalized Darwinian models to areas of biology other than traditional evolutionary theory. More speculative applications include those of Gerald Edelman, author of an account of a semi-Darwinian brain development that he calls ‘neural Darwinism’, and William Calvin, with his clonal model of competing representations in the brain. Just as biological evolution can be considered a phylogenetic inquiry process or learning system, neural system development and the vertebrate immune system may be considered ontogenetic learning systems. Thus, evolutionary models are proving useful in developmental biology. Universal evolutionists extend the claim to learning theory and to all production of novel design.

Since the 1960s, founder John Holland and the many other contributors to the field of evolutionary computing have done more than anyone to extend the BV + SR methodology far beyond Darwinian evolutionary biology, to the extent that Darwinian biological evolution can now be represented as a single point or small region in a large space of BV + SR processes. In the past decade evolutionary computing has enjoyed explosive growth and is now employed in thousands of technical papers in dozens of disciplines every year.⁷

If the universal evolutionists are correct, then we have (or need) a new paradigm of innovation. For on this view *all* successful innovation, the emergence of all novel design, is the product of BV + SR. Not only is all adaptation design but also all design is a kind of evolutionary adaptation. This includes inquiry, where we need to think of problem solutions and other results as things that have evolved, grown, or emerged by a process of adaptation rather than as things that have simply been inferred by a logical process, whether deductive or inductive. In this sense the evolutionary paradigm supplants or transcends the old *logical*

⁴ Desmond & Moore (1991, p. 263), quoted by Dennett (1995, p. 130).

⁵ See the references at the end of the chapter. The BV + SR claim has other late-nineteenth-century sources that are not necessarily Darwinian, including Alexander Bain and Paul Souriau (Campbell 1960, 1974a). Also, by ‘universal Darwinism’, Dawkins (1976) originally referred to the Darwinian basis for life forms that may exist elsewhere in the universe.

⁶ Interestingly, Jerne was led to his solution to the central problem of immunology by seeing it as similar to Plato’s Meno problem.

⁷ Key references for this paragraph include Campbell (1960, 1974a, 1974b), Rechenberg (1965), Holland (1992), Plotkin (1993), Dennett (1995), Cziko (1995, 2000), Edelman (1987), Schwefel (1995), and Calvin (1996).

paradigm of innovation.⁸ It also replaces the *romantic paradigm*, which relies heavily upon processes that are both nonnatural and nonlogical.

In insisting that all innovation involves an element of trial and error, the BV+SR paradigm incorporates at least a modicum of luck or chance. It thereby claims that all innovation involves an element of serendipity, normally many instances of scarcely recognized micro-serendipity rather than one big, lucky break. The BV+SR paradigm is not deterministic, but neither does it depend solely upon sheer blind luck. The process is iterative and cumulative and therefore builds on its previously established platforms (Dawkins, 1986, ch. 3). Nor need it be directionless, as biological evolution is. After all, Darwin himself was much instructed by the artificial selection techniques practiced by animal and plant breeders. However, according to the new paradigm of innovation, it would take *considerable* luck to realize the goals of a research program precisely specified in advance and adhered to religiously. As Campbell (1974, 435ff) points out, serendipitous discoveries depend upon having multiple selection criteria, upon being flexible and opportunistic. Ironically, then, it is the old design paradigm (the rigid, intelligent design or rational planning model) that actually requires luck in large quantities. The irony is doubled by the fact that the need for large chunks of luck arises out of the very attempt to eliminate the need for luck through detailed rational planning.

What is Innovation?

It is impossible to define ‘innovation’ and ‘creativity’ precisely in a context-free manner. Clearly, what is innovative or creative for you may not be for your community, much less for the human race or the universe as a whole. The advanced inhabitants of Lagado or of the planet Zork may have achieved it already. Let us call ‘the attribution problem’ or ‘the credit-assignment problem’ the task of assigning credit for an innovation. Margaret Boden (1990, p. 32) distinguishes an individual’s psychologically creative (P-creative) efforts, or personal firsts, from historically creative (H-creative) accomplishments, or historical firsts. (She limits the term to human history.) According to the naturalistic line that I am taking in this chapter, nothing is truly innovative if it is simply externally injected by an outside agency such as a teacher or even God. Good students are not necessarily creative students. They may ‘get the point’ without being able to improvise upon it. And if God gave Schrödinger and Heisenberg the laws of quantum

mechanics, then those two men are proportionately less creative, and their work is practically a form of plagiarism! (Recall the literal meaning of ‘inspire’.) Similarly, simple instructive empiricism, according to which we can directly read the truth off Nature, diminishes attributions of innovation.

What about the apparently similar case in which someone or something arrives at a result by mechanically following an available recipe or method or algorithm? Isn’t the result already implicitly contained in the method and so already implicit in the method-plus-user system? I would say so, but things become less clear when the methods are less specific and the algorithms complex. This latter issue somewhat resembles the question of whether you can get more out of a computer than you program into it. According to the ‘Lady Lovelace objection’, the computer deserves no credit for innovation.⁹ I agree with Boden (1990, 6ff) and many others that you *can* get more out than you put in.

One issue is how we characterize what we put in. With simple, highly specific programs you do not get more than you put in, except, typically, more speed and accuracy. (These can make a real difference in performance, as the chess, checkers, and domino victories over human champions vividly demonstrate.) But with more general or complex programs the case is different. Here a distinction between potential and actual is necessary. From any set of statements or rules, an infinite number of logical consequences follow and are potentially recognizable by a rational cognizer. However, finite cognizers can actually recognize only a relatively small, finite set of these in any real-time situation. For this reason a purely deductive consequence can be *epistemically* novel, even though it is not *deductively* novel. Logically nonampliative inference can be epistemically ampliative. The computer, in exploring areas of consequence space that we have not explored, can produce something epistemically novel for us.

Similarly, by using a method we may be led to explore areas of search space previously unknown to us. Thus we cannot say that a method can produce nothing more than was explicitly built into it. Obviously, what its human designers built into it explicitly was already known and so cannot count as innovation. Here we encounter a tradeoff, to be further discussed below. Insofar as a method is both helpfully directive and warranted by domain knowledge, it relies upon knowledge already achieved in order to achieve a rather routine sort of problem-solving. And insofar as it is directive but unwarranted by domain knowledge, it is risky: it can lead us to major new results, but it will often fail badly. In this respect, such a method is hypothetical in character. So although I do not deny

⁸ Logical inference often plays crucial roles in the BV+SR process. My point is that we should not essentially characterize innovation in terms of the old logical paradigm. There is a sense in which the BV+SR model also replaces the knowledge-based paradigm of artificial intelligence. See below and Koza et al. (1999).

⁹ Ada Lovelace was the daughter of Lord Byron, who assisted Charles Babbage in the design of his analytical engine.

that methods can help us to innovate, the old view that methods are what produce discoveries is exactly backwards in my view. The methods routinely employed by the scientific community to solve already mastered problem domains are the final *result* of the discovery process, not the tool that produced the discoveries in the first place. A method is a final-stage streamlining of a trial-and-error process that was once full of false starts and blind alleys.

The credit-assignment problem can also be raised for the BV+SR model of innovation. Since BV+SR ‘only’ reorganizes and selects materials already present, with an occasional, exogenously caused chance mutation thrown in, does it really produce anything new? Isn’t all the ‘knowledge’ already built into the system consisting of population-plus-environment? Well, yes and no. Given the power of the process to explore vast regions of design space efficiently, and given the fact that the original designs were very simple (for probabilistic reasons), there remains a lot of novel design to be ‘found’ or generated.¹⁰ Still, to count as genuinely novel design, it has to be something that did not actually exist before.

In some sense, then, “genuine originality must be a form of creation *ex nihilo*” (Boden, 1990, p. 29). Boden rejects this view, on the ground that it requires a miraculous explanation. However, there is a qualified sense in which evolution does just this. New design *emerges* from something that was not design, or at least not *that* design. But, of course, not even evolution creates something from absolutely nothing. Rather, as many authors in this volume point out, it works by adapting mechanisms or designs or resources already available. New design genuinely emerges from old. Novel design is an *emergent* phenomenon. It is precisely characteristic of emergent phenomena that they manifest novel features although resulting from combinations of ingredients already present. They reduce to what was already there, except for their organizational pattern or design, and thus do not require appeal to any distinct sphere of metaphysical reality; yet they are also nonreductive in manifesting that novel design. Any satisfactory solution to the Meno problem must show how genuinely new knowl-

edge can emerge from available resources, including old knowledge.

In speaking of design, I follow Dennett’s (1995) formulation of innovation as bringing new design into being. And so I have generalized the Meno problem as asking how it is possible that original design enters the world. Speaking of design does have the advantage that it embraces the arts and other human doings in addition to specifically scientific and technological innovation. However, I cannot claim more than a heuristic function for this move, since what counts as design in the relevant sense is also difficult to say. Clearly, not just any pattern counts as design in the relevant sense (as Dennett fully recognizes). Roughly speaking, to be a design, it must be adaptive to some context or purpose, it must display a degree of fitness.

Similarly, I agree with Robert Sternberg et al. (this volume) that creativity (or at least innovation) involves more than producing novelty. It must be useful novelty, in a suitably broad sense of ‘useful’. To this degree, ‘innovation’, like ‘discovery’, is a success term, an achievement term. For me such success requires recognition (part of the larger-scale Meno problem!) that can only be conferred by a community of people who can authoritatively locate the innovation as a contribution to their project. However, there can be attempted innovations that fail because, although verbally recognized, they are not integrated into the practices of the community. So in this respect, ‘innovation’ is not as definitive an achievement term as ‘discovery’.

Traditionally, credit assignment for innovation has been highly individualistic. I want to emphasize that social recognition and attribution are crucial, although they are not, of course, the whole story.¹¹ In my view, unlike that of many philosophers and psychologists, creativity and innovation tend to be highly distributed across communities, and this is especially true of deep innovation. At the frontier of research or of artistic production, no one can know the extent and magnitude of the ramifications (see below). A highly centralized

¹⁰ Useful though it is, talk of search spaces and design spaces, as if all the possibilities already existed there waiting for us to discover them, can be misleadingly Platonic. It also threatens to reduce all discovery or recognition to the Columbus-discovers-a-new-continent model. And if we consider the knowledge to be already implicit in the population-plus-environment system, then one facet of the Meno problem becomes how to *transfer* this knowledge more explicitly to those members of the population that we call scientists (or artists or whatnot). See Section 5 for the Meno transfer and transformation problems.

¹¹ In short, I employ the term ‘discovery’ in a broad, non-realist sense that leaves room for social construction. For sophisticated accounts of the negotiation and construction of discovery attributions, see Brannigan (1981) and Simon Schaffer (1986, 1994), who point out that the attributions should not be naively accepted as accurate history of who did what. Thus Brannigan and other historical investigators have exploded the myth that Mendel was the neglected discoverer of modern genetics. More controversially, Thomas Kuhn (1978) has exploded the myth that Planck was the founder of quantum theory. I agree with the sociologists and social historians that social attribution is crucial, but I disagree insofar as they suggest that this is the whole story and that cognitive psychological accounts (for example) are beside the point.

cognitive process is not nearly efficient enough to account for the problem-formulating-and-solving successes we find in the sciences—and in the arts for that matter. Nor is innovation simply a matter of having new ideas, for inarticulate practices, institutions, social structures, and the like can also be creative. The gradual emergence of a market economy, from the Italian Renaissance on, was not the deliberate, conscious design of social planners. Not until hundreds of years later (Adam Smith in 1776) were some of the essential features even recognized.

According to the universal evolutionary paradigm, innovation does not flow directly either from logical inference alone or from the creative inspiration of a poetic individual alone, for it does not flow directly from anything. Although pieces of inquiry can be highly directed and the larger chunks directed somewhat more loosely, the process as a whole is quite indirect (but less indirect than biological evolution). No trial-and-error process in which the goals and problems themselves are initially only loosely defined can be very direct overall. And it is precisely characteristic of highly innovative work that the goals, standards, and problems themselves evolve and become sharpened during the course of the work.

So is trial and error essential to innovation or is it to be avoided? My answer in the remainder of this chapter will be Yes and No! According to universal Darwinism, yes, it is in some way essential. But no, this does not mean that all problem-solving and all productive practices are nothing more than blind, mechanical trial and error. My position is far from a simple reductionist one.

The Evolutionary Design vs. Intelligent Design Models, Human and Divine

As indicated, the leading alternative model, which has dominated the explanation of innovation until recently, is the intelligent design model, according to which deliberate, directed, pre-planned inquiry is both necessary and sufficient for innovation, aside from the occasional, improbable lucky hit. The intelligent design model has two well-known versions: the human-design model and the God-design model. The central premise, or principle, of intelligent design models is that *there can be no intelligent design without an intelligent designer; no genuine innovation, or at least no systematic innovation, without an intelligent innovator; no genuine design without a rational planner*. This idea is familiar from old, natural theological debates about the design of biological organisms and the creation of biological species. However, the premise holds equally for the extension of the theological argument from design to human innovation. After all, as William Paley's (1802) example of the watch found on the heath reminds us, the human intelligent design model itself is the source of the God-design model and of the intelligent design

model of innovation in general.¹² Paley himself considered biological organisms and specific organs such as the eye to be artifacts, artifacts constructed by the Great Artificer. The God-design model is the human-design model writ large.¹³

While many students of innovation today steer clear of divine inspiration and the like, the human-design model still underlies many accounts of discovery and innovation in science and technology as well as in the arts. According to its proponents, trial-and-error methods are typically brought in only as a last resort, when rational planning fails. Yet the human-design model leaves us with a very poor understanding of human innovation, for it is plausible only insofar as its alleged applications remain vaguely stated. We never get enough detail to see how the model could really work. Indeed, the more detail we get for a given case, the easier it is to see that the *pure* human-design model gets no purchase at all. By contrast, a progressive scientific understanding yields better-defined models and/or stronger empirical confirmation the more closely the problems are examined.

Ironically, if the evolutionists are correct, it is the BV + SR model that is fundamental and not a mere stopgap, last resort when all else fails. The claim by Campbell and a host of other evolutionists is not that rational, informed planning and directed inquiry are impossible, but rather that all of the knowledge that those activities presuppose was originally acquired by means of BV + SR processes, and that even such planning, insofar as it goes beyond already available design, must resort to trial and error. Fully planned activities are not in themselves innovative.

If we do treat *knowledge* as a kind of design (as we did in our extension of the Meno problem), then the intelligent design model is committed to the thesis that there is no epistemically successful design without a *knowledgeable* designer, no intelligent inquiry without an at least equally intelligent and informed inquirer. But if the designer, or the intelligent method employed by the designer, already contains the design, then it is difficult to see how this process can produce genuine innovation, or more knowledge from less. Stated more explicitly in terms of knowledge, the point is that if the intelligent designer must already know everything necessary, then the new knowledge is not a genuine

¹² Very briefly, Paley's argument was this. Suppose that in walking on the heath you come upon something that looks and works exactly like a watch. What is the probability that this object is the product of a chance coming together of the natural elements rather than the product of intelligent human design? Answer: negligible. Well, we may conceive of the human body from head to toe as a machine that is far more complex than the watch. So the probability of intelligent design is even more overwhelming in this case.

¹³ My purpose is not to construct arguments against God's existence but to study the conditions that can produce genuine innovation.

innovation at all but simply a routine application of what the designer already knows. There is no genuine inquiry, for the process is impaled on the first horn of the Meno dilemma.

This point parallels the criticism leveled by evolutionists against the God hypothesis: that appeal to God cannot really explain design, for creationists are merely positing more design (infinitely more!) to explain less, rather than the other way around.¹⁴ Theists may reply that it is possible that such a God does in fact exist and that God is self-explanatory or is beyond human understanding. I will not argue here against such a possibility but only point out that although God then provides an in-principle explanation of all novelty, we are far short of a precise model or explanation, since an infinitely powerful being can do *anything* (possible). To be able to explain everything so easily in these terms, without having to provide a precise mechanism, is really to explain nothing. We understand no more about how innovations can emerge than when we began. The theistic account replaces the mystery of creativity by a much bigger mystery.

In its strong form, then, as a complete solution to the Meno problem, the intelligent design model turns out to be no solution at all, for it holds that general human intelligence or human reason already contains all possible human knowledge, at least potentially or implicitly, a view reminiscent of Plato's own solution to the Meno problem (see Section 5). One reason why this point is little noted is that traditional epistemology (theory of knowledge) has been conservative and retrospective, focusing on the justification of knowledge claims already in hand rather than upon the process of gaining serious new knowledge candidates at the frontier.¹⁵

Surprisingly, common accounts of scientific method are committed to the intelligent design model. For the method allegedly contains the general principles that define scientific intelligence—principles sufficient to mine scientific discoveries from incoming data streams and that, in this sense, already contain those discoveries. But how could a powerful method of discovery be warranted in advance?

Thus we encounter an exasperating clash of views. Just when we seem to have discovered the key to all

innovation, including the growth of knowledge, and hope to methodize this discovery as the only known solution to the Meno problem, that problem itself appears to deny us the ability to methodize or mechanize the secret. For the method itself would already contain the design, at least potentially, and hence would merely instantiate the old thesis of no design without a designer and, as a result, would impale itself upon the first horn of the Meno dilemma. This clash will be spelled out more fully below.

The thesis that BV + SR lies behind all genuine innovation has always met considerable resistance. Because it threatens traditional views about human nature, it has had to fight once again the old battles once faced by physicists and evolutionary biologists about the reality and explanatory power of *chance*, the possibility of genuinely statistical-probabilistic *explanation* (Lestienne, 1993). For example, we meet again the objection that appeal to chance only masks our ignorance, that if we could locate the underlying causes or (better yet) the logic or the specific inspiration, then we could discover the genuine springs of innovation. Unlike intelligent design, it is alleged, chance disappears upon closer inspection. Chance and design appear to be mutually exclusive. In my view, this objection has things exactly backwards.

Somewhat as God was invoked in the nineteenth century to account for the stability of social and physical statistics, many writers are tempted to invoke a special, non-natural intuitive power to explain how we humans hit on as many successful ideas as we do.¹⁶ Likewise, there is a tendency to dismiss as mere bothersome noise the variation that we find in scientists' and technologists' beliefs and practices, their numerous misunderstandings¹⁷ of one another's work, and the historical contingencies that often affect the direction of their work. This noise allegedly masks the true process of scientific innovation and is something

¹⁶ These remarks should not be misconstrued. I am not saying that all appeal to chance, including the BV + SR account of innovation, essentially depends upon an underlying physical or psychological indeterminism.

¹⁷ These misunderstandings often result from a scientist's reading the work of other scientists whiggishly, from the standpoint of his or her *own* problem. Thus Kuhn (1978) argues that Einstein and Ehrenfest in 1905 misread Planck's 1900 works as addressing *their* problem (which Ehrenfest dubbed 'the ultraviolet catastrophe') rather than the Clausius–Boltzmann problems that Planck was actually addressing. Brannigan (1981) makes the same claim about the reception of Mendel's work. Dawkins (1986, p. 130) remarks: "Insofar as I can claim to have had any original scientific ideas, these have sometimes been misunderstandings, or misreadings, of other people's ideas". In this vein, Alfred North Whitehead supposedly quipped: "Everything has been said before, but not necessarily by someone who knew they were saying it".

¹⁴ See Dennett (1995, chap. 3) for a version of this objection.

¹⁵ See Dewey (1929, chap. 7). In virtually all of his major works (e.g. 1962), Popper has featured the problem of the growth of knowledge as his central problem, while denying that there is a method of innovation. For Popper the absence of a logic of discovery implies that the search for new theories must be, to some degree, blind. Popper explicitly developed a BV + SR methodology (see Campbell, 1974). I believe that a BV + SR model is also implicit in Thomas Kuhn's account of normal and revolutionary science. In any case, the preface to Kuhn (1962) indicates that he will not employ the discovery-justification distinction invidiously and that much of his work will concern discovery. See Nickles (2003) for details.

to be eliminated whenever possible—and certainly to be eliminated from our methodological accounts of scientific research. But according to universal evolutionism, this is again the wrong attitude, for variation is essential to the process (Edelman, 1987). Far from being ideal, a noiseless system would be completely uncreative.

Noise also enters the system at the selection and transmission stages of the evolutionary BV + SR process, so we should not see these as strictly temporal stages in which the variants are produced entirely antecedently to stages two and three. Whether someone's work catches hold depends upon audience reception and transmission (reproduction). While scientific recognition systems canonize a few 'greats', the actual authorship of deep developments is typically more distributed and more anonymous. Here the 'author function' largely disappears and can be regarded as a post-hoc social construction (Schaffer, 1986, 1994).

Insofar as the world at bottom is genuinely stochastic, the creationist 'model' is stretched even thinner, for then not even an omniscient being can create a specific world by setting up a deterministic causal system and letting its history unfold. Rather, such a being would have to survey in advance all possible probabilistic worlds, history and all, and then choose a particular world (whatever that could mean). For in a genuinely stochastic universe, as in a deterministic universe, not even an omniscient being is allowed to interfere to keep it on track. Furthermore, a being that is thus omniscient cannot really be creative in the sense of generating novel design, since it *already* possesses all possible design. Making the world is 'simply' applying what it already knows.

In what follows I shall unpack and defend a version of Campbell's BV + SR claim that somewhat reconciles the evolutionary model and the human-design model. Much of the debate has been spoiled by a tiresome polarization between two extremum positions, neither of which is held by any responsible writer today. At one extreme we have the view that scientific discovery (say) is determined by application of 'the' scientific method and leaves no room for chance. Such a view of discovery comes close to being oxymoronic. Meanwhile, advocates of evolutionary accounts are often characterized as committed to the opposite extreme, as saying that there is nothing more to creative work than totally random or mechanical trial and error.

Campbell and his precursors already insisted that the BV + SR thesis does not at all deny the existence of rational planning or of problem-solving or learning algorithms of other kinds, only that these are not yet known or justified at the frontier of research where genuine innovation occurs. Innovation has to do with pushing back the frontier, not with the routine application of known rules. While there is a grain of truth to the claim that trial and error is employed as a 'last

ditch' effort when intelligent design runs out of intelligence, the point is that, at the frontier, it always *does* run out. Since that knowledge itself was once a product of frontier research, the grand irony is that BV + SR processes ultimately underlie the knowledge presupposed by intelligent design. In this logical and empirical respect, trial and error is a 'first ditch' effort rather than last ditch.

While I defend Campbell's BV + SR thesis,¹⁸ I do not share his tendency to conclude that, because they are blind, BV + SR processes are the very antithesis of method; and that, therefore, there is no scientific method or method of innovation in any field. In other words, I adopt a wider conception of method than the traditional one that is linked to the intelligent design model. The BV + SR thesis may thus have positive methodological significance after all.

Campbell is correct if he only means to say that any particular BV + SR learning rule is too weak to be considered an efficient *general* method of innovation, but he is mistaken if he denies that they are methods at all. For in fact, BV + SR methods can be powerful and creative search engines when tailored appropriately to a domain. Campbell himself deeply appreciated the creative power of evolutionary processes, but he perhaps underestimated their methodological possibilities. After all, Campbell's famous paper, 'Evolutionary Epistemology', was written in praise of Karl Popper, who adamantly rejected the possibility of methods of discovery. The same paper quotes Souriau's anti-methodological stance at length, with seeming approval (Campbell, 1974a, 428ff). The thesis of Souriau (1881) is 'le principe de l'invention est le hazard'. But in fact, the emerging field of evolutionary computing generalizes and methodizes the Darwinian insight.

As Campbell knew, there is also a certain vagueness in speaking so broadly of trial and error or even of BV + SR in the same breath as evolution. There are many such processes, ranging from 'random' guessing to highly directed search, that are not evolutionary in the full-blooded sense of selection from a *population* of competing variants, a selection that in turn will breed the next generation of the population. Consider a few of the many variations on the trial-and-error idea. A one-trial, all-or-nothing search clearly is not evolutionary. (E.g. you examine the first 28 characters formed by a monkey at a typewriter and 'select and retain' this string if and only if it perfectly matches 'Methinks it is like a weasel'.) Nor is an iterated version of this kind of search evolutionary (e.g. you give one monkey a thousand chances, or a thousand monkeys one chance

¹⁸ Campbell himself usually wrote BVSR instead of BV + SR. I shall retain the 'plus' to distinguish my version from his.

each). However, if selection of partial matches is allowed and successful matches are allowed to accumulate,¹⁹ then we approach the idea of an evolutionary process (albeit one based on goal-directed artificial selection rather than natural selection), even though we still have one trial at a time rather than a population of simultaneously competing individuals. For even in this simple sort of slow, serial evolution, success is allowed to 'breed true' into the next generation, while the incorrect parts are varied. Also, depending on how it is set up, a process that involves a population of competing and potentially crossbreeding individuals (trials) can amount to parallel processing.

This discussion makes clear that only a small minority of BV + SR processes are completely blind, let alone random in the above sense. Not even biological evolution is nearly random in this sense, because it involves: (a) highly constrained variation (the offspring of rabbits resemble their parents, not to mention other rabbits); (b) including nonrandom mutation and cross-over operations; (c) an iterated BV + SR process rather than a one-shot chance-arrangement of materials; and so on. In the field of evolutionary computation, specific choices of codings for individuals, choice of search operators, and of parameter values all represent departures from purely random search. In general, however, the weaker our domain knowledge, the weaker and less constrained (hence the more blind) the search procedures available to us. I shall develop this point below.

What then of the metaphor of monkeys at typewriters to describe the bare baseline of inquiry, the complete absence of method or direction? In the absence of cumulative selection, monkeys at typewriters are certainly inefficient producers of interesting novelty, but even here we could do worse. For example, a student who uses the 'copy from my neighbor' method of taking a true-false test but who gets the questions one number out of order may do much worse than chance!

Is the innovation process *convergent* or *divergent* according to the BV + SR model? The answer to this highly ambiguous old question is, Both! The production of variants is: in a sense, divergent, while the selection process could be said to be convergent. However, the question is misleading.²⁰ The degree of divergence and convergence will depend upon how tightly constrained the processes are. In biological

reproduction, for example, the production of variants is highly constrained: they result from such normal factors as sexual mating, noise in the system (copy errors and the like), and the occasional cosmic ray. And the selection process is convergent in weeding out the vast majority of variants that stray very far from the norm. As Campbell (1974, Section 4) points out, there is a tension between variation and selection. In effect, large variants are not recognized by the community-plus-niche system. Overall, this makes biological evolution a pretty conservative process in the short run. This tension corresponds to Thomas Kuhn's 'essential tension' between innovation and tradition as manifested in normal science. He describes normal science as a convergent process even though it is a puzzling process and, as such, involves the production of variant attempts to solve nonroutine puzzles (Nickles, 2003).

Both the Meno problem, with its two horns, and the BV + SR model predict that there will always be an essential tension between innovation and tradition. Innovation implies change, but changes that are too great will not be recognized as a contribution to *that* enterprise. In the case of human inquiry, decisions as to whether to include any significant change are socially negotiated (Schaffer, 1994). Is it art? Is it good science? Is it good solid-state physics? Does it really solve the original problem or does it change the subject?

The Meno Problem Elaborated

What was Plato's own solution to the Meno paradox? Plato's Socrates concludes that learning is really only 'recollection' of knowledge already gained by souls between lives, when they supposedly enjoyed unencumbered epistemic access to reality, which knowledge was rendered subconscious by the rigors of childbirth. Thus learning, successful inquiry, is really only a matter of transforming this implicit, subconscious knowledge into explicit knowledge. That is, for Plato the only possible kind of inquiry is conversion of knowledge from one form to another. This amounts to a kind of conservation principle: the amount of knowledge (in all its forms) possessed by embodied human beings is a conserved quantity in the sense that normal human inquiry cannot increase it. (Notice that the God model of design also conserves knowledge at the cosmic level, since an omniscient God already possesses all knowledge in advance. Nothing can be gained or lost.) Plato's solution begs the Meno question, of course, for he fails to explain exactly how it is possible for souls to learn between lives. But his solution does contain grains of truth.

The problem of whether and how knowledge can be converted from one form to another is extremely important. Many researchers today are investigating the relations of various forms of knowledge representation, knowledge embodiment, and knowledge

¹⁹ Dawkins (1986, ch. 3), who gave the weasel example, convincingly demonstrates the power of accumulative BV + SR.

²⁰ If a research result decisively favors one theory or practice over another and thus reduces the set of competitors, is this convergence? Is it still convergence if the eliminated theory is the reigning paradigm?

engineering, including habit formation,²¹ tacit knowledge, skills, procedural knowledge (knowing-how) vs. declarative, propositional knowledge (knowing-that), how items in short-term memory get fixed in long-term memory, how ignorance is transformed into a good problem, and so on.²² Let us term this the *epistemic conversion* or *epistemic transformation* form of the Meno problem.

There are also fundamental problems in understanding the ‘transfer’ of knowledge from person to person (e.g. teacher–pupil), person to machine, and so on. This is the *epistemic transfer problem*. After all, the central question of the *Meno* is whether virtue can be taught by one person to another. In this case the recipient of the transfer clearly learns, but the system as a whole does not. Here, for example, we face the problem of understanding the transfer of scientific, technological, and artistic knowledge from one generation to the next, for it is by means of reproducing themselves in this way that disciplinary enterprises sustain themselves.

A third important Meno problem remains: how to acquire genuinely new knowledge (previously unknown to anyone or anything who could otherwise transfer it to you). Let us call this the *problem of epistemic innovation*.²³ This tripartite division of Meno problems is rather crude, but it is sufficient for our purposes. The three problems overlap, and the processes involved in solving any of them can be extremely complex, requiring much refinement of our ordinary talk about skills, habits, and the like.²⁴

Even Plato’s original formulation of the Meno problem suggests (correctly, in my view) that explicit inquiry is a kind of *search* and that the Meno problem is basically a problem of *recognition* (or construc-

tion),²⁵ namely, how to recognize and select the (or a) correct answer, or at least a somewhat promising answer, out of a noisy background of zillions of potential alternatives.²⁶ Plato’s text also raises the crucial issue of the relevance of old knowledge to the search for new knowledge. It is on this second problem that Plato begs the question with his epistemic transmigration story. Within a normal human life, he seems to conclude, there is no answer to the Meno. In this life, genuine inquiry, and hence genuine innovation, are indeed impossible, and knowledge is conserved.

There are other kinds of learning discussed in the educational, psychological, and artificial intelligence (AI) literature. For example, improving one’s problem-solving skills certainly counts as one kind of learning even when the capacity to solve *new* kinds of problems does not increase. Much of AI has been concerned with developing problem-solving systems that operate more efficiently.²⁷ However, my focus here will remain on epistemic innovation as described above. In this case the Meno problem is ‘How is innovation possible at all?’ and not ‘What is the most efficient or optimal means to achieve it?’

Many nonnatural accounts of cognition suppose that we possess a kind of divine spark in the form of human intellect or a faculty of reason. But invoking a theological or supernatural account of knowing will not help here. The limiting case is an omniscient god, but, as noted above, such a being cannot inquire at all, given the first horn of the dilemma, for it already knows everything. The God model of knowing is not helpful to theory of inquiry—or even possible. Nor, for the same reason, is the intelligent design ‘theory’ of genuinely innovative design a viable model.

Ditto for the historical attempts to evade the paradox by positing special forms of human knowing such as the intellectual intuition of the rationalist philosophers, clairvoyance, precognition, or some other sort of

²¹ In effect, Aristotle solved the problem of the Meno by means of his theory of potentiality, applied to habit formation.

²² See Karmiloff-Smith (1992) and Root-Bernstein’s chapters in this Handbook for examples.

²³ I could have kept Popper’s old label, “the problem of the growth of knowledge”. There are other ways to parse the Meno problems. One could argue, I suppose, that even learning new things about actual natural phenomena is a kind of information-transfer problem (as simple instructionists from Aristotle to the British empiricists sometimes seem to have thought), whereas the full innovation problem concerns the creation of designs that previously were no part of the learning system (agent-plus-object) at all. Instructionist theories are clearly incapable of explaining this sort of innovation.

²⁴ Even simple verbal communication of an everyday sort (“I’ll meet you at the clock in Grand Central Station at the same time tomorrow”) is an extremely complex affair. See, Brandom (1994) for one recent account of how semantic content is constituted.

²⁵ For simplicity I shall characterize the Meno problem and the BV + SR selection problem in terms of recognition, which means that the system in question registers sufficient agreement with fitness criteria. The term ‘recognition’ can be contentious, for like the term ‘discovery’ vs. ‘construction’ or ‘invention’, it can beg questions of realism. In some contexts at least we do not discover (by recognizing) a solution just waiting there to be found; rather, we construct a solution. Moreover, whether discovered or constructed, the solution need not be optimal, as Simon (1947) emphasized in his discussion of satisficing.

²⁶ I do not mean that a search always must be literal, deliberate, conscious search for something predesignated, for I want to extend the idea of evolutionary biology to subconceptual human practices.

²⁷ See Simon & Lea (1979) and Dietterich (1986) for ‘classical’ discussions of these issues.

prescience.²⁸ Most of these solutions are as question begging as Plato's own response to the problem of innovation. Some of them, e.g. prescience, again impale themselves upon the first horn of the dilemma. Typically, the 'mechanism' by which the extraordinary faculty works remains unspecified. Notice that if 'intuition' and 'inspiration' (whatever they might be)²⁹ are analogous to ordinary vision, then they, too, involve an element of blind search. As Campbell has shown convincingly, even systematic visual scanning, e.g. by a creature that may be both predator and prey, is blind in the specific sense that the animal does not know in advance whether predator or prey will show up at all, or where and in what form, in the region scanned.

The more promising attempts to solve the Meno problem all 'go between the horns', thereby dismissing the argument as a false dilemma. The basic idea is that there are grades of knowledge. Our epistemic situation is not that of completely explicit, justified knowledge or else nothing at all. Rather, we possess inferior grades of knowledge or quasi-knowledge that, through inquiry, can be upgraded or converted into a more usable form. Hence we have the possibility of search that impales itself on neither horn of the dilemma. We can search because, although we do already have the answer in one respect, in another respect we do not. Moreover, we can hope to recognize the thing sought, should we stumble upon it, since we already possess some knowledge of it, explicit or tacit. Despite the fatal difficulties, there is something right in Plato's account.

The power of the iterative, 'multi-pass' BV + SR solution to the problem resides in the fact that recognition need not be an all-or-nothing affair and in the fact that BV + SR processes can be massively parallel, with many agents exploring vast regions of the search space rather than a single agent, who is likely to get stuck on a local fitness peak. (This second point does concern efficiency but more than that, since the parallel nature of the process helps BV + SR avoid traditional difficulties of hill-climbing heuristics, such as getting stuck on a local maximum.) BV + SR can parlay even the coarsest, partial recognition or 'fit' by one or more candidate solutions into a series of better

solutions. That is, low-grade recognition by one or more candidate solutions or 'variants' triggers a new generation of variants parented by those first generation variants of above-average fitness. If there is a pattern or solution to be found or constructed, it is likely that some second-generation variants will achieve still higher fitness, and merit their selection for production of the third generation of variants; and so on. Stated somewhat differently, the earlier populations of variants provide a widely dispersed set of explorers of the fitness landscape. Those found a little higher on the hills or peaks of the landscape will have a higher probability of reproducing. As the process iterates from generation to generation, the exploratory focus on the more promising regions of the search space increases exponentially. According to the clonal selection model, this is basically the manner in which the vertebrate immune system can muster its limited resources to 'recognize' any of a vast domain of invading antigens and then can proceed to sharpen its criteria of recognition.³⁰

It is this ability to utilize low-grade information as a pointer that makes iterative BV + SR *heuristically* powerful. The selection criteria at each stage function as a mechanism for heuristic appraisal, that is, evaluation of the promise of pursuing a line of investigation (Nickles, 1989). (Here we humans have an advantage over nature in that we can look ahead to longer-term goals and do not always have to worry about the immediate survivability of the present model in competition with more robust but less promising ones.) Thus heuristic appraisal does not reduce to standard confirmation theory as discussed by philosophers. Scientific survivability depends upon far more than empirical track record to date.

One implication of this gradualist solution to the Meno problem of recognition is that 'micro-aha' recognition experiences will vastly outnumber the 'macro-aha' experiences widely reported in the popular romantic literature on innovation (cf. Gruber, 1974). In fact, most of the microrecognition surely takes place at the subconscious level.

The Meno problem can also be parsed into two (or more) subproblems in a different way. First, assuming that a still unanswered question or unsolved problem has already been posed (which itself requires a sophisticated sort of recognition or construction), there is *the starting problem*, the problem of knowing where and how to search for an answer. Second, there is *the stopping problem*, the problem of knowing whether and when you have found a suitable answer, or at least

²⁸ It is remarkable how many people take seriously the 'predictions' of Nostradamus, for example. There are problems even if you seem to receive direct instruction from a crystal ball or the voice of God. How do you determine whether this crystal ball is veridical? And even if it is, do you have to use it as a scanning device? How do you know what you are seeing? In the other case, how do you know that it is the voice of God and, if so, what God's message means?

²⁹ Here I am speaking of intuition and inspiration of a transcendental kind. I have no objection to speaking of intuition and inspiration of a down-to-earth, naturalistic sort. Indeed, I believe that culturally acquired intuition and the intuitive flow we can acquire through skilled practice are important phenomena.

³⁰ Nowadays, the clonal selection model is no longer the last word in immunology. See, for example, Tauber (1994). However, later developments do not undermine my point.

an answer worth pursuing in order to achieve a still better fit.³¹

The process of solving at least the first subproblem would seem to require a degree of blind search in the form of trial and error. For even if you already possess some knowledge of where to look for the answer, you must still search for it once you get there; and, by definition, search involves an element of blindness in Campbell's sense. For if no search at all were required, then you would already have the answer. Of course, if you know where to search, this will be highly constrained search. Your search procedure will be 'biased' (in the good sense in favorable cases) by knowledge you already possess about which small region of a potentially much larger search space you need to examine. Of course, such biases can also be unfavorable in cases where an unexpected sort of answer is superior.

The second subproblem is just the problem of recognition. A third subproblem would then be what to do with the item(s) now recognized in terms of using them to conduct a more refined search, that is, how to conduct the iteration.

Taken together, these processes amount to a blind generate and test procedure. Thus the Meno problem itself points toward its own solution, a process of BV + SR. Only resistance to the idea of blind trial and error can explain why it took so long to recognize this path to solution. Yet this is not so surprising when we recall that, until Darwin, there seemed no way other than intelligent design to explain any significant design innovation, including the epistemological design that constitutes a body of knowledge.

Search Operations: Generality and Efficiency

A look at developments in artificial intelligence (AI) over the past 50 years will reveal the importance of domain knowledge as a constraint on efficient evolutionary computation.

It has taken the AI community a long time to appreciate the need for, and power of, evolutionary adaptation as a search process.

The breakthrough results that got AI rolling were the Logic Theorist and General Problem Solver of Allen Newell and Herbert Simon, developed in the 1950s and 1960s. Their premise was the then-plausible idea that human reason or intelligence resides in relatively few general principles, namely, logical and heuristic princi-

ples that would do for problem-solving what the laws of mechanics do for physics. But despite the historical, revolutionary importance of this approach, it turned out not to have the problem-solving power expected.³²

From the late 1960s on, prominent members of the AI community promulgated the informal truth that completely general, a priori, content-neutral, 'logical' problem-solving methods are inefficient at best and not very innovative, that inquiry can be highly focused only insofar as we already possess substantial knowledge of the domain in question.³³ It takes domain-specific knowledge to solve domain-specific problems (and thus to gain interesting knowledge) with any efficiency. As Edward Feigenbaum, a former student of Simon and one of the most enthusiastic leaders of the new movement once put it:

There is a kind of 'law of nature' operating that relates problem-solving generality (breadth of applicability) inversely to power (solution successes, efficiency, etc.) and power directly to specificity (task-specific information).³⁴

Newell and Simon already recognized, of course, that the more highly constrained a problem could be, the more readily it could be solved. As Newell (1969) remarked:

Evidently there is an inverse relationship between the generality of a method and its power. Each added condition in the problem statement is one more item that can be exploited in finding the solution, hence in increasing the power.

But the new knowledge-based computation movement went considerably further in the direction of domain-specific knowledge by incorporating large quantities of domain-specific knowledge in the program itself and not only in the statement of the problem. The basic idea is that intelligence is a function of domain knowledge, not of general logic and heuristics alone. Thus we get a new paradigm of innovation: innovation flows from specific knowledge, not from logic or reason. It is sometimes quipped that the ratio of A to I in AI is very high. Be that as it may, it is surely an important insight that knowledge is artificial, something constructed (in various ways and to various degrees), and hence something that can, in principle, be engineered.

The lesson that it takes knowledge to get new knowledge at all efficiently was already implicit in

³¹ Gigerenzer & Todd (1999) divide heuristics into search rules (what I am calling starting rules), stopping rules that determine when it is no longer cost-effective to continue searching, and decision rules that select an action decision among those options available at stopping time. My account is simplified. I also make no attempt here to extend this 'knowledge' and 'search' talk to biological processes, although I believe that it is fruitful to do so. In a sense nature solves problems that it does not pose.

³² For their masterful summary of their previous work, see Newell & Simon (1972). For a fairly comprehensive 'insider' history of AI through the early 1990s, see Crevier (1993).

³³ Compare the rejection of traditional syllogistic logic as sterile because it is not ampliative, by Bacon (1620), Descartes (1637), and many others. Critics make the same point more generally against the rational, pre-planned design strategy of the human-design model.

³⁴ Feigenbaum (1969), repeated in Feigenbaum et al. (1971, p. 167).

Plato's treatment of the Meno paradox and is readily apparent in the history of any branch of science or mathematics—indeed, in the history of any major constructive endeavor, anything that results in 'design'.³⁵ The short history of AI merely recapitulates the history of science in this respect. Scientists themselves have recognized this characteristic of scientific inquiry. In his 1901 Presidential Address to the British Association, Lord Kelvin remarked:

Scientific wealth tends to accumulate according to the law of compound interest. Every addition to knowledge of the properties of matter supplies the naturalist with new instrumental means for discovering and interpreting phenomena of nature, which in their own turn afford foundations for fresh generalizations.³⁶

Insofar as it is correct (and of course there are exceptions, as when all the major problems in a field have been solved and sterility sets in), the claim that problem-solving power depends upon appropriate domain knowledge has major implications for the debate about scientific method. For the idea of a completely general, content-neutral scientific method becomes oxymoronic. On the one hand, such a method would be too strong—already containing potentially any number of possible scientific discoveries across many fields. On the other hand, it would be such a weak search tool as to be practically useless.³⁷ The traditional idea of a general scientific method harbors a greedy desire for a one-step solution to the problem of the growth of knowledge, namely: Follow my method!

Incidentally, since the mid-nineteenth century, the most widely touted general method of science is the so-called hypothetico-deductive (H-D) method. This is the method of hypothesis and test, and it can be regarded as a slow BV + SR process: the H-D method typically considers hypotheses serially and in isolation instead of in parallel, as members of a population of simultane-

ously competing hypotheses.³⁸ Its complete, content-neutral generality renders it incapable of providing guidance to hypothesis formation in any particular case. But in specific domains in which we already possess knowledge, the process can be more directed. One way in which it can be more directed is by considering variants of a previous hypothesis that showed some promise. So it is better to regard the general H-D method as a high-level schema that includes domain- or problem-specific H-D methods as instances rather than as a specific method in itself. There are various H-D methods, depending on the modes of variation, selection, and retention and, specifically, the ways of modifying previous hypotheses.

Returning now to AI: the leading implementation of knowledge-based computation was and is that of 'expert systems'. The idea is to elicit the domain knowledge of human experts and then to incorporate this content into the problem-solving program, typically in the form of rules (e.g. if-then production rules). At first the possibilities for expert systems seemed unbounded, but progress on this front, while genuine, was also ultimately disappointing. Knowledge did not compound in anything close to Kelvin's manner. One difficulty was that the more knowledge that was incorporated into expert systems, the slower they ran.³⁹ Another was that of transferring problem-solving expertise (domain knowledge-how as well as knowledge-that) from human expert to machine. Among other things, this obstacle suggested that explicit rules might be the wrong way to represent most expert knowledge. So here we have both the epistemic transfer and epistemic conversion forms of the Meno problem that I distinguished above.

More serious for our study of innovation is that standard expert systems do not happily solve the innovation problem either, for they turn out to be innovative only to a limited degree. They can be

³⁵ The universal evolution thesis applies to any process that produces novel design, whether or not that process is conceptual or subconceptual, conscious or subconscious or nonconscious.

³⁶ Kelvin (1901, p. 114). Gigerenzer (1994) adds the reverse heuristic, which he calls 'the tools-to-theories heuristic'.

³⁷ I like to illustrate this point with my 'crowbar' or 'pry bar' model of method. A method is a tool that we use to investigate the world. Consider a crowbar as a representative tool. Now a crowbar is useful only insofar as it fits the world at one end and the human hand at the other. If the world were tomato soup or if we were fish, a crowbar would be useless. Similarly for methods in general: they are useful only insofar as they fit the world at one 'end' and human capabilities at the other. A good method cannot be totally out of kilter with the way the world is, and it must also sufficiently fit human capacities (which may be considered another part of the world). Thus we cannot regard usable or successful methods as content-neutral anymore than hypotheses are.

³⁸ Another irony! Despite the historical resistance to BV + SR and to any suggestion that chance, luck, or serendipity could be an element of method, the dominant, H-D method itself turns out to be a slow BV + SR procedure. Proposals such as Chamberlain's (1897) 'method of multiple working hypotheses' and Paul Feyerabend's (1975, ch. 3; 1981, pp. 104ff and 139ff) theory proliferation methodology in effect turn the process into a fully populational one, although the populations will usually be rather small.

³⁹ Kevin Kelly (1994, p. 295) quotes Danny Hillis et al. as saying:

The more knowledge you gave them, the slower computers got. Yet with a person, the more knowledge you give him, the faster he gets. So we were in this paradox that if you tried to make computers smarter, they got stupider. . . .

There are only two ways we know of to make extremely complicated things. One is by engineering, and the other is evolution. And of the two, evolution will make the more complex.

immensely valuable, of course, in coordinating incoming information or queries with large databases, e.g. to give faster and more reliable medical diagnoses than human experts. But from the standpoint of genuine innovation, the popular old saw that a computer contains only that knowledge deliberately programmed into it remained too close to the truth in this case (Crevier, 1993, ch. 8). Even a perfect lateral transfer of routine problem-solving ability from human to machine would not necessarily endow the machine with significant creative powers, so there would be no overall gain in knowledge or creativity by the human-machine system. (Compare the knowledge transfer from professor to dependable but uncreative student.) Of course, once a machine with greater speed became available, that might give it a higher productivity and hence more creative ‘hits’ than the human investigator whom it simulates; and hit rate is one measure of creative potential (see Simonton, this volume).

In sum, knowledge-based computation of the traditional, expert-systems type runs into some practical and theoretical difficulties with the first and second Meno problem (the epistemic conversion and transfer problems) and into major difficulties with the third Meno problem (the innovation problem). Evolutionary epistemologists, including evolutionary computational theorists, believe that their approach will have more success.⁴⁰ Interestingly, some of them tout their approach as a new, general paradigm that does *not* depend heavily upon domain-specific knowledge (Koza et al., 1999).

The ‘No Free Lunch’ (NFL) Theorems

Recently, the above knowledge-based insights have received formal backing. David Wolpert and William Macready (1997 and elsewhere) have proved a series of seemingly fundamental theorems, commonly called the ‘No Free Lunch’ theorems (NFL theorems), according to which there is no one, best, general, problem-solving algorithm. The proofs are highly technical results showing, basically, that the average performance, for any relevant performance measure, is the same for any two algorithms, when averaged over all cost functions and the space of all problems, or, as we might say, all inductive learning problems in all possible problem domains or possible worlds.

Although these results are still undergoing critical evaluation and interpretation, they are not totally surprising, certainly not to knowledge-based computation advocates and to those philosophers of science

who have noticed the domain specificity of powerful problem-solving methods and research techniques in the history of the various sciences. In fact, David Hume himself (1748, Section IV) vaguely anticipated such results when he wrote (among many similar things) that Adam, upon coming afresh into the world with full powers of reasoning but without any experience, would have no knowledge of anything in nature. In particular, Adam would be able to draw no inferences, either logical or psychological, about what would happen next. Hume’s argument was that, absent empirical knowledge of what the world is like, reason is powerless to provide an inductive projection rule that is either correct, or the best possible, or better than average, or even better than some specified rule. That is, there is no reason to think that any rule is best or even better than some other rule, when averaged across all possible worlds. Contrary to the rationalists, pure reason can teach us nothing about empirical reality. Stated differently still, the point is that, under a veil of complete ignorance about which world we inhabit, or of the problem domain in which we are now working, we have no reason to believe that any particular induction rule will dominate all others, or, indeed, *any* others. Nor is there any a priori justification for projecting any perceived pattern in a given data set. In this situation, one can only proceed by adopting a (so far unjustified) learning bias and seeing how well it works. Readers of Ludwig Wittgenstein’s *Tractatus* or Rudolf Carnap’s *Continuum of Inductive Methods* will come away with similar intuitions in sharpened form.⁴¹

It is these intuitions that the NFL theorems formalize and prove. In fact, Wolpert himself quotes Hume’s *Treatise* as the motto for Wolpert (1996), where he broadly characterizes the NFL theorems as follows:

(T)he implication of the NFL theorems that there is no such thing as a general-purpose learning algorithm that works optimally . . . is not too surprising. However, even if one already believed this implication, one might still have presumed that there are algorithms that usually do well and those that usually do poorly, and that one could perhaps choose two algorithms so that the first algorithm is usually

⁴⁰ Another approach was/is to train an inductive learning system on sets of examples rather than to try to extract rules from human experts. This method can be used with or without evolutionary algorithms. For a discussion of ‘Feigenbaum’s bottleneck’ in philosophical context, see Gillies (1996, pp. 25ff).

⁴¹ For an introduction to these ideas, see Carnap (1950, 1952) and Salmon (1966, pp. 70ff), on Carnap’s use of state descriptions and structure descriptions in possible worlds. Assignment of equal weights to state descriptions corresponds to a world in which learning from experience is not possible. Unfortunately, Carnap’s logical conception of probability required a priori choices of weights. See also Mitchell’s insightful paper (1990), originally written in 1980. The Carnap sort of treatment also makes the issue simply one of inductive connectivity among phenomena, whereas it is also one of metaphysics—the nature of the underlying entities and processes that constitute a domain.

superior to the second. The NFL theorems show that this is not the case (Wolpert, 1996, p. 1362).

What implications, if any, do the NFL theorems have for our topic? Their interpretation is controversial, as some commentators deny that they seriously affect inquiry in our world. Here is the significance that I read into them, as a series of overlapping claims.

- (1) ‘No free lunch’ suggests that something is conserved, that you can’t get something for nothing, that it takes domain knowledge in order to warrant using any inductive rule with confidence, much less to establish that it is superior to another rule. This means empirical domain knowledge in the case of learning about the natural world. One way in which to state this idea is that the inductive success of any given rule will be zero when averaged over all possible learning situations. It will fail as often as it succeeds. C. Schaffer (1994) and Rao et al. (1995) provide technical discussions of conservation.
- (2) We cannot determine purely a priori the relative power or efficiency of learning rules for an arbitrary domain.
- (3) Efficient learning procedures are domain-specific and not general, regardless of whether or not anyone knows which rules or algorithms these are. The theorems themselves are ‘objective’ and not relative to the state of our knowledge.
- (4) There is no completely general scientific method (across all possible problem domains or ‘worlds’) that is more efficient than other possible methods or learning rules, let alone a method that can be justified a priori or even by convention, as methodologists from Descartes to Popper have supposed. Specifically, there is no maximally efficient hypothetico-deductive method, let alone a maximally efficient ‘logic of discovery’.
- (5) Available domain knowledge can be used to select ‘biased’ (in the nonpejorative, engineering sense) search procedures with superior efficiency. That is, we *can* know that a rule is more (or less) efficient than the average rule or some specific rule, in a particular domain, given relevant domain knowledge. Choice of an efficient learning procedure is justified only insofar as we possess relevant domain knowledge.
- (6) Conversely, the less domain knowledge we possess, the more ‘blind’ and general, and hence weak and inefficient, our search procedure becomes. For as long as significant domain knowledge is lacking, we have no way of knowing which of the possible rules is indeed more efficient.
- (7) Thus Campbell’s BV + SR thesis (the necessity of using BV + SR at the research frontier) is true.
- (8) For in a state of ignorance we can only proceed blindly, by trying this solution or rule or that one. Once we have determined that some rules or techniques work better than others, we can then try, *post hoc*, to *explain* this fact by attributing a particular structure to the domain. Confirmation of that attribution can then warrant the use of biased rules. This basic idea was already incorporated in the traditional method of hypothesis.
- (9) Thus at the frontier of knowledge, inquiry is consequentialist rather than generative, relative to the domain knowledge already available (see below).
- (10) It takes knowledge to get knowledge at all efficiently, yet, contrary to Plato’s version of the conservation of knowledge, we can still get more knowledge from less. This claim goes beyond the NFL theorems in assuming that the domain in question does have some structure and that a BV + SR process can find some of it. Under these conditions, creation *ex nihilo* is possible, not in the sense of innovation from absolutely nothing but in the sense of the emergence of more knowledge from less, of more design from less.
- (11) However, the more innovative the knowledge (relative to our ignorance of the domain), the weaker, more inefficient our search procedures will be and the more difficult the corresponding recognition problem.
- (12) Therefore no strong methods of discovery are possible in the sense of efficient methods for producing major innovations. However, weak discovery procedures are possible. And, when iterated, the ultimate result can be highly innovative.
- (13) Random trial and error is not the weakest of all methods. For, averaged over all possible domains, it is as strong (or weak) as any other method.

⁴² See Thornton (2000, pp. 141ff). Of course, neither the NFL theorems nor the data-compression techniques that Thornton proceeds to promote ultimately *solve* Hume’s philosophical problem of induction. Inductive moves will always remain risky.

⁴³ I cannot address here the converse question of whether a sufficiently weak BV + SR procedure will work to produce learning if any rule will work.

- (14) Moreover, for any particular domain, there exist any number of methods (learning rules) that are worse than random trial and error.⁴⁴
- (15) Given that there are many distinct varieties of BV + SR, not all BV + SR rules should be labeled 'mere' trial and error or 'random' trial and error.
- (16) Specific BV + SR methods will be more or less efficient than each other in a given domain but equally good (or bad) when averaged across all possible domains of problems.

A few words of explanation are in order. With reference to (7) and (8), the NFL theorems do not single out BV + SR rules as objectively special in any way. Given any particular domain, there is no reason to think that a BV + SR rule will be among the objectively more efficient rules for that domain. So, as objective existence claims, the NFL theorems offer no positive support for the Campbell thesis that innovative inquiry must employ some BV + SR. It may even appear that they undermine the thesis. However, they do not, for Campbell's thesis concerns inquiry under conditions of ignorance and not the mere mathematical existence of learning rules for a given domain. The relevance of the NFL theorems to this epistemic situation is the familiar Humean one: we have no a priori reason to prefer one rule over another. In this case, BV + SR rules of one sort or another become special in the sense that we have no alternative but to use one of them. A new scientific domain may be subject to very powerful search rules. The trouble is, the investigators first opening up the domain do not know what they are. They can only proceed blindly, according to the degree of their ignorance.

Obviously, even when a powerful rule happens to exist, you cannot use it until you hit upon it, and you cannot make justified efficiency claims for it until you have shown its superiority to other rules. To be sure, you may select any arbitrary learning rule or problem-solving procedure as a hypothesis, but, a priori, it will have as much or as little chance as any other rule. This choice in itself is therefore blind. You may subsequently try another rule and yet another. You are now implementing a BV + SR procedure at the level of rules.

Once your research community achieves some domain knowledge, you may graduate to a stronger form of inquiry. Suppose that previous BV + SR has produced sufficient domain knowledge to justify more direct procedures for solving problems in this domain.

⁴⁴ Writes Wolpert (1996, p. 1355):

In other words, one can just as readily have a target for which one's algorithm has *worse than random guessing* as one in which it performs better than random. The pitfall we wish to avoid in supervised learning is not simply that our algorithm performs as poorly as random guessing, but rather that our algorithm performs worse than randomly!

Now you may use these newly found rules to solve these classes of problems routinely, but of course this exercise is no longer seriously innovative. As I said before, discovery of efficient problem-solving methods is the *product* of innovation and not the original source and explanation of those problem solutions. The problem solutions are streamlined and methodized as the final stage of the discovery process, as it were. Meanwhile, research goes on at the frontier of the problem domain, where new problems remain unsolved. And here the conditions of the previous paragraph obtain: you can only proceed (more or less) blindly. Typically, your domain knowledge will place constraints on the candidates you generate, but, beyond that, you must grope for a promising solution. In the domain of mechanical problems, for example, it would be crazy to keep generating solution candidates that violate conservation of energy or momentum, once those principles become known. To take another sort of example, a systematic scan of a domain (e.g. a woodchuck scanning the horizon) requires domain knowledge in order for the scan to be systematic. In general, the more domain knowledge available, the more constrained or 'biased' the variation and selection mechanisms can be.

With reference to (9), a *consequentialist* methodology of innovation or discovery is one that proceeds by *post hoc* or consequential testing.⁴⁵ The old H-D method of science is an example: propose a solution and then check it by deriving testable consequences from it. Insofar as the solution goes beyond any previous knowledge and hence any epistemically justified selection criterion, it is selected solely on the basis of the success of its logical consequences. By contrast, a *generative* process proceeds from premises to novel conclusions and can, in principle, be deductive. However, if the universal evolutionists are correct, then even the process of finding deductive arguments to novel conclusions will involve an element of BV + SR. Nonetheless, this latter case shows that ultimate *justification* can be generative even when first selection or 'discovery' is not. A new deductive proof must be found by a BV + SR process, but, once found, it is, after all, a deductive proof. Finally, it is worth noting that neither a generative nor a consequentialist approach need restrict itself to deductive inferences.

The previous paragraph is misleading insofar as it suggests that inquiry is globally consequentialist, that is, consequentialist 'all the way down'. For domain knowledge that enables us to cut down the size of the search space and/or to select a more efficient learning procedure amounts to a generative contribution to inquiry. The fact that that knowledge itself is a former product of BV + SR does not prevent it from serving a generative role in the current stage of inquiry.

⁴⁵ For further discussion of consequentialist and generative methodologies, see Laudan (1980) and Nickles (1987).

With reference to (13), Campbell always insisted that blind search is not the same as purely random search.

It is important to realize that there are zillions of actual and possible BV + SR procedures available. The class of these processes or learning rules is not at all restricted to the one or relatively few operative in biological evolution. Depending on the kinds of individuals and populations one is considering, there are any number of different possible mechanisms of variation, selection, and transmission. So here, as elsewhere, the wise choice of particular learning rule will depend upon domain knowledge.

David Fogel, one of the leading researchers in evolutionary computing, applies the NFL results to his field thus:

[The NFL theorem shows that] there is no best algorithm, whether or not that algorithm is 'evolutionary', and moreover whatever an algorithm gains in performance on one class of problems is necessarily offset by that algorithm's performance on the remaining problems.

This simple theorem has engendered a great deal of controversy in the field of evolutionary computation, and some associated misunderstanding. There has been considerable effort expended in finding the 'best' set of parameters and operators for evolutionary algorithms since at least the mid-1970s. These efforts have involved the type of recombination, the probabilities for crossover and mutation, the representation, the population's size, and so forth. Most of this research has involved empirical trials on benchmark functions. But the no free lunch theorem essentially dictates that the conclusions made on the basis of such sampling are in the strict mathematical sense limited to only those functions studied. Efforts to find the best crossover rate, the best mutation operation, and so forth, in the absence of restricting attention to a particular class of problems are pointless.

For an algorithm to perform better than even random search (which is simply another algorithm) it must reflect something about the structure of the problem it faces. By consequence, it mismatches the structure of some other problem. Note too that it is not enough to simply identify that a problem has some specific structure associated with it: that structure must be appropriate to the algorithm at hand. Moreover, the structure must be specific (Fogel, 1999, p. 56).

Fogel notes that this result contradicts much conventional practice in evolutionary computing. Numerous investigators have sought general results as to which types of representations or codings of individuals in a population and which types and specific values of variation, selection, and heritability operators are more efficient than others. While specific claims of this sort

may still hold, they are false if made completely general.

In sum, the NFL theorems sharpen the intuitive remarks of Hume, Wittgenstein, and Carnap. Insofar as we possess relevant domain knowledge, a more restricted selection of BV + SR procedures is possible; but as long as there are important, unsolved problems beyond the limits of current domain knowledge, we can only proceed blindly. Here we may apply Hume's so-called method of challenge: If you remain unconvinced that we must resort to BV + SR procedures at the frontier of research, then, pray tell, what alternative procedure is there, and how do you justify it?

Having touted knowledge-based inquiry in the last two sections, a word of caution is in order. It is possible that our perspective may change as faster machines and machines of different architectures (e.g. parallel machines and neural networks) become readily available. For example, John Koza and associates (Koza et al., 1999) are developing, with some success, genetic programs capable of solving problems that are given as high-level problem descriptions without explicit instruction as to how to go about solving them. Their aim is to realize the dream of 'getting a computer to do what needs to be done without telling it how to do it'. Such a method would be pretty general and not knowledge-intensive in the way that knowledge-based computation is. The ratio of intelligence-out to intelligence-in would be quite high, by contrast with most knowledge-based computation. In a sense the machine is self-programming. If this sort of research program succeeds, it reopens the possibility of a more general problem-solving method. (See Nickles, forthcoming, for further discussion of this idea.) For the purposes of this chapter it is important to note that Koza's approach is inspired by Darwinian evolution. Basically, he breeds populations of computer programs and tests the individuals of each generational cohort for fitness as defined by the problem to be solved. His approach is therefore highly representational, since computer programs are symbolic structures. However, like biological evolution, the artificial evolutionary computation is, in a sense, parallel and distributed. Other investigators are pursuing nonrepresentational, subconceptual sorts of computation using neural nets.

Some Objections Considered: From Impossible to (Almost) Necessary

The BV + SR thesis has a peculiar status in discussion today. Many investigators still consider it an absurdly impossible mode of innovation, or at the very least hugely inefficient compared to the techniques that scientists, artists, *et alia* actually employ in their creative work. This is the 'monkeys at typewriters' family of objections. At the other extreme, some critics consider the thesis trivial or even tautologous. Here I can respond only briefly to a few of the more frequent

objections. Additional responses can be found in Nickles (forthcoming).

1. The BV + SR thesis is trivial, even tautologous, a priori true. Hence, it cannot explain anything. For it follows from the very meanings of the key words that any attempt to go beyond present knowledge must proceed blindly. How else could it possibly proceed? By your own account nonnaturalistic modes of inquiry are incoherent insofar as they claim to avoid BV + SR. And you claim that the Meno problem itself virtually requires a BV + SR solution, as do the NFL theorems under conditions of ignorance.

The thesis has surprisingly far-ranging philosophical, scientific, and policy consequences, as Campbell and Dennett, among others, have shown. So it can hardly be trivial. Nor is it tautologous or a priori true. I do claim that today broadly Darwinian selectionist processes are the only viable account we have, but the future remains open. After all, 'no design without an intelligent designer' seemed virtually tautologous until Darwin came along. It remains to be seen whether present-day and future competitors to the adaptationist program in evolutionary biology—and their analogues for wider selection theory—can seriously complement or (in some cases) replace selectionist models. The argument that, at the frontier of research, trial and error is unavoidable at least provides strong heuristic motivation for the selectionist-adaptationist program.

Tautologies do have the merit of being true, and some have the merit of being useful, even in a creative context. (After all, the Gödel theorems are just logic!) But is the BV + SR claim really tautologous? If it is, then its denial is logically false, and so are alternatives such as divine creation, Larmarckianism, and instructionism. (I do believe that these alternatives are false, but not logically false.) In short, as a thoroughly naturalistic account of design, universal Darwinism can hardly be a priori true. Moreover, not all forms of naturalism embrace universal Darwinism, so the thesis is again at risk. And even within evolutionary biology, the adaptationist thesis (according to which, roughly, all adaptive traits were selected because of their contribution to fitness) is subject to empirical challenge. So here are three levels at which universal BV + SR is at risk.⁴⁶

2. On the contrary, the universal evolution thesis is absurdly wrong. We can easily provide an alternative model of innovation, namely intelligent design. Scien-

tists and other inquirers can often use methods far more powerful than blind trial and error. The human design model is both familiar and conveys intuitive understanding. Paley's explanation of the origin of the watch found on the heath was exactly right. In similar terms we explain the invention and development of the automobile, the airplane, television, and scientific theories. Such explanations are far more plausible and explanatory than appeals to blind chance.

This is basically the reply that creation theorists and religious intelligent design theorists give to biological evolutionists (e.g. Dembski, 1998, 2001). The reply assumes that we well understand the springs of innovation and that they lie in deliberate, intelligent design. The view I have defended holds, quite to the contrary, that we still possess a very poor understanding of creativity and that the intelligent design model (no design without an intelligent designer possessing at least as much intelligence as that incorporated in the design) is both question-begging and hopelessly unscientific. In this case, familiarity with the God-design story breeds intellectual laziness. I claim that when we look closely at any genuinely innovative design, we discover a design history consisting of step-by-step modifications and recombinations of previously extant designs. It is not for nothing that the first automobiles resembled horse buggies. Moreover, at each stage we typically find a lot of trial and error search for suitable modifications in order to solve some problem or other. That story can certainly be told for the design of Paley's watches. As Campbell suggests, the human design model suppresses its evolutionary past.

3. But the previous objection is not just a 'religious' objection. Don't scientists and engineers and other innovators often use problem-solving methods far more powerful than trial and error? Don't artists sometimes carefully design their work?

Of course they do. Once we learn how to solve a class of problems, their solution can often be reduced to routine, a process that is often automated. However, such efforts only provide streamlined ways to solve problems that we can already solve. As such, they can support further research and routinized components of larger design projects, but they themselves do not produce novel design. It is also normally the case that searches for novel solutions are *directed* to some degree. Sometimes they are highly direct or constrained. That is the whole point about the importance of relevant domain knowledge and constrained generation. Nevertheless, constrained search is still search and, to that degree, blind. Campbell (1974a) provides an elaborate discussion under the head of a 'nested hierarchy of vicarious selectors'. No one claims that inquiry in a typical scientific or artistic or

⁴⁶ For further discussion of the a priori issue, see Gamble (1983). For the adaptationist controversy, see Sober (2000, ch. 5). A universal Darwinist need not be an extreme adaptationist, I think, and can allow design features that are by-products of other adaptive processes; but the issues become sticky here.

administrative problem situation is so completely lacking in constraints that any and every candidate solution, however crazy, must be considered. No one denies that routine problem-solving is helpful in many design tasks, only that it does not suffice for genuinely novel design. As noted above, the BV + SR model does call attention to the importance of heuristic appraisal of variants—better than chance ways of deciding which candidates are worth pursuing. This is a topic sadly neglected by traditional confirmation theory in philosophy of science (Nickles, 1989).

4. Changing the representation of a problem can sometimes render a difficult problem easily solvable. There are also other ways of reducing a challenging problem to one that is already familiar. Are not these cases counterexamples to the BV + SR thesis?

Interesting question, but no; for we must first search for an alternative problem representation or a reduction technique. Again, every problem representation has its own evolutionary history. It is hitting upon a representation that makes the problem easily solvable that produces many ‘aha’ experiences, which are themselves Meno recognition events.

5. Some discoveries are purely deductive and thus do not involve BV + SR.

There are two points to this reply. First, the discovery of a genuinely innovative proof is not a matter of simple, routine deduction, else much of mathematics would be trivial. On the contrary, some results are totally unexpected: e.g. the (relative) consistency of non-Euclidean geometry, Gödel’s theorems. Dietterich (1986, p. 12) and Cherniak (1986) rightly reject defining the knowledge of an agent in terms of the deductive closure of everything the agent knows. Simon & Lea (1979, p. 26) write:

(F)rom a logical standpoint the processes involved in problem-solving are inductive, not deductive. To be sure, the proof of a theorem in a formal mathematical or logical system (such as Logic Theorist) is a deductive object; that is to say, the theorem stands in a deductive relation to its premises. But the problem-solving task is to discover this deduction, this proof; and the discovery process, which is the problem-solving process, is wholly inductive in nature. It is a search through a large space of logic expressions for the goal expression—the theorem.

Any program that requires genuine search, any program that includes any genuine test operations, such as generate-and-test, has an element of BV + SR

(although not necessarily evolutionary BV + SR in the full-blooded sense). Hence, contrary to appearances, Campbell’s BV + SR thesis is not incompatible with Simon’s work.

Second, we cannot take even deductive reasoning as an innate, God-given human ability that needs no further explanation. At the microcognitive level, various naturalistic theorists treat recognizing deductive structures of even a routine sort as a matter of pattern matching, that is, trial-and-error fitting, much of which occurs at the subconscious level (Johnson-Laird & Byrne, 1991; Margolis, 1987).

6. Nowadays, Biblical creationists as well as intelligent design theorists often grant that some evolution has occurred but insist that it is microevolution rather than macroevolution, that is, adaptation within a species rather than the emergence of entirely new species. They therefore reject Darwinian claims for the immense creative power of BV + SR processes. How do we know that evolutionary computation can get beyond microevolution, so to speak, to produce genuinely novel epistemic designs?

This is an important question. We cannot really know until more results are in. However, there are reasons for optimism. How else could we have done it in the past than by implicitly implementing an evolutionary process? I believe that evolutionary biologists have an adequate answer to the biological objection. Moreover, human cultural BV + SR processes can be much more rapid than biological ones. For example, we humans can identify and study the errors of our trial and error processes in order to learn the reasons for failure. We can learn from our mistakes more directly than biological nature can, where mistakes are simply eliminated from the population of the next generation. In nature, roughly speaking, learning or creative problem-solving becomes a matter of sex and death (Sterelny & Griffiths, 1999). In addition, our design failures are not fatal. We can make modifications that are seriously deleterious without totally losing that line of development to extinction. In terms of fitness landscapes, we are therefore able to descend from a local maximum through a valley in order to reach a higher peak. Also, we are not restricted to a branching tree structure of design, corresponding exactly to biological speciation. In effect, we can combine good ideas from different branches into a single new design. With the advent of fast, parallel computational possibilities we are also beginning to catch up with nature’s ability to try out huge populations of variants at once.

Notice that even microevolution refutes the *old* model of design, according to which you cannot get

more design from less.⁴⁷ So there can no longer be the same, principled objection to macroevolution.

7. The Meno problem of inquiry, as you characterize it, is so abstract and artificial that it fails to fit scientific and artistic practice. Specifically, all inquiry begins from a problem, and to have a problem at all is to have some idea of what would count as a solution. So we are never in a position of having to go from zero knowledge to some knowledge, completely blindly.

Correct, but this point does not threaten the BV + SR thesis. As long as we do not currently know how to solve a problem, we can only proceed blindly. We are at a 'personal frontier' (or at a frontier for the whole scientific community) as far as usable knowledge is concerned. A well-formulated problem already incorporates knowledge, or design, and that knowledge itself could have grown out of ignorance only on the basis of prior applications of BV + SR. The history of every well-formulated problem will *also* be an evolutionary history.

There are, of course, larger issues here that I can only mention. One is the origins problem. How did inquiry begin, so to speak? And how could BV + SR methods apply there? (Compare the problem of origins in evolutionary biology, a problem that Darwin himself sidestepped.) This brings us to a second issue. Biological nature is frequently and fruitfully considered, metaphorically, as a problem-solver. But here the variation and selection and transmission mechanisms are not, of course, 'known' to the creative agency. Rather, they are implicit in nature itself. Again, learning or creative problem-solving becomes a matter of sex and death. Much more remains to be said about bridging these different ways of considering creative problem-formulating and -solving.

8. In many cases, for problems at the furthest frontier of research or problems that have been posed but are not yet really on the research agenda, we may have no domain knowledge and hence have to use blind search as a 'method'. However, many of these problems do in fact have sufficient structure, or belong to a sufficiently structured domain, that a stronger method will be far more efficient.

Yes, but without our domain knowledge we do not know which methods these are or how to recognize and

⁴⁷ A slight qualification is in order. Paley and company did not claim that small chance combinations in nature are absolutely impossible, although they would not have considered these productive of genuine design. But for them it was overwhelmingly improbable that you could get even complex *apparent* designs by chance. In other words, complex *apparent* designs are almost certainly *genuine* designs and hence (by definition of 'genuine design') the work of an intelligent designer.

apply them even should we hit upon them by accident. We can only search for these methods randomly at this point, namely, by learning more about the domain itself. So we are back to square one. It is important not to confuse the mathematical existence of a rule with our knowledge of it. The point of scientific inquiry, after all, is to find the strongest rules we can for a domain. But inquiry means bootstrapping our way to those rules from a condition of relative ignorance.

9. The NFL theorems imply that if an algorithm works better than average over one domain of problems, then its performance must be worse than average over another. Remarks Wolpert (1996, p. 1362), "There are just as many priors (prior probabilities) for which your favorite algorithm performs worse than pure randomness as for which it performs better". Doesn't this mean that there are domains in which no particular BV + SR procedure works well?

Yes, but this consequence does not undercut the BV + SR thesis. Campbell and other universal Darwinists do not claim that BV + SR will always work. There are possible domains in which *nothing* will work in the sense of finding humanly intelligible scientific results. Nor is it Campbell's claim that a BV + SR is always, or ever, optimal, objectively speaking. The claim is that, in a condition of ignorance, we have nothing better to go on than some BV + SR process or other.

10. In a completely 'cracked' Humean universe, learning is impossible. There it does seem plausible that no learning rule is better than any other. But we know that our universe is not like that. So why must we take seriously the NFL theorems?

Knowing that our *universe* is 'not like that' provides some empirical knowledge about our universe, but this does not automatically carry over to every domain that we happen to define. Such general knowledge should not be confused with domain-specific knowledge. As Wolpert and Fogel say, in the passages quoted in Section 7, the choice of an efficient learning rule must match the structure of that particular domain. One large-scale example is the familiar lesson that it is not a good idea to model all other sciences on physics. Early investigators assumed not only that the world is lawfully 'connected' but also that it is connected everywhere just like simple mechanics. One cannot take for granted the existence of coherent domains of phenomena or problems that call for a unified treatment. They, too, have their evolutionary histories (Shapere, 1974). Think how much effort it took to determine the state variables of physical and chemical systems.

11. In a condition of minimal domain knowledge, no learning rule is justified. Therefore, no particular version of BV + SR is justified either. So how can

Campbell's BV + SR thesis be true? For choosing a non-BV + SR rule is equally justified.

To be sure, one can choose a non-BV + SR rule, but, in a state of ignorance, one is then choosing blindly at the rules level, the meta-level, so to speak. Thus one is still resorting to trial and error, to some form of BV + SR.

12. Artificial intelligence experts discuss the weaknesses and the limits of genetic algorithms. How is that possible if the BV + SR thesis is correct?

These experts are (or should be) discussing the comparative strength of algorithms, their optimality, dominance characteristics, and so on for specific domains. Campbell's thesis claims neither that BV + SR rules are generally stronger than others nor that any particular BV + SR rule is universally useful.

13. If BV + SR underlies all innovative design, then why so much resistance to the idea, including resistance among scientists and AI experts as well as the general public?

Ignorance, Madam! This objection had more intuitive punch a decade or two ago, before the present boom in evolutionary computing. Resistance can be largely explained in the usual ways: reluctance to give up comfortable, traditional views; failure to think critically about them; and exaggerating the degree of blindness and chance in evolutionary processes while neglecting their cumulative nature. BV + SR advocates do not say that major innovations come in one big, improbable, chance occurrence. This is the counterpart to the wrongheaded creationist objections to biological evolution—that evolution equates the appearance of organisms with an explosion in a print shop producing the works of Shakespeare, or a hurricane blowing through a junkyard and producing a Boeing 747. On the contrary, BV + SR advocates are gradualists, step-by-step evolutionists, in which later steps build upon earlier ones. Big, greedy jumps are more characteristic of the romantic model of innovation.

Conclusion

Plato's Meno paradox concludes that genuine learning and (by extension) innovation are *impossible*. Darwin and his successors, however, argue convincingly that, when the relevant conditions are satisfied (blind variation plus selective retention in a stable environment with selection pressures), then evolution is *inevitable*. Campbell and others contend, in effect, that the conditions for evolutionary adaptation *are*, in fact, satisfied in many problem contexts, including all of those in which genuine learning or innovation occurs, and that learning and innovation (the introduction of novel design) can therefore be regarded as adaptation. Conversely, all adaptations can be considered knowledge (often implicit knowledge). As Holland (1995,

p. 31) puts the crucial point, "Perpetual novelty is the hallmark of complex adaptive systems". Short of destroying the system, we cannot prevent novel developments even if we want to (e.g. mutating viruses and bacteria, and attempts to 'fix' permanently a natural language such as French).

So the Meno problem is solved by a quasi-biological process of emergence of novel variants from predecessors in the genealogy. BV + SR is the only way we know to produce more design from less, the only way we know to produce genuine innovation. Although I cannot pretend to have offered a complete defense of that claim here, it does appear that an intelligent design model, whether theological or secular (as in appeals to 'the scientific method' in place of God), cannot, by itself, explain how innovation is possible. Thus we must be very careful how we describe the work of highly creative individuals working at an investigative frontier.

Following Campbell and company, I do *not* claim that unconstrained BV + SR is the source of all innovative design. Hence, I do not claim that adaptations are solely the product of BV + SR. Physical constraints are always operative, and perhaps the physical systems are sometimes self-organizing to some degree. However, insofar as there is cumulative BV + SR at all (and there always is at the frontier of innovation), then it makes sense to speak of adaptation.

My chapter explains and defends this BV + SR thesis with some qualifications. I have tried to meet some leading objections to the thesis without pretending to survey all possible modes of innovation. In particular, I have given little attention to biological processes themselves. To extend the discussion to those areas would require modifying some of my talk about domain knowledge and ignorance, e.g. to speaking instead of variations on a given biological platform. Nor have I investigated the sources of BV + SR other than to make some casual remarks about the noise introduced by linguistic slack, misinterpretation, and historical contingencies. These sources surely include situational and social-contextual as well as individual factors. I have also assumed, without much argument, that learning and innovation amount to bringing novel design into the world.

One point with which Campbell would surely have agreed is that not all BV + SR processes are evolutionary in the full sense (although they are still fully naturalistic). He is less likely to have agreed with my claim that trial and error processes, with their corresponding elements of chance and luck, should be considered *methods* or learning rules rather than signaling the complete absence of method; but such a view is now standard in evolutionary computing. More generally, BV + SR, and full evolutionary BV + SR, when available, can be considered a methodological

shell or family of shells that yield usable methods when the variation, selection, and retention mechanisms are specified in concrete contexts (Nickles, forthcoming). After all, if philosophers count the so-called hypothetico-deductive method as a method, how can they refuse the label to BV + SR?

In addition, I have argued that the NFL theorems support the BV + SR thesis, given that, at the frontier of research, we lack relevant domain knowledge to justify some non-BV + SR rule. BV + SR is the default position in the absence of domain knowledge. Typically, more than one BV + SR process will be available, but it is important to remember that the *warranted* use even of a particular BV + SR rule requires domain knowledge. The NFL theorems may be regarded as formal articulations of Humean intuitions.

And I have shown why the fact that BV + SR rules are not often, or even usually, the most efficient rules for a given domain does not undercut the BV + SR thesis. Campbell's thesis does not assert that BV + SR processes are optimal in some objective sense, and certainly not for routine problem-solving; but rather that they are the *only* procedures available at the frontier of innovation, given our ignorance of what lies beyond. Thus articles such as Baum et al. (2001), while certainly interesting, are not relevant, one way or the other, to the fate of the BV + SR thesis.

Overall, the chapter supports the claim that innovation is better considered a selective-adaptive process than a theorem-proving process or a rational planning or human design process in the traditional sense. Application of this point to human contexts places more emphasis on innovative communities, their traditions and practices, than upon individual creative 'geniuses'. The human design model is not completely wrong, of course, but it turns out to rest on previous applications of BV + SR. Hence the difficult and ironic historical intellectual reversal: when it comes to genuine innovation, BV + SR is the *first* resort rather than the last resort. Not only *can* there be novel, intelligent design without a prescient, intelligent designer, but also we have no other defensible account of it!

The Three-Ring Conception of Giftedness: Its Implications for Understanding the Nature of Innovation

Joseph S. Renzulli

The National Research Center on the Gifted and Talented, The University of Connecticut, USA

Abstract: The Three-Ring Conception of Giftedness focuses on creative/innovative productivity, which differs from schoolhouse or lesson-learning giftedness. Giftedness that leads to innovation emerges from the interaction and overlap of three clusters of traits—well above average ability in a particular domain, task commitment, and creativity—and occurs in certain individuals, at certain times, under certain conditions. A broader conception of giftedness will allow researchers, theorists, and educators to more fully address, answer, and respond to the most pressing questions about where innovation ‘comes from’. Simultaneously, this model, when applied, will assist in the development of individuals most capable of engaging in innovation and improving the quality of life for society.

Keywords: Innovation; Gifted; Creativity; Motivation; Task commitment

Introduction

The age-old issue of ‘what makes giftedness’ and how the contributions of gifted individuals have helped us understand the nature of innovation has been debated by scholars for decades. In the past 20 years, a renewed interest has emerged on this topic. This chapter will attempt to shed some light on this complex and controversial question by describing a broad range of theoretical issues and research studies that have been associated with the study of gifted, talented, and innovative persons. Although the information reported here draws heavily on the theoretical and research literature, it is written from the point of view of an educational practitioner who respects both theory and research, but who also has devoted a major amount of his efforts to translating these types of information into what he believes to be defensible identification and programming practices. Those in the position of offering advice to school systems that are faced with the reality of identifying and serving highly able students must also provide the types of underlying research that lend credibility to their advice. Accordingly, this chapter might be considered a theoretical and research rationale for two separate publications that describe a plan for identifying and programming

for gifted and talented students (Renzulli, 2000; Renzulli & Reis, 1997).

This chapter attempts to show a connection between the development of giftedness in young people and the ways in which gifted behaviors influence the process of innovation. Innovation is defined as original, solution-oriented *actions* that address previously unsolved problems in unique and creative ways. ‘Action’ is emphasized because innovation requires that the innovator will *do something* that leads to development or improvement of a product or process rather than merely thinking about or contemplating that product or process. The chapter is divided into three sections. The first section deals with several major issues that might best be described as the enduring questions and sources of controversy in a search for the meaning of giftedness and related attempts to define this concept. It is hoped that a discussion of these issues will establish common points of understanding between the writer and the reader and, at the same time, point out certain biases that are unavoidable whenever one deals with a complex and value-laden topic.

The second section describes a wide range of research studies that support the writer’s ‘three-ring’ conception of giftedness. The section concludes with

an explicit definition and a brief review of research studies that have been carried out in school programs using an identification system based on the three-ring concept. The final section examines a number of questions raised by scholars and practitioners since the time of the original publication (Renzulli, 1978) of this particular approach to a conception of giftedness.

Issues in the Study of Conceptions of Giftedness

Purposes and Criteria for a Definition of Giftedness

One of the first and most important issues that should be dealt with in a search for the meaning of giftedness is that there must be a purpose for defining this concept. The goals of science tell us that a primary purpose is to add new knowledge to our understanding about human conditions, but in an applied field of knowledge there is also a practical purpose for defining concepts. Persons who presume to be the writers of definitions should understand the full ramifications of these purposes and recognize the practical and political uses to which their work might be applied. A definition of giftedness is a formal and explicit statement that might eventually become part of official policies or guidelines. Whether or not it is the writer's intent, such statements will undoubtedly be used to direct identification and programming practices, and therefore we must recognize the consequential nature of this purpose and the pivotal role that definitions play in structuring the entire field. Definitions are open to both scholarly and practical scrutiny, and for these reasons it is important that a definition meet the following criteria:

- (1) It must be based on the best available research about the characteristics of gifted individuals rather than romanticized notions or unsupported opinions.
- (2) It must provide guidance in the selection and/or development of instruments and procedures that can be used to design defensible identification systems.
- (3) It must give direction and be logically related to programming practices such as the selection of materials and instructional methods, the selection and training of teachers; and the determination of procedures whereby programs can be evaluated.
- (4) It must be capable of generating research studies that will verify or fail to verify the validity of the definition.

In view of the practical purposes for which a definition might be used, it is necessary to consider any definition in the larger context of overall programming for the target population we are attempting to serve. In other words, the way in which one views giftedness will be a primary factor in both constructing a plan for identification and in providing services that are relevant to the characteristics that brought certain youngsters to our attention in the first place. If, for example, one

identifies giftedness as extremely high mathematical aptitude, then it would seem nothing short of common sense to use assessment procedures that readily identify potential for superior performance in this particular area of ability. And it would be equally reasonable to assume that a program based on this definition and identification procedure should devote major emphasis to the enhancement of performance in mathematics and related areas. Similarly, a definition that emphasizes artistic abilities should point the way toward relatively specific identification and programming practices. As long as there are differences of opinion among reasonable scholars there will never be a single definition of giftedness, and this is probably the way that it should be. But one requirement for which all writers of definitions should be accountable is the necessity of showing a logical relationship between definition on the one hand and recommended identification and programming practices on the other.

Two Kinds of Giftedness

A second issue that must be dealt with is that our present efforts to define giftedness are based on a long history of previous studies dealing with human abilities. Most of these studies focused mainly on the concept of intelligence and are briefly discussed here to establish an important point about the process of defining concepts rather than any attempt to equate intelligence with giftedness. Although a detailed review of these studies is beyond the scope of the present chapter, a few of the general conclusions from earlier research are necessary to set the stage for this analysis.¹

The first conclusion is that intelligence is not a unitary concept, but rather there are many kinds of intelligence and therefore single definitions cannot be used to explain this complicated concept. The confusion and inconclusiveness about present theories of intelligence have led Sternberg (1984) and others to develop new models for explaining this complicated concept. Sternberg's 'triarchic' theory of human intelligence consists of three subtheories: a contextual subtheory, which relates intelligence to the external world of the individual; a two-facet subtheory, which relates intelligence to both the external and internal worlds of the individual; and a componential subtheory, which relates intelligence to the internal world of the individual. The contextual subtheory defines intelligent behavior in terms of purposive adaptation to, selection of, and shaping of real-world environments relevant to one's life. The two-facet subtheory further constrains this definition by regarding as most relevant to the demonstration of intelligence contextually intelligent behavior that involves adaptation to novelty or

¹ Persons interested in a succinct examination of problems associated with defining intelligence are advised to review 'The Concept of Intelligence' (Neisser, 1979).

automatization of information processing, or both. The componential subtheory specifies the mental mechanisms responsible for the learning, planning, execution, and evaluation of intelligent behavior.

In view of this work and numerous earlier cautions about the dangers of trying to describe intelligence through the use of single scores, it seems safe to conclude that this practice has been and always will be questionable. At the very least, attributes of intelligent behavior must be considered within the context of cultural and situational factors. Indeed, some examinations have concluded that “(t)he concept of intelligence *cannot* be explicitly defined, not only because of the nature of intelligence but also because of the nature of concepts” (Neisser, 1979, p. 179).

A second conclusion is that there is no ideal way to measure intelligence, and therefore we must avoid the typical practice of believing that if we know a person’s IQ score, we also know his or her intelligence. Even Terman warned against total reliance on tests: “We must guard against defining intelligence solely in terms of ability to pass the tests of a given intelligence scale” (1921, p. 131). E. L. Thorndike echoed Terman’s concern by stating, “to assume that we have measured some general power which resides in (the person being tested) and determines his ability in every variety of intellectual task in its entirety is to fly directly in the face of all that is known about the organization of the intellect” (Thorndike, 1921, p. 126).

The reason I have cited these concerns about the historical difficulty of defining and measuring intelligence is to highlight the even larger problem of isolating a unitary definition of giftedness. At the very least we will always have several conceptions (and therefore definitions) of giftedness; but it will help in this analysis to begin by examining two broad categories that have been dealt with in the research literature. I will refer to the first category as ‘schoolhouse giftedness’ and to the second as ‘innovative giftedness’. Before going on to describe each type, I want to emphasize that:

- (1) Both types are important.
- (2) There is usually an interaction between the two types.
- (3) Special programs should make appropriate provisions for encouraging both types of giftedness as well as the numerous occasions when the two types interact with each other.

Schoolhouse Giftedness

Schoolhouse giftedness might also be called test-taking or lesson-learning giftedness. It is the kind most easily measured by IQ or other cognitive ability tests, and for this reason it is also the type most often used for selecting students for entrance into special programs. The abilities people display on IQ and aptitude tests are exactly the kinds of abilities most valued in traditional

school learning situations. In other words, the games people play on ability tests are similar in nature to games that teachers require in most lesson-learning situations. Research tells us that students who score high on IQ tests are also likely to get high grades in school. Research also has shown that these test-taking and lesson-learning abilities generally remain stable over time. The results of this research should lead us to some very obvious conclusions about schoolhouse giftedness: it exists in varying degrees; it can be identified through standardized assessment techniques; and we should therefore do everything in our power to make appropriate modifications for students who have the ability to cover regular curricular material at advanced rates and levels of understanding. Curriculum compacting (Renzulli, Smith & Reis, 1982), a procedure used for modifying curricular content to accommodate advanced learners, and other acceleration techniques should represent an essential part of any school program that strives to respect the individual differences that are clearly evident from scores yielded by cognitive ability tests.

Although there is a generally positive correlation between IQ scores and school grades, we should not conclude that test scores are the only factors that contribute to success in school. Because IQ scores correlate only from 0.40 to 0.60 with school grades, they account for only 16%–36% of the variance in these indicators of potential. Many youngsters who are moderately below the traditional 3–5% test score cutoff levels for entrance into gifted programs clearly have shown that they can do advanced-level work. Indeed, most of the students in the nation’s major universities and 4-year colleges come from the top 20% of the general population (rather than just the top 3–5%) and Jones (1982) reported that a majority of college graduates in every scientific field of study had IQs between 110 and 120. Are we ‘making sense’ when we exclude such students from access to special services? To deny them this opportunity would be analogous to *forbidding* a youngster from trying out for a basketball team because he or she missed a predetermined ‘cutoff height’ by a few inches! Basketball coaches are not foolish enough to establish *inflexible* cutoff heights because they know that such an arbitrary practice would cause them to overlook the talents of youngsters who may overcome slight limitations in inches with other abilities such as drive, speed, teamwork, ball-handling skills, and perhaps even the ability and motivation to outjump taller persons who are trying out for the team. As educators of gifted and talented youth, we can undoubtedly take a few lessons about flexibility from coaches!

Innovative Giftedness

If scores on IQ tests and other measures of cognitive ability only account for a limited proportion of the common variance with school grades, we can be

equally certain that these measures do not tell the whole story when it comes to making predictions about innovative giftedness. Before defending this assertion with some research findings, let us briefly review what is meant by this second type of giftedness, the important role that it should play in programming, and, therefore, the reasons we should attempt to assess it in our identification procedures—even if such assessment causes us to look below the top 3–5% on the normal curve of IQ scores.

Innovative giftedness describes those aspects of human activity and involvement where a premium is placed on the development of original material and products that are purposefully designed to have an impact on one or more target audiences. Learning situations that are designed to promote innovative giftedness emphasize the use and application of information (content) and thinking processes in an integrated, inductive, and real-problem-oriented manner. The role of the student is transformed from that of a learner of prescribed lessons to one in which she or he uses the *modus operandi* of a firsthand inquirer. This approach is quite different from the development of lesson-learning giftedness that tends to emphasize deductive learning, structured training in the development of thinking processes, and the acquisition, storage, and retrieval of information. In other words, innovative giftedness is simply putting one's abilities to work on problems and areas of study that have personal relevance to the student and that can be escalated to appropriately challenging levels of investigative activity. The roles that both students and teachers should play in the pursuit of these problems have been described elsewhere (Renzulli, 1982, 1983).

Why is innovative giftedness important enough for us to question the 'tidy' and relatively easy approach that traditionally has been used to select students on the basis of test scores? Why do some people want to rock the boat by challenging a conception of giftedness that can be numerically defined by simply giving a test? The answers to these questions are simple and yet very compelling. The research reviewed in the second section of this chapter tells us that there is much more to the making of a gifted person than the abilities revealed on traditional tests of intelligence, aptitude, and achievement. Furthermore, history tells us it has been the innovative and productive people of the world, the producers rather than consumers of knowledge, the reconstructionists of thought in all areas of human endeavor, who have become recognized as 'truly gifted' individuals. History does not remember persons who merely scored well on IQ tests or those who learned their lessons well.

The Development of Potential Innovations

Implicit in any efforts to define and identify gifted youth is the assumption that we will 'do something' to provide various types of specialized learning experi-

ences that show promise of promoting the development of characteristics implicit in the definition. In other words, the *why* question supersedes the *who* and *how* questions. Although there are two generally accepted purposes for providing special education for the gifted, I believe that these two purposes in combination give rise to a third purpose that is intimately related to the definition question.

The first purpose of gifted education² is to provide young people with maximum opportunities for self-fulfillment through the development and expression of one or a combination of performance areas where superior potential may be present.

The second purpose is to increase society's supply of persons who will help to solve the problems of contemporary civilization by becoming innovators and producers of knowledge and art rather than mere consumers of existing information.

We value innovators, as opposed to replicators, because they are the persons who go beyond our current levels of knowledge and understanding to bring forth new ideas, questions, solutions to problems, and new products and services that did not exist prior to their application of the creative process. It is the innovators that, in effect, create thousands of jobs for replicators. One creative idea such as a book, a symphony, a new device or software program for a computer starts the wheels of production turning, thereby creating thousands of jobs in both manufacturing and a host of other areas such as finance, advertising, marketing, packaging, transportation, and sales. Thomas Edison's invention of the storage battery gave rise to an entire industry that still prospers today, and has the added benefit of providing a vehicle for the many innovative modifications and improvement that have been made on this innovative product over the years.

Although there may be some arguments for and against both of the above purposes, most people would agree that goals related to self-fulfillment and/or societal contributions are generally consistent with democratic philosophies of education. What is even more important is that the two goals are highly interactive and mutually supportive of each other. In other words, the self-satisfying work of scientists, artists, and leaders in all walks of life usually produces results that might be valuable contributions to society. Carrying this point one step farther, we might even conclude that appropriate kinds of learning experiences can and should be engineered to achieve the twofold goals described above. Keeping in mind the interaction of these two goals, and the priority status of the self-fulfillment goal, it is safe to conclude that supplementary investments of public funds and systematic

² The term *gifted education* will be used in substitution for the more technically accurate but somewhat awkward term *education of the gifted*.

effort for highly able youth should be expected to produce at least some results geared toward the public good. If, as Gowan (1978) has pointed out, the purpose of gifted programs is to increase the size of society's reservoir of potentially innovative and productive adults, then the argument for gifted education programs that focus on creative productivity (rather than lesson-learning giftedness) is a very simple one. If we agree with the goals of gifted education set forth earlier in the chapter, and if we believe that our programs should produce the next generation of leaders, problem-solvers, and persons who will make important contributions to the arts and sciences, then does it not make good sense to model our training programs after the *modus operandi* of these persons rather than after those of the lesson learner? This is especially true because research (as described later in the chapter) tells us that the most efficient lesson learners are not necessarily those persons who go on to make important contributions in the realm of creative productivity. And in this day and age, when knowledge is expanding at almost geometric proportions, it would seem wise to consider a model that focuses on how our most able students access and make use of information rather than merely on how they accumulate and store it.

In other words, innovation almost always takes place in context—in part because of innovation's close association with creativity, which is integrally related to context (Sternberg, Pretz & Kaufman, in press). A person is not always innovative or never innovative. Innovation occurs in certain people (not all people), at certain times (not all the time), and under certain circumstances. To be certain, there are some people who have long and continuous records of creative productivity, but there are others for whom lightning strikes only once! So while we celebrate the monumental record of more than 2000 patents by Edison, we also recognize the singular contribution of *Gone With the Wind* by Margaret Mitchell. The key issue for educators is creating the context that nurtures innovation. By providing young people with opportunities, resources, and encouragement *within their existing or developing areas of interest*, and by helping them experience the joys and rewards of creative productivity, we create a contextual environment that, for some people, will become a lifestyle. It is these people who usually gravitate toward the innovative rather than replicative roles in their respective professions—the medical research scientist rather than the medical practitioner, the fashion designer rather than the person who produces the garments. Both roles (innovator and replicator) are highly valued and necessary for progress in any field, but the trigger for any and all productivity is the one pulled by the innovator.

The Gifted and the Potentially Gifted

A further issue relates to the subtle but very important distinction that exists between the 'gifted' and the

'potentially gifted'. Most of the research reviewed later in the chapter deals with student and adult populations whose members have been judged (by one or more criteria) to be gifted. In most cases, researchers have studied those who have been identified as 'being gifted' much more intensively than they have studied persons who were not recognized or selected because of unusual accomplishments. The general approach to the study of gifted persons could easily lead the casual reader to believe that giftedness is a condition that is magically bestowed on a person in much the same way that nature endows us with blue eyes, red hair, or a dark complexion. This position is *not* supported by the research. Rather, what the research clearly and unequivocally tells us is that *giftedness can be developed* in some people if an appropriate interaction takes place between a person, his or her environment, and a particular area of human endeavor.

It should be kept in mind that when I describe, in the paragraphs that follow, a certain trait as being a component of giftedness (for example, creativity), I am in no way assuming that one is 'born with' this trait, even if one happens to possess a high IQ. Almost all human abilities can be developed, and therefore my intent is to call attention to the potentially gifted (that is to say, those who could 'make it' under the right conditions) as well as to those who have been studied because they gained some type of recognition. Implicit in this concept of the potentially gifted, then, is the idea that giftedness emerges or 'comes out' at different times and under different circumstances. Without such an approach there would be no hope whatsoever of identifying bright underachievers, students from disadvantaged backgrounds, or any other special population that is not easily identified through traditional testing procedures.

Are People 'Gifted' or Do They Display Gifted Behaviors?

A fifth and final issue underlying the search for a definition of giftedness is more nearly a bias and a hope for at least one major change in the ways we view this area of study. Except for certain functional purposes related mainly to professional focal points (i.e. research, training, legislation) and to ease of expression, I believe that a term such as *the gifted* is counterproductive to educational efforts aimed at identification and programming for certain students in the general school population. Rather, it is my hope that in the years ahead we will shift our emphasis from the present concept of 'being gifted' (or not being gifted) to a concern about developing *gifted behaviors* in those youngsters who have the highest potential for benefiting from special education services. This slight shift in terminology might appear to be an exercise in heuristic hairsplitting, but I believe that it has significant implications for the entire way we think about the concept of giftedness and the ways in which we

structure the field for important research endeavors³ and effective educational programming.

For too many years we have pretended that we can identify gifted children in an absolute and unequivocal fashion. Many people have been led to believe that certain individuals have been endowed with a golden chromosome that makes them 'gifted persons'. This belief has further led to the mistaken idea that all we need to do is find the right combination of factors that prove the existence of this chromosome. The further use of such terms as the 'truly gifted', the 'moderately gifted', and the 'borderline gifted' only serves to confound the issue and might result in further misguided searches for silver and bronze chromosomes. This misuse of the concept of giftedness has given rise to a great deal of confusion and controversy about both identification and programming, and the result has been needless squabbling among professionals in the field. Another result has been that so many mixed messages have been sent to educators and the public at large that both groups now have a justifiable skepticism about the credibility of the gifted education establishment and our ability to offer services that are qualitatively different from general education.

Most of the confusion and controversy surrounding the definition of giftedness can be placed in proper perspective by raising a series of questions that strike right at the heart of key issues related to this area of study. These questions are organized into the following clusters:

- (1) Are giftedness and high IQ one and the same? And if so, how high does one's IQ need to be before one can be considered gifted? If giftedness and high IQ are not the same, what are some of the other characteristics that contribute to the expression of giftedness? Is there any justification for providing selective services for certain students who may fall below a predetermined IQ cutoff score?
- (2) Is giftedness an absolute or a relative concept? That is, is a person either gifted or not gifted (the absolute view) or can varying kinds and degrees of gifted behaviors be displayed in certain people, at certain times, and under certain circumstances (the relative view)? Is gifted a static concept (i.e. you have it or you don't have it) or is it a dynamic concept (i.e. it varies both within persons and within learning-performance situations)?
- (3) What factors cause only a minuscule number of Thomas Edisons or Langston Hugheses or Isadora Duncans to emerge as innovators, whereas millions of others

with equal 'equipment' and educational advantages (or disadvantages) never rise above mediocrity? Why do some people who have not enjoyed the advantages of special educational opportunities become innovators, whereas others who have gone through the best of educational programming opportunities fail to make an innovative contribution?

In the section that follows, a series of research studies will be reviewed in an effort to answer these questions. Taken collectively, these research studies are the most powerful argument that can be put forth to policymakers who must render important decisions about the regulations and guidelines that will dictate identification practices in their states or local school districts. An examination of this research clearly tells us that gifted behaviors can be developed in those who are not necessarily individuals who earn the highest scores on standardized tests. The two major implications of this research for identification practices are equally clear.

First, an effective identification system must take into consideration other factors in addition to test scores. Research has shown that, in spite of the multiple criterion information gathered in many screening procedures, rigid cutoff scores on IQ or achievement tests are still the main if not the only criterion given *serious* consideration in final selection (Alvino, 1981). When screening information reveals outstanding potential for gifted behaviors, it is almost always 'thrown away' if predetermined cutoff scores are not met. Respect for these other factors means that they must be given equal weight and that we can no longer merely give lip service to non-test criteria; nor can we believe that because tests yield 'numbers' they are inherently more valid and objective than other procedures. As Sternberg (1982a) has pointed out, *quantitative* does not necessarily mean *valid*. When it comes to identification that might lead to the development of innovators, it is far better to include rather than exclude those with the potential for developing innovative ideas and products. In order to create environments that produce innovators, educators could focus on opportunities for students to engage in authentic learning. This brand learning consists of *applying* relevant knowledge, thinking skills, and interpersonal skills to the solution of real problems and what happens in real-world situations. For example, students might focus on their learning activities by addressing these essential questions in any given discipline:

- (1) What do people with an interest in this area do?
- (2) What products do they create and/or what services do they provide?
- (3) What methods do they use to carry out their work?
- (4) What resources and materials are needed to produce high-quality products and services?

³ For example, most of the research on the 'gifted' that has been carried out to date has used high-IQ populations. If one disagrees (even slightly) with the notion that giftedness and high IQ are synonymous, then these research studies must be reexamined. These studies may tell us a great deal about the characteristics, and so on, of high-IQ individuals, but are they necessarily studies of the gifted?

- (5) How, and with whom, do they communicate the results of their work?
- (6) What steps need to be taken to have an impact on intended audiences?

This type of focus would allow students to build a foundation of knowledge and pursue innovative strategies to solve a real problem. Rather than providing students with answers to these questions, the teacher organizes and guides instruction but does not dominate the exploration process. As the facilitator of situations to foster innovation, the teacher helps students select challenging projects. These activities should be student-driven, with the teacher playing an advisory role. Learning experiences that follow this model will provide for opportunities for students to take creative risks which may lead to the development of innovations.

The second research-based implication will undoubtedly be a major controversy in the field for many years, but it needs to be dealt with if we are ever going to defuse a majority of the criticism that has been justifiably directed at our field. Simply stated, we must reexamine identification procedures that result in a total pre-selection of certain students and the concomitant implication that these young people are and always will be 'gifted'. This absolute approach (i.e. you have it or you don't have it) coupled with the almost total reliance on test scores is not only inconsistent with what the research tells us, but almost arrogant in the assumption that we can use a single one-hour segment of a young person's total being to determine if he or she is 'gifted'.

The alternative to such an absolutist view is that we may have to forgo the 'tidy' and comfortable tradition of 'knowing' on the first day of school who is gifted and who is not gifted. Rather, our orientation must be redirected toward developing 'gifted behaviors' in certain students (not all students), at certain times (not all the time), and under certain circumstances. The tradeoff for tidiness and administrative expediency will result in a much more flexible approach to both identification and programming and a system that not only shows a greater respect for the research on gifted and talented people but is both fairer and more acceptable to other educators and to the general public.

Research Underlying the Three-Ring Conception of Giftedness

One way of analyzing the research underlying conceptions of giftedness is to review existing definitions along a continuum ranging from conservative to liberal. *Conservative* and *liberal* are used here not in their political connotations but rather according to the degree of restrictiveness that is used in determining who is eligible for special programs and services.

Restrictiveness can be expressed in two ways. First, a definition can limit the number of specific performance areas that are considered in determining eligibility for special programs. A conservative definition, for example, might limit eligibility to academic performance only and exclude other areas such as music, art, drama, leadership, public speaking, social service, and creative writing. Second, a definition can limit the degree or level of excellence that one must attain by establishing extremely high cutoff points.

At the conservative end of the continuum is Terman's (1926) definition of giftedness as 'the top 1% level in general intellectual ability as measured by the Stanford-Binet Intelligence Scale or a comparable instrument' (1926, p. 43).

In this definition, restrictiveness is present in terms of both the type of performance specified (i.e. how well one scores on an intelligence test) and the level of performance one must attain to be considered gifted (top 1%). At the other end of the continuum can be found more liberal definitions, such as the following one by Witty (1958):

There are children whose outstanding potentialities in art, in writing, or in social leadership can be recognized largely by their performance. Hence, we have recommended that the definition of giftedness be expanded and that we consider any child gifted whose performance, in a potentially valuable line of human activity, is consistently remarkable (p. 62).

Although liberal definitions have the obvious advantage of expanding the conception of giftedness, they also open up two 'cans of worms' by introducing a values issue (What are the potentially valuable lines of human activity?) and the age-old problem of subjectivity in measurement.

In recent years the values issue has been largely resolved. There are very few educators who cling tenaciously to a 'straight IQ' or purely academic definition of giftedness. 'Multiple talent' and 'multiple criteria' are almost the bywords of the present-day gifted student movement, and most persons would have little difficulty in accepting a definition that includes almost every area of human activity that manifests itself in a socially useful form of expression.

The problem of subjectivity in measurement is not as easily resolved. As the definition of giftedness is extended beyond those abilities that are clearly reflected in tests of intelligence, achievement, and academic aptitude, it becomes necessary to put less emphasis on precise estimates of performance and potential and more emphasis on the opinions of qualified human judges in making decisions about admission to special programs. The crux of the issue boils down to a simple and yet very important question: How much of a trade-off are we willing to make on the objective-subjective continuum in order to allow recognition of a broader spectrum of human abilities? If

Figure 1. The three-ring conception of giftedness.

some degree of subjectivity cannot be tolerated, then our definition of giftedness and the resulting programs will logically be limited to abilities that can be measured only by objective tests.

The Three-Ring Conception of Giftedness

Research on innovative people has consistently shown that although no single criterion can be used to determine giftedness, persons who have achieved recognition because of their unique accomplishments and creative contributions possess a relatively well-defined set of three interlocking clusters of traits. These clusters consist of above-average, though not necessarily superior, ability, task commitment, and creativity (see Fig. 1). It is important to point out that no single cluster 'makes giftedness'. Rather, it is the interaction among the three clusters that research has shown to be the necessary ingredient for innovative accomplishment (Renzulli, 1978). This interaction is represented by the shaded portion of Fig. 1. It is also important to point out that each cluster plays an important role in contributing to the display of gifted behaviors. This point is emphasized because one of the major errors that continues to be made in identification procedures is to overemphasize superior abilities at the expense of the other two clusters of traits.

Well-Above-Average Ability

Well-above-average ability can be defined in two ways.

General ability consists of the capacity to process information, to integrate experiences that result in appropriate and adaptive responses in new situations, and the capacity to engage in abstract thinking. Examples of general ability are verbal and numerical reasoning, spatial relations, memory, and word fluency. These abilities are usually measured by tests of general aptitude or intelligence, and are broadly applicable to a variety of traditional learning situations.

Specific abilities consist of the capacity to acquire knowledge, skill, or the ability to perform in one or more activities of a specialized kind and within a restricted range. These abilities are defined in a manner that represents the ways in which human beings express themselves in real-life (i.e. non-test) situations.

Examples of specific abilities are chemistry, ballet, mathematics, musical composition, sculpture, and photography. Each specific ability can be further subdivided into even more specific areas (e.g. portrait photography, astrophotography, photo journalism, etc.). Specific abilities in certain areas such as mathematics and chemistry have a strong relationship with general ability, and, therefore, some indication of potential in these areas can be determined from tests of general aptitude and intelligence. They can also be measured by achievement tests and tests of specific aptitude. Many specific abilities, however, cannot be easily measured by tests, and, therefore, areas such as the arts must be evaluated through one or more performance-based assessment techniques.

Within this model the term *above-average ability* will be used to describe both general and specific abilities. *Above average* should also be interpreted to mean the upper range of potential within any given area. Although it is difficult to assign numerical values to many specific areas of ability, when I refer to 'well above average ability' I clearly have in mind persons who are capable of performance or the potential for performance that is representative of the top 15–20% of any given area of human endeavor.

Although the influence of intelligence, as traditionally measured, quite obviously varies with specific areas of performance, many researchers have found that creative accomplishment is not necessarily a function of measured intelligence. In a review of several research studies dealing with the relationship between academic aptitude tests and professional achievement, Wallach (1976) has concluded that: "Above intermediate score levels, academic skills assessments are found to show so little criterion validity as to be a questionable basis on which to make consequential decisions about students' futures. What the academic tests do predict are the results a person will obtain on other tests of the same kind" (p. 57).

Wallach goes on to point out that academic test scores at the upper ranges—precisely the score levels that are most often used for selecting persons for entrance into special programs—do not necessarily reflect the potential for innovative accomplishment. Wallach suggests that test scores be used to screen out persons who score in the lower ranges and that beyond this point, decisions should be based on other indicators of potential for superior performance.

Numerous research studies support Wallach's findings that there is a limited relationship between test scores and school grades on the one hand, and real-world accomplishments on the other (Bloom, 1963; Harmon, 1963; Helson & Crutchfield, 1979; Hudson, 1960; Mednick, 1963; Parloff et al., 1968; Richards, Holland & Lutz, 1967; Wallach & Wing, 1969). In fact, in a study dealing with the prediction of various dimensions of achievement among college students, Holland & Astin (1962) found that "getting good

grades in college has little connection with more remote and more socially relevant kinds of achievement; indeed, in some colleges, the higher the student's grades, the less likely it is that he is a person with creative potential. So it seems desirable to extend our criteria of talented performance" (pp. 132–133). A study by the American College Testing Program (Munday & Davis, 1974) entitled 'Varieties of Accomplishment After College: Perspectives on the Meaning of Academic Talent', concluded that:

the adult accomplishments were found to be uncorrelated with academic talent, including test scores, high school grades, and college grades. However, the adult accomplishments were related to comparable high school nonacademic (extra curricular) accomplishments. This suggests that there are many kinds of talents related to later success which might be identified and nurtured by educational institutions (p. 2).

The pervasiveness of this general finding is demonstrated by Hoyt (1965), who reviewed 46 studies dealing with the relationship between traditional indications of academic success and postcollege performance in the fields of business, teaching, engineering, medicine, scientific research, and other areas such as the ministry, journalism, government, and miscellaneous professions. From this extensive review, Hoyt concluded that traditional indications of academic success have no more than a very modest correlation with various indicators of success in the adult world and that "There is good reason to believe that academic achievement (knowledge) and other types of educational growth and development are relatively independent of each other" (p. 73).

The experimental studies conducted by Sternberg (1981) and Sternberg & Davidson (1982) added a new dimension to our understanding about the role that intelligence tests should play in making identification decisions. After numerous investigations into the relationship between traditionally measured intelligence and other factors such as problem-solving and insightful solutions to complex problems, Sternberg (1982b) concludes that:

tests only work for some of the people some of the time—not for all of the people all of the time—and that some of the assumptions we make in our use of tests are, at best, correct only for a segment of the tested population, and at worst, correct for none of it. As a result we fail to identify many gifted individuals for whom the assumptions underlying our use of tests are particularly inadequate. The problem, then, is not only that tests are of limited validity for everyone but that their validity varies across individuals. For some people, tests scores may be quite informative, for others such scores may be worse than useless. Use of test score cutoffs and formulas

results in a serious problem of underidentification of gifted children (p. 157).

The studies raise some basic questions about the use of tests as a major criterion for making selection decisions. The research reported above clearly indicates that vast numbers *and* proportions of our most productive persons are *not* those who scored at the 95th percentile or above on standardized tests of intelligence, nor were they necessarily straight A students who discovered early how to play the lesson-learning game. In other words, more innovative persons came from below the 95th percentile than above it, and if such cutoff scores are needed to determine entrance into special programs, we may be guilty of actually discriminating against persons who have the greatest potential for high levels of accomplishment.

The most defensible conclusion about the use of intelligence tests that can be put forward at this time is based on research findings dealing with the 'threshold effect'. Reviews by Chambers (1969) and Stein (1968) and research by Walberg (1969, 1971) indicate that accomplishments in various fields require minimal levels of intelligence, but that beyond these levels, degrees of attainment are weakly associated with intelligence. In studies of creativity it is generally acknowledged that a fairly high though not exceptional level of intelligence is necessary for high degrees of creative achievement (Barron, 1969; Campbell, 1960; Guilford, 1964, 1967; McNemar, 1964; Vernon, 1967).

Research on the threshold effect indicates that different fields and subject matter areas require varying degrees of intelligence for high-level accomplishment. In mathematics and physics the correlation of measured intelligence with originality in problem-solving tends to be positive but quite low. Correlations between intelligence and the rated quality of work by painters, sculptors, and designers is zero or slightly negative (Barron, 1968). Although it is difficult to determine exactly how much measured intelligence is necessary for high levels of innovative accomplishment within any given field, there is a consensus among many researchers (Barron, 1969; Bloom, 1963; Cox, 1926; Harmon, 1963; Helson & Crutchfield, 1970; MacKinnon, 1962, 1965; Oden, 1968; Roe, 1952; Terman, 1954) that once the IQ is 120 or higher other variables become increasingly important. These variables are discussed in the paragraphs that follow.

Task Commitment

A second cluster of traits that consistently has been found in innovative persons is a refined or focused form of motivation known as task commitment. Whereas motivation is usually defined in terms of a general energizing process that triggers responses in organisms, task commitment represents energy brought to bear on a particular problem (task) or specific

performance area. The terms that are most frequently used to describe task commitment are perseverance, endurance, hard work, dedicated practice, self-confidence, and a belief in one's ability to carry out important work. In addition to perceptiveness (Albert, 1975) and a better sense for identifying significant problems (Zuckerman, 1979), research on persons of unusual accomplishment has consistently shown that a special fascination for and involvement with the subject matter of one's chosen field "are the almost invariable precursors of original and distinctive work" (Barron, 1969, p. 3). Even in young people whom Bloom & Sosniak (1981) identified as extreme cases of talent development, early evidence of task commitment was present. Bloom & Sosniak report that "after age 12 our talented individuals spent as much time on their talent field each week as their average peer spent watching television" (p. 94).

The argument for including this nonintellectual cluster of traits in a definition of giftedness is nothing short of overwhelming. From popular maxims and autobiographical accounts to hard-core research findings, one of the key ingredients that has characterized the work of gifted persons is their ability to involve themselves totally in a specific problem or area for an extended period of time.

The legacy of both Sir Francis Galton and Lewis Terman clearly indicates that task commitment is an important part of the making of a gifted person. Although Galton was a strong proponent of the hereditary basis for what he called 'natural ability', he nevertheless subscribed heavily to the belief that hard work was part and parcel of giftedness:

By natural ability, I mean those qualities of intellect and disposition, which urge and qualify a man to perform acts that lead to reputation. I do not mean capacity without zeal, nor zeal without capacity, nor even a combination of both of them, without an adequate power of doing a great deal of very laborious work. But I mean a nature which, when left to itself, will, urged by an inherent stimulus, climb the path that leads to eminence and has strength to reach the summit—on which, if hindered or thwarted, will fret and strive until the hindrance is overcome, and it is again free to follow its laboring instinct (Galton, 1869, p. 33, as quoted in Albert, 1975, p. 142).

The monumental studies of Lewis Terman undoubtedly represent the most widely recognized and frequently quoted research on the characteristics of gifted persons. Terman's studies, however, have unintentionally left a mixed legacy because most persons have dwelt (and continue to dwell) on 'early Terman' rather than the conclusions he reached *after* several decades of intensive research. As such, it is important to consider the following conclusion that he reached as a result of 30 years of follow-up studies on his initial population:

A detailed analysis was made of the 150 most successful and 150 least successful men among the gifted subjects in an attempt to identify some of the non-intellectual factors that affect life success. . . . Since the less successful subjects do not differ to any extent in intelligence as measured by tests, it is clear that notable achievement calls for more than a high order of intelligence.

The results (of the follow-up) indicated that personality factors are extremely important determiners of achievement. . . . The four traits on which (the most and least successful groups) differed most widely were *persistence in the accomplishment of ends, integration toward goals, self-confidence, and freedom from inferiority feelings*. In the total picture the greatest contrast between the two groups was in all-round emotional and social adjustment, and in *drive to achieve* (Terman, 1959, p. 148; italics added).

Although Terman never suggested that task commitment should replace intelligence in our conception of giftedness, he did state that 'intellect and achievement are far from perfectly correlated'.

Several research studies support the findings of Galton and Terman and have shown that innovative persons are far more task-oriented and involved in their work than are people in the general population. Perhaps the best known of these studies is the work of Roe (1952) and MacKinnon (1964, 1965). Roe conducted an intensive study of the characteristics of 64 eminent scientists and found that *all* of her subjects had a high level of commitment to their work. MacKinnon pointed out traits that were important in creative accomplishments: "It is clear that creative architects more often stress their inventiveness, independence and individuality, their *enthusiasm, determination, and industry*" (1964, p. 365; italics added).

Extensive reviews of research carried out by Nicholls (1972) and McCurdy (1960) found patterns of characteristics that were consistently similar to the findings reported by Roe and MacKinnon. Although the studies cited thus far used different research procedures and dealt with a variety of populations, there is a striking similarity in their major conclusions. First, academic ability (as traditionally measured by tests or grade point averages) showed limited relationships to innovative accomplishment. Second, nonintellectual factors, and especially those related to task commitment, consistently played an important part in the cluster of traits that characterized highly productive people. Although this second cluster of traits is not as easily and objectively identifiable as general cognitive abilities are, these traits are nevertheless a major component of giftedness and should, therefore, be reflected in our definition.

Creativity

The third cluster of traits that characterizes gifted persons consists of factors usually lumped together under the general heading of 'creativity'. As one reviews the literature in this area, it becomes readily apparent that the words *gifted*, *genius*, and *eminent creators* or *highly creative persons* are used synonymously. In many of the research projects discussed above, the persons ultimately selected for intensive study were in fact recognized *because* of their creative accomplishments. In MacKinnon's (1964) study, for example, panels of qualified judges (professors of architecture and editors of major American architectural journals) were asked first to nominate and later to rate an initial pool of nominees, using the following dimensions of creativity:

- (1) Originality of thinking and freshness of approaches to architectural problems.
- (2) Constructive ingenuity.
- (3) Ability to set aside established conventions and procedures when appropriate.
- (4) A flair for devising effective and original fulfillments of the major demands of architecture, namely, technology (firmness), visual form (delight), planning (commodity), and human awareness and social purpose (p. 360).

When discussing creativity, it is important to consider the problems researchers have encountered in establishing relationships between creativity tests and other more substantial accomplishments. A major issue that has been raised by several investigators deals with whether or not tests of divergent thinking actually measure 'true' creativity. Although some validation studies have reported limited relationships between measures of divergent thinking and creative performance criteria (Dellas & Gaier, 1970; Guilford, 1967; Shapiro, 1968; Torrance, 1969) the research evidence for the predictive validity of such tests has been limited. Unfortunately, very few tests have been validated against real-life criteria of creative accomplishment; however, future longitudinal studies using these relatively new instruments might show promise of establishing higher levels of predictive validity. Thus, although divergent thinking is indeed a characteristic of highly creative persons, caution should be exercised in the use and interpretation of tests designed to measure this capacity.

Given the inherent limitations of creativity tests, a number of writers have focused attention on alternative methods for assessing creativity. Among others, Nicholls (1972) suggests that an analysis of creative products is preferable to the trait-based approach in making predictions about creative potential (p. 721), and Wallach (1976) proposes that student self-reports about creative accomplishment are sufficiently accurate to provide a usable source of data. Simonton (in press)

and Weisberg (in press) provide extensive summaries of issues related to the study of creativity and creative potential; much of the literature they review confirms the importance and complexity of the interactions among nature, the environment—including the Zeitgeist—and ability.

Although few persons would argue against the importance of including creativity in a definition of giftedness, the conclusions and recommendations discussed above raise the haunting issue of subjectivity in measurement. In view of what the research suggests about the questionable value of more objective measures of divergent thinking, perhaps the time has come for persons in all areas of endeavor to develop more careful procedures for evaluating the products of candidates for special programs.

Discussion and Generalizations

The studies reviewed in the preceding sections lend support to a small number of basic generalizations that can be used to develop an operational definition of giftedness. The first of these generalizations is that giftedness consists of an interaction among three clusters of traits—above-average but not necessarily superior general abilities, task commitment, and creativity. Any definition or set of identification procedures that does not give equal attention to all three clusters is simply ignoring the results of the best available research dealing with this topic.

Related to this generalization is the need to make a distinction between traditional indicators of academic proficiency and innovation. A sad but true fact is that special programs have favored proficient lesson learners and test takers at the expense of persons who may score somewhat lower on tests but who more than compensate for such scores by having high levels of task commitment and creativity. It is these persons whom research has shown to be those who ultimately make the most innovative contributions to their respective fields of endeavor.

A second generalization is that an operational definition should be applicable to all socially useful performance areas. The one thing that the three clusters discussed above have in common is that each can be brought to bear on a multitude of specific performance areas. As was indicated earlier, the interaction or overlap among the clusters 'makes giftedness', but giftedness does not exist in a vacuum. Our definition must, therefore, reflect yet another interaction, but in this case it is the interaction between the overlap of the clusters and any performance area to which the overlap might be applied. This interaction is represented by the large arrow in Fig. 2.

A third and final generalization concerns the types of information that should be used to identify superior performance in specific areas. Although it is a relatively easy task to include specific performance areas in a definition, developing identification procedures

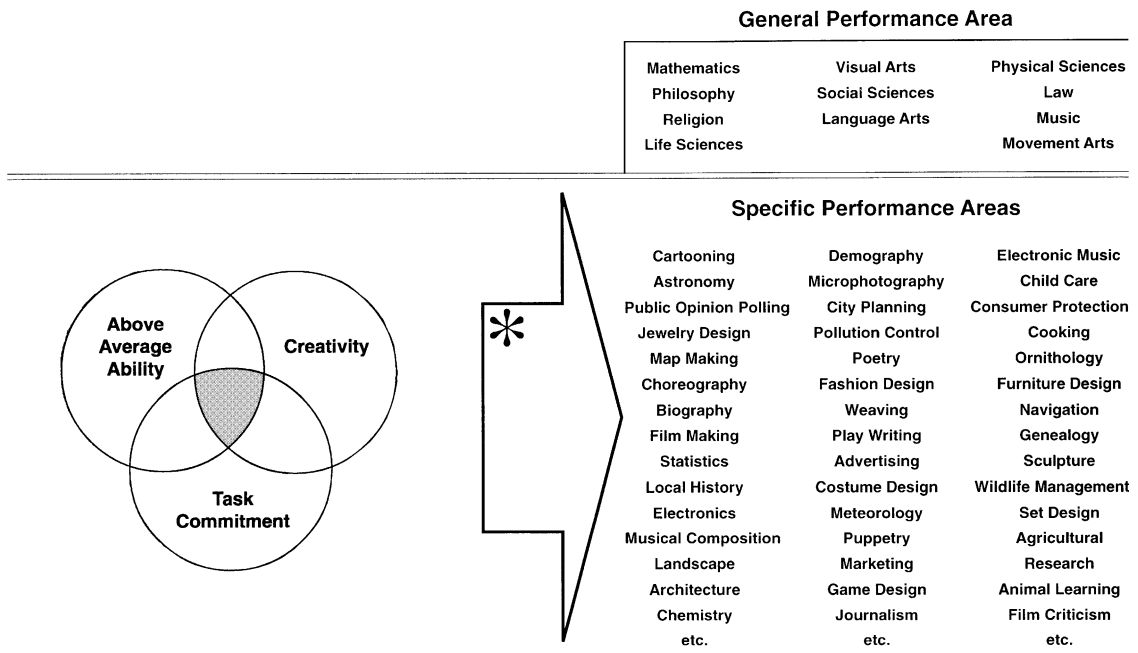

Figure 2. Relationship between the three-ring conception of giftedness and contexts for innovation.

that will enable us to recognize specific areas of superior performance is a more difficult problem. Test developers have thus far devoted most of their energy to the development of measures of general ability, and this emphasis is undoubtedly why these tests are relied on so heavily in identification. However, an operational definition should give direction to needed research and development, especially in the ways that these activities relate to instruments and procedures for student selection. A defensible definition can thus become a model that will generate vast amounts of appropriate research in the years ahead.

A Definition of Gifted Behavior

Although no single statement can effectively integrate the many ramifications of the research studies I have described, the following definition of gifted behavior attempts to summarize the major conclusions and generalizations resulting from this review of research:

Gifted behavior consists of behaviors that reflect an interaction among three basic clusters of human traits—these clusters being above average general and/or specific abilities, high levels of task commitment, and high levels of creativity. Gifted and talented children are those possessing or capable of developing this composite set of traits and applying them to any potentially valuable area of human performance. Children who manifest or are capable of developing an interaction among the three clusters require a wide

variety of educational opportunities and services that are not ordinarily provided through regular instructional programs.

A graphic representation of this definition is presented in Fig. 2, and the following 'taxonomy' of behavioral manifestations of each cluster is a summary of the major concepts and conclusions emanating from the work of the theorists and researchers discussed in the preceding paragraphs:

Well-above-average ability

General ability:

- (1) High levels of abstract thinking, verbal and numerical reasoning, spatial relations, memory, and word fluency.
- (2) Adaptation to and the shaping of novel situations encountered in the external environment.
- (3) The automatization of information processing; rapid, accurate, and selective retrieval of information.

Specific ability:

- (1) The application of various combinations of the above general abilities to one or more specialized areas of knowledge or areas of human performance (e.g. the arts, leadership, administration).
- (2) The capacity for acquiring and making appropriate use of advanced amounts of formal knowledge, tacit knowledge, technique, logistics, and strategy

- in the pursuit of particular problems or the manifestation of specialized areas of performance.
- (3) The capacity to sort out relevant and irrelevant information associated with a particular problem or area of study or performance.

Task commitment

- (1) The capacity for high levels of interest, enthusiasm, fascination, and involvement in a particular problem, area of study, or form of human expression.
- (2) The capacity for perseverance, endurance, determination, hard work, and dedicated practice.
- (3) Self-confidence, a strong ego and a belief in one's ability to carry out important work, freedom from inferiority feelings, drive to achieve.
- (4) The ability to identify significant problems within specialized areas; the ability to tune in to major channels of communication and new developments within given fields.
- (5) Setting high standards for one's work; maintaining an openness to self and external criticism; developing an aesthetic sense of taste, quality, and excellence about one's own work and the work of others.

Creativity

- (1) Fluency, flexibility, and originality of thought.
- (2) Openness to experience; receptive to that which is new and different (even irrational) in the thoughts, actions, and products of oneself and others.
- (3) Curious, speculative, adventurous, and 'mentally playful'; willing to take risks in thought and action, even to the point of being uninhibited.
- (4) Sensitive to detail, aesthetic characteristics of ideas and things; willing to act on and react to external stimulation and one's own ideas and feelings.

As is always the case with lists of traits such as the above, there is an overlap among individual items, and an interaction between and among the general categories and the specific traits. It is also important to point out that not all of the traits need be present in any given individual or situation to produce a display of gifted behaviors. It is for this reason that the three-ring conception of giftedness emphasizes the interaction among the clusters rather than any single cluster. It is also for this reason that I believe gifted behaviors take place in certain people (not all people), at certain times (not all the time), and under certain circumstances (not all circumstances).

Discussion About the Three Rings

Since the original publication of the three-ring conception of giftedness (Renzulli, 1977), a number of questions have been raised about the overall model and the interrelationships between and among the three rings. In this section, I will use the most frequently

asked questions as an outline for a discussion that will, I hope, clarify some of the concerns raised by persons who have expressed interest (both positive and negative) in this particular approach to the conception of giftedness.

Are There Additional Clusters of Abilities that Should be Added to the Three-Ring Conception of Giftedness?

One of the most frequent reactions to this work has been the suggestion that the three clusters of traits portrayed in the model do not adequately account for the development of gifted behaviors. An extensive examination of the research on human abilities has led me to an interesting conclusion about this question and has resulted in a modification of the original model. This modification is represented figurally by the houndstooth background in which the three rings are now imbedded (see Fig. 1).

The major conclusion is that the interaction among the original three rings is still the most important feature leading to the display of gifted behaviors. There are, however, a host of other factors that must be taken into account in our efforts to explain what causes some persons to display gifted behaviors at certain times and under certain circumstances. I have grouped these factors into the two traditional dimensions of studies about human beings commonly referred to as personality and environment. The research⁴ clearly shows that each of the factors listed in Table 1 plays varying roles in the manifestation of gifted behaviors. What is even more important is the interaction between the two categories and among the numerous factors listed in each column (In fact, a houndstooth pattern was selected over an earlier checkerboard design in an effort to convey this interaction.) When we consider the almost limitless number of combinations between and among the factors listed in Table 1, it is easy to realize why so much confusion has existed about the definition of giftedness.

Each of the factors is obviously a complex entity in and of itself and could undoubtedly be subdivided into numerous component parts. The factor of socioeconomic status, for example, accounts for such things as prenatal care and nutrition, educational opportunities, and even things such as 'occupational inheritance'. Werts (1968) found, for example, that there is a clear tendency for college students to gravitate toward the occupation of their fathers. On the personality side of the ledger, MacKinnon (1965) found that in studies of highly effective individuals it was discovered time and time again that persons of the

⁴ Literally hundreds of research studies have been carried out on the factors listed. For persons interested in an economical summary of personality and environmental influences on the development of gifted behaviors, I would recommend the following: D. K. Simonton (1978); B. T. Eiduson & L. Beckman (1973).

Table 1. Personality and environmental factors influencing giftedness.

Personality factors	Environmental factors
Perception of self	Socioeconomic status
Courage	Parental personalities
Character	Education of parents
Intuition	Stimulation of childhood interests
Charm or charisma	Family position
Need for achievement	Formal education
Ego strength	Role-model availability
Energy	Physical illness and/or well-being
Sense of destiny	Chance factors (financial inheritance, death, living near an art museum, divorce, etc.)
Personal attractiveness*	Zeitgeist

* Although personal attractiveness is undoubtedly a physical characteristic, the ways in which others react to one's physical being are quite obviously important determinants in the development of personality.

most extraordinary effectiveness had life histories marked by severe frustrations, deprivations, and traumatic experiences. Findings such as these help to highlight the complexity of the problem. The advantages of high socioeconomic status, a favorable educational background, and early life experiences that do not include hardship, frustration, or disappointment may lead to a productive career for some individuals, but for others it may very well eliminate the kinds of frustration that might become the 'trigger' to a more positive application of one's abilities.⁵

An analysis of the role that personality and environment play in the development of gifted behaviors and potentially innovative behaviors is beyond the scope of this chapter, and in many ways for school persons who are charged with the responsibilities of identifying and developing gifted and potentially innovative behaviors, they are beyond the realm of our *direct* influence. Each of the factors above shares one or a combination of two characteristics. First, most of the personality factors are long-term developmental traits or traits that in some cases are genetically determined. Although the school can play an important role in developing things like courage and need for achievement, it is highly unrealistic to believe that we can shoulder the major responsibility for overall personality formation. Second, many factors such as socioeconomic status, parental personalities, and family position are chance factors that children must take as givens when they are born and that educators must take as givens when young people walk through the schoolhouse door. We cannot tell a child to be the firstborn or to have parents who stress achievement! It is for these reasons that I have concentrated my efforts on the three sets of clusters set forth in the original model. Of course, certain aspects of the original three clusters are also

chance factors, but a large amount of research clearly has shown that creativity and task commitment are in fact modifiable and can be influenced in a highly positive fashion by purposeful kinds of educational experiences (Reis & Renzulli, 1982). And although the jury is still out on the issue of how much of one's ability is influenced by heredity and how much by environment, I think it is safe to conclude that abilities (both general and specific) can be influenced to varying degrees by the best kinds of learning experiences.

Are the Three Rings Constant?

Most educators and psychologists would agree that the above-average-ability ring represents a generally stable or constant set of characteristics. In other words, if an individual shows high ability in a certain area such as mathematics, it is almost undeniable that mathematical ability was present in the months and years preceding a 'judgment day' (i.e. a day when identification procedures took place) and that these abilities will also tend to remain high in the months and years following any given identification event. In view of the types of assessment procedures most readily available and economically administered, it is easy to see why this type of giftedness has been so popular in making decisions about entrance into special programs. Educators always feel more comfortable and confident with traits that can be reliably and objectively measured, and the 'comfort' engendered by the use of such tests often causes them to ignore or only pay lip service to the other two clusters of traits.

In our identification model (Renzulli et al., 1981), we have used above-average ability as the major criterion for identifying a group of students who are referred to as the Talent Pool. This group generally consists of the top 15–20% of the general school population. Test scores, teacher ratings, and other forms of 'status information' (i.e. information that can be gathered and analyzed at a fixed point in time) are of

⁵ I am reminded of the well-known quote by Dylan Thomas: 'There's only one thing that's worse than having an unhappy childhood, and that's having a too-happy childhood'.

practical value in making certain kinds of first-level decisions about accessibility to some of the general services that should be provided by a special program. This procedure guarantees admission to those students who earn the highest scores on cognitive ability tests. Primary among the services provided to Talent Pool students are procedures for making appropriate modifications in the regular curriculum in areas where advanced levels of ability can be clearly documented. It is nothing short of common sense to adjust the curriculum in those areas where high levels of proficiency are shown. Indeed, advanced coverage of traditional material and accelerated courses should be the 'regular curriculum' for youngsters with high ability in one or more school subjects.

The task commitment and creativity clusters are a different story! These traits are not present or absent in the same permanent fashion as pointed out in our mathematics example above. Equally important is the fact that we cannot assess them by the highly objective and quantifiable means that characterize test score assessment of traditional cognitive abilities. We simply cannot put a percentile on the value of an innovative idea, nor can we assign a standard score to the amount of effort and energy that a student might be willing to devote to a highly demanding task. Creativity and task commitment 'come and go' as a function of the various types of situations in which certain individuals become involved.

There are three things that we know for certain about the creativity and task commitment clusters. First, the clusters are variable rather than permanent. Although there may be a tendency for some individuals to 'hatch' more innovative ideas than others and to have greater reservoirs of energy that promote more frequent and intensive involvement in situations, a person is not either creative or not creative in the same way that one has a high ability in mathematics or musical composition. Almost all studies of highly accomplished individuals clearly indicate that their work is characterized by peaks and valleys of both creativity and task commitment. One simply cannot (and probably should not) operate at maximum levels of output in these two areas on a constant basis. Even Thomas Edison, who is still acknowledged to be the world's record holder of original patents, did not have an innovative idea for a new invention every waking moment of his life. And the most productive persons have consistently reported 'fallow' periods and even experiences of 'burnout' following long and sustained encounters with the manifestation of their talents.

The second thing we know about task commitment and creativity is that they can be developed through appropriate stimulation and training. We also know that because of variations in interest and receptivity, some people are more influenced by certain situations than others. The important point, however, is that we cannot predetermine which individuals will respond most

favorably to a particular type of stimulation experience. Through general interest assessment techniques and a wide variety of stimulus variation we can, however, increase the probability of generating a greater number of innovative ideas and increased manifestations of task commitment in Talent Pool students. In our identification model, the ways in which students *react* to planned and unplanned stimulation experiences has been termed 'action information'. This type of information constitutes the second level of identification and is used to make decisions about which students might revolve into more individualized and advanced kinds of learning activities. The important distinction between status and action information is that the latter type cannot be gathered before students have been selected for entrance into a special program. Giftedness, or at least the beginnings of situations in which gifted behaviors might be displayed and developed, is in the *responses* of individuals rather than in the stimulus events. This second-level identification procedure is, therefore, part and parcel of the general enrichment experiences that are provided for Talent Pool students, and is based on the concept of *situational testing* that has been described in the theoretical literature on test and measurements (Freeman, 1962, pp. 538–554).

Finally, the third thing we know about creativity and task commitment is that these two clusters almost always stimulate each other. A person gets an innovative idea; the idea, is encouraged and reinforced by oneself and/or others. The person decides to 'do something' with the idea, and thus his or her commitment to the task begins to emerge. Similarly, a large commitment to solving a particular problem will frequently trigger the process of creative problem-solving. In this latter case we have a situation that has undoubtedly given rise to the old adage 'necessity is the mother of invention.'

This final point is especially important for effective programming. Students participating in a gifted program should be patently aware of opportunities to follow through on innovative ideas and commitments that have been stimulated in areas of particular interest. Similarly, persons responsible for special programming should be knowledgeable about strategies for reinforcing, nurturing, and providing appropriate resources to students at those times when creativity and/or task commitment are displayed.

Are the Rings of Equal Size?

In the original publication of the three-ring conception of giftedness, I stated that the clusters must be viewed as 'equal partners' in contributing to the display of gifted behaviors. I would like to modify this position slightly, but will first set forth an obvious conclusion about lesson-learning giftedness. I have no doubt that the higher one's level of traditionally measured cognitive ability, the better equipped he or she will be to

perform in most traditional (lesson) learning situations. As was indicated earlier, the abilities that enable persons to perform well on intelligence and achievement tests are the same kinds of thinking processes called for in most traditional learning situations, and therefore the above-average ability cluster is a predominant influence in lesson-learning giftedness.

When it comes to innovative giftedness, however, I believe that an interaction among all three clusters is necessary for high-level performance. This is not to say that all clusters must be of equal size or that the size of the clusters remains constant throughout the pursuit of innovative endeavors. For example, task commitment may be minimal or even absent at the inception of a very large and robust innovative idea; and the energy and enthusiasm for pursuing the idea may never be as large as the idea itself. Similarly, there are undoubtedly cases in which an extremely innovative idea and a large amount of task commitment will overcome somewhat lesser amounts of traditionally measured ability. Such a combination may even cause a person to increase her or his ability by gaining the technical proficiency needed to see an idea through to fruition. Because we cannot assign numerical values to the creativity and task commitment clusters, empirical verification of this interpretation of the three rings is impossible. But case studies based on the experience of innovative individuals and research that has been carried out on programs using this model (Reis, 1981) clearly indicate that larger clusters do in fact compensate for somewhat decreased size on one or both of the other two areas. The important point, however, is that all three rings must be present and interacting to some degree in order for high levels of productivity to emerge.

Summary: What Makes Innovative Giftedness?

In recent years we have seen a resurgence of interest in all aspects of the study of giftedness and related efforts to provide special educational services for this often neglected segment of our school population. A healthy aspect of this renewed interest has been the emergence of new and innovative theories to explain the concept and a greater variety of research studies that show promise of giving us better insights and more defensible approaches to both identification and programming. Conflicting theoretical explanations abound and various interpretations of research findings add an element of excitement and challenge that can only result in greater understanding of the concept in the years ahead. So long as the concept itself is viewed from the vantage points of different subcultures within the general population and differing societal values, we can be assured that there will always be a wholesome variety of answers to the age-old question: What makes innovative giftedness? These differences in interpretation are indeed a salient and positive characteristic of any field that attempts to further our understanding of the human condition.

This chapter provides a framework that draws upon the best available research about gifted, talented, and innovative individuals. There is a growing body of research offered in support of the validity of the three-ring conception of giftedness. The conception and definition presented in this chapter have been developed from a decidedly educational perspective because I believe that efforts to define this concept must be relevant to the persons who will be most influenced by this type of work. I also believe that conceptual explanations and definitions must point the way toward practices that are economical, realistic, and defensible in terms of an organized body of underlying research and follow-up validation studies. These kinds of information can be brought forward to decision-makers who raise questions about why particular identification and programming models are being suggested by persons who are interested in serving gifted youth.

The task of providing better services to our most promising young people cannot wait until theorists and researchers produce an unassailable ultimate truth, because such truths probably do not exist. Educators need to create learning environments with numerous opportunities to foster the development of innovation and support the potential innovators in our society. We can not ignore this vital potential asset.

Innovation and Strategic Reflexivity: An Evolutionary Approach Applied to Services

Jon Sundbo

Department of Social Sciences, Roskilde University, Denmark

Abstract: Innovation in firms is discussed by using the notion of strategic reflexivity and applying a strategic innovation theory, which is within the evolutionary tradition. Market conditions and internal resources are the drivers of the innovation process. Firms manage their innovation process and market position through the strategy. Reflexivity is a social process in the firm in which managers and the employees consider the innovation process and the strategy. The social process includes organizational patterns, interaction and role patterns and organizational learning. The theory is applied to case studies of development of service concepts in service firms.

Keywords: Innovation; Strategic reflexivity; Evolutionary approach; Services; Social process.

Introduction

Aim of the Chapter

This chapter will discuss how firms develop by innovating. Innovation will be understood within the framework of the strategic innovation theory, which sees innovation as being determined by the firm's strategy (Sundbo, 1998a, 2001, 2002). Strategic reflexivity (Sundbo & Fuglsang, 2002) is an important concept within this theory. The concept refers to behavior which guides the innovation process. Strategic reflexivity leads to organizational learning. The aim of the chapter is to demonstrate how the concepts of strategic reflexivity and innovation can be used to attain a general understanding of the firm's development.

Innovation and Strategic Reflexivity

The topic of innovation belongs, in part, to economics (see for example Swedberg & Granovetter, 2001), but the approach taken here is primarily sociological. The explanation of innovation provided here takes a middle path between those who argue that innovation is determined by social structure and those who maintain that it is solely dependent on the acts of individuals. The view is that there is an element of truth in both of these approaches, which is to say that whilst social structure heavily influences the behavior of individuals, individuals' actions also determine social structure.

This view is common amongst sociologists (e.g. Bourdieu & Wacquant, 1992; Giddens, 1984).

Strategic reflexivity is a concept that can unite economic and sociological explanations of innovation. The contribution from economics is that we can understand the development of the firm in terms of a market game with an arbitrary outcome (a game in which the outcome cannot be predicted, but the outcome can be stated with a certain degree of probability). Since the outcome of market game is arbitrary, firms do not—and cannot—successfully just follow certain trajectories or just rely on being part of institutions (such as a stable network). The market changes continuously, as does the rest of the society, and the firm needs to act in new, path and institutional breaking ways to survive.

Economics has invented some theoretical approaches, such as game theory, to explain the situation with arbitrary outcome (Gintis, 2000; Owen, 1995). Such situations have also been described by cybernetics and systems theory (Beer, 1959; Boulding, 1985). However, this chapter will focus on the sociology behind the firm's understanding of possible outcomes and market strategy. The analysis emphasizes the social process of defining, maintaining and changing the way that the firm tackles a market with arbitrary outcome. The fundamental approach here is that the firm is not a living entity. A firm cannot assess probabilities and decide routes. People within (or

perhaps outside) the firm assess and decide routes. They do so not as anarchistic individuals (such as the classic entrepreneur, cf. Schumpeter, 1934) or as social beings determined by structure (for example by institutions). They do assess probabilities and decide routes within a social system (namely the firm's organization) characterized by interaction, repeating patterns of acting, norms and so on as well as regularly changing patterns of behavior.

The firm formulates a strategy, which defines the goals for its future activities. Innovation is a social process. The social process is *reflexive* in the way that the employees and managers consider how the firm should develop to avoid the external threats from competitors, changes in customers preferences and political regulation, and further, how the firm could utilize the possibilities for new market positioning (e.g. marketing new products or decreasing prices through process innovations). The overall idea of how the firm should develop is encapsulated in the strategy.

This chapter thus discusses how the interaction processes within the firm can be understood as an explanation of the firm's innovation activities. The latter may only, to a certain degree, be done in theoretical terms because the interaction processes follow varied patterns. Empirical studies are necessary to investigate the different empirical forms of the interaction processes.

The strategic reflexive approach is within the tradition of evolutionary theory (e.g. Metcalfe, 1998).

Core Concepts

The core concepts that will be used in the chapter are the following:

Innovation takes place when either a new element or a new combination of old elements (cf. Schumpeter, 1934) is introduced. This is Schumpeter's classic definition of innovation which emphasizes both the act (to introduce something) as well as the result (the new product or the new organization). Schumpeter's definition will be employed here.

However, there are various types of innovation and innovative activity.

Product innovation refers to the introduction of a new product to the market.

Process innovation refers to the introduction of new production processes such as those enabled by new technology, or new work routines.

Organizational innovation designates the introduction of a new organizational form or a new management philosophy.

Market innovation denotes a firm's new market behavior such as a new strategy, new marketing, new alliances and so forth.

Innovative behavior concerns the firm's organization of the innovative activities: the production of ideas or

inventions and their development into marketed products or practically implemented processes or organizational forms. Innovative behavior can be observed from outside the firm. The internal social process by which an innovation is developed and implemented is called the *innovation process*. The innovation process is an interaction between several actors (managers and employees); the constellation of these actors is called an *interaction system*.

There are many *small changes* in firms—products, processes, etc. Not any change is an innovation. To be classified as an innovation, the change must be substantial, which means that it is reproduced (cf. Gallouj, 1994; Sundbo, 1997, 1998b): if the innovation is a product (or a service), it is an innovation when it is produced in many copies. A process or an organizational innovation is one that is implemented throughout, or at least a large part of, the organization. However, even small changes which are not substantial enough to be called innovations may develop the firm. These will also be dealt with in this chapter.

Learning is the collection of experiences of what is good and what is bad. In relation to innovation and strategic reflexivity, it means the experience of which strategies and innovations were successful. It also refers to evaluating how the process of formulating strategies and organizing innovation activities can be successful. Learning can be both *individual* (each employee and manager learns) and *organizational* (the individual learning is dealt with others in the organization) (cf. Argyris & Schon, 1978).

Firm development concerns a firm developing either when it grows (in turnover, number of employees or profit) because of innovation or small changes or when it gains a competitive advantage by innovating (even though it does not grow immediately). Development can be achieved through innovation, small changes, learning, and by strategic reflexivity.

Structure of the Chapter

I will begin the chapter by discussing how the development of the firm can be understood theoretically. First, I will explain how strategic innovation theory, including the notion of strategic reflexivity, is based on evolutionary theory. Next, I will state the axioms of the strategic reflexivity explanation of innovation, which will then be outlined in the following section.

The theoretical discussion is applied to empirical cases, namely the development of service concepts in service firms.

A *service concept* is the total system of a service product (Desrumaux et al., 1998). A service concept includes the way the service product is produced and delivered (including the involvement of the customer and how the service solves the problem), the market position that the service enterprise and its products obtain, and the internal life of the firm (such as

corporate culture, HRM and so on). The development of a new service concept combines product, process, organization and market innovations, as well as technological and social innovations.

The cases presented here have been selected because innovation in services normally includes many factors: new products, new processes, organizational and delivery systems, new market behavior, etc. Thus the cases can illustrate the various aspects of innovation.

The final section will sum up the theory and findings.

The Basic Position: A ‘Soft’ (or Non-functionalistic) Evolutionary Approach

The use of the concept of strategic reflexivity is not based on a universal interpretation of the development of the firm. The development of the firm is historical, which means that firms act in different ways in different situations. Further, the theory of innovation employed here is not a general theory of the firm. This theory only concerns how firms develop, which means how they change and innovate.

The theory of innovation presented here may be characterized as an evolutionary theory. However, it is not a ‘hard’ evolutionary theory such as functionalistic versions of Darwin’s biological theory of ‘the survival of the fittest’ (cf. Smith, 1977). Such theories are based on the belief that a limited number of factors guide the selection process and the individuals or species which meet those requirements will survive. The task for the firm, according to the hard version of a social evolutionary theory, is to find out what these factors are, and then the future development of the firm can be predicted. The hard versions are based on linear determination chains.

The hard versions of evolutionary theory can also be found within economics and sociology. Hannan & Freeman (1989) have postulated a theory of organizational ecology concerning which firms will survive competition. An example of a hard version is also Nelson & Winter’s (1982) attempt to find the ultimate mechanism of the development of the firm, a mechanism they called a ‘routines’. Another example is the use of the concepts of knowledge and competence as explanation of the development of the firm, cf. Hodgson (1998), and Hamel & Prahalad (1994). The theories of social change in the 1950s and 1960s (Barnett, 1953; LaPierre, 1965; Moore, 1963; Ogburn, 1950; Rogers, 1995—most of which were based on Tarde, 1895) are examples of sociological theories, which used the diffusion of technology as a core concept to explain social change. A ‘hard’ evolutionary theory is fundamentally functionalistic: those organisms (e.g. in economics—firms) that develop the best functions in relation to the environment will survive.

Modern biology has, based on studies of ecological systems, launched a ‘soft’ version of evolutionary theory (Eldredge, 1999; Jørgensen, 1992; Krebs, 1988;

Prigogine & Stengers, 1986). The development of species is created by many factors and by relations between these factors. There are many determinants, and even relations may be determinants (cf. the discussion within physics between Bohr, Einstein and others about relativity, e.g. that measuring instruments distort the results). Such interdependencies mean that imbalances in the system often happen, but there are also periods of balance. The development mechanisms are extremely difficult to grasp because there are so many, and they differ from situation to situation. Future development cannot, or only with extreme difficulty, be predicted and general laws may only be stated in terms of probability. In such a system, the individual or species has better possibilities to influence the system to its benefit if this person or species can act consciously. However, the individual or species may be prepared of other individuals and species will also attempt to influence the system to own their benefit. The entrance of other actors means that not only will there be a competition between these two actors, but the competitive behavior of the actors may also affect the system, and thus change the rules of survival. This ‘soft’ evolutionary model can be applied to social and economic systems such as a firm, and this is what is attempted here. The ‘soft’ variant is not functionalistic: it claims that the firms which survive and grow are not necessarily the ‘fittest’. The firms which are most successful at the moment can be the least successful in the very near future. The firm can not rely on routines (cf. Nelson & Winter, 1982) and existing capacities: it must continuously reflect and frequently develop new strategies to influence the market system and to grow. It may even change the rules of survival.

The ‘soft’ evolutionary system can be characterized as a ‘chaotic system’ as in the modern version of the mathematical chaos theory (Devaney, 1992). This theory says that the system is complex, and there are no straight lines and no simple cause–effect relationships, so one cannot predict the outcome of a certain causal factor. The system may seem to be without any order, but, some patterns are repeated throughout the system. For example, cascading running water seems to flow coincidentally, but some types of whirl can be found at several places in the whirlpool. Thus there is a certain probability of finding a particular whirl type in a certain part of the whirlpool. Chaos theory has been applied to social systems as well (Kiel & Elliott, 1996; Quinn, 1985; Stacey, 1993). An example of how it has been applied is project-organized firms such as those which are research- and development-intensive. Their organization may be without much formal structure, having no formal leaders, and every person has several roles in different projects. The organization seems to be anarchistic to a certain degree. However, one may find some patterns that are repeated. For example, in most project teams, certain roles are developed such as those

of the conflict-solving person, the critical person who asks questions, and the person who presents creative, new ideas, etc.

The 'soft' evolutionary system could also be characterized by a metaphor drawing on the modern version of health, a series of physical, psychological and social factors, all of which influence our health. A complete explanation of the total system cannot be provided, but explanations of parts of the system can, however, even sub-systems can be influenced by changes in other sub-systems. If, for example, social conventions among the managers in the managerial system are changed, they may influence the informal social conventions that exist among the employees making them less creative and less interested in participating in innovative activities.

The insecurity of the evolutionary system is the reason why strategic reflexivity is so important. Strategic reflexivity is the firm's attempt to manage its competitive behavior. The firm should beat its competitors and set the rules under which the market system functions so that they are advantageous to that particular firm.

Axioms of the Innovation Theory

I will now discuss how innovation and change can be theoretically understood by using the notion of strategic reflexivity. This is a new approach and demands that some axioms be stated. I will therefore start with three statements that define the framework for the coming detailed discussion.

First Statement: Innovation Concerns Human Beings Within the Firm

In recent decades, in both economics and business administration, there has been an increasing interest in innovation, knowledge management, technological development, organizational learning and so forth. Innovation may be seen as the core notion within this group. Innovation is something that is going on in firms and in systems of firms (cf. Edquist, 1997; Nelson, 1993).

Fundamentally, the reason for the increasing interest in these topics is a desire to understand the development of the firm as an explanation for economic growth. If we are really to develop such an understanding, we need to go back to Schumpeter's work (1934) and his views concerning economic development. To Schumpeter, economic development means new solutions to society's problems and needs. One could see the process of developing new solutions in terms of social change, which a sociological discipline was called (e.g. LaPiere, 1965; Moore, 1963). However, one does not need to formulate the notion of social change in a functionalist manner within a 'hard' evolutionary approach. The process of diffusing the innovation does not need to be rational in the sense that a problem can be defined, and the new element solves

that problem. The diffusion of a new element can be caused by people just choosing another way of living, which the new elements make possible (Barnett, 1953).

Introducing the concept of strategic reflexivity re-introduces the idea of social change but in a 'soft' evolutionary way. However, here the idea is restricted to social change within firm organizations, and it is also limited to economic actions. The latter means actions which—directly or indirectly—lead to initiatives taken in the market.

The objective of the strategic reflexivity approach thus is broader than new, physical products of technology. The approach emphasizes the behavior that leads to the development of the firm, economic growth, and social change. Innovation is traditionally identified as the result of that behavior—a new product, a new production process, etc. (Coombs et al., 1987; Freeman & Soete, 1997). The results (the innovations) are of course important since they change the world. However, if we want to understand and explain the development process so that we are in a position to guide it, we need to study it. The process is therefore more important than the results. That is why innovation in this chapter has been defined as the process as well as the result (however, compared to the traditional innovation theory, the emphasis is on the process).

Innovation could be interpreted as a process of social change. New elements are invented and diffused throughout society changing it, our lives or particular sub-structures of the society (such as how we transport ourselves, how we spend our free time, how we work, etc.).

Actions, including innovation, are undertaken by persons in a social system. The approach here is to understand innovation and change as sociological processes which take place within the firm organization and between the persons within the firm and outsiders.

Second Statement: The Changes Are Neither Institutional Nor Unpredictable Anarchical

The process of change that innovation (and the small changes) brings about do not follow a constant trajectory and are not totally anarchical and unpredictable. Innovation and change is a trial-and-error process, but one which can be managed to some degree. However, the management must be ready to introduce new principles of management in each phase of the trial-and-error process, since the conditions for the innovative activity may change for each phase.

Understanding innovation in terms of the notion of strategic reflexivity differs from the institutional approach that has become popular in social sciences during the last decade (Hodgson, 1993; Nielsen & Johnson, 1998). Innovation patterns and change are not institutionalized processes and cannot be. Some institutional theories try to respond to this fact and maintain the institutional approach by saying that change itself

can be institutionalized (Johnson, 1992; Nelson & Winter, 1982). A social system such as a firm can be oriented towards change, and change becomes a value and a norm. However, the point is that the conditions of change are constantly changing, and so new goals, values, norms and types of actions are regularly needed. Thus it makes no sense to call such a change system an institution. Institutions are systems where norms, action patterns and goals are relatively permanent (e.g. the family, the church). To call the firm's innovation and change system an institution within the framework outlined here would be a complete watering down of the concept 'institution', which would then just mean a social system or structure. The interpretation of the development of the firm presented in this chapter thus implies a critical approach to institutional theory's explanation of change.

The interpretation also implies that a firm's development cannot be explained by any deterministic, trajectorial approach. Theories of path dependency have been presented (e.g. Dosi, 1982; Freeman & Perez, 1988; Teece, 1986), stating that people's behavior become institutionalized. People follow well-known paths, even when they participate in a change process. The fact that they participate in a social system also leads them to follow existing paths because the change process is a social process, and people are conservative when they operate within a social system. Innovations are seen as a result of logical trajectories which exist within the system of innovation (cf. Dosi, 1982; Freeman & Soete, 1997). This is only partly true. People and even social systems are able to break the inertia and trajectory and create new paths. They can innovate rules and new ways in which the innovation process is managed and executed.

The path dependency theories come from within the technology-economic paradigm (e.g. Dosi et al., 1988; Mensch, 1979; Piatier, 1984; Rosenberg, 1972—cf. Sundbo, 1998a), which emphasizes the technology and science push. The technology and science push precondition is valid in some industries and firms (e.g. high-tech) where the scientific discoveries and technological inventions are so useful and marketable that they guarantee market success. However, this only happens in the minority of situations. In most firms, it is difficult to market an innovation and difficult to know which innovations will be successful. Therefore, the firms will act carefully and follow the way of strategic reflexivity. The rise and fall of the ICT-software-Internet industry in 1999–2000 illustrates how, in such a short time, even a high-tech industry can rely on technology push as its driving force.

Recently, there has been a tendency to treat knowledge as the key factor in explaining the development of the firm and economy (Eliasson, 1989; OECD, 1996). However, this is also insufficient. Some theories explain firms' behavior as if knowledge in itself

presents the solutions and way forward. According to these theories, knowledge is the determinant and therefore the most important factor in explaining economic growth (e.g. Boden & Miles, 2001; OECD, 1996). Within the framework adopted here, knowledge is not such a determinant. Knowledge is an important raw material, but it is people who, in the social change process, create changes by using knowledge. The people decide which knowledge to select. Firms may often follow a technological or other trajectory (e.g. a service professional trajectory; cf. Sundbo & Gallouj, 2000). However, they may often have greater success by not adapting to the most advanced steps in a trajectory, but by using low technology or technology from another trajectory, adding services to the product, or just changing the trajectory. Innovation through strategic reflection is not just knowledge but action, as the entrepreneur theory states (Binks & Vale, 1990; Schumpeter, 1934). The human will to act—even if it does not make sense in terms of existing knowledge—is the most important. This assumption also makes innovation into a social process where self-interest, firm policy and so forth play a role.

Certain patterns can be established for firms' innovative behavior. Such patterns could, for example, be that some firms follow a technological trajectory where the technological inventions determine the innovations that the firms develop. Another pattern could be that the firm establishes a strategy, picks up different technological elements and mixes them with new organizational and marketing elements (cf. the chapter by Veryzer in this book).

An individual-anarchical approach has characterized the early innovation and social change literature (e.g. Johannisson, 1987; McClelland, 1961; Menger, 1950; see also Sexton & Kasarda, 1992), inspired by the individual approach of the two classic authors, Schumpeter (1934) and Tarde (1895). The entrepreneur has been seen as the change agent and the one who creates innovation, and the entrepreneur is an individual. Since entrepreneurs are creative, the change process is anarchical and unpredictable; there is no pattern. However, single individuals alone do not create innovation within modern firms. They may play an important role (cf. Drucker, 1985; Kanter, 1984; Pinchot, 1985), but the innovation is developed within a social system in which several individuals take part in the process. The implication of these assumptions is that the innovation process in the firms follows certain—but not universal—patterns and is not completely anarchical.

Third Statement: Managers are Seeking Interpretation and Social Interaction

Managers are seeking the efficient solution for the firm's development. To find that demands interpretation of the environment and of their own possibilities (statement of the internal resources; cf. the resource

based theory of the firm, e.g. Penrose, 1959; Grant, 1991). A seeking interpretation becomes the result of the attempt to efficiently develop the firm. The managers within the firm look for the best interpretation of the future way to go and the best kind of innovations. However, they are uncertain of which interpretation and which solution is the best. Therefore, they turn to other people—particularly the employees—to discuss and develop the best solution. They engage in reflexive strategic behavior, which is an interactive social process that creates innovation (as already stated; cf. also Gallouj, 2002).

The Development of the Firm: Innovation and Change by Reflexive Learning

In this section I will outline the theory of strategic reflexivity. I will first discuss the relationship between innovation and small changes, and how both these phenomena can be included in the theory. Next, the discussion of the theory starts by emphasizing its point of departure, the market and strategy, which are connected to firms' market relations. After that, I will discuss the concept of reflexivity, which emphasizes the internal processes that take place in the firm. I will sum up by discussing how the innovation and change processes result in reflexive organizational learning.

Innovation and Change

The border between innovations and what are called here small changes is fluid (cf. Sundbo, 1997). The small changes are improvements in given situations and are not reproduced, and individually they do not, therefore, lead to a significant development of the firm. How can the management benefit from the many small changes? By making them as reproducible as possible, which is achieved by creating a general learning system in the organization. The other employees in the firm ought to imitate these changes, and the organization should collect knowledge about the experiences.

Firms develop through a mixture of two types of activities. First, more formalized innovation activities, which may be both top-down and bottom-up. Second, many small changes which are made general through organizational learning, which means the imitation of best practices within the firm.

The firm develops by learning from the innovation activities and the launching of new products and other innovations, as will be explained later. This form of development can be characterized as reflexive learning based. In the reflexive organizational learning the firm unites the innovation and small change efforts into a common one, which is to develop a better awareness throughout the company of possibilities for the future development of the firm.

Innovation is a Market-Oriented Development Process

The point of departure, and the end goal, for any innovation process is the market because that is where

the firm makes its profit, which is the ultimate goal. Marketing as an explanation of the development of innovation processes can also be found in the chapters by Veryzer and Trott in this book (see also Kotler, 1983).

The firm has to interact with the market. It must 'read' market trends and must innovate either to keep up with the trends or to alter them and be in a position to create the market trend. The firm also has to follow the effects of its own market behavior to see whether it is successful or not.

This market-oriented approach emphasizes the pull side of the development process—how the market possibilities determine the development process. However, as mentioned earlier, the firm is also characterized by following some trajectories (the push side).

Strategy

I will now go on to the core discussion of the firms' development process. The notion of strategic reflexivity is the core of the development theory discussed here. Therefore, I will start by defining what I mean by strategy in this section, and by reflexivity in the next one.

Important for the firm's development is not the actual market situation, but the future one. The firm has to make an interpretation of where the future market, including the wants of the customers and the competitors, is moving. For example, whether customers' preferences in the future become more ethically determined, they want extra services attached to the products or new, innovative competitors may occur in the future. Then the firm has to choose its direction and make a strategy which defines its goals in terms of its market position and its development. Furthermore, the strategy defines (at least generally) how the firm should reach these goals. The strategy is the means that the firm uses to navigate through the uncertain waters of the market.

The strategy is based not only on market possibilities, but also on the internal resources (competencies, financial strength, customer relations, innovation capabilities, etc.) that the firm possesses (Sundbo, 2001). Further, the strategy is based on the organization and the employees (including the managers) that the firm has and their competencies. The future development of the firm must be created by that organization and the employees and managers, or by some other employees or managers that the firm hires externally. The firm may also change the organization and its way of functioning, for example by creating a new corporate culture, a new organizational structure, or by employing new people with new competencies.

When I say *the firm* interprets the future market possibilities, and decides the strategy, I mean some person(s) within the firm, namely the top management. It may very well be that the other employees are also involved in this process, or it may be that the

interpretation and strategy are formulated by only some persons within the top management, or by managers outside the top management. However, the top management has the final responsibility.

The strategy is the framework for making decisions about the development of the firm, including innovation, and is also a source of inspiration for innovative ideas (since the strategy tells people where the firm wants to go). Innovation and change activities should follow the strategy and be within its limits. The top management has the task of ensuring that the firm's development is in tune with the strategy, but the firm's development is not a totally rational process where the management can guarantee the outcome. The management will attempt to carry out the process rationally and will succeed in many situations but also fail in many others. The management could fail, for example, because the interpretation of the market and competitors' moves turns out to be mistaken, or the people in the organization act in unforeseen ways, or the necessary resources cannot be procured.

The strategy is therefore continuously under consideration. If it seems to be wrong, it should be corrected. Again this is not always a smooth rational process. It is a difficult decision when and how to change the strategy, and it cannot be rationally based, although some rules of sense may be used.

Strategy has been understood in different ways (cf. Chaffee, 1985; Mintzberg, 1994; Sundbo, 1998b): rational, processual, intentional, and political. Here I present an interpretation of strategy as interpretative and processual, which means that the strategy is a result of reflections about the business environment. Further, strategy is also a result of reflections over internal resources, and an interpretation of where the business environment will move in the future.

Reflexivity

Until now I have discussed strategy. Strategy marks *that* the firm has to find its way through an uncertain but arbitrary predictable future market. The other part of the central concept employed here is reflexivity, which concerns *how* the firm finds its way, and when it should change its ways or perhaps even strategy. The concept of reflexivity belongs to theories of organization, and emphasizes the process aspect of those theories (which is another aspect of the organization apart from the structural one).

Reflexivity as a Form of Human Behavior

Reflection is based on the assumption that people seek to act rationally. They try to set up a strategy for themselves, or the social system in which they participate. However, they cannot in situations which are changing rapidly just rely on existing routines and trajectories, and consequently individuals' behavior becomes reflexive.

Reflection occurs at the level of the individual member of the organization whether he or she is a manager or an employee. Reflection means that the individual considers an unknown future with arbitrary outcomes. One must mobilize all the formal, trajectory knowledge that one has, and use it creatively to produce new solutions. One has to break norms and patterns to develop new solutions, and get them accepted and implemented. At the same time, one has to ensure that the social system (in our case the organization) is not completely dismantled, because learning from the past, which is useful, may then end, leading to the demise of the firm. Otherwise, one has to choose to follow existing routines and patterns.

Is reflection an automatic reaction, a biological, behavioristic response to a stimulus (as Pavlov's behavioristic theory expresses? (Pavlov, 1966)) Or is reflection an intentional behavior, manifestation of which demands an act of will, and here even an act of creativity (which means that the individual or a social system has to remember to analyze the situation, and that it may be possible to do something new in a situation)? The assumption here is definitely the latter. Studies of innovation tell us that there are no systems, based on nature, which simply respond to economic stimuli.

Reflections are considerations that individuals make about innovation possibilities, and the development of the firm based on three premises:

- (1) The goal for the development of the firm (which is expressed in the strategy, which is mostly, but not always, taken as the framework for reflections);
- (2) The knowledge that the individuals possess;
- (3) Ideas of what could be concretely done.

The concept of reflexivity has become popular within contemporary sociology (e.g. Bourdieu & Wacquant, 1994) and is one of the core concepts of Ulrik Beck's work (1992). He discusses reflexivity in relation to what he describes as the risk society—a complex and dangerous world, which is primarily due to environmental pollution, in which we now live. The citizen becomes occupied by the possibility of considering what pollution means for his or her life and what can be done about it. The citizen becomes dependent on experts for making these considerations. Another approach within sociology emphasizes that people themselves become reflexive or employ strategies towards the world in their everyday life. This latter approach is based on the assumption that contemporary citizens have become more individualistic, better educated, more career-oriented, etc. This approach has been argued for by Anthony Giddens (1984), for example. However, such ideas are not new; similar thoughts can be found in Durkheim (1933), where he expressed his worries concerning the early industrial society.

Reflexivity as an Organizational Factor

Reflection implies interaction. The individual makes his personal reflections in interaction with other people, and the firm's reflections are also based on interaction: the result of a collective, social process as mentioned before. Generally, the group will be the unit which reflects, and may often be good at doing so, but individuals may do better. Despite being potentially better, individuals often talk to others to reduce their responsibility for unsuccessful innovations.

I view that part of the organization which carries out the innovation activities as being a dual organization (cf. Daft, 1978; Sundbo, 1998b). On one level it consists of the top management, who primarily have the task of managing the firm's development, and lower line management which is responsible for day-to-day production. The top management may consist of one or more managers. Generally, one may talk about a management structure (which may differ depending on the number of managers). The top management concentrates on the firm's general lines of the firm's development, which primarily means the strategy, but also ensures that the innovation and the reflection processes are running smoothly. On the other level, the dual organization consists of the employees and the middle managers. They are all placed within a formal structure, but they establish a network structure, which is informal, loosely coupled and interactive. This loosely coupled network structure is not a part of the formal structure of the organization; it cannot be found in the official schemes depicting the organization. Nevertheless, this structure exists and is created by the organization's members. It is part of their social nature, and it creates a common organizational culture. The network structure is a 'greenhouse' for innovative ideas and informal reflections because it constitutes a collective, a creative milieu. The network structure operates in relation to specific tasks such as innovations, analyses, the storing and use of knowledge and experiences, etc.

The development process (innovation and reflection) may be a top-down process where the top management takes the initiative and involves the employees. It may also be a bottom-up process where ideas, knowledge and entrepreneurship come from individual employees or from a collective process within the network structure, or managers start a process of development of innovation and reflection. Often it will be a mixture of both. Whatever, the top management will guide the process and finally decide upon the usefulness of the innovations and what consequences can be drawn from the reflections that have been made by the employees and managers in the network structure. The top management structure and network structure interact. Their mutual life is often harmonious and complementary. The top management needs the network

structure to generate innovative ideas. The top managers can rarely get the ideas they need themselves and they cannot just rely on scientific or expert trajectories. They also need the network structure for reflections on whether the strategy, the innovative ideas, and the way the innovation process is organized are the right ones in a given market situation. However, if the management were not there, the firm would be broken down by individual, anarchic entrepreneur behavior. The top management keeps the firm together, the network structure cannot contribute to the firm's development without the effort of the top management. However, the relation between the two parts might also be conflictual and destructive.

Special expert departments such as an R&D department or a strategy department, which have development (innovation, strategy, analyses or reflexivity) as their formal task, are in a third position in the organization. Mostly expert departments are related to the top management because they are placed in a hierarchical structure, but they may also play their own game, which will be organized more formally than the aforementioned bottom-up process.

Does reflexivity here mean leaving the formulation and fulfillment of the business strategy to experts or to 'ordinary people', which here would be the employees and middle managers in the firms (cf. the discussion in 'Reflexivity as a Form of Human Behavior')? Traditional innovation theory (e.g. Coombs et al., 1987; Freeman & Soete, 1997) emphasizes experts as those who innovate (researchers in R&D departments, marketing experts, etc.). The assumption here is that the effort of the 'ordinary people'—the employees and middle managers—is the most important, but that they and experts work together in the innovation process. The 'ordinary people' often ensure that innovation takes place, since experts outside the R&D department may hinder innovation (cf. Trott's analysis in his chapter of this book on how marketing experts hinder innovation).

Sometimes, the expert department (for example an R&D department) undertakes the whole innovation process, but this is very rare. Since the market and the customers' needs and reactions to innovations are the crucial factors, the firm needs information and reflections concerning these factors. The employees interact with the customers and are therefore play a necessary part in the process. Besides, many firms (service firms and small firms in particular) have no R&D department or any other expert department.

The involvement of the employees in the innovation process and the reflection process may be formally organized. This organizing will often take the form of creating project teams. The empirical part of this chapter investigates the forms the reflexivity process may take under different conditions.

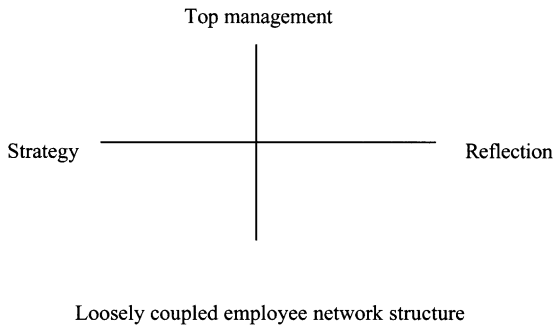

Figure 1. Model of the firm's core development factors.

The firm interacts also with several external actors and participates in formal and informal external networks to develop innovations. However, the external network is not a crucial notion in understanding the development of the firm from within the strategic reflexivity framework (as it is in the 'Uppsala school'; cf. Håkansson, 1987).

The Functional Core of Strategic Reflexivity—Organizational Learning as the Overall Process

To sum up the theoretical discussion, we can state the core of the interpretation of the firm's development function presented here and express it in Fig. 1.

The development of the firm is a dialectic process between action and analysis. The strategic part of the core notion compares to the action aspect of the model, and the reflexive part to the analytical aspect. By dialectic, I mean a situation where there are two factors, which are in opposition to each other but nevertheless only function if they interact with each other. Reflection is in conflicts with strategy because when actors reflect, they question strategy. Nevertheless, a workable strategy only exists if there are continuous reflections about its appropriateness.

The success of the firm depends on the mixture of strategy and reflection, and the management of the daily production because innovation and development are not always the primary goals. Firms develop cyclically. They will have steady periods in which they are driven by some non-innovative logic of production. If the firm is going well, there is no need to make radical changes that could destroy it. Innovation and change is risky. Successful firms may be assumed to take steps towards development only when they are aggravated by situations in the market situation (or a little before).

The other dimension in Fig. 1 is the dialectic between the top management and the informal network structure.

The whole dialectic process can be characterized as one of organizational learning, which is the overall attempt of the firm to guide the development. Organizational learning is the experience of how the four

elements of this model (cf. Fig. 1) should be combined in concrete situations. Even organizational learning can help the firm only some of the way. There are often several new factors in new situations, with the consequence that former experiences cannot be used. The learning must be combined with an entrepreneurial daring to try something new—an action perspective. I will come back to how organizational learning is carried out in 'Reflexive Feedback and Organizational Learning'.

A Case Study: The Creation of New Service Concepts and the Development of the Firm

As I have stated, the concrete way in which strategic reflexivity is developed varies according to the situation. It is assumed that certain patterns can be found, and the conditions for these patterns specified. These patterns are discovered by concrete empirical analyses, one of which we will now turn to.

Innovations in services can take many forms (cf. Gallouj, 1994). Earlier empirical analyses (Sundbo, 1998b) have demonstrated that the strategy defines the framework for the innovative activity. Here I will investigate whether strategy is developed reflexively and whether the process of developing innovations is reflexive. If the process is reflexive, it will combine considerations and corporate entrepreneurship, creativity, knowledge and learning.

I will begin this section by presenting the cases. Next I will describe how the service firms have formulated their strategies, and then move on to describe how the innovation process was carried out in the firms. Finally I will discuss learning.

The notion of strategic reflexivity and the theoretical statements established above will be the general framework for understanding the development processes. The concrete patterns that the development process follows will be investigated inductively. In the final part of the section, I will attempt to conclude whether several more general (although not universal) patterns can be identified. As far as general patterns can be identified, some models will be presented.

Empirical Data and Method

The empirical data are interviews and documentary material from case studies in different service firms. The aim is to investigate the formulation and importance of strategy, how the innovation process is undertaken, and how organizational learning is carried out. This investigation is done by studying how the service firms develop new service concepts.

Eight case studies will be used. The cases are the following: Two insurance companies, ((a) Hafnia and (b) Family Insurance), a bank ((c) Lån & Spar), a payment and credit card company ((d) The Payment Company), a chain of lawyers ((e) Ret & Råd, an engineering consultancy company ((f) COWI), a com-

pany providing cleaning and other manual services ((g) ISS) and (h) a municipal home help in one district of Copenhagen. The data have been collected throughout the 1990s in a project concerning the organization of innovation in service firms (Sundbo, 1998b) and a project on service development, internationalization and competence development (SIC, 1999).

The cases are analyzed in greater detail elsewhere (case (a), (b), (d): Sundbo, 1998b, case (c): Sundbo, 2000, case (e): Henten, 2000, case (f): Larsen et al., 2001, case (g): Sundbo, 1999; Illeris & Sundbo, 2000, case (h): Fuglsang, 2000, 2001).

The Formulation of Strategies

The firms had different ways of formulating the strategies and made different strategies. The interesting questions are: Why did they take different paths, and what made them choose different strategies?

Different Patterns of Strategy Formulation in Service Firms

I will describe briefly what the firms did—which means what the top management and other employees did. This can be placed on a scale, which is not exact, relating to the degree of control by the top management. I will start with the firm where top management's control was the greatest and work my way down to where it was least.

The insurance company Hafnia, was dominated by a top entrepreneur (who was employed as a general manager but acted like an entrepreneur. cf. Sundbo, 1998b). He decided on the strategy on the basis of his own personal purposes: insurance companies have large capital because people pay the premium before the company has to pay for damages. He wanted to use the company's fortune for investment to create industrial activities. He wanted to be a new type of capitalist. Therefore, the strategy was to create as large a premium as possible, even if the company might have high damages. The company thus selected a market segmentation strategy: they chose the private upper income market. There was a clear entrepreneurial strategy, but no reflection about whether this strategy was wise. The role of the employees was only to restrict the 'wildness' of the top entrepreneur and that was only pure reaction, not prospectively reflexive. This case demonstrates that the absence of reflexivity can be a disaster, because the company went bankrupt as the entrepreneur and some of his closest managers—who were not reflexive either—were 'too creative' in the firm's investment and accountancy policy. The company went into deficit and then went bankrupt. The social system within the firm had become a back up and follow system for this one entrepreneur and was not a reflexive one.

The home help's strategy was also decided from above, i.e. by the political system. There had been

criticisms of how the public home-help system functions for the users, absenteeism among the employees had been large, and there had been several organizational problems. A new strategy was introduced to improve client quality and job satisfaction by making the system more flexible. There had been much reflection during the political process about the purpose of the home-help organization. Further, the detailed goals and means had been discussed nationwide by professional groups within the system. However, the reflections seem to have limited effects nationwide since the same problems continued. In this particular district the strategy of the home help was adapted in a way that made it work because of the professional tradition and a particular team system that was developed (see 'Examples of Service Concepts').

The Payment Company also had a top-down strategy process. The top management formulated the strategy. However, the firm was owned by a number of banks, and it had to be very careful in its strategy not to provoke the owners, who could very easily become competitors as well. This forced the top management to take a grip of the strategy process. In return, The Payment Company had established an innovation department. Its task was to initiate the development of new service concepts among the employees and to develop a detailed strategy based on innovative ideas and the strategic arguments behind them. They should then be responsible for its implementation. The reflection thus was professionalized and the responsibility for reflection allocated to a formal department. The result was a cautious strategy of product development.

Family Insurance had a top-down strategy process as well. The choice of this form of process was due to experience. The company had had a top entrepreneur as managing director a few years before I carried out the interviews. He had got the employees and managers so occupied with innovation and change that it took up time from daily production and sale, and the company nearly went bankrupt. However, the employees and managers were still involved in innovation activities, which led to ideas concerning strategic changes, and the process was more controlled by the top management. In this case, reflections concerning the strategy were based on experience. The outcome of the process was a market segmentation strategy—the company chose the lower-income private market.

ISS is in an in-between position. The strategy process was run by an office in the headquarters, but the strategy was discussed by the managers throughout the company. The particular structure of the organization—many employees worldwide (about 250,000) and a large labor turnover—made it impossible for the firm to involve the employees and even lower managers. It was the upper managers, who were involved in the strategy process. The involvement of the upper managers was achieved by having them discuss the strategy in

local groups combined with general meetings in which all involved managers were assembled. The process resulted in a strategy which emphasized productivity increase and the development of new, specialized, manual services.

In COWI the top management had the responsibility for the strategy. The market for engineering consultancies was undergoing constant change so the firm had adopted a fluent strategy. The ideas for new strategy elements mostly came from the daily product, which is solving engineering problems for customers, organized as teamwork. The company combines technical solutions with administrative, sociological and economic approaches such as the creation of a democratic administration in a developing country. Reflection was continuous, based on the experiences from projects that should solve the customers' problems. The top management combined these with speculations about what competitors—who potentially can come from other industries—will do in the future. The strategy formulation process resulted in a careful product development strategy. Old products were renewed and some new products (among those management consultancy) were introduced.

Lån & Spar has had a very broad strategy process in which all employees and managers have been involved. The bank is a small bank in an industry with tough competition, so the strategy is a matter of survival. The top management organized training courses where the employees learned what a strategy is, were obliged to discuss the bank's strategy and were requested to present proposals for a new strategy. The final strategy was a result of very comprehensive interactive reflection processes. The top management guided the process to a certain degree since the general manager decided on the final strategy with help from his nearest managers. The bank had chosen a market segmentation strategy which went for the middle and upper income private customers.

Ret & Råd had the most extreme bottom-up process. The chain was established by a group of lawyers, who could see that the market for lawyers would be dominated by large firms. They believed that if small, independent lawyers were to survive, they needed to unite in some way. The strategy thus was one of economics of scale. The strategy of Ret & Råd was also very reflexive. Since Ret & Råd was a chain of independent lawyers, all partners had to agree to any change in the strategy. This condition ensures that everybody is equally involved in the reflection and decision process (perhaps except the employees of the single lawyer), which means that they in fact do not need to be reflexive, but only need to say 'no' to hinder the formulation of a strategy. A common secretariat has been established. The leader of the secretary wanted to develop the chain and strategy further, but it had been extremely difficult to do this. Such a chain of independent professionals seems to be conservative,

and inertia and actual self-interest seem to be impediments to the long-term development of the strategy.

General Lessons from the Service Firms

The lessons from the cases are:

The service firms have generally become more strategy- and reflection-oriented during the period under study (the 1990s). In the beginning, they were mostly focused on competitors and only moved when the competitors did. The reflexive basis was limited to competitor watch. Later, they all employed a strategy and were broadly oriented towards many actors, trajectories and internal resources and competencies. Their reflection basis was broader.

The different patterns of strategy formulation can be summed up as the following:

Some of the firms (such as Hafnia) had a top-down process of strategy formulation. Others (such as Ret & Råd) had a bottom-up process. However, most of the firms had a process that was both top-down and bottom-up. These firms had a dual interaction form of strategy formulation. This means that the top management had the final responsibility and control of the strategy process, but the employees and managers were involved in the process. The employees made the reflections in interaction with other employees and actors. The top management also discussed the strategy with their closest managers and sometimes other employees. The two systems, the top-down management system and the bottom-up loosely coupled network system among the employees, interacted with each other. The interaction implies that the initiatives and ideas came sometimes from above and sometimes from below, and these two sets of initiatives and ideas met each other and sometimes melted together. They acted in accordance with the theoretical model established in 'Reflexivity as an Organizational Factor'.

The question to address here is: Which pattern is the most efficient if the firm is to develop successfully? This is difficult to determine. In the cases presented here the two most extreme (top-down and bottom-up) ones were not efficient. The pure top-down system of top entrepreneurship in Hafnia led to bankruptcy because of insufficient reflection, and at the other extreme anarchical entrepreneurship formerly executed in Family Insurance nearly did the same. The extreme egalitarian system of Ret & Råd led to action paralysis. The home help is part of a public, political system with many actors involved in the formulation of the strategy. This did not lead to an efficient strategy, since the clients and employees saw many problems which the system had difficulties in solving. This result also suggests that a decision and reflection system that is too broad but has a weak top management is not the most efficient development system. The system in the home help is not sufficiently dual.

The majority of service firms, who had a dual form of strategy process followed a pattern in which there

was a more equal balance between entrepreneurship, top-down control and employee involvement. Such a pattern was the case with ISS, COWI, Lån & Spar and Family Insurance (during the period studied). These firms were all characterized by a defensive market situation with stagnant markets and hard competition. Therefore, they needed all the inputs they could get without losing control. The Payment Company had professionalized a reflexive strategy process. This company was in a growing market with a good, almost monopolized, situation, but with very hard owners. These firms were more successful in formulating a sustainable strategy.

One may, on the basis of the results, state another hypothesis that the more pressed the firm is on the market, the more they involve employees and managers in the development process. In a very pressed market situation, the firm needs a more radical development with a new strategy and many innovations, which is difficult in that situation. The less pressed they are on the market, the more the development process will be professionalized. In a less pressed situation, innovations within the existing strategic framework will be useful to the firm. However, in that situation, experimenting too much with new strategies should not disturb the favorable market situation. Risky experimentation could be the case if the formulation of the strategy is left to the employees. The above considerations also underlines a hypothesis of a cyclical movement (between pressed and non-pressed market situations) in the development and thus in strategic reflexivity.

The Innovation Process

I shall now turn to discuss the innovation process within the firms. The discussion and conclusions relating to the theory emphasize several elements of the organizational system such as interaction and roles. These organizational elements are important factors in explaining the innovation producing system in the service firms.

The analysis will deal only with innovation. Non-reproduced small changes exist in service firms. Since they are not reproduced, there is no process to describe, and no organizational system to analyze. These changes are important, but they are created by single employees. To study them would demand a comprehensive method of observation or diary writing. There have been insufficient resources in the research projects to use such methods. The process of creating small changes must therefore, unfortunately, be left out of this analysis.

Examples of Service Concepts

To begin with I briefly describe a few selected service concepts and how they were developed in the case firms, just to give an impression of what a service concept can be.

In Family Insurance a new insurance concept for bicycles was invented. The insurance policy could include or exclude validity at different places where the theft of bicycles has a high probability and the premium was correspondingly differentiated. The concept was developed as a collective process in one department.

An insurance agent (which is close to its customers) invented a particular questionnaire to investigate the customers' insurance needs in Hafnia. Somebody else in the company heard about the questionnaire, some of the managers discussed it with the insurance agent, and the questionnaire was developed and made general for use throughout company. The questionnaire was a product as well as a marketing tool, and functioned also as a process innovation (a tool in creating individually modularized insurance by combining standard elements).

ISS developed a new cleaning concept for small and medium-sized business customers. Instead of the normal cleaning assistants following a detailed routine managed by inspectors, the management of the cleaning division had developed a new concept. Flexible teams were established, and they agreed with the customers and planned their work themselves. The team leaders gained a special role. Not only did they manage the day-to-day work, but they did it in a way that involved the team members, and they created attractive social conditions in the teams. This behavior resulted in increased quality, productivity, customer satisfaction, and decreased absenteeism. The behavior was developed by a particular type of team leaders, typically 30 to 40-year-old women.

In the home help a similar type of team leader was developed. The process was managed by a group of managers in the district but again was the particular team leader type developed through the process.

The Payment Company developed a chip-based cash payment card. The card can be used in payment instead of cash. The card was more like a traditional manufacturing product and was developed in an R&D like department.

Lån & Spar had organized a large organization development project where the employees were involved in strategy development and innovation activities in teams. A couple of the results were two service concepts. One was a new credit card characterized by a low interest rate, and it only took very short time (about 15 minutes) to get the card due to a new IT-based credit assessment system. The credit card concept was developed by one team, which had been set up as a result of a training course. One employee became particularly engaged in the process and later became the leader of the group that produced and marketed the credit card. Another new concept was a customer database with information about the customers. The database was useful for marketing and advising. It was

developed as a collective project within the IT department.

Ret & Råd was based on an organizational innovation, namely to unite independent lawyers in a chain and to utilize their different competencies. A division of labor was established, and the lawyers remained independent. The idea was created by a few lawyers and was diffused to, and further developed by, other lawyers, who entered the chain.

The service concepts thus are of a very different kind and are developed in different ways, but in most of these cases they were developed by involving a large part of the organization.

The Innovation Process and Strategic Framework

Earlier analyses of some of these cases have demonstrated that the strategy was the framework for the innovation activities (Sundbo, 1998b). The strategy thus generally functions as a limitation of, but also inspiration for, innovative activities. This is as more the true the more top management emphasizes the strategy, and invites the employees to develop new ideas. The middle managers have a particular role here. They are generally the most innovative people, they implement the strategy and top management's effort in the day to day work, and they often become leaders in the interaction process.

One might assume that the employees and managers would have a greater self-interest that makes them fight for their own ideas. They do, but their ideas were within the strategy. They had to be that to be accepted in the firm and this acceptance is the basis for personal success and career. New ideas were, in rare cases, implemented just by entrepreneurship and were then results not of reflections but of pure action orientation. Sometimes the entrepreneurs succeeded, which resulted in a change of the real strategy, but mostly they were squeezed out and may have established their own firm.

Thus, the process of strategic reflexivity is continuing in the innovation process. Corporate culture, which has been seen as a fundamental factor for creating innovation (e.g. Sjölander, 1985), might not be the most important factor as my empirical studies demonstrated. Culture is a long-lasting, fundamental factor and therefore not reflexive and not strategically based. Culture cannot change as fast as strategy. Corporate culture might be reflexive in the way that it is created by the management as Schein (1984) says. However, the corporate culture is then part of the strategy, and the strategy is the core key to understanding the social processes within the firm.

The case studies have demonstrated that people within the organization can be oriented towards being innovative. Such an innovation orientation demands a comprehensive effort from the management, but that may be done, as the Lån & Spar case demonstrates (Sundbo, 2000) even though there are problems in

doing this. The problems are also demonstrated in the Lån & Spar case. The employees in the bank have been more occupied by the general motivation factor—how they relate to other people and how they can personally learn from change processes—than by innovating.

Patterns of Interaction

The ideas for innovation are often developed in a certain pattern within the interaction system. These ideas may be the result of the employees' daily interaction, for example with colleagues and customers. Even when the customers are the source of ideas, the innovative idea in most cases is a result of the interaction between the employee and the customer. The customer has a problem or a want, which the employee cannot guess unless he meets the customer. The customer does not express his or her wants or problem as an idea for a new service concept. The employee translates the interaction into an idea for a service concept. That was how the insurance agent in Hafnia developed the Hafnia questionnaire. The development of the idea and the implementation of the service concept are also interaction processes in which several employees and managers from different departments participate.

In the case firms I found different interaction patterns, which can be generalized. The interaction patterns reflect the way in which ideas for innovations come to the surface and the innovations are developed. These are generalizations, and the interactions had more details, which followed different ways in the single case. Now I will outline the main patterns (a development of innovative organizational models that have been studied previously; Sundbo, 1998b). The interaction patterns also show the power system within the firm and how the organization in general is built and functions.

Four different interaction patterns can be identified. The first one is the most top-down pattern found in Family Insurance and Hafnia. The top management guided the process by signaling which type of service concept was wanted and often picked out which persons should work with an idea. The interaction was of course between these persons, but the top management was deeply involved in almost all interactions. This pattern could be called *the management pattern*. A particular variant was Hafnia where the managing director was the entrepreneur himself. The interaction system was largely centered around commenting and developing his ideas.

The pattern in Ret & Råd and The Payment Company could be called *the professionalized pattern*. A particular department had the task of initiating new service concepts and of initiating interactions in the organization to develop the concepts. In Ret & Råd, the professional secretariat of the network had to convince the independent lawyers of the new ideas, which made the task extremely difficult. The leader of the secretar-

iat quitted his job during the period of investigation because of the difficulties in getting changes accepted in the network.

The third pattern is *the team pattern*. Service concepts are developed through an intense interaction process within a team. The team members also interact with external individuals and the top management, but the main part of the interaction is within the team. Only in the final implementation period is the interaction pattern diffused to a larger part of the organization. This pattern was found in COWI, ISS and the home help.

Lån & Spar had the most extended interaction pattern for development of new service concepts. A very large part of the organization was involved. The top management participated in the daily interactions—although the managing director had the power to decide on all service concepts, and did that after having consulted other managers. This fourth pattern could be called *the total pattern*.

Role Patterns

In the development of new service concepts people had different roles in the interaction process. These roles have different functions in getting the innovation process running. Role is a core concept within social psychology and sociology (Maccoby et al., 1966; Parsons, 1951) and is a useful concept in this analysis. Formerly some roles in Family Insurance and The Payment Company have been described (Sundbo, 1998b). These roles were: the entrepreneur role, which is creation of ideas and struggle for implementing them (the entrepreneur is a type exposing him—or herself very much); the analyst role, which has the reflection function and analyses the possibilities and outcomes—this is a purely reflexive role; and the producer role. The first two had a function in the innovation process while the third concerns the effort of having the daily production system running. A role is something that the organization members play when he or she is at work. An individual does not need to play the role the whole time and can play several roles simultaneously.

From the other case studies referred to here, I can identify three roles which fulfil three functions in the innovation process of developing service concepts. These are the *entrepreneur* and the *analyst*, as were formerly found, plus a new role, the *interactor* (Sundbo, 2001), which has the function of having the interaction process running. Theoretically, one may state that a balance with all three roles equally represented is the optimal for innovation (here we can forget the producer role because we only are dealing with innovation). This can be expressed in the model of Fig. 2.

Interaction is what makes this system of role mixture reflexive in relation to the pure entrepreneurship system. The process where more than one individual is involved leads to more reflection due to a certain

opposition (cf. Tarde, 1897). Opposition means that there is always a certain skepticism towards new ideas.

Reflexive Feedback and Organizational Learning

Theoretically one must state that if the social system is reflexive, the innovation processes should result in learning: the experiences about how the process went and how the innovations worked in practice should be collected, analyzed and result in strategic changes. The reflexive practice should result in a feedback to the overall goal, the strategy.

The feedback mechanism concerns how suitable the actual strategy and the way in which the innovation process is carried out are. Firstly, the feedback mechanism includes how the learning of the innovation processes could result in a change of the strategy. An experience might for example be that the firm has difficulties in implementing certain innovations, which could result in a change of the strategy. Secondly, the feedback mechanism includes how learning about the innovation process could result in a change in the way in which the service concept development process is organized and carried out. It might, for example, be that some project teams function badly or there are difficulties in engaging the employees in developing new ideas.

The total feedback and learning development process can theoretically be expressed in the model shown in Fig. 3.

The process starts with reflections concerning the market and the internal resources. The reflections are interpreted by the management, which leads to a strategy. The strategy leads to innovation processes that—in this case—resulted in new service concepts. Experiences from the innovation process may lead to a change in the strategy or in the way of carrying out the innovation activities, which is another reflection. When the final outcome of the innovation process (here, the service concept) has worked for some time, further considerations may lead to the conclusion that a new market position or new internal resources are needed, which are further processes of reflection.

All these processes are experience-based learning, which leads to feedbacks to earlier factors in the model. The reflections may involve theoretical elements (found in management books or procured from consultants), but these will be considered within the framework of the concrete experiences.

The model above is of course very formalized. The model might give associations to cybernetics (e.g. Beer, 1964). The real processes are not fully rational and may have all variants of extra loops, inefficiencies, and mistakes as the empirical cases demonstrate. Therefore, the postulate here is not that the process is a smooth-running efficient process that can be described by a cybernetic model. The model is an abstract heuristic model that presents the elements in

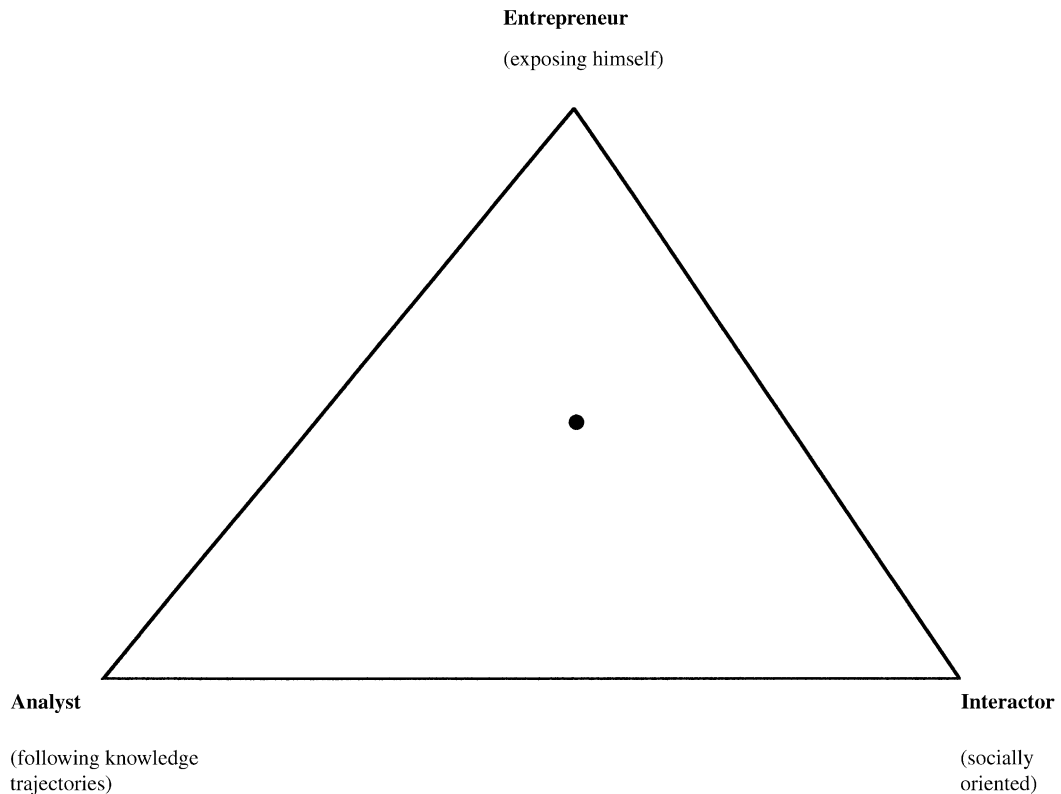

Figure 2. Model of the roles in the innovation process.

the process. The real pattern is chaotic as stated, so the real model should be extremely complex, which would be impossible to draw.

Examples of some chaotic elements of the model in real life can be found in the case studies. Organizational learning functioned generally poorly in the service firms studied. The firms wanted to collect the experiences from innovation processes but had difficulties. For example Lån & Spar had difficulties, even though the management actively attempted to create a feedback system, and the title of the total organiza-

tional development project was ‘the learning organization’ (Sundbo, 2000). The difficulties were caused by at least two factors. One was that the employees and managers were not interested in formally registering the general experiences. Such registering was considered an activity that counts not as a valuable competence but as a bureaucratic duty. Further, the bank had difficulties in storing the experiences. They tried to use note sheets in the IT system, but that did not work as a general learning data bank and the experiences were not systematized.

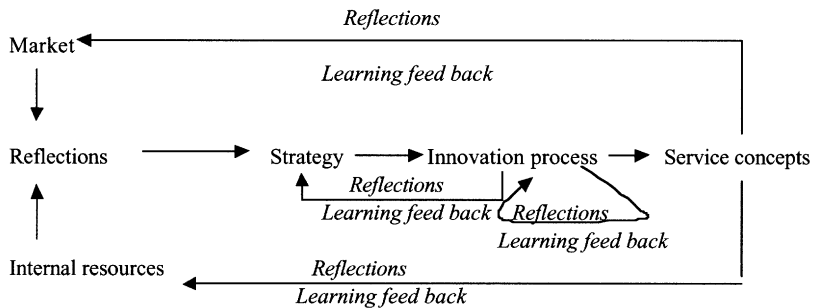

Figure 3. Model of the organizational learning process and feedback mechanisms.

COWI had difficulties in collecting experiences from the work and development in the project teams. The team members were already engaged in new projects before the first ones were completed and never did have time to systematize the experiences and communicate them to other parts of the organization.

The strategy was changed as a consequence of innovation experiences in some of the service firms. Family Insurance changed their strategy from being innovative and going for an advanced market segment to going more conservatively for the medium- and lower-income private market due to its experiences with problems of managing the internal personnel resources (whether they should be innovative or productive). The Payment Company has recently changed its strategy away from launching technical tools such as the chip-based cash payment card back to basics, credit cards, because of a failing market.

Summing Up

This chapter has presented a theoretical approach to the development of the firm, namely a strategic innovation theory (cf. Sundbo, 1998a, 2001, 2002). The theory focuses on the activities that lead to innovations. This theoretical approach is a 'soft' evolutionary one. Primarily, the firm relates to the market developments and this is decisive for its innovation activities. However, the firm also relates itself to the internal resources and their ability to contribute to the development. External trajectories, which include new knowledge and technology, also play a role, but only by presenting possibilities; they do not determine the development of the firm. The firm's relation to these factors is expressed in the strategy, which is not just a written plan, but a management policy.

The strategy defines the goal(s) for the development of the firm in broad terms and is the overall means for attempting to guide the firm's development. This statement expresses a quasi-rational approach: the top management attempts to steer the process, but that is only possible to a certain degree. The top management becomes dependent on involving the employees and middle managers in all steps of the process—from formulating the strategy over innovation activities to organizational learning.

Innovation and change can be characterized as a process of strategic reflexivity. The strategic reflexive process is a process of innovation and of small changes made by individuals or small groups. There is a certain organizational structure within which these activities are carried out, but the structure varies in different situations.

Therefore, innovation cannot be described by one causal or descriptive model, but certain patterns, which vary and are repeated in different combinations, may be observed (as is expressed in chaos theory; cf. Kiel & Elliott, 1996; Quinn, 1985; Stacey, 1993). In the chapter, such patterns were investigated in one type of

firm, namely different service firms. The results of this investigation were:

The processes are taking place in a reflexive, interactive organization system as was demonstrated by an empirical case: the development of service concepts. Four interaction patterns within the innovation process could be observed. The interaction process depends on three core roles as entrepreneur, analyst and interactor.

A theoretical organizational learning system in the form of a feedback mechanism was outlined. This learning system is learning by experience and reflexive. The feedback loops may lead to a change in strategy (and thus the way the firm should go in its innovation activities) and of how the innovation activities should be carried out and organized.

Empirically, it was observed that the service firms had difficulties in establishing efficient feedback mechanisms and learning because employees and managers were not motivated to do this and because of a lack of tools for storing the experiences.

The Nature and Dynamics of Discontinuous and Disruptive Innovations from a Learning and Knowledge Management Perspective

Elias G. Carayannis¹, Edgar Gonzalez¹ and John Wetter²

¹ School of Business and Public Management, The George Washington University, Washington, D.C., USA

² Xerox Corporation, USA

Abstract: In this chapter we will discuss and profile the evolutionary and revolutionary dimensions of the nature and dynamics of innovation as a socio-technical phenomenon. We will focus in particular on the *process, content, context, and impact* of both *discontinuous* and *disruptive* innovations. We postulate that at the heart of the competence to generate and perhaps more significantly *to leverage discontinuous and in particular disruptive innovations, lies the individual and organizational capacity for higher-order learning* and for managing the stock and flow of specialized and domain-specific knowledge. We will provide both concepts and cases to illustrate our ideas and supply thematic anchors for academic and practitioner contexts.

Keywords: Disruptive innovation; Discontinuous innovation; Higher-order technological learning; Knowledge management.

Introduction

A little revolution now and then, is a good thing

Thomas Jefferson

‘Innovation’ is a word derived from the Latin meaning ‘to introduce something new to the existing realm and order of things’. In this sense, innovation is endowed with a faculty of discontinuity and possibly disruptiveness in the form of a continuum of discontinuities reflected by a simple analogy to the way we walk. From a business perspective, an innovation is perceived as the happy ending of the commercialization journey of an invention, when that journey is indeed successful and leads to the creation of a sustainable and flourishing market niche or new market. Not all innovations are discontinuous, and not all discontinuous innovations prove to be disruptive. This is determined by the scope, timing, and impact of the innovation under consideration.

The literature on innovation, particularly regarding technological innovation, is populated by a number of taxonomies which attempt to categorize innovations by

significance, similarity (and dissimilarity), technical domain, and other characteristics. As the vocabulary used to describe innovation has grown and evolved, scholars naturally generate multiple taxonomies which are at times overlapping, redundant, or divergent. A recent review of the literature on new product development found that in just 21 empirical studies, researchers have developed 15 different constructs for describing various aspects of innovation (Garcia & Calantone, 2002). Some of the distinctions produced by previous authors include *process vs. product* innovation (Utterback & Abernathy, 1975), *incremental vs. radical* innovation (Henderson & Clark, 1990), and *evolutionary vs. revolutionary* innovation (Utterback, 1996):

Technological innovation is defined here as a situationally new development through which people extend their control over the environment. Essentially, technology is a tool of some kind that allows an individual to do something new. A technological innovation is basically information organized in a new way. So technology transfer amounts to the

communication of information, usually from one organization to another.

This chapter focuses on the recent discussion by Christensen (1997) of *disruptive* (as opposed to sustaining) technologies, and the related concept of *discontinuous* (as opposed to continuous) innovation (Anderson & Tushman, 1990). This particular type of innovation is significant, as there have been many attempts to determine the extent to which discontinuous innovations can be ‘managed’, and how companies can try to predict and leverage the emergence of disruptive technologies. In this chapter we will discuss and profile the evolutionary and revolutionary dimensions of the nature and dynamics of innovation as a socio-technical phenomenon and focus in particular on the process, content, context, and impact of both discontinuous as well as disruptive innovations.

We postulate that at the heart of the competence to generate and perhaps more significantly to leverage discontinuous and in particular disruptive innovations, lies the individual and organizational capacity for higher-order learning and for managing the stock and flow of specialized and domain-specific knowledge. We will provide both concepts and cases to illustrate our ideas and supply thematic anchors for academic and practitioner contexts.

The Nature and Dynamics of Innovation

Basic research is what I am doing when I do not know what I am doing.

Dr Wehrmer von Braun

Before a definition of innovation can be discussed, the related term ‘invention’ must be understood. Florida considers invention as a breakthrough and innovation as an actualization (Florida, 1990). Hindle further clarifies invention by labeling it as the creative origin of new process and the enabler of innovation (Hindle, 1986), which has impacts on social, economic, and financial processes. Thus the emerging definition of invention may be stated as the creative process of progress while innovation is defined by the impact on societies and markets (actualization). “Innovation generally lowers the cost of responding to a change in the commercial environment” (Wallace, 1995). Thus, innovation has the connotation of market influence.

Identifying the source of innovation may assist in the definition. The pace of improvements brought about by innovation, the rate of innovation, may be determined by the technology pull or market push factors. The question of a specific source of innovation is brought about by a process of ‘*learning by doing*’ (Rosenberg, 1976). In this is meant that innovation, through the continuous incremental effects of knowledge acquisition, has the effect of cumulatively impacting on future innovations.

Other related terms, like science and technology, should be defined in the context of innovation. Traditional epistemology defines science and scientific knowledge as the world of objective theories, objective problems and objective arguments. Further clarification is found in Kuhn (1962) defining *science* as research firmly based on one or more past achievements.

Technology is defined as that “which allows one to engage in a certain activity. . . with consistent quality of output”, the “*art of science and the science of art*” (Carayannis, 2001) or ‘*the science of crafts*’ (von Braun, 1997). Diwan adds that technological foundations are market size, standards, innovation, high motivation, and supply of capital (Diwan, 1991) The impact of innovation may be directed to multiple sectors. For example, Jonash lists product/service, process, and business innovation as the key impact areas. Product/service is the development and commercialization of hard goods, process is new ways of producing and delivering cost-time-quality advantages, and business innovation is new models of conducting business for competitive advantage (Jonash & Sommerlatte, 1999).

A fundamental challenge to the present analysis is the distinction between what is and what is not an innovation. When related to technologies, one common definition of an innovation is “an idea, practice, or object that is perceived as new by an individual or other unit of adoption” (Rogers, 1983, p.11). Thus, a technological innovation is a new idea, practice, or object with a significant technology component.

A technical discovery or invention (the creation of something new) is not significant to a company unless that new technology can be utilized to add value to the company, through increased revenues, reduced cost, and similar improvements in financial results. This has two important consequences for the analysis of any innovation in the context of a business organization.

First, an innovation must be integrated into the operations and strategy of the organization, so that it has a distinct impact on how the organization creates value or on the type of value the organization provides in the market.

Second, an innovation is a social process, since it is only through the intervention and management of people that an organization can realize the benefits of an innovation.

The discussion of innovation clearly leads to the development of a model, to understand the evolving nature of innovation. Innovation management is concerned with the activities of the firm undertaken to yield solutions to problems of product, process, and administration. Innovation involves uncertainty and dis-equilibrium. Nelson & Winter (1982) propose that almost any change, even trivial, represents innovation. They also suggest, given the uncertainty, that innovation results in the generation of new technologies and changes in relative weighting of existing technologies

(ibid). This results in the *disruptive process* of dis-equilibrium. As an innovation is adopted and diffused, existing technologies may become less useful (reduction in weight factors) or even useless (weighing equivalent to '0') and abandoned altogether. The adoption phase is where uncertainty is introduced. New technologies are not adopted automatically but rather, markets influence the adoption rate (Carayannis, 1997, 1998). Innovative technologies must propose to solve a market need such as reduced costs or increased utility or increased productivity. The markets, however, are social constructs and subject to non-innovation related criteria. For example, an invention may be promising, offering a substantial reduction on the cost of a product which normally would influence the market to accept the given innovation; but due to issues like information asymmetry (the lack of knowledge in the market concerning the invention's properties), the invention may not be readily accepted by the markets. Thus the innovation may remain an invention. If, however, the innovation is market-accepted, the results will bring about change to the existing technologies being replaced, leading to a change in the relative weighting of the existing technology. This is in effect dis-equilibrium.

Given the uncertainty and change inherent in the innovation process, management must develop skills and understanding of the process a method for managing the disruption. The problems of managing the resulting disruption are strategic in nature. The problems may be classified into three groups, *engineering, entrepreneurial, and administrative* (Drejer, 2002). This grouping correlates to the related types of innovation namely, *product, process, and administrative innovation*:

- The engineering problem is one of selecting the appropriate technologies for proper operational performance.
- The entrepreneurial problem refers to defining the product/service domain and target markets.
- Administrative problems are concerned with reducing the uncertainty and risk during the previous phases.

In much of the foregoing discussion, a recurring theme about innovation is that of *uncertainty*, leading to the conclusion that an effective model of innovation must include a multi-dimensional approach (uncertainty is defined as unknown unknowns whereas risk is defined as known knowns). One model posited as an aide to understanding is the Multidimensional Model of Innovation (MMI) (Cooper, 1998). This model attempts to define the understanding of innovation by establishing three-dimensional boundaries. The planes are defined as product-process, incremental-radical, and administrative-technical. The product-process boundary concerns itself with the end product and its relationship to the methods employed by firms to produce and

distribute the product. Incremental-radical defines the degree of relative strategic change that accompanies the diffusion of an innovation. This is a measure of the disturbance or dis-equilibrium in the market. Technological-administrative boundaries refer to the relationship of innovation change to the firm's operational core. The use of technological refers to the influences on basic firm output while the administrative boundary would include innovations affecting associated factors of policy, resources, and social aspects of the firm.

A Historical and Socio-Technical Perspective on Innovation

But in capitalist reality, . . . it is not price competition which counts but the competition from the new commodity, the new technology, the source of supply, the new type of organization, . . . competition which . . . strikes not at the margins of the existing firms but at their foundations and their very lives.

Joseph A. Schumpeter
Capitalism, Socialism and Democracy, 1942

To review the history of innovation, one must look toward the classic works of Schumpeter. Schumpeter, an economist, wrote 'The Theory of Economic Development' in 1934 as an inquiry into profit, capital, credit, interest, and the business cycles. His main contributions were: (a) the expansion of Adam Smith's economic principles of land-labor-capital into land-labor-capital-technology-entrepreneurship; and (b) the introduction of the concept of dis-equilibrium into economic discourse.

It is interesting to note that Schumpeter was a socialist and believed that the capitalist system would eventually collapse from within and be replaced by a socialist system. On this point he agreed with Marx, but his version of socialism was in many respects very different. Marx felt very strongly that the economic model employed would determine the construct of society. The cornerstone of his theoretical structure was the 'Theory of Value' (*Das Kapital*) where the value of a commodity, given perfect equilibrium and perfect competition, is proportional to the input of labor. Schumpeter disagreed with Marx on this issue offering the conclusion that both perfect equilibrium and perfect competition were problematic at best. Additional disagreements centered on the inclusion of the value of land in the equation. Another point on which Schumpeter disagreed, is Marx's contention that the capitalist system would implode (*Zusammenbruchstheorie*) as a result of its intrinsic inequities. In Schumpeter's view, the natural evolution of capitalism would destroy the foundations of capitalism from within. In fact, he believed that the economic depression of the 1930s was an indication of a paradigm shift, reinforcing his beliefs. Schumpeter viewed capitalism in much the same way as he viewed the process of innovation. Both

were generally considered stable processes (under perfect conditions) from a theoretical model perspective but Schumpeter introduced the conceptual theory of dis-equilibrium as the key influential factor and this could be further expanded into the concept of continuum of punctuated dis-equilibria (Carayannis, 1994b) to capture and articulate the concept of successive Fisher–Pry curves (S-curves) with discontinuous and/or disruptive innovations causing a change of curve and/or change of ‘the rules of the game’ as we will see later:

Michael Tushman and Charles O’Reilly suggest that discontinuous innovation involves breaking with the past to create new technologies, processes, and organizational ‘S-curves’ that result in significant leaps in the value delivered to customers. Similarly, Clay Christensen, Gary Hamel and C. K. Prahalad, and James Utterback describe discontinuous innovation as involving ‘disruptive technologies’, ‘discontinuities’, or ‘radical innovations’ that permit entire industries and markets to emerge, transform, or disappear (Kaplan, 1999).

Early capitalism is often referred to as ‘laissez-faire’ but post-WWII capitalism is much more bounded by social, political and legal norms. In following Schumpeter’s principle of evolutionary capitalism, it may be that the bounded capitalism of the modern era is a logical extension of Schumpeter’s theory.

The concept of innovation as a ‘socio-technical’ system is well established. Rogers (1995), for example, defined innovation in terms of the perceptions of the individuals or groups which adopt an innovation. Attempts to classify innovations in purely technical terms fall into the trap of portraying the result of a social process as something entirely divorced from human influence.

We propose an approach to classifying and subdividing the concepts of innovation along four fundamental dimensions:

- (1) The *process* of innovation (the way in which the innovation is developed, diffused, and adopted)
- (2) The *content* of innovation (the specific technical or social nature of the innovation itself)
- (3) The *context* of innovation (the environment in which the innovation emerges, and the effect of that environment on the innovation)
- (4) The *impact* of innovation (the social and technological change which results from the completion of the innovation process) (Carayannis, 2002).

Using these four dimensions of innovation, we can delve more deeply into the social implications of disruptive and discontinuous innovation, which in turn facilitates the integration of innovation management concepts with those of organizational learning and knowledge management. In putting these elements in

perspective, one needs to bear in mind the following key creativity and innovation drivers and qualifiers:

- (1) Context: In what context do all of the above occur?
- (2) Process: What is the process by which the above are realized?
- (3) Content: What is the content of the above in terms of reaction on the others?
- (4) Impact: What is the impact of each of the above on the others?
 - All of these attributes must be considered at all levels including the firm, industry, national and global levels;
 - What you invent determines the content of the innovation;
 - Commercialization is a necessary but not sufficient condition for innovation;
 - Creativity and competition may be exogenous factors to competitiveness;
 - Competition facilitates or suppresses competitiveness (see Fig. 1);
 - Consolidation may breed complacency;
 - Disruptive technologies can renew competitiveness.

However, excessive rivalry may sap competitiveness leading to the *Acceleration Trap* (von Braun, 1997) and the *Differentiation Trap* (Christensen, 1997) (see Fig. 1). These are situations of increasingly shorter and unsustainable product cycles and spiraling R&D costs with shrinking profit margins and market shares—the result of excessive competition and declining competitiveness (what we term *hyper-rivalry* in the private sector). In these situations, change takes place so fast that firms often fail to benefit fully from it (their learning curves are not steep enough) and they also end up using resources inefficiently and undermining their market position by engaging in price wars or frivolous innovation races. Then firms can find themselves ‘trapped’ in a vicious spiral of increasing competition and declining competitiveness and end up rendering their market niches increasingly hard to sustain.

Common Frameworks and Typologies for Characterizing Innovation

Comforted by idols, we can lose the urge to question and thus we can willingly arrest our growth as persons: ‘One must invoke tremendous counterforces in order to cross this natural, *all too natural progressus in simile, the continual development of man toward the similar, average, herdlike common!*’

Nietzsche, Thus Spake Zarathustra, 58

Innovation may be generally categorized as product, process, or administrative (Tidd, 2001). Others classify innovation by regional influences (Evangelista et al., 2001), or decision criteria (Rogers, 1995). Still others view innovation as product-process-radical-techno-

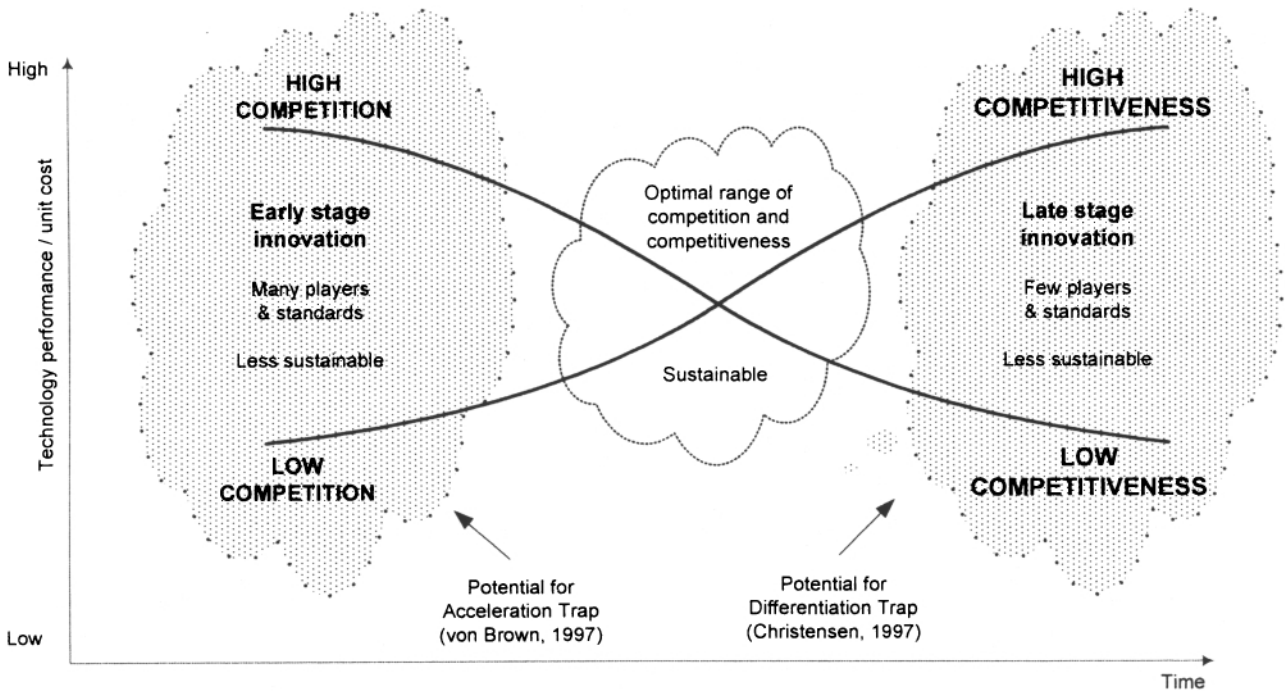

Figure 1. Competitiveness vs. competition trade-offs.

logical (Cooper, 1998). Another view of classifying types characterizes innovation by decision systems (Rogers, 1995). This method relies on the principle that adoption of innovation may be influenced by both individuals and entire social systems. There is also a distinction between sustaining and disruptive innovations (Christensen, 1997) and continuous and discontinuous innovations (Tushman, 1990):

Discontinuities are often described as technological breakthroughs that help companies rewrite industry rules or create entirely new industries. Rarely have distinctions been made within the concept of ‘discontinuity’, not to mention how to identify these radical innovations. For the corporate strategist, a big question remains: how to actually structure opportunity identification so it becomes a rational process—one that yields breakthroughs reliably (vs. waiting for opportunities to arise serendipitously) (Kaplan, 1999).

Process innovation refers to change in the methods employed by a firm in delivering products or services. An example is the use of Internet technologies for supply-chain management, where the process of ordering, tracking, and billing would be Internet-based. *Product innovation* reflects change in the end product or service of the firm. An example of product innovation is the addition of a new feature such as adding a remote to a television to improve the user interaction. *Administrative innovation* refers to change in the characteristics of organizational or institutional elements. Changes in policy, organization structure, or resource allocation are examples of administrative innovations.

Using regional differences to classify innovation is a very narrow view, usually reserved to a specific technology innovation comparison. One of the drawbacks with this method is assessment of the regional nature of an innovation. For example, in the case of R&D measured by the number of patents, the region of patent invention may differ from the locale of registration—especially in the case of multinational corporations (MNC). A patent for an invention of Asian origin may be initiated in a U.S. patent filing if the headquarters is a U.S. MNC—thus the patent would be considered U.S. if measured regionally.

Integrating numerous past studies on technological innovation (especially those by Abernathy, Anderson, Clark, Henderson, Tushman & Utterback) produces a common framework distinguishing four generic types of technological innovation: *incremental*, *generational*, *radical* and *architectural*.

Incremental innovations exploit the potential of established designs, and often reinforce the dominance of established firms. They improve the existing functional capabilities of a technology by means of small scale improvements in the technology’s value-adding

attributes such as performance, safety, quality, and cost.

Generational or next-generation technology innovations are incremental innovations that lead to the creation of a new but not radically different system.

Radical innovations introduce new concepts that depart significantly from past practices and help create products or processes based on a different set of engineering or scientific principles and often open up entirely new markets and potential applications. They provide ‘a brand-new functional capability which is a discontinuity in the then-current technological capabilities’.

Architectural innovations serve to extend the radical-incremental classification of innovation and introduce the notion of changes in the way in which the components of a product or system are linked together.

Another common distinction is the difference between *evolutionary* innovation, where technological change appears to follow a process of ‘natural selection’ (with technical improvements resulting from the ‘survival of the fittest’) and *revolutionary* innovation, where the change appears as a break or non-contiguous change in the course of the technology. These two approaches to envisioning innovation are not mutually exclusive, however.

Using the four perspectives given above, we can show how these concepts relate to one another in a more complete framework for the analysis of innovation.

Process	Content
Evolutionary innovation	Incremental innovation or Generational innovation
Revolutionary innovation	Radical innovation or Architectural innovation

The complete framework with all four dimensions provides us with a way to relate *discontinuous and disruptive* technologies to these other concepts.

Process	Content	Context	Impact
Evolutionary innovation	Incremental innovation	Continuous innovation	Non-disruptive or
	Generational innovation	Continuous innovation	Disruptive innovation
Revolutionary innovation	Radical innovation	Discontinuous innovation	Non-disruptive or
	Architectural innovation	Discontinuous innovation	Disruptive innovation

Not all innovations are discontinuous, not all discontinuous innovations prove to be disruptive and not all disruptive innovations are discontinuous. This is determined by the scope, timing, and impact of the innovation under consideration and there are different strategies to deal with the challenges and opportunities arising from planned or serendipitous technological discontinuities and disruptions. Christensen (1997, p. 179) recommends three strategies for leveraging such contingencies and specifically in the case of ‘*technological performance over-supply*’ that creates the potential for *an acceleration and/or a differentiation trap* (von Braun, 1997) (see Figs 2 and 3):

- Strategy 1 is to ascend the trajectory of sustaining technologies into ever-higher tiers of the market;
- Strategy 2 is to march in lock step with the needs of customers in a given tier of the market;
- Strategy 3 is to use marketing initiatives to steepen the slopes of the market trajectories so that customers demand the performance improvements that the technologists provide.

Kaplan (1999) discusses four strategies for leveraging such contingencies:

Substantial growth over the long horizon requires discontinuous innovation—disruptive technologies, radical innovations and discontinuities that permit entire industries and markets to emerge. Soren Kaplan’s experiences as process technology manager with Hewlett-Packard’s Strategic Change Services in Palo Alto serves as a framework for all businesses dealing with the new innovation paradigms. He proposes four strategies: radical cannibalism, competitive displacement, market innovation and industry genesis. A strategy involving industry creation has a big advantage in that direct competition does not usually exist. It results in a new form of customer value with a new-to-the-world value proposition.

The Process of Innovation

The lowest form of thinking is the bare recognition of the object.

The highest, the comprehensive intuition of the man who sees all things as part of a system.

Plato

An adequate definition of the process of innovation is inherently problematic. The field is nascent and there seems to be as many different definitions as there are researchers. However, there is sufficient information available to evoke a common understanding on many points.

The innovative process is defined by the correlation of its elements of study (Nelson, 1977). Inventions may be measured and the R&D process may be studied and defined. Science and invention may be linked, sources

of innovation elaborated upon, organization factors investigated, the evolution of technology studied, diffusion of innovation measured, and the learning phenomena exposed. Invention is viewed as complementary, cumulative, and leap-frogging (Rosenberg, 1982). *Complementary invention* is the invention of a new process/product that is related to an existing technology; the invention of the mouse to support computer-human interaction is an example. *Cumulative inventions* are those that build upon, or ‘tweak’ an existing invention, such as a product improvement like the pouring spout on juice containers. Leap-frog invention infers a radical change away from existing technologies and echoes discontinuity in markets.

In understanding the process, one must understand the concept of innovation ‘imperative’ (Cooper, 1998) as a key driver. In a competitive environment, managers are driven to success, both individually and organizationally. In order to achieve organization success, the manager must do more than develop, implement, and approve innovation. They are compelled to constantly innovate in order to attain success, driving the organization to higher levels of innovation diffusion.

Most models of innovation are based on three basic ideas (Drejer, 2002). First, organization can act to create or choose their environment. Second, management’s strategic choices shape the organization’s structure and processes. Third, once chosen, the structure and processes constrain strategy. This is a very interesting insight into innovation models. If an organization can choose its environment, and if the choice is rational, it should be able to choose the best environment for success of its strategy. There are numerous examples of firm strategies that did not perform as expected. Is this principle negated by non-performance of strategy? It may be that exogenous factors influence the choice of environment. This is an interesting question for further study but it is not in the scope of this paper.

In the U.S., economic policy has an influence on innovation. In general, U.S. policy may be categorized as selective targeting (Nelson, 1982). Historically, U.S. policy could not necessarily be labeled as supportive of innovation. Advances have been uneven (disruptive) and slow to influence productivity and relative costs. This is evidenced by a review of Total Factor Productivity (TFP) comparisons:

TFP was developed by Solow in 1957 as the Growth Theory and has become the dominant approach to measuring productivity. Solow’s theorem is that the Productivity Residual is uncorrelated with any variable that is uncorrelated with the rate of growth or in other words the Productivity Residual is a measure of the shift of the production function (increase in efficiency). TFP considers the traditional inputs to productivity of labor and output and adds

Figure 2. Competitiveness vs. competition trade-offs.

the dimension of the influence of capital. TFP is often referred to as Solow's residual. Prior to TFP, measurement of productivity was subject to factors that may incorrectly influence the outcome, like a rise in demand or a rise in price would cloud the real measurement. It is interesting to note that the TFP calculation is neutral to a rise in demand or a rise in price.

The TFP residual is considered to be an indicator of R&D performance and, as such, can be a measure of the effectiveness of innovation—at the industry or national level. Many researchers (Nelson, 1982) have concluded that TFP residual, as a measure of industry wide R&D effort, is more influential than measuring a single firm.

There are several key recurring principles of innovation. They are an integrated organizational approach, incentives for innovators, a systematic process to convert invention into innovation, team skills, communications, learning, and project management (Rolfe, 1999). These principles are instrumental in developing a innovation process. It is interesting to note the interdependencies of learning and team skills to innovation. Generally, in a team environment, individual members of a team do not possess sufficient knowledge in themselves but if collectively the team 'knowledge sum' is greater than non-team knowledge, the team will be a successful implementor of innovation. Since the common construct of teams is subject to change, the ability of the team to retain knowledge through effective learning is an important criterion for long-term success.

Identifying innovation as a process as opposed to a discrete event or outcome is generally credited to Peter Drucker (Cooper, 1998; Drejer, 2002). The control of the process of innovation is referred to as innovation management. In this context, innovation management is defined by five key activities; technological integration, the process of innovation, strategic planning, organizational change, and business development (Drejer, 2002). Technological integration refers to the relationship between technologies and the product of the firm. The process of innovation is the set of cross-functional activities that create and sustain innovation. Strategic planning involves the planning of technologies related to the innovation. Organizational change comprehends the disruptive nature of innovations on knowledge/skill requirements, new markets, new employees, etc. Business development refers to the creation of new markets for the products of innovation. It is interesting to note that innovation may be a driver of business development and also may be driven by it. This dichotomy may be explained by the fact that, in the early stages, innovation causes a disruptive change in the organization by its very nature, creating new markets for example. As the business evolves, 'technology pull' becomes evident. As competition catches up

or competitive innovations become evident, the requirement for more and more innovation to maintain market position will surface, thus causing the firm to drive innovation.

The organization is influenced by innovation in several ways. Creativity is driven by competition, change, externalities, learning, climate, communications, processes, and social interaction of individuals (Rolfe, 1999). While innovation is a purposeful act, the prime characteristic is uncertainty (Nelson, 1977). This characteristic tends to influence the set of drivers affecting the organization. In this way, as characteristics such as creativity drive innovation, the creativity itself is impacted. The impact may be positive or negative, and so the creativity may be changed and strategic plans may ineffectual. Soren Kaplan (1999) discusses the four types of discontinuities identified at Hewlett Packard and outlines a framework that could serve as a guideline for technology managers and policy makers alike:

We have discovered four types of discontinuities through our work at HP. As a result, we have developed a framework to help leaders with discontinuous innovation opportunity identification—the process of exploring new revenue streams and identifying compelling propositions for providing heightened forms of customer value. This is the strategic intent that defines compelling new business possibilities capable of driving substantial growth. The framework takes the perspective of an organization that wishes to explore opportunities for discontinuous innovation and is founded upon three assumptions. First, we believe discontinuous innovation involves creating new forms of customer value within existing or new markets. Second, by pursuing discontinuous innovations, organizations create new competitive space or displace existing methods of delivering value to customers. Our final assumption involves the structure of the model itself. We define four discrete innovation strategies but suggest that these classifications not be regarded as mutually exclusive. Instead, these categories should focus efforts on opportunity identification by providing an understanding of 'gray areas' that all too often cloud the definition of 'discontinuity' (Kaplan, 1999).

Measures of Innovation

Truth emerges more readily from error than from confusion.

Sir Francis Bacon

How should innovation be measured, if indeed it can be measured? Research and Development (R&D) is generally the initial measurement tool utilized (Evangalista et al., 2001) but R&D itself may be measured based on different attributes. For example, as an R&D/Intellectual Property rights (IPR) measurement, the

number of patents is generally the measurement axiom. However, other attributes are frequently measured also, such as research funding budgets, number of researchers, number of significant inventions, number of new products, amount of published research, etc. (Tidd, 2001). Still, other attributes are linked in a more subtle way, such as increased productivity and growth or lower costs (Nelson & Winter, 1982). Another classification of measurable characteristics is the social impact of innovation. Examples would include the ability to measure the user benefits, lower consumer prices, user time savings, and other social enablers (Mansfield et al., 1977). A typology of measurable characteristics may help to bring together the disparate measurables (Table 1).

The main categorization is between ‘hard’ and ‘soft’ measurables. Hard measurables are those characteristics that may be directly linked to the innovation process. For example, the number of patents issued is direct outcome of the process of research and generally is not influenced by outside factors. Productivity improvements, however, may be the direct result of an innovation but the link is less clear due to other influential characteristics—productivity increases could be influenced by the mere fact of managerial increased interest surrounding the implementation of a productivity innovation. This is not to assume that the innovation was not the primary influence of productivity gains but rather the measurement process may not be sufficiently rigorous to differentiate the various influences.

R&D has a direct effect on output. In studies conducted in the manufacturing field, it was noted that *applied* research and development funding was a more powerful explanation of differences in productivity growth across manufacturing industries than total R&D funding by the entire industry (Nelson, 1977). This would indicate that R&D expenditures are a direct measure of firm productivity. Firm productivity is

greater than the norm, as expressed by industry norms.

The adoption of measures of innovation may be influenced by a firm’s business and technology strategy. A firm with a high profit objective, may choose to measure innovation characteristics that have a proclivity to specific goals (Nelson & Winter, 2000). This type of weighting may be more beneficial when characteristics are more directly linked, namely, hard measurables.

Managing Innovation Through Knowledge Management and Learning

Until philosophers are kings, or the kings and princes of this world have the spirit and power of philosophy, . . . cities will never have rest from their evils—no, nor the human race as I believe . . .

Plato, *The Republic*, Vol. 5, p. 492

The proposition that innovation can be ‘managed’ has been explored by numerous authors. For example, Burns & Stalker (1961) wrote their book *The Management of Innovation* based in part on an earlier study of the research and development laboratory at a local company. Whereas industrial innovation previously seemed to occur in a haphazard and disorganized manner, the post-war era brought strong interest in the idea that innovation could occur systematically, and could even be ‘planned’. The merging of the field of organization studies (e.g. Cyert & March, 1963) and the study of the function of management (e.g. Barnard, 1938; Drucker, 1999a, 1999b) provided a new foundation for understanding the innovation process. Further studies on innovation form the basis for a new field of expertise and knowledge on the nature of technological and organizational innovation. Knowledge management is not always fully or properly understood by managers. Instead, in many cases, practitioners and often academics mean information and technology

Table 1. Innovation measures—hard vs. soft.

Hard Measurables		Soft Measurables	
Characteristic	Measure	Characteristic	Measure
R&D	<ul style="list-style-type: none"> • Patents • R&D Budget • New Products • R&D Staff • Publications • R&D Incentives • New Features • Inventions • New Markets • Product Extensions • Conferences • CRADAs • Partnerships 	Impact	<ul style="list-style-type: none"> • Productivity • Growth • Lower Costs • Flexibility • Supply/Demand • Firm Size • Market Influence
		Social	<ul style="list-style-type: none"> • User Benefits • Lower Prices • Social Enablers • Time Savers

management when they talk about knowledge management. Knowledge management is more about the art of truly understanding organizational culture dynamics and accessing, leveraging and sharing tacit know-how:

A McKinsey survey of 40 companies in Europe, Japan, and the United States showed that many executives think that knowledge management begins and ends with building sophisticated information technology systems.

Some companies go much further: they take the trouble to link all their information together and to build models that increase their profitability by improving processes, products, and customer relations. Such companies understand that true knowledge management requires them to develop ways of making workers aware of those links and goes beyond infrastructure to touch almost every aspect of a business (Hauschild et al., 2001).

The Role of Knowledge in Innovation

Since innovation is not a purely technical undertaking, the knowledge required for the successful management of innovation goes beyond science and engineering. Innovation can be subdivided into two domains: technical knowledge and knowledge transfer (Bohn, 1994), and learning about the administrative processes appropriate for managing technology (Jelinek, 1979). To facilitate the systematic development of innovations, an organization needs to have access to both types of knowledge: technical and administrative:

To be *organizational, rather than individual, learning*, knowledge must be accessible to others rather than the discoverer, subject to both their application or use, and to their change and adaptation Organizational learning, to be learning rather than ‘mere adaptation’ must be generalized. It must go beyond simple replication to application, change, refinement. It must include ‘rules for learning’ and their change and adaptation, rather than the rote iteration of past successful actions Finally, if learning is to include innovation, it must encompass a system for governing the future as well as the present (Jelinek, 1979, pp. 162–163).

The most challenging aspect of studying the application of knowledge to innovation is to distinguish what information is most relevant and significant to the management of innovation and what is not. The features of the knowledge embedded in the innovation process can vary greatly. Some of that knowledge will be explicit, in the form of technical papers, drawings, and other documents which are codified and easily defined, and some will be tacit, integrated into organizational routines which are transferred only through socialization and collaboration. Therefore, the successful management of innovation can clearly

benefit from a systematic approach to knowledge management.

Knowledge, learning and cognition are classical terms that have been re-discovered in the context of the information technology and knowledge management revolutions. Knowledge management can be viewed as a socio-technical system of tacit and explicit business policies and practices. These are enabled by the strategic integration of information technology tools, business processes, and intellectual, human, and social capital (Conference Board, 1996). Managerial and organizational cognition can be perceived as the human and organizational capability for individual and collective reasoning, learning, emoting and envisioning. Organizational memory, intelligence, and culture are important determinants of cognition processes at both the individual and the organizational levels. We perceive managerial and organizational cognition and knowledge management as transitions across progressively higher levels of knowledge and meta-knowledge.

The Relationship Between Knowledge and Learning Knowledge/Meta-knowledge

The main Greek achievement was to remove explanation of the workings of the world from the realms of religion and magic, and to create a new kind of explanation—*rational explanation*—which was the subject of a new kind of enquiry.

Peter Checkland
Systems Thinking, Systems Practice, 1981, p. 32

Beckman (1998) compiled a number of useful and relevant definitions of knowledge and organizational knowledge:

- Knowledge is organized information applicable to problem-solving (Dictionary (1));
- Knowledge is information that has been organized and analyzed to make it understandable and applicable to problem-solving or decision-making (Turban (2));
- Knowledge encompasses the implicit and explicit restrictions placed upon objects (entities), operations, and relationships along with general and specific heuristics and inference procedures involved in the situation being modeled (Sowa (3));
- Knowledge consists of truths and beliefs, perspectives and concepts, judgments and expectations, methodologies and know-how (Wiig (4));
- Knowledge is the whole set of insights, experiences, and procedures which are considered correct and true and which therefore guide the thoughts, behaviors, and communication of people (van der Spek & Spijkervet (5));
- Knowledge is reasoning about information to actively guide task execution, problem-solving, and

- decision-making in order to perform, learn, and teach (Beckman (6));
- Organizational knowledge is the collective sum of human-centered assets, intellectual property assets, infrastructure assets, and market assets (Brookings (26));
 - Organizational knowledge is processed information embedded in routines and processes which enable action. It is also knowledge captured by the organization's systems, processes, products, rules, and culture (Myers (27)).

Beckman (1998) proposes a five-level *Knowledge Hierarchy* in which knowledge can often be transformed from a lower level to a more valuable higher level.

A number of other authors have also proposed knowledge typologies. Nonaka & Takeuchi (7) have divided knowledge accessibility into two categories: tacit and explicit. Beckman (1998) identifies three stages of accessibility: tacit, implicit, and explicit:

- (1) Tacit (human mind, organization)—accessible indirectly only with difficulty through knowledge elicitation and observation of behavior;
- (2) Implicit (human mind, organization)—accessible through querying and discussion, but informal knowledge must first be located and then communicated;
- (3) Explicit (document, computer)—readily accessible, as well as documented into formal knowledge sources that are often well organized.

Relationship Between Knowledge and Learning

But even though the first step along the road to a momentous invention may be the outcome of a conscious decision, here, as everywhere, the spontaneous idea—the hunch or intuition—plays an important part. In other words, the unconscious collaborates too and often makes decisive contributions. So it is not the conscious effort alone that is responsible for the result; somewhere or other the unconscious with its barely discernible goals and intentions, has its finger in the pie. . . . *Reason alone does not suffice.*

Carl Jung

The Undiscovered Self, 1958, pp. 99–100

Early research on organizational learning in the context of organization theory focused most substantially on attempting to describe learning processes in organizational settings, without necessarily assigning a normative value to learning (cf. Cyert & March, 1963; Levitt & March, 1988; March & Simon, 1958; Nelson & Winter, 1982). Learning as an organizational activity is perceived as an integration of individual efforts and group interactions. Thus, organizational learning becomes a process embedded in relationships among

individuals, through such mechanisms as information sharing, communication, and organizational culture. Some authors use the action-oriented concept of the 'learning organization' to identify paths to maximize organizational learning through a systems approach (Ciborra & Schneider, 1992; Senge, 1990). This perspective presumes that firms which are better at organizational learning will perform better than others in the market.

Other authors point out that learning can decrease organizational performance. Huber (1991) notes, "Entities can incorrectly learn, and they can correctly learn that which is incorrect". Ineffective or inappropriate learning processes can erode firm competitive advantage if they reinforce incorrect linkages between managerial activities and firm performance (Levitt & March, 1988). Even effective learning processes can be undermined by changes in market and environmental conditions which render them irrelevant, or worse, damaging to firm performance. Thus, learning activities can change from core competencies to core rigidities (Leonard-Barton, 1992). It is also possible that competence-destroying technological learning can limit firm performance in the short run but lead to superior performance in the long-term when market conditions adapt to new technologies (Christensen, 1997). Therefore, there is no linear relationship between learning and organizational performance; rather, performance improvement depends on the quality, not quantity, of organizational learning.

- (1) Individual learning;
- (2) Organizational learning;
- (3) Inter-organizational learning.

Types of Learning

Computo, ergo sum. Particeps sum, ergo sum.
Cogito, ergo sum.

Rene Descartes

We identify three levels of learning, based on previous theory-building about the impact of learning on building firm capabilities and on modifying operating modes (Carayannis, 1994a, 1994b, 1994c; Carayannis & Kassicieh, 1996). In this hierarchy, we posit three layers of technological learning:

- (1) operational learning or learning and unlearning from experience;
- (2) tactical learning or learning how-to-learn and unlearn from experience; and
- (3) strategic learning or learning to learn-how-to-learn and unlearn from experience.

On the operational learning level, we have accumulated experience and learning by doing: we learn new things (Carayannis, 1994b). This is the short- to medium-term perspective on learning, focusing on new or improved capabilities built through the content learned by an

organization. This learning contributes to the management of core organizational capabilities (Prahalad & Hamel, 1990), resource allocation (Andrews, 1965), and competitive strategy (Porter, 1991).

On the tactical learning level, we have learning of new tactics about applying the accumulating experience and the learning process (redefinition of the fundamental rules and contingencies of our short-term operating universe): we build new contingency models of decision-making by changing the rules for making decisions and/or adding new ones (Carayannis, 1994b). This is the medium- to long-term perspective on learning, resulting in a process of re-inventing and re-engineering the corporation. Tactical learning enables firms to approach new organizational opportunities in a more efficient and more effective manner, and to leverage or combining existing core capabilities in novel formations for greater competitive advantage.

On the strategic learning level, we have development and learning (internalization and institutionalization) of new views of our operating universe or *Weltanschauungen* (Hedberg, 1981); hence we learn new strategies of learning (Cole, 1989). Thus, we redefine our fundamentals (our rules and contingencies) for our decision-making, or we redefine the fundamentals of our operating universe. This is the very long-term perspective on learning, that focuses on re-shaping our re-inventing and re-engineering organizational 'tools' (methods and processes) (Bartunek, 1987; Bateson, 1972, 1991; Krogh & Vicari, 1993; Nielsen, 1993). The strategic learning level involves the expansion and reformulation of concepts about the limits and potential of the firm's strategic environment, where the older framework is seen as simply a 'special case' within the new, more inclusive framework (akin to the relationship between 'normal' and 'revolutionary' science developed by Kuhn, 1962).

Strategic learning serves to 'leap-frog' to a new competitive realm and "to increase the slope of the learning curve as well as the rate by which the slope per se increases by means of enhanced and innovative organizational routines" (Carayannis, 1994b, pp. 582–583). The result is what other authors refer to as "changing the rules of the game" (Brandenburger & Nalebuff, 1996; D'Aveni, 1994) or creating new "ecologies of business" (Moore, 1996). The firm pioneers a new conceptualization of its business, its market, and/or its overall competitive environment, which gives it greater strategic flexibility not only in its own course of actions but also in influencing and leading the firms around it.

Learning/Meta-Learning

The primary process by which firms change their capabilities to better fit the environment is through learning. In the case of learning like the case of most other fundamental concepts, there is little consensus as

to what learning is and how it takes place. In economics, learning is perceived as tangible, quantifiable improvements in value-adding activities, in management, learning is seen as the source of "sustainable competitive efficiency" (Dodgson, 1993, p. 376), whereas in the innovation literature, learning is considered as a source of "comparative innovative efficiency" (ibid, p. 376). As noted in Doz (1996), there is a distinction in the organizational context between cognitive learning and behavioral learning. Cognitive learning occurs when members of a firm realize that some change is needed in a given situation; behavioral learning occurs when the organizational routines of that firm are actually changed (the implementation of cognitive learning). Expanding the concept of learning further, organizational learning occurs when the new behavior is replicated throughout the firm, leading to broad-based organizational change (Teece et al., 1997, p. 525).

Knowledge Management

Knowledge management is defined as: "the systematic, explicit, and deliberate building, renewal, and application of knowledge to maximize an enterprise's knowledge-related effectiveness and returns from its knowledge assets" (Wiig, 1993). Sveiby (1998) defines knowledge management as "the art of creating value from an organization's intangible assets". Moreover, Sveiby (1998) identifies two main tracks of knowledge management activities: one track focuses on knowledge management as the management of information and the other track as management of people.

Cognition/Meta-Cognition

Cognition is the human capacity to perceive, interpret, and reason about environmental and conceptual environmental or organizational stimuli and meta-cognition the capacity "to think about thinking, as meta-learning means to learn about learning" (Carayannis, 1994a, p. 8).

The knowledge creation, transfer, selection, acquisition, storage, and retrieval processes can be viewed from an information-theoretic (Shannon & Weaver, 1949) and a meta-cognitive (Halpern, 1989; Simon, 1969; Sternberg & Frensch, 1991) linguistic perspective (Chomsky, 1971, 1993), where the human problem-solver and technology manager is seen as both a technician and a craftsman (Schon, 1983), a 'lumper' and a 'splitter' (Mintzberg, 1989). Individuals, teams, and organizations rely on multi-layered technological learning and unlearning (Carayannis, 1992, 1993, 1994a, 1994b, 1994c; Dodgson, 1993) to create, maintain, and enhance the capacity of individuals,

groups, and organizations to transfer and absorb embodied and disembodied (von Hippel, 1988) technology in the form of artifacts, beliefs, and evaluation routines (Garud & Rappa, 1994) and tacit and explicit knowledge (Nonaka, 1988, 1994; Polanyi, 1958, 1966). Moreover, it is critical to realize that individual and organizational learning and knowledge are mutually complementing and reinforcing entities using the medium of organizational memory:

Moreover, this learning process must be endowed with an organizational memory that is both, accurate and precise to build, maintain, and renew continuously the firm's reservoir of skills and competencies: If an organization is to learn anything, then the distribution of its memory, the accuracy of that memory, and the conditions under which that memory is treated as a constraint become crucial characteristics of organizing. (Weick, 1979, p. 206.) (in Carayannis, 1994b, 2001).

In this context, it is important to remember that "knowledge does not grow in a linear way, through the accumulation of facts and the application of the hypothetico-deductive method, but rather resembles an upward spiral, so that each time we reevaluate a position or place we've been before, we do so from a new perspective" (in Carayannis, 1994b, p. 52). This concept sets the scene for the development of the Organizational Cognition Spiral (OCS), as part of our organizational knowledge management model. Organically relevant to these concepts is intuition, which Weick defines as 'compressed expertise' (Davenport & Prusak, 1998, p. 11) along with meta-knowledge as knowledge (awareness) about the knowledge you possess.

The OCS Model

A model for understanding the key issues involved in organizational knowledge management is proposed. The model defines different knowledge states that are a function of two dimensions—knowledge (K) and meta-knowledge (MK) as defined earlier and it consists of successive 'knowledge cycles' where an individual or organization can transition and traverse four stages of awareness or ignorance. As each cycle is traversed and then a transition to the next cycle occurs, the overall level of knowledge and meta-knowledge is rising (see Fig. 3).

Typically, but not always the transition takes place from *ignorance of ignorance* (you do not know what you do not know) to *awareness of ignorance* (you know what you do not know) to *awareness of awareness* (you know what you know: the result of search, discovery, and learning) to *ignorance of awareness* (you do not know what you know: the result of routinized as well as tacit awareness).

For the sake of simplicity, the dimensions are assumed to be at two levels representing the presence and absence of (meta) knowledge. The levels of the two dimensions are thus represented as K and K, and MK and MK. These two levels of the two dimensions result in a total of four knowledge states:

- (1) K, MK (Awareness of awareness);
- (2) K, MK (Ignorance of awareness);
- (3) K, MK (Awareness of ignorance);
- (4) K, MK (Ignorance of ignorance).

Organizations may exist in any one of these states that include current, desired, and/or intermediate levels. The states can be represented in the following way (Fig. 3).

Knowledge management can be viewed as the process of managing the transitions across these four states.

The evolutionary knowledge transformation process is *both differential and integrative in nature* (Carayannis, 1992, 1993, 1994a, 1994b, 1996, 1997, 1998, 1999, 2001, 2002), in that it consists of *unlearning, learning and meta-learning* components, differentiating new against old experience, selecting and retaining the currently useful knowledge modules and integrating the lessons learned throughout. This process reflects the dynamic of the synthetic progression at the individual and the organizational levels *from data to information to knowledge to wisdom to intuition*. In this manner, increasingly broader and deeper levels of *organizational knowing* (Chun Wei Choo, 1998) are attained and both quantitative as well as qualitative transformations of the organizational and individual knowledge stock and flow occur.

Case in Point: Innovation at Xerox: From Unrealized Potential to Real Success

XEROX Background & History

The last decade has given rise to the terms *old economy* and *new economy*. The old economy, industry based, traditionally has been characterized by economies of scale while the new economy, knowledge based, is considered the economy of networks—as a collaborative (Shapiro, 1999). The shift from the old economy to the new economy can be described as a paradigm shift. In Kuhn, a paradigm is defined as "an object for further articulation and specification under new or more stringent specifications" (Kuhn, 1962). In Moore, the traditional old economy is defined as a firm going up against its competition, in a win-loose scenario (Moore, 1996). The new economy paradigm is defined as market creation or co-evolution in a win-win scenario.

Xerox has a rich history of both success and failure in innovation. The successes are evident in the office environment of today. Copiers, laser printers, and

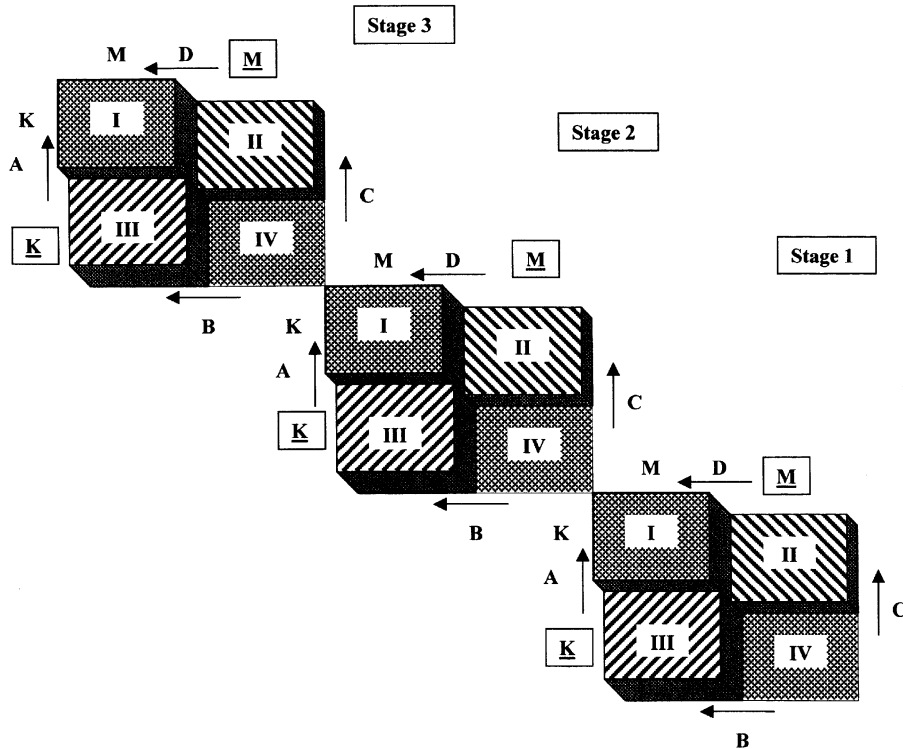

Figure 3. The Organizational Cognition Spiral (OCS).

State I: Awareness of Awareness (MK, K)—State II: Ignorance of Awareness (\overline{MK} , K)—State III: Awareness of Ignorance (MK, \overline{K})—State IV: Ignorance of Ignorance (\overline{MK} , \overline{K}). (Possible Pathways: a. IV to II to I or b. IV to III to I). The successive stages (I, II, III) denote cumulatively higher levels of knowledge (K) and meta-knowledge (MK).

networked offices are all around us, thanks to the successful innovation of Xerox. Not only has Xerox been successful on the hardware side of the office; the service (maintenance) of copiers and supplies (toner, paper, etc.) businesses is extremely successful—as well as supporting consulting services and document processing services (solutions).

The innovations of Xerox proliferate, as evidenced by over 7000 active patents in their intellectual property portfolio. However, despite the innovation successes, there have been failures along the way.

The invention of the personal computer with a GUI, desktop, mouse, Ethernet, and the first WYSIWYG word processor never led to a Xerox innovation. The same is true of the first laser printer. In both cases Xerox invented but did not innovate. It took other firms to capture and market the inventions to reach the stage of innovation.

- (1) What criteria led to the success?
- (2) What criteria led to failure?

These are important questions to be asked. The answers may help to categorize the hegemony of ideas and

define success criteria, allowing the development of methodologies for creating and sustaining innovation best practices. In studying innovation it is best to look at both successes and failures as a root-cause analysis. The following is a case study of innovation at Xerox Corporation.

On October 22, 1938 in Astoria, Queens, Chester Carlson invented what later would be referred to as Xerography. In Carlson's thinking, he was revolutionizing the office process, but he would find that the world did not see his invention in the same frame of reference as he did. Carlson, born in 1906, worked as a printer's helper during his early career, including publishing a small newsletter on his own.

This early experience impressed him with the physical difficulty of putting words on paper and sharing knowledge. Later he received a degree in physics from the California Institute of Technology and began to work as a research engineer at Bell Labs. A depression-era job loss, followed by a degree in Law, led him to a second career as a patent attorney. As a patent attorney he faced the continuous problem of never having enough carbon copies.

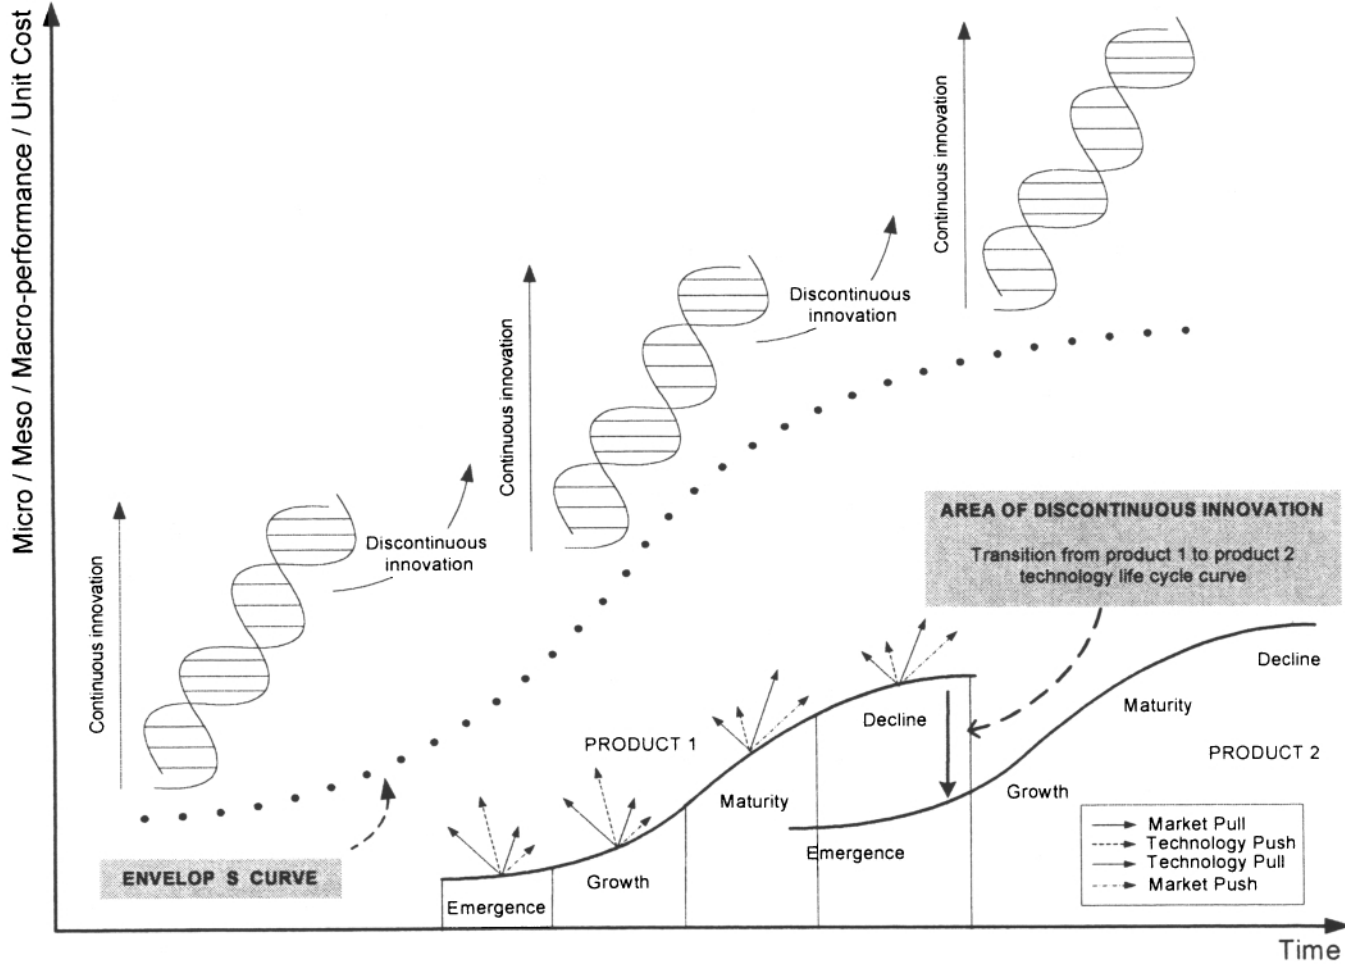

Figure 4. Continuous and discontinuous innovation: Technology performance road map.

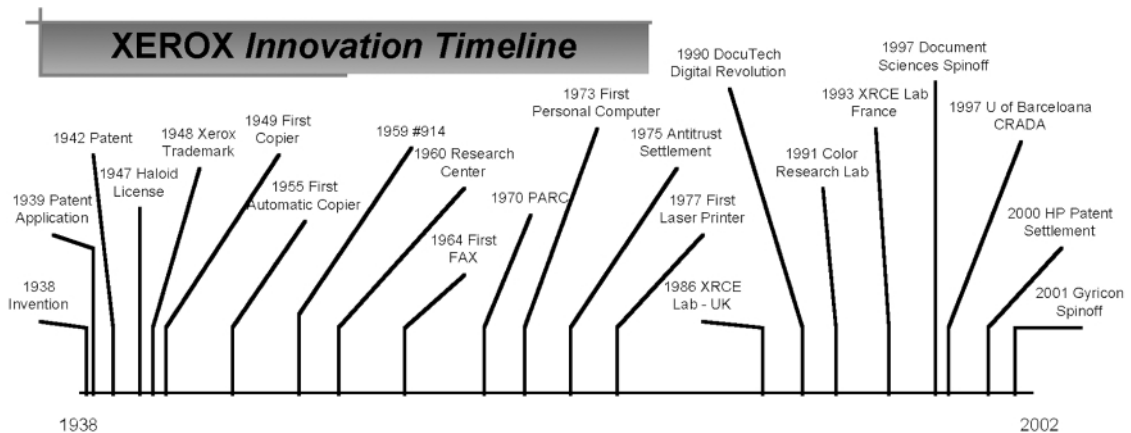

Figure 5. No caption copy supplied.

The only alternatives were to use an expensive photographic process or retyping (and reproofing) lengthy patent applications. In his spare time he researched alternative technologies, eventually finding the work of Hungarian physicist Paul Selenyi on photoconductivity. He performed experiments in his kitchen, eventually replicating the image of ‘10–22–38 ASTORIA’ on a sulfur-coated zinc plate. Innovation is not an easy process, as Carlson was to find out. He searched for a company that would be interested in financing further research in his invention. For 10 years he had no success.

The market was not ready for alternative solutions—the common thinking was that carbon copies, the current technology, were sufficient and another technology was not needed. In 1944, Battelle Memorial Institute, a non-profit research institute, became interested in assisting Carlson in further developing his invention. During the Battelle era, selenium was introduced as an improved photoconductor, and dry ink toner was developed. Finally, in 1947, the Haloid Company, a manufacturer of photo-paper, acquired a license to manufacture a machine to produce xerography. Within one year, the first Xerox copier was shipped, beginning the age of Xerography.

The early copy machine was complex to operate, but it found a niche in producing working masters for offset duplicators—one should remember that the printing technology of the period was ‘letterpress’, printing from individually cast metal images; a very expensive process. ‘Offset’ printing was in its infancy and was utilized in low-end, inexpensive printing environments.

By 1959, Haloid improved the equipment and released the no. 914 copier—the first true office copier. The no. 914 was an innovative breakthrough.

The competition of the time, the AB Dick mimeograph, 3M Thermo-Fax, and the Kodak Verifax, were eclipsed within a short period of time. The no. 914 was

so successful that it continued to be the leading technology until 1972.

Xerox continued to innovate throughout its history, albeit not always successfully. In 1973 the first desktop personal computer was developed, leading to the PC revolution. Xerox, due to marketing strategies to be discussed later, did not benefit from this development. Again, in 1977 Xerox developed laser printing but did not move quickly to capture the early market for laser printers like its competitor Hewlett-Packard.

Xerox corrected its innovation strategy when it introduced the DocuTech high-volume black & white print system in 1990, thus creating the digital revolution in putting words on paper. Xerox plans to introduce the iGen3, a color version of the DocuTech technology. It is expected that this will mark the beginning of another revolution, digital color, and bring Xerox the financial rewards of innovation.

In order to fully understand Xerox, one must view the mix of products and services and the market space that is occupied. Currently Xerox products and services may be divided into two major categories—products and services. These can be further divided from products into office, production, equipment maintenance, and the necessary supporting supplies. The services can be further divided into outsourcing, process re-engineering, Solutions (integration services), and software applications.

It is interesting to note that research into the history of products uncovered some interesting products that were once core to the Xerox portfolio—electronic typewriters, workstations, and computer systems. These are no longer in the current portfolio.

Xerox sells its products through a variety of channels including direct sales, telebusiness, resellers, agents, concessionaires, and via the Internet. These channels are managed by various organizations—see table below. The sales organization is global and divided into regional territories. The largest territory is

Table 2. Xerox innovation group research & technology centers.

Group	Location	Est.	Core Expertise	Additional Functions
Digital Imaging Technology Center	Palo Alto, CA	1994	Digital imaging 1:1 communications On-demand printing	Core competence in digital imaging
Solutions and Services Technology Center	Webster, NY	2001	Color science Image sciences and processing Systems architecture Work process studies Software development	Create, assess, acquire, apply technologies Coherence and architected set of solutions and services

Palo Alto Research Center Incorporated (PARC)	Palo Alto, CA	1970	Electronic materials Micro-electro-mechanical systems (MEMS) Semiconductor devices software Engineering, Image analysis Human-computer interaction Wireless computing Knowledge representation	Ubiquitous computing Licensing, collaborative research and spin-off creation Developed first personal computer with WYSIWYG word processor, mouse, Ethernet, and GUI Developed first laser printer

the U.S. covered by the North American Solutions Group (NASG).

It was noted that almost 50% of total Xerox employees work for Xerox Services, most of which are located physically within a customer site. One area of understanding that many researchers of Xerox find difficult, is that of the Solutions business. Xerox defines Solutions as “an integrated offering that includes hardware, software and people-based services, which solves a problem, improves a work process, or creates a market or competitive advantage”. Xerox has divided its Solutions delivery into four main business operations and focuses on production market (graphic arts firms), the office market, and services. The four groups are Documents Systems and Solutions Group (DSSG), Office Systems Group (OSG), Office Printing Business Group (OPBG), and Xerox Global Services (XGS).

Xerography was invented in 1938 but it was not until 1959 that the initial invention was actualized and became an innovation. The 19-year travel from invention to innovation was consumed with both finding a financial partner to further develop the idea (1938–1947) and later by an attempt to define the market (1948–1959). In the 1930s to 1950s the technology of the office was defined by carbon paper and the emerging offset printing process.

Carbon paper allowed for a real-time duplicate of a document, possibly up to eight copies, and early offset duplication was available for 8+ copies, but the cost of the 8–500 copies was somewhat prohibitive. What Chester Carlson and Haloid first found in the search for a market was that the perceived need for the innovation was non-existent. The challenge to Haloid was to develop a market.

The first machine to reproduce copies via Xerography was released in 1949. The market it captured was within the nascent offset printing technology. Specifically, the first Xerox copier was targeted toward making masters for offset duplication. The masters would then in turn be used in the duplicating process, thus making ‘copies’. The Xerox master copy process for offset duplication was expensive and complex to operate, and would soon be overtaken by other, photo-based less expensive technologies. As Haloid refocused its attention back toward replacing carbon paper technology, it found a winner in the 1959 introduction of the no. 914 copier. This combination of market pull and technology push would drive revenue and profits well into the 1970s. From the early Haloid days of unstructured innovation, Xerox has developed a culture of organizing for innovation. Currently, the Xerox organization chart reflects the Innovation Group as directly reporting to the CEO. This underscores the relative importance affixed to innovation within the organization.

Innovation—Faux Pas

In 1970 Xerox formed the Palo Alto Research Center (PARC), famed as the epicenter of the computer revolution. Researchers at PARC were given freedom to conduct basic research from the beginning. This led to, among other inventions, the first personal computer in 1973 and the first laser printer in 1977.

The personal computer was advanced for its time and consisted of an operating system, a WYSIWYG word processor, and a graphical user interface with a desktop, a mouse, and Ethernet connectivity. With this advanced invention in its portfolio, Xerox should have led the computer revolution—but as history shows us, Xerox did not capitalize on its inventive resources and let others drive the birth of a new market. The question to the student of innovation is why did Xerox let this happen and what can be done to avoid this type of costly mistake in the future! In other words, what is the lesson to be learned from this?

In order to understand Xerox strategies, the authors have taken the approach of investigating the history of Xerox innovation and interviewing key players of the era. In one such interview with Mr. RT, a 30-year veteran of Xerox and an executive involved in West Coast operations for much of his career, the following information was developed.

In the 1970s, in addition to PARC, Xerox had substantial operations centered on the West Coast. One must remember that Xerox is Rochester, NY-based, where the single largest geographical concentration of employees (about 16,000) is located. The visionary of the ‘office of the future’ was Joe Wilson II, then Chairman of Xerox. At that time, in addition to PARC, Xerox-West consisted of Versatec (plotters), XSoft (software application development), Xerox Network Services (Ethernet, networks), Shugart (disk manufacturing), Total Recall (scan and retrieval applications), plus a substantial copier hardware manufacturing facility. This was a very advanced portfolio of technical capabilities and capacity for the time.

PARC itself was a central clearinghouse of computer information in the early 1970s. PARC developed a professional forum as a tool for motivating researchers. Each week, PARC would host a public event to allow its researchers to present their research findings. This forum was well attended by non-Xerox professionals from universities, engineers from the nascent computer industry, and others interested in the research. This early knowledge sharing aided the birth of the computer industry in the Silicon Valley area.

When the personal computer was originally developed, Xerox strategy was to market the PC as a proprietary business-to-business tool. It was more of a ‘portable’ computer than a ‘personal’ computer. The computer consisted of a 32” wide portable unit, a hard drive basically, that could be ported or moved from location to location as required. The computer was to

be inserted into a docking station to be used. The original operating system, MESA, was unique. MESA, it should be noted, eventually became the basis for artificial intelligence systems of today.

The PC was code named STAR and it was soon marketed as the 6085 workstation. Eventually, a spin-off called GlobalView was formed and the computer later became known as the GlobalView System. There were approximately 50 applications developed, like word processing, spreadsheets, graphics programs, specialized graphics (chemical and math applications), messaging, hyperlinks, browsers, etc. It contained many features like the 'Clearing House', giving the user a shared knowledge area. One application allowed the user to create custom applications (a forerunner of JAVA). All applications were proprietary and could only be used on the GlobalView system.

Around this time, Xerox began to staff its West Coast management ranks with former IBM executives, mostly from the mainframe business. It should be noted that the emerging PC market in the 1970s was influenced by the big three of the time—Xerox, IBM, and WANG. As one may know from various studies of IBM, the mainframe management mentality was not easily aligned with what eventually became the PC market. Importing IBM mainframe-experienced managers was probably one of the greatest mistakes made by Xerox. The former IBM executives did not fit well into the existing culture of Xerox and had difficulty dispersing their ideas within the Xerox management infrastructure. Xerox executives had the correct vision but they lacked proper execution.

While Xerox may have had the vision of the 'office of the future', it was not sure how to market it. Xerox was known for selling copiers and it did this very well ('selling iron'). The PC market was forming-storming-norming and Xerox management found it difficult to predict the path the industry would take. It placed its bet on business-to-business channels, ignoring the 'personal' or hobbyist market as it was known. As business-to-business was the target market, the selection of proprietary systems may have seemed the best strategy. Hindsight gives us the knowledge that the PC industry formation was driven by the hobbyist, who was the bridge between—offering insights as to the utility of the computer for both personal and business use. With the rise of Apple Computers, the market was better defined. It is interesting to note that the main attraction of the Apple computer was the graphical interface/desktop/mouse, an idea borrowed during a visit to PARC. Another issue within Xerox, limiting the market strategy, was the sales force alignment. Xerox had a well-trained and well-equipped sales force—aligned to copiers—hardware/service/supplies driven. In order for Xerox to market its new innovation, the PC, it needed a sales force that was aligned to a different conceptual product—software driven. Xerox strategy did not take into account the realignment of its

sales force, particularly the compensation plans. Xerox possessed a successful sales force primarily because its compensation plan was very liberal. In order for the existing compensation plans to benefit the individual sales person, the only end sale of computers that was attractive, from a compensation perspective, was a multi-million dollar computer sale. In the 1970s the only clients able to invest millions in computers were already mainframe customers of IBM, WANG, Digital and others—the market for PC-based business-to-business was too ill defined for major capital investment. Large corporations were not ready to move from the mainframe to the PC, even if it was networked. In essence, Xerox was compensating its sales force to sell to a market niche that did not yet exist. In a situation like this, Xerox strategy should have been to realign its compensation plan to incentivize its sales force. The consequences were obvious. Another inhibitor to success was cultural. Xerox was Rochester, NY-based and the computer revolution was West Coast-oriented. The resulting clash of cultures led to a 'not invented here' syndrome in Rochester. Because the resources and management for supporting innovation were Rochester-based, the new inventions of West Coast origin were not readily understood. An example of this is Xerox development of web-capability technologies. The technology was developed in West Coast operations and, after development, it was ported to Rochester for further development—a clear case of cultural conflict as Rochester had little infrastructure to support the emerging web technology. Marketing decisions and funding, also Rochester-based, did not understand and strategize to align to emerging market perceptions. Copier marketing strategy was the concentration, and any marketing for the PC was aligned to copier marketing strategies. The issue of new marketing strategies for newly emerging markets was misinterpreted. The culture differences were not recognized early and not managed properly. Eventually, GlobalView was ported to non-proprietary environments like Sun workstations, the IBM 6000, and the IBM/Microsoft compatible platforms in an effort to compete but the decision was made too late in the technology life cycle for any hope of securing a place in the market. The porting itself was burdened with technological inconsistencies. For example, when it was ported to the MS platform, the nominal PC did not have sufficient memory to run GlobalView and, given that memory was expensive at the time, the initial cost of setup was prohibitive.

An attempt was made to spin-off the technology development organizations but cultural influences intervened. By the early 1990s Xerox strategy seemed to be one of closing the West Coast technology operations and merging them into Rochester-based organizations. Today, technology organizations are managed and geographically centered in Rochester. PARC in Palo Alto, California and Xerox Research

Centers in Ontario, Canada and Grenoble, France are driven, directed and managed by Rochester technology management.

Another influence on Xerox innovation strategy was a 1975 antitrust settlement. In the settlement, Xerox agreed to open its protective envelope of intellectual property confinement and agree to license what was previously considered proprietary technologies. While the settlement did not produce an instant change in culture for Xerox, it eventually influenced the innovation strategy as evidenced by the current organization of the Innovation Group.

Intellectual property eventually became a source of revenue for Xerox and not just a cost of doing business. It took almost a generation for this culture change to be fully implemented.

Conclusions

On the other side of success is a list of failures to innovate. The failures of innovation are summarized as follows:

- (1) Intellectual Property Management—Patent and Trade Secret Strategies;
- (2) Cultural Influences and Strategies to Mitigate;
- (3) Marketing Strategy.

One cannot accept the reasons for failure without an evaluation of the lessons learned. Such a process allows for a metamorphosis of failures into the successes of the future.

In the first failure, *Intellectual Property Management—Patent and Trade Secret Strategies*, the strategy employed by PARC to recognize the output of researchers had the disastrous effect of exposing trade secrets to competitors without managing the exchange within a boundary—such as a CRADA (Cooperative Research and Development Agreement), licensing agreement, or other controlled knowledge-sharing arrangement. Diffusion of technology must be protected and a financial strategy is imperative. Capturing inventions and actualizing them into innovations is difficult and should not be hindered by uncontrolled information flows.

The second failure is one of *Cultural Influences and Strategies to Mitigate*. This is a very intricate issue as culture may not be readily evident within an organization. In the case of Xerox, there are two distinct cultural influences to be considered.

Initially, the culture of the corporation was heavily influenced by a ‘home office’ viewpoint. Rochester, NY is the de-facto operational hub of Xerox, with an employee concentration of over 20% of the global workforce. This made for an endemic situation. Rochester is also home to much of the historical innovation influence, since the mid 1940s. In 1970, when the innovation center (PARC) was developed on the West Coast, there was a natural resistance in the

Rochester employee group to an invention emanating out of a non-Rochester-based organization. Additionally, the management of the West Coast operations mainly consisted of recent hires from IBM. The culture of IBM and the culture of Xerox were not compatible and this led to further separation from Rochester.

The third failure, *Marketing Strategy*, is intrinsically linked to the existing cultural influences. Because Rochester, home of the marketing group, did not link with the West Coast operations culturally, marketing did not understand the pith of the inventions made in PARC and other West Coast operations. This lack of understanding was pernicious to any marketing plans developed. Rochester did not understand the true nature of the inventions, which tended to exacerbate the situation. This lack of understanding led to faulty marketing plans and an underestimation of the market potential.

What are the lessons learned from this case study? Innovation may be considered a two-sided coin. On one side there is success—a rich history of invention evolving into innovation. On the other side of the coin is failure—either the lack of inventing or not transforming the invention into an innovation. Remember the definition of innovation given earlier in this paper is one of *actualization*; using the invention for improvement or taking the invention to market.

The case of Xerox Corporation gives us examples of both sides of innovation, the rich history of successes and disappointment of failure. Also, it supports our definition of innovation—actualization, as the key criteria in separating invention from innovation.

The attempt in the paper to add to the understanding of innovation is but a mere scratch on the surface of the literature. Innovation, its theory and practice, is beginning to emerge as a separate discipline of study. From what was briefly touched upon in the previous material, the influence of actors and organizational variables on innovation would be an interesting cause for further investigation and study.

Profitable Product Innovation: The Critical Success Factors

Robert G. Cooper

Product Development Institute Inc. and McMaster University, Hamilton, Ontario, Canada

Abstract: This chapter focuses on the critical success factors that underlie new product performance. It is based on the author's and other's research into hundreds of new product launches, probing the question: What distinguishes the best from the rest? Ten common denominators or factors appears to drive new product success, profitability and time-to-market; this chapter outlines these ten critical success factors, and notes the management implications of each. The chapter concludes with a discussion of portfolio management techniques, issues and challenges.

Keywords: Product innovation; New product development; Management; Portfolio management; Success factors.

Introduction

Product innovation—the development of new and improved products—is crucial to the survival and prosperity of the modern corporation. According to a PDMA survey, new products currently account for 33% of company sales, on average (Griffin, 1997). And product life cycles are getting shorter: a 400% reduction over the last 50 years, the result of an accelerating pace of product innovation (Von Braun, 1997).

New products fail at an alarming rate, however. Approximately one in ten product concepts succeeds commercially, according to several studies (Page, 1991; Griffin, 1997), while only one in four development projects is a commercial success (Cooper, 2001). Even by the launch phase—after all the product tests and market testing are done—one-third of product launches still fail commercially. In the high-tech field, the odds are even worse: only 20% of software projects are commercial winners, according to a survey by Kleinschmidt (1999); companies scrap almost one-third of new projects for a loss of \$80 billion annually (King, 1997); and “only one-quarter of IT projects are completed on time, on budget and with all the functions originally specified” (*Risk Magazine*, 1999).

The huge amounts at stake coupled with the high odds of failure make product innovation one of the riskiest endeavors of the modern corporation. Thus many managers, researchers and pundits have sought answers to the age-old question: What makes a new

product a winner? And why are some businesses so much more successful at product development than the rest?

This chapter looks first at the critical success factors that underlie success in product innovation.¹ Next, these many success factors are crafted into a methodology, game plan or process for managing new product projects—a systematic new product process or Stage-Gate system. The chapter concludes with a look at portfolio management—methods for selecting the right new product projects.

The Critical Success Factors

Much research over the years has uncovered those factors that separate winning new products from less successful ones, and businesses that succeed at product innovation (Cooper, 1999b, 1999c; Cooper & Kleinschmidt, 1986, 1993, 1995a, 1996; Di Benedetto, 1999; Maidique et al., 1984; Mishra et al., 1996; Montoya-Weiss et al., 1994; Rothwell et al., 1974; Sanchez et al., 1991; Song & Parry, 1996). Here are the more important success factors based on these studies:

A Unique Superior Product

A superior and differentiated product is the number one driver of success and profitability, with success rates reported to be three to five times higher than for ‘me

¹ This chapter is taken from a number of articles and books by the author. See Cooper (1996, 1999a, 2000, 2001).

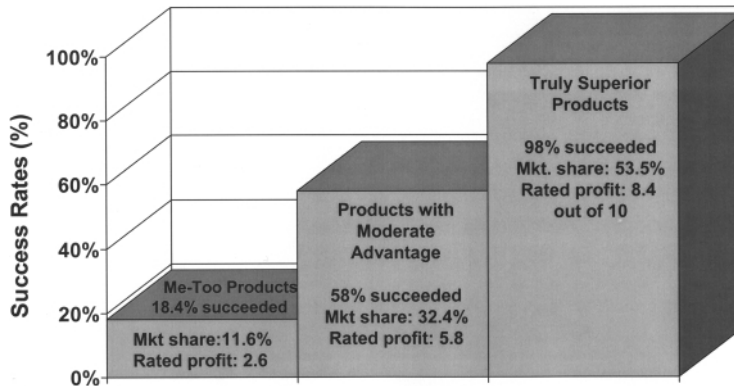

Figure 1. Impact of product superiority on success.

Source: Cooper (2001).

too', reactive products (Cooper, 1999b, 1999c; Cooper & Kleinschmidt, 1993, 1995a, 1996; Mishra et al., 1996; Song & Parry, 1996; Souder & Song, 1997). The NewProd studies² show the dramatic impact of product superiority: here the sample of firms was divided into the top 20% and bottom 20% in terms of product superiority: note the differences in performance in Figure 1—much higher success rates, market shares and profitabilities for unique, superior products (Cooper, 2001; Cooper & Kleinschmidt, 1986, 1996). For example, such products (the top 20% in Figure 1) when compared to those with the least degree of differentiation (the bottom 20%):

- have an exceptional commercial success rate of 98.0%, vs. only 18.4% for undifferentiated ones;
- have a market share of 53.5% of the defined target market, vs. only 11.6% for 'me too' new products;
- have a rated profitability of 8.4 out of 10 (vs. only 2.6 out of 10 for undifferentiated products—here 10 = exceptional profits, far exceeding the company's minimum hurdle); and
- meet company sales and profit objectives to a greater degree than do undifferentiated products.

The same studies show, however, that *reactive products*, *undifferentiated products* and *technically driven products that lack customer benefits* are the rule rather than the exception, however; and the majority fail!

What are the ingredients of these unique, superior products with significant competitive advantage?

² The *NewProd studies*: a series of investigations by the author and co-workers between 1975 and 2000 that identified the success factors in new product development—the factors that differentiated between winners and losers. The typical methodology was a paired comparison of successful vs. unsuccessful new product projects. NewProd™ is a legally registered trademark of R. G. Cooper & Associates Consultants Inc.

According to research cited above, they are superior to competing products in terms of meeting users' needs, offer unique features not available on competitive products, or solve a problem the customer has with a competitive product. They provide excellent product quality, relative to competitors' products, and in terms of how the user measures quality; they feature good value for money for the customer, reduce the customer's total costs (high value-in-use), and boast excellent price/performance characteristics. And such winning products offer benefits or attributes easily perceived as useful by the customer, and benefits that are highly visible. A point of distinction: *benefits* are what customers or users value and pay money for; by contrast, *attributes* are product features, functionality and performance—the things that engineers and scientists build into products. And note that the product must be superior in the eyes of the customer, not just the eyes of the engineer, scientist or designer: often developers heavily overestimate the customer benefits and desirability of their products (Friar, 1995).

A Strong Market Orientation—Market-Driven, Customer-Focused

A thorough understanding of customers' needs and wants, the competitive situation, and the nature of the market is an essential component of new product success. This finding is supported in virtually every study of product success factors (Cooper, 2001; Di Benedetto, 1999; Mishra et al., 1996; Montoya-Weiss, 1994; Song & Montoya-Weiss, 1998; Song & Parry, 1996). Recurring success themes include:

- need recognition;
- understanding user needs;
- market need satisfaction;
- constant customer contact;
- strong market knowledge and market research;
- quality of execution of marketing activities; and

- more spending on the up-front marketing activities.

Even in the case of technology-driven new products (where the idea comes from a technical or laboratory source), the likelihood of success is greatly enhanced if customer and marketplace inputs are built into the project soon after its inception.

Conversely, a failure to adopt a strong market orientation in product innovation, an unwillingness to undertake the needed market assessments and to build in the voice of the customer, and leaving the customer out of product development spells disaster. Poor market research, inadequate market analysis, weak market studies, test markets, and market launch, and inadequate resources devoted to marketing activities are common weaknesses found in almost every study of why new products fail (de Brentani, 1989; Calantone et al., 1979; Griffin & Page, 1993).

A strong market orientation is missing in the majority of firms' new product projects, however. Detailed market studies are frequently omitted—in more than 75% of projects, according to several investigations (Cooper, 2001; Cooper & Kleinschmidt, 1986). Further, marketing activities are the weakest rated activities of the entire new product process, with relatively few resources and little money spent on the marketing actions (less than 20% of total project expenditures).

A strong market orientation must be built into every stage of the new product process in order to achieve success (Verzyer, 1998):

- Idea generation: focusing on the customer, and using the customer as a source of ideas;
- Product design: employing market research as an input to product design, not just an after-the-fact check;
- During development via constant customer contact and feedback (e.g. continuous customer testing of facets of the product);
- After development: undertaking customer trials, preference tests and test markets to verify market acceptance and launch plan;
- Launch: employing a well-designed, carefully targeted, properly resourced, guided by a well-conceived marketing plan, based on solid market information.

3. The World Product—An International Orientation in Product Design, Development, and Target Marketing

International products targeted at world and nearest neighbor export markets are the top performers (Cooper, 2001; Kleinschmidt, 1988). By contrast, products designed with only the domestic market in mind, and sold to domestic and nearest neighbor export markets, fare more poorly. The magnitude of the differences between these international and exported new products

vs. domestic products is striking: differences of two- or three-to-one on various performance gauges.

The comfortable strategy of “design the product for domestic requirements, capture the home market, and then export a modified version of the product sometime in the future” is myopic. It leads to inferior results today; and with increasing globalization of markets, it will certainly lead to even poorer results in the years ahead. The threat is that one's domestic market has become someone else's international market: to define the new product market as ‘domestic’ and perhaps a few other ‘convenient countries’ severely limits market opportunities. For maximum success in product innovation, the objective must be to design for the world and market to the world. Sadly, this international dimension is an often overlooked facet of new product game plans or one which, if included, is handled late in the process, or as a side issue.

An international orientation means defining the market as an international one, and designing products to meet international requirements, not just domestic. The result is either a *global* product (one version for the entire world) or a *glocal* product (one development effort, one product concept, but perhaps *several product variants* to satisfy different international markets). An international orientation also means undertaking market research, concept testing and product testing in multiple countries, rather than just the home country; and it means relying on an international or global project team (about one NPD project team in five is now reported to be a global development team (McDonough et al., 2001)).

Pre-development Work—The Up-front Homework

The steps that precede the design and development of the product make the difference between winning and losing (Cooper, 1999b, 1999c; Cooper & Kleinschmidt, 1993, 1995a, 1996; Mishra et al., 1996; Montoya-Weiss et al., 1994; Song & Parry, 1996; Thomke & Fujimoto, 2000). New product projects that feature a high quality of execution of activities that precede the development phase—the *fuzzy front end*—are more successful:

- a success rate of 75.0% (vs. only 31.3% for projects where the predevelopment activities are found lacking);
- a higher rated profitability (7.2 out of 10 vs. only 3.7 for projects where pre-development activities are poorly undertaken); and
- a market share of 45.7% (vs. 20.8%) (Cooper, 2001).

Successful businesses spend about twice as much time and money on these vital up-front or pre-development activities, such as initial screening, preliminary market and technical assessments, detailed market studies or marketing research (success factor 2 above) and

business and financial analysis just before the decision to 'Go to Development' (Cooper, 2001).

Most businesses confess to serious weaknesses in the up-front or pre-development steps of their new product process. Small amounts of time and money are devoted to these critical steps: only about 7% of the expenditure and 16% of the effort (Cooper, 2001). Far from adding extra time to the project, research reveals that homework pays for itself in reduced development times, the result of sharper and more stable product definition, and fewer surprises (and time wasters) later in the project (Thomke & Fujimoto, 2000).

Sharp and Early Product Definition

Successful products have *much sharper definition prior to development* (Cooper, 1999b, 1999c; Cooper & Kleinschmidt, 1993, 1995a, 1996; Mishra et al., 1999; Rauscher & Smith, 1995; Wilson, 1991). Projects that have these sharp definitions are 3.3 times as likely to be successful; have higher market shares (by 38 share points on average); are rated 7.6 out of 10 in terms of profitability (vs. 3.1 out of 10 for poorly defined products); and do better at meeting company sales and profit objectives (see Figure 2).

This definition includes:

- specification of the target market: exactly who the intended users are;
- description of the product concept and the benefits to be delivered;
- delineation of the positioning strategy (including the target price);
- and a list of the product's features, attributes, requirements and specifications.

Unless these four items are clearly defined, written down and agreed to by all parties prior to entering the development stage, the odds of failure increase by a factor of three.

Projects that have sharp product and project definition prior to development are considerably more successful. The reasons are as follows (Cooper, 2001):

- (1) Building a definition step into the new product process forces more attention to the up-front or pre-development activities;
- (2) The definition serves as a communication tool and guide. All-party agreement or 'buy in' means that each functional area involved in the project has a clear and consistent definition of what the product and project are—and is committed to it;
- (3) This definition also provides a clear set of objectives for the development phase of the project, and the development team members. With clear product objectives, development typically proceeds more efficiently and quickly: no moving goalposts and no fuzzy targets!

6. A Well-conceived, Properly Executed Launch Backed by a Solid Marketing Plan

The best products in the world will not sell themselves! A strong marketing and selling effort, a well-targeted selling approach, and effective after-sales service are central to the successful launch of the new product (Cooper & Kleinschmidt, 1986; Di Benedetto, 1999; Mishra et al., 1996; Song & Montoya-Weiss, 1998; Song & Parry, 1996). But a well-integrated and properly targeted launch does not occur by accident; it is the result of a *fine-tuned marketing plan*, properly backed and resourced, and proficiently executed.

There are four requirements for an effective market launch plan:

- (1) The development of the market launch plan is an *integral part of the new product process*: it is as central to the new product process as is the development of the physical product;

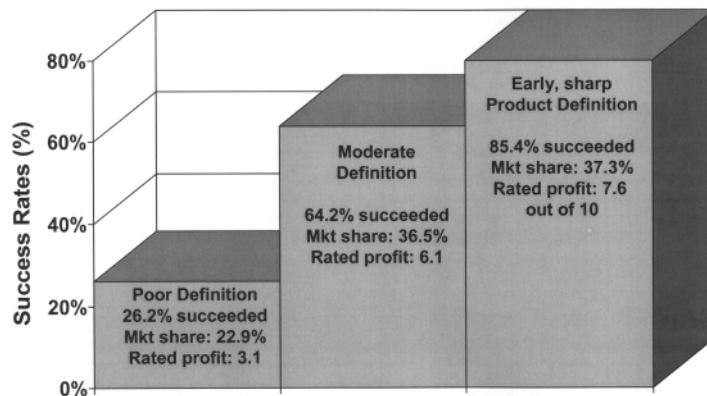

Figure 2. Impact of early, sharp product definition.

Source: Cooper (2001).

- (2) The development of the market launch plan *must begin early* in the new product project. It should not be left as an afterthought to be undertaken as the product nears commercialization;
 - (3) A market launch plan is only as good as the *market intelligence* upon which it is based. Market studies designed to yield information crucial to marketing planning must be built into the new product game plan;
 - (4) These who will execute the launch—the sales force, technical support people, other front line personnel—must be engaged in the development of the market launch plan. This ensures valuable input and insight into the design of the launch effort, availability of resources when needed, and buy-in by those who must execute to the product and its launch—elements so critical to a successful launch (Hultink, E. J. & Atuahene-Gima, 2000).
- organized as a *cross-functional team* with members from R&D, Engineering, Marketing & Sales, Operations and so on (as opposed to each function doing its own part independently);
 - where the team is dedicated and focused (i.e. devotes a large percentage of their time to this project, as opposed to spread over many projects or other work);
 - where the team members are in constant contact with each other, via frequent but short meetings, interactions, project updates and even co-location;
 - where the team is accountable for the entire project from beginning to end (as opposed to accountability for only one stage of the project); and
 - where there is a strong project leader or champion who leads and drives the project (Barczak, 1995; Markham & Griffin, 1998).

7. The Right Organizational Structure, Design and Climate

Product innovation is not a one-department show. It is very much a multidisciplinary, cross-functional effort. Investigations into new product success consistently cite interfaces between R&D and marketing, coordination among key internal groups, multidisciplinary inputs to the new product project, and the role of project teams and the team leader or champion (Cooper, 2001; Markham & Griffin, 1998; Song et al., 1997; Song & Parry, 1996). Successful new product projects feature a balanced process consisting of critical activities that fall into many different functional areas within the firm: marketing and marketing research, engineering, R&D, production, purchasing, and finance (Cooper, 1998; Cooper & Kleinschmidt, 1995b, 1995c, 1996). The Stanford Innovation Project study of new product launches in high-technology firms reveals that a critical distinguishing factor between success and failure is the “simultaneous involvement of the create, make, and market functions” (Maidique et al., 1984). The NewProd studies show that projects undertaken by empowered multifunctional teams are more successful (Cooper, 1999a, 1999c; Cooper & Kleinschmidt, 1993, 1995b, 1996). Similarly, analyses of Japanese successes emphasize their attention to manufacturability from the start of development efforts, the location in one place of engineers, designers, and manufacturers, and the conception of management unconstrained by traditional American functionalism (Peters, 1986, p. 261). Finally Griffin’s review of multiple benchmarking studies, along with her own PDMA best practices study, reveals that effective cross-functional teams are fundamental to success (Griffin, 1997).

Product development must be run as a multidisciplinary, cross-functional effort. Good organizational design means projects that are:

While the ingredients of good organizational design should be familiar, surprisingly many firms have yet to get the message (Cooper & Kleinschmidt, 1996).

Peters argues strongly in favor of project teams: “the single most important reason for delays in development activities is the absence of multifunction (and outsider) representation on development projects from the start” (Peters, 1986). Peters continues: “The answer is to co-mingle members of all key functions, co-opt each function’s traditional feudal authority, and use teams”.

A second organizational success ingredient is climate and culture. A positive climate is one which supports and encourages intrapreneurs and risk-taking behavior; where new product successes are rewarded and recognized (and failures not punished); and where team efforts are recognized, rather than individuals. For example, the Best companies in the PDMA best practices study emphasize employee recognition for new product performance (Griffin, 1997). A positive climate also means senior managers refraining from ‘micro-managing’ projects and second-guessing the team members; and resources and time being made available for creative people to work on their own ‘unofficial projects’. Idea-submission schemes (where employees are encouraged to submit new product ideas), and open project review meetings (where the entire project team participates), are other facets of a positive climate.

Top Management Support

Top management support is a necessary ingredient for product innovation. But it must be the right kind of support. The Stanford project, a Hewlett-Packard study, and other investigations have found top management support to be directly linked to new product success (Cooper, 2001; Maidique & Zirger, 1984; Song & Parry, 1996; Wilson, 1991).

Top management’s role in product development is as a facilitator—to set the stage—and not be an actor front and center. One important role of senior management is

to articulate a new product strategy for the business, something that is often missing. An effective new product strategy means defined new product goals (e.g. percentage of the business's sales to be derived from new products); delineated arenas of focus (e.g. product-types, markets, technologies and technology platforms where the business unit intends to concentrate its development efforts); and strategies that have a longer-term orientation and are visible to everyone in the business. Management must also deploy the necessary product development resources, and keep the commitment. And it must commit to a disciplined process to drive products to market. These three factors—an articulated new product strategy, adequate resources, and a disciplined new product process—are the strongest drivers of new product performance at the business unit level, according to a major benchmarking study (Cooper, 1998; Cooper & Kleinschmidt, 1995b, 1995c, 1996). Finally, senior management must empower project teams and support committed champions by acting as mentors, facilitators, 'godfathers', or executive sponsors to project leaders and teams—acting as 'executive champions', as Peters calls them (Peters, 1986, p. 302).

Leveraging Core Competencies

Leverage and synergy is the common thread that binds the new business to the old. When translated into product innovation, the ability to leverage existing and in-house strengths, competencies, resources, and capabilities increases the odds of success of the new product project. By contrast, 'step-out' projects take the firm into territory that lies beyond the experience and resource base of the company, and increase the odds of failure (Cooper, 1999a, 1999c; Cooper & Kleinschmidt, 1995a, 1995b, 1995c, 1996; Mishra et al., 1996; Song & Parry, 1996).

The reasons for the impact of leverage are clear:

- (1) Resources are available and at marginal cost;
- (2) Operating within one's field of expertise—either familiar markets or familiar technologies—provides considerable 'domain knowledge', which is available to the project team;
- (3) The more often one does something, the better one becomes at doing it—the experience factor. If new product projects are closely related to (leveraged from) current businesses, the chances are that there has been considerable experience with such projects in the past, hence lower costs of execution and fewer misfires.

Two types of leverage are important to product innovation:

- (1) *Technological leverage*: the project's ability to build on in-house development technology, utilize inside engineering skills, and use existing manu-

facturing or operations resources and competencies.

- (2) *Marketing leverage*: the project/company fit in terms of customer base, sales force, distribution channels, customer service resources, advertising and promotion, and market-intelligence skills, knowledge and resources.

These two dimensions of leverage—technological and marketing, and their ingredients—become obvious checklist items in a scoring or rating model to help prioritize new product projects. And if leverage is low, yet the project is attractive for other reasons, then steps must be taken to bolster the internal resources and competencies. Low leverage scores signal the need for outside resources—partnering or out-sourcing (Bonaccorsi & Hayashi, 1994). But neither solution is a panacea—there are risks and costs to both routes to securing the needed resources and competencies (Campbell & Cooper, 1999).

Market Attractiveness

Market attractiveness is an important strategic variable. Porter's 'five forces' model considers various elements of market attractiveness as a determinant of industry profitability (Porter, 1985). Similarly, various strategic planning models—for example, models used to allocate resources among various existing business units—employ market attractiveness as a key dimension in the two-dimensional map or portfolio grid (Day, 1986).

In the case of new products, market attractiveness is also important: products targeted at more attractive markets are more successful (Cooper, 1999a, 1999c; Cooper & Kleinschmidt, 1995a, 1995b, 1995c, 1996; Maidique et al., 1985; Mishra et al., 1996; Song & Parry, 1996). There are two dimensions of market attractiveness:

- (1) *Market potential*: positive market environments, namely large and growing markets—markets where a strong customer need exists for such products, and where the purchase is an important one for the customer. Products aimed at such markets are more successful.
- (2) *Competitive situation*: negative markets characterized by intense competition, competition on the basis of price, high quality, and strong competitive products; and competitors whose sales force, channel system, and support service are strongly rated. Products aimed at such negative markets are less successful, according to the studies cited above.

The message is this: both elements of market attractiveness—market potential and competitive situation—impact the new product's fortunes; and both should be considered as criteria in any model or scoring scheme for project selection and prioritization.

Tough Go/Kill Decision Points and Better Focus

Most companies suffer from too many projects and not enough resources to mount an effective or timely effort on each—a lack of focus. This stems from inadequate project evaluation and poor project prioritization. Project evaluations are consistently cited as weakly handled or nonexistent: decisions involve the wrong people from the wrong functions (no functional alignment); no consistent criteria are used to screen or rank projects; or there is simply no will to kill projects at all (Barczak, 1995; Cooper et al., 1998, 1999; Cooper, 1998; Cooper & Kleinschmidt, 1986, 1995a, 1995b, 1995c, 1996).

The desire to weed out bad projects coupled with the need to focus limited resources on the best projects means that tough Go or Kill and prioritization decisions must be made. Some companies have built *funnels* into their new product process via decision-points in the form of gates. At gate reviews, senior management rigorously scrutinizes projects, and makes Go or Kill and prioritization decisions based on visible Go/Kill criteria (see Figure 5 for sample Go/Kill criteria). Progressive businesses are also moving to portfolio management, which attempts to select the right set of new product projects in order to maximize the value of the portfolio, achieve the right balance of projects, and yield a portfolio of projects that supports the business's strategy (Cooper et al., 1997a, 1997b; Roussel et al., 1991).

Quality of Execution

Certain key activities—how well they are executed, and whether they are done at all—are strongly tied to profitability and reduction in time-to-market. Particularly pivotal activities include: the vital homework actions outlined above; and market-related activities. But proficiency of most activities in the new product process impacts on outcomes, with successful project teams consistently doing a better quality job across many tasks (Cooper, 1999a, 1999c; Cooper & Kleinschmidt, 1986, 1995d, 1996; Mishra et al., 1996; Song & Montoya-Weiss, 1998; Song & Parry, 1996).

There is a *quality crisis* in product innovation, however. Investigations reveal that the typical new product project is characterized by serious errors of omission and commission:

- Pivotal activities, often cited as central to success, are omitted altogether. For example, more than half of all projects typically leave out detailed market studies and a test market (trial sell);
- Quality of execution ratings of important activities are also typically low. In postmortems on projects, teams typically rate themselves as 'mediocre' in terms of how good a job they did on these vital activities.

New product success is thus very much within the hands of the men and women leading and working on

projects. To improve quality of execution, the solution that leading firms in a variety of industries, such as DuPont, Procter & Gamble, Exxon, Bayer, Lego, ITT, International Paper and Pillsbury-General Mills, have adopted is to treat *product innovation as a process*. They have adopted a formal stage-and-gate product delivery process; they build in quality-assurance approaches, such as check points and metrics that focus on quality of execution; and they design quality in by making mandatory certain vital actions that are often omitted, yet are central to success.

The Necessary Resources

Too many projects simply suffer from a lack of time and money commitment. The results are predictable: much higher failure rates (Cooper, 1998; Cooper & Kleinschmidt, 1995b, 1995c, 1996). Some facts:

- A strong market orientation is missing in the typical new product project. And much of this deficiency is directly linked to a lack of marketing resources available for the project;
- Another serious pitfall is that the homework does not get done. Again much of this deficiency can be directly attributed to a lack of resources: simply not enough money, people, and time to do the work.

The reason: as the competitive situation has toughened, companies have responded with restructuring and doing more with less, and so resources are limited or cut back (Cooper & Edgett, 2002). This short-term focus takes its toll. Certain vital activities, such as market-oriented actions and predevelopment homework are highly under-resourced, particularly in the case of product failures.

Speed—But Not at the Expense of Quality of Execution

Speed yields: competitive advantage (the first on the market) (Song et al., 2000; Song & Montoya-Weiss, 1998); less likelihood that the market situation has changed; and a quicker realization of profits (Ali et al., 1995). So the goal of reducing the development cycle time is admirable. A word of caution here: speed is only an interim objective; the ultimate goal is profitability. While studies reveal that speed and profitability are connected, the relationship is anything but one-to-one (Cooper, 1995; Lynn et al., 1999). Further, often the methods used to reduce development time yield precisely the opposite effect, and in many cases are very costly. The objective remains successful products, not a series of fast failures! Additionally, an over-emphasis on speed has led to trivialization of product development in some businesses—too many product modifications and line extensions, and not enough real new products and new platforms (Cooper & Edgett, 2002; Crawford, 1992).

Some of the ways which project teams have reduced time-to-market have been highlighted above: a true

cross-functional team; solid up-front homework; sharp, early product definition (Rauscher & Smith, 1995); and better focus—doing fewer projects (Cooper, 1995, 2001; Cooper & Kleinschmidt, 1994). Other methods include:

- *Parallel processing*: activities are undertaken in parallel (rather than sequentially) with the team members constantly interacting with each other. New product rugby with time compression is the result;
- *Flowcharting*: the team maps out its entire project from beginning to end, and focuses on reducing the time of each element or task in the process;
- *A time-line and discipline*: project teams use computer software to plan their projects in a critical path or Gantt chart format. The rules are simple: practice discipline; the time-line is sacred; and resources can be added but deadlines never relaxed.

A Multistage, Disciplined New Product Process

A systematic new product process—a *Stage-Gate™ process*³—is the solution that many companies have turned to in order to overcome the deficiencies which plague their new product programs (Cooper, 1998, 2001; Lynn et al., 1999; Menke, 1997). *Stage-Gate* processes are simply road maps or ‘play books’ for driving new products from idea to launch, successfully and efficiently. About 68% of U.S. product developers have adopted *Stage-Gate* processes, according to the PDMA best practices study (Griffin, 1997). And the payoffs of such processes have been frequently reported: improved teamwork; less recycling and rework; improved success rates; earlier detection of failures; a better launch; and even shorter cycle times (by about 30%).

Doing Projects Right: A Stage-Gate™ Process or Road Map from Idea to Launch

A *Stage-Gate* process is a *conceptual and operational roadmap* for moving a new product project from idea to launch—a blueprint for managing the new product process to improve effectiveness and efficiency. The goals of a *Stage-Gate* process include:

- Doing projects right—such processes lay out prescribed actions and best practices as a guide to the project team;
- Building in the critical success factors—as was seen above, most project teams miss the mark on success factors 1–14. And so *Stage-Gate* processes attempt to build these in to every project by design.

Stage-Gate approaches break the innovation process into a predetermined set of stages, with each stage

consisting of a set of prescribed, cross-functional and parallel activities (see diagram below). The entrance to each stage is a gate, which serves as the quality control and Go/Kill check points in the process.

The Stages

Stages are where the action occurs. The players on the project team undertake key tasks in order to gather information needed to advance the project to the next gate or decision point. Stages are cross-functional: There is no R&D or Marketing stage. Rather, each stage consists of a set of parallel activities undertaken by people from different functional areas within the firm, working together as a team and led by a project team leader. In order to manage risk via a *Stage-Gate* method, the parallel activities in a certain stage must be designed to gather vital information—technical, market, financial, operations—in order to drive down the technical and business risks. Each stage costs more than the preceding one, so that the game plan is based on incremental commitments. As uncertainties decrease, expenditures are allowed to mount: risk is managed.

A Typical Stage-Gate™ Process

The general flow of the typical or *generic* stage-gate process is shown in Figure 3 (Cooper 2001). Here, following idea generation or Discovery, there are five key stages:

Stage 1. Scoping

A quick investigation and sculpting of the project. This first and inexpensive homework stage has the objective of determining the project’s technical and marketplace merits. Stage 1 involves desk research or detective work—little or no primary research is done here. Prescribed activities include preliminary market, technical and business assessments.

Stage 2. Build the Business Case

The detailed homework and up-front investigation work leading to a *business case*—a defined product, a business justification and a detailed plan of action for the next stages. This second homework stage includes actions such as a detailed market analysis, user needs and wants studies to build in voice of customer, concept testing, detailed technical assessment, source of supply assessment, and a detailed financial and business analysis.

Stage 3. Development

The actual design and development of the new product. Stage 3 witnesses the implementation of the Development Plan and the physical development of the product. Lab tests, in-house tests or alpha tests ensure that the product meets requirements under controlled conditions. The ‘deliverable’ at the end of Stage 3 is a lab-tested prototype of the product. While the emphasis in Stage 3 is on technical work, marketing and

³ The term ‘Stage-Gate’ was coined by the author and first appeared in print in Cooper (1988). *Stage-Gate* is a legal tradename of the author. For more on *Stage-Gate™* methods, see Cooper (2001); also the *Stage-Gate* web-page: www.prod-dev.com

Stage-Gate™: A five stage, five-gate model along with Discovery and Post-Launch Review

operations activities also proceed in parallel. For example, market-analysis and customer-feedback efforts continue concurrently with the technical development, with constant customer opinion sought on the product as it takes shape during development. Additionally, the manufacturing (or operations) process is mapped out, the marketing launch and operating plans are developed, and the test plans for the next stage are defined. An updated financial analysis is prepared, while regulatory, legal, and patent issues are resolved.

Stage 4. Testing & Validation

The verification and validation of the proposed new product, its marketing and production. This stage tests and validates the entire viability of the project: the product itself, the production process, customer acceptance, and the economics of the project. A number of activities are undertaken at Stage 4, including in-house product tests (extended lab tests or alpha tests to check on product quality and product performance); user or field trials of the product (to verify that the product functions under actual use conditions, and to establish purchase intent); trial, limited, or pilot production (to test, debug, and prove the production process); pre-test market, test market, or trial sell (to gauge customer reaction and measure the effectiveness of the launch plan); and revised business and financial analysis.

Stage 5. Launch

Full commercialization of the product—the beginning of full production and commercial launch and selling.

Here the market roll-out or launch plan is implemented. Final production equipment installation and commissioning occurs, along with full production start-up. Finally, the post-launch plan—monitoring and fixing—is implemented, along with early elements of the life cycle plan (new variants and releases, continuous improvements).

Some 12–18 months after launch, the Post Launch Review occurs: the performance of the project vs. expectations is assessed along with reasons why and lessons learned; the team is disbanded but recognized or rewarded; and the project is terminated.

At first glance, this overview portrays the stages as relatively simple steps in a logical process. But what you see above is only a high-level view of a generic process. In an operational process in a real company, drilling down into the details of each stage reveals a much more sophisticated and complex set of activities: a detailed list of activities within each stage, the how to's of each activity, best practices that the team ought to consider, and even the required deliverables from each activity in that stage (for example in the format of templates). In short, the drill-down provides a *detailed and operational road map* for the project team—everything they need to know and do to successfully complete that stage of the process and project.

The Gates

Preceding each stage is an entry gate or a Go/Kill decision point, shown as diamonds in Figure 3.

Effective gates are central to the success of a fast-paced, new product process:

- Gates serve as quality control checkpoints: is this project being executed in a quality fashion?;
- Gates also serve as Go/Kill and prioritization decisions points: gates provide the funnels, where mediocre projects are culled out at each successive gate;
- Finally, gates are where the path forward for the next stage is decided, along with resource commitments.

Gate meetings are usually staffed by senior managers from different functions, who own the resources required by the project leader and team for the next stage. These decision-makers are called ‘gatekeepers’.

Gates have a common format:

- *Deliverables*: these are the *inputs* into the gate review—what the project leader and team deliver to the meeting. They are the results of the actions of the previous stage, and are based on a standard menu of deliverables for each gate;
- *Criteria*: these are questions or metrics on which the project is judged in order to make the Go/Kill and prioritization decision;
- *Outputs*: these are the results of the gate review—a decision (Go/Kill/Hold/Recycle); an action plan approved; and the date and deliverables for the next gate agreed upon.

Doing the Right Projects: Project Selection and Portfolio Management

An effective new product process, such as *Stage-Gate™* in Figure 3, improves the odds of success. And it leads to the second way to win at new products, namely doing the right projects or an effective portfolio management.⁴ Portfolio management deals with the vital question: How should the business most effectively invest its R&D and new product resources (Roussel et al., 1991)? Much like a stock market portfolio manager, those senior executives who optimize their R&D investments—select winning new product projects and achieve the ideal balance of projects—will win in the long run.

Three Goals in Portfolio Management

There are three macro or *high-level goals* in portfolio management (Cooper et al., 2002a, 2002b):

1. Value Maximization

Here, one selects projects so as to maximize sum of the values or *commercial worths* of all active projects in terms of some business objective (such as long-term

profitability, EVA, return-on-investment, likelihood of success, or some other strategic objectives).

2. Balance

Here, the principal concern is to develop a balanced portfolio—to achieve a desired balance of projects in terms of a number of parameters; for example, the right balance in terms of high-risk vs. lower-risk projects; or long-term vs. short-term; or across various markets, technologies, product categories, and project types.

3. Strategic Direction

The main goal here is to ensure that, regardless of all other considerations, the final portfolio of projects truly reflects the business’s strategy—that the breakdown of spending across projects, areas, markets, etc. is directly tied to the business strategy (e.g. to areas of strategic focus that management has previously delineated); and that all projects are ‘on strategy’.

Goal 1: Maximizing the Value of the Portfolio

A variety of methods can be used to achieve this goal, ranging from financial models through to scoring models (Cooper et al., 1997a, 1997b, 2000). Each has its strengths and weaknesses. The end result of each method is a rank-ordered or prioritized list of ‘Go’ and ‘Hold’ projects, with the projects at the top of the list scoring highest in terms of achieving the desired objectives: the value in terms of that objective is thus maximized.

Net Present Value (NPV)

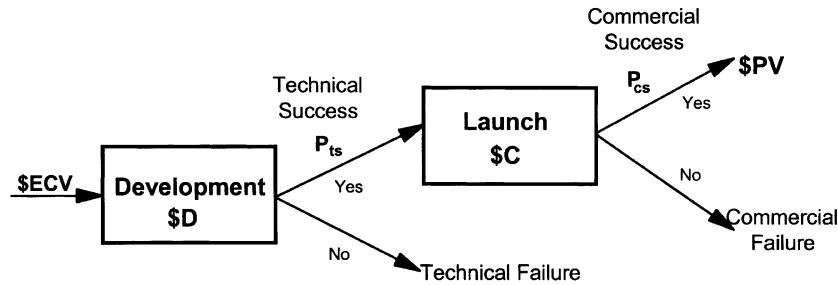

The simplest approach is merely to calculate the NPV of each project on a spreadsheet; and then rank all projects according to their NPVs. The Go projects are at the top of the list. . . one continues to add projects down the list until out of resources. Logically this method should maximize the NPV of the portfolio.

Fine in theory! But the NPV method ignores probabilities and risk; it assumes that financial projections for new products are accurate (they usually are not!); it assumes that only financial goals are important; and it fails to deal with constrained resources—the desire to maximize the value for a limited resource commitment. A final objection is more subtle: the fact that NPV assumes an all-or-nothing investment decision, whereas in new product projects, the decision process is an incremental one—more like buying a series of options on a project (Deaves & Krinsky, 1997; Faulkner, 1996). In spite of their apparent rigor, financial approaches—NPV as well as some listed below—yield the worst performing portfolios, and were poorly rated by managers in a major portfolio study of methods in practice (Cooper et al., 1998, 1999, 2001a).

Expected Commercial Value (ECV)

This method seeks to maximize the value or *commercial worth* of the portfolio, subject to certain budget

⁴ Much of this section on Portfolio Management is based on a book by the author and co-workers (Cooper et al., 2002a) and a chapter in the PDMA handbook (Cooper et al., 2002b).

$$ECV = [(PV * P_{cs} - C) * P_{ts} - D]$$

\$ECV = Expected Commercial Value of the project

P_{ts} = Probability of Technical Success

P_{cs} = Probability of Commercial Success (given technical success)

\$D = Development Costs remaining in the project

\$C = Commercialization (Launch) Costs

\$PV = Present Value of project's future earnings (discounted to today)

Figure 4. Determination of expected commercial value of a project.

Source: Cooper, Edgett & Kleinschmidt (2002a).

constraints, and introduces the notion of risks and probabilities. The ECV method determines the risk-adjusted value or commercial worth of each project to the corporation, namely its *expected commercial value*. The calculation of the ECV is based on a decision tree analysis, and considers the future stream of earnings from the project, the probabilities of both commercial success and technical success, along with both commercialization costs and development costs (see Figure 4 for the calculation and definition of terms). A variety of techniques are available for estimating probabilities of success, including scoring models, data tables and behavioral approaches such as Delphi (Cooper et al., 2002a; Davis et al., 2001).

In order to arrive at a prioritized list of projects, the ECV of each project is first determined. Then, one considers what resources are scarce or limiting—for example, R&D or marketing people or dollars or work-months, or even capital funds. Thus, the ratio of what one is trying to maximize (namely the ECV) *divided by the constraining resource* (for example, the R&D costs per project) is determined for each project. Projects are rank-ordered according to this ECV/R&D Cost ratio until the budget limit is reached. Those projects at the top of the list are Go, while those at the bottom (beyond the budget limits) are placed on Hold. The method thus ensures the greatest ‘bang for buck’: that is, the ECV is maximized, for a given R&D budget.

This ECV model has a number of attractive features: it recognizes that the Go/Kill decision process is an

incremental one (the notion of purchasing options). Indeed some experts indicate that this ECV decision tree method comes very close to approaching a *real options approach to valuing projects* (Deaves & Krinsky, 1997; Faulkner, 1996). Finally, the ECV method deals with the issue of constrained resources, and attempts to maximize the value of the portfolio in light of this constraint.

The major weakness of the method is the *dependency on extensive financial and other quantitative data*. Accurate estimates must be available for *all* projects’ future stream of earnings and their costs and also for probabilities of success—estimates that are often unreliable or, at best, simply not available early in the life of a project. A second weakness is that the method *does not look at the balance* of the portfolio—at whether the portfolio has the right balance between high- and low-risk projects, or across markets and technologies. A third weakness is that the method considers only a *single financial criterion* for maximization.

Scoring Models as Portfolio Tools

Scoring models have long been used for making Go/Kill decisions at gates. But they also have applicability for project prioritization and portfolio management. Projects are scored on each of a number of criteria by management. (A sample list of project prioritization criteria, from which a scorecard is constructed, is shown in Figure 5). The Project Attractiveness Score is

1. **Strategic:**
 - degree to which project aligns with BU's strategy
 - strategic importance
 2. **Product Advantage:**
 - unique benefits
 - meets customer needs better
 - value for money
 3. **Market Attractiveness:**
 - market size
 - market growth
 - competitive situation
 4. **Synergies (Leverages Core Competencies):**
 - marketing synergies
 - technological synergies
 - manufacturing / operations synergies
 5. **Technical Feasibility:**
 - technical gap
 - complexity
 - technical uncertainty
 6. **Risk Vs. Return:**
 - expected profitability (magnitude; e.g. NPV)
 - return (e.g. IRR)
 - payback period
 - certainty of return/profit estimates
- ✓ **The six Factors (in bold) are scored (e.g. 1-5 or 0-10) on a scorecard**
- ✓ **Factor scores must clear minimum hurdles**
- ✓ **Also added (weighted/unweighted) to yield the Project Attractiveness Score, which is used to make Go/Kill decisions & also to prioritize projects**

Figure 5. Best practice go-to-development decision criteria.

Copyrighted: Cooper, Edgett & Kleinschmidt (2002a).

the weighted addition of the factor ratings, and becomes the basis for developing a rank-ordered list of projects. Projects are ranked until there are no more resources.

Scoring models generally are praised in spite of their limited popularity. Research into project selection methods reveals that scoring models produce a strategically aligned portfolio and one that reflects the business's spending priorities; and they yield effective and efficient decisions, and result in a portfolio of high value projects (Cooper et al., 2002a).

Goal 2: A Balanced Portfolio

The second major goal is a balanced portfolio—a balanced set of development projects in terms of a number of key parameters. The analogy is that of an investment fund, where the fund manager seeks balance in terms of high risk vs. blue chip stocks; and balance across industries, in order to arrive at an optimum investment portfolio.

Visual charts are favored in order to display balance in new product project portfolios. These visual representations include portfolio maps or bubble diagrams (Figure 6).

Risk–Reward Bubble Diagrams

The most popular bubble diagram is a variant of the *risk/return chart* (see Figure 6). Here one axis is some measure of the *reward* to the company, and the other is a *success probability* (Cooper et al., 2002a; Evans 1996; Roussel et al., 1991). A sample bubble diagram is shown in Figure 6 for a business unit of a major chemical company. Note that the size of each bubble shows the annual resources spent on each project.

Traditional Charts for Portfolio Management

There are numerous parameters, dimensions or variables across which one might wish to seek a balance of projects. As a result, there are an endless variety of histograms and pie charts which help to portray portfolio balance. Some examples:

Project types is of vital concern. What is the spending on genuine new products vs. product renewals (improvements and replacements), or product extensions, or product maintenance, or cost reductions and process improvements? And what should it be? Pie charts effectively capture the spending split across project types—actual vs. desired splits (Figure 7).

North-South axis is risk
 East-West axis is Reward, measured by NPV
 (reverse direction)

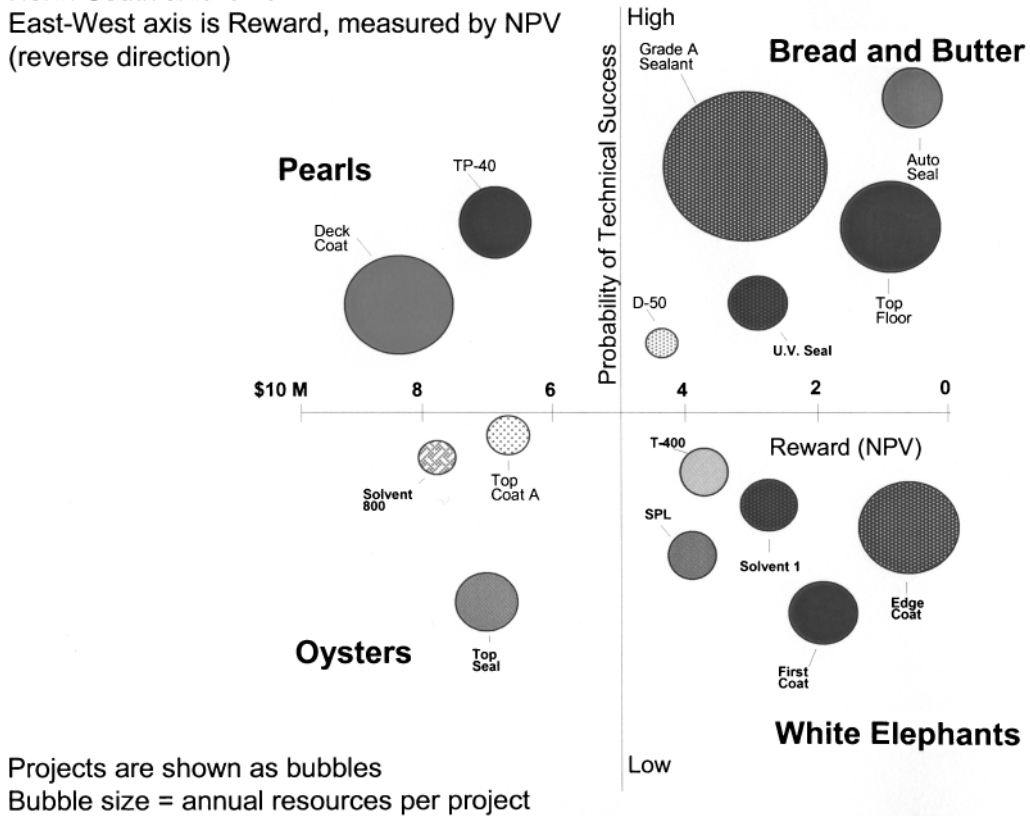

Figure 6. A typical & popular risk-reward bubble diagram.

Source: Cooper (2001).

Markets, products and technologies provide another set of dimensions across which managers seek balance. Pie charts are again appropriate for capturing and displaying this type of data (again, Figure 7).

Goal 3: Building Strategy into the Portfolio

Strategy and new product resource allocation must be intimately connected. *Strategy becomes real when one starts spending money!* The mission, vision and strategy of the business are made operational through the decisions management makes on where to spend money. For example, if a business's strategic mission is to 'grow via leading edge product development', then this must be reflected in the mix of new product projects underway—projects that will lead to growth (rather than simply to defend) and products that really are innovative.

Linking Strategy to the Portfolio: Approaches

There are three main ways to build in the goal of strategic alignment:

- (1) *Bottom up*—building strategic criteria into project selection tools: here strategic fit is achieved by including numerous strategic criteria into the Go/Kill and prioritization tools;
- (2) *Top-down*—Strategic Buckets method: this begins with the business's strategy and then moves to setting aside funds—envelopes or buckets of money—destined for different types of projects;
- (3) *Top-down*—Product Roadmap: here the business's strategy defines what major initiatives or platform developments to undertake.

Bottom Up—Strategic Criteria Built into Project Selection Tools

Not only are scoring models effective ways to maximize the value of the portfolio, but they can also be used to ensure strategic fit. One of the multiple objectives considered in a scoring model, along with profitability or likelihood of success, can be to maximize strategic fit, simply by building into the scoring model a number of strategic questions. In the

Pie slices show actual annual spending breakdowns

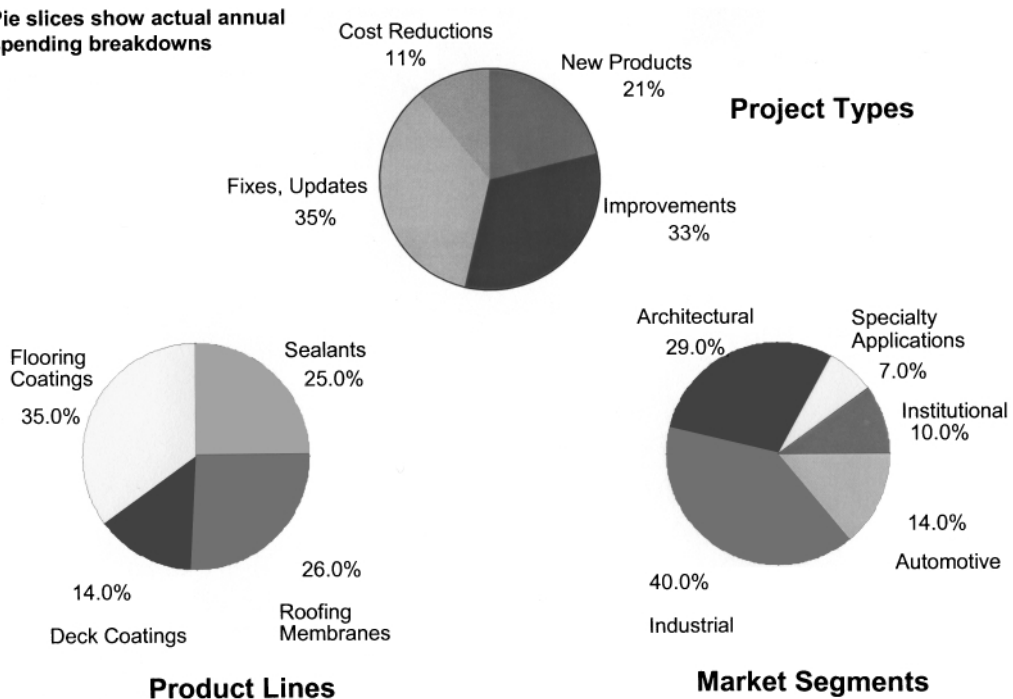

Figure 7. Breakdown of resources by project types, product lines & markets.

scoring model displayed in Figure 5, for example, three major factors out of six are strategic; and low scores on these will all but kill the project. Thus, projects that fit the business's strategy, offer competitive advantage, and leverage the firms' core competencies likely to rise to the top of the list. Indeed, it is inconceivable how any 'off strategy' projects could make the active project list at all: this scoring model naturally weeds them out.

Top-down Strategic Approach—Strategic Buckets Model

While strategic fit can be achieved via a scoring model, a top-down approach is the only method designed to ensure that where the money is spent mirrors the business's strategy (Cooper et al., 2002a). The Strategic Buckets model operates from the simple principle that *implementing strategy equates to spending money on specific projects*. Thus, setting portfolio requirements really means 'setting spending targets'.

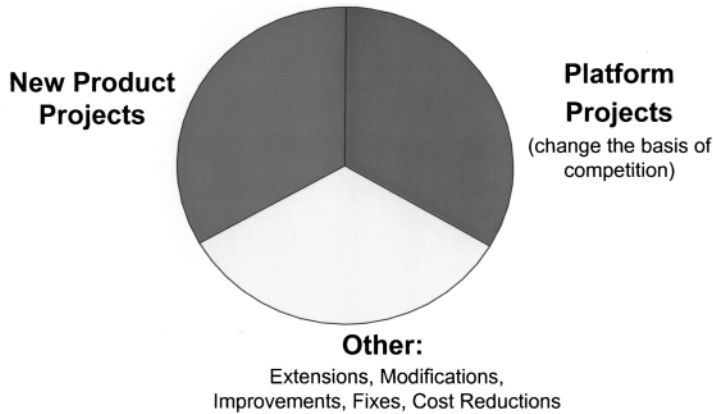

The method begins with the business's strategy, and requires the senior management of the business to make forced choices along each of several dimensions—choices about how they wish to allocate their scarce money resources. This enables the creation of 'envelopes of money' or 'buckets'. Existing projects are categorized into buckets; then one determines whether actual spending is consistent with desired spending for each bucket. Finally projects are priori-

tized within buckets to arrive at the ultimate portfolio of projects—one that mirrors management's strategy for the business.

In practice, senior management first develops the vision and strategy for the business. Next, they make forced choices across key strategic dimensions; that is, based on this strategy, development resources are split across categories on each dimension. Some common dimensions are:

- **Strategic goals:** Management splits resources across the specified strategic goals. For example, what percentage should be spent on Defending the Base? On Diversifying? On Extending the Base? and so on;
- **Product lines:** Resources are split across product lines: e.g. how much should be spent on Product Line A? On Product Line B? On C? A plot of product line locations on the product life cycle curve is used to help determine this split;
- **Project type:** What percentage of resources should go to new product developments? To maintenance-type projects? To process improvements? To fundamental research? etc;
- **Familiarity Matrix:**⁵ What should be the split of resources to different types of markets and to

⁵ The familiarity matrix was first proposed as a strategic tool by Ed Roberts (Roberts & Berry, 1983).

The business's strategy dictates the split of resources into buckets; projects are rank ordered within buckets, but using different criteria in each bucket.

Figure 8. Strategic buckets method of resource allocation.

Source: AlliedSignal-Honeywell; reported in: Cooper, Edgett & Kleinschmidt (2002a).

different technology types in terms of their *familiarity to the business*? (Roberts & Berry, 1983);

- *Geography*: What proportion of resources should be spent on projects aimed largely at North America? At Latin America? At Europe? At the Pacific? Or at global?

Now, management develops *strategic buckets*. Here the various strategic dimensions (above) are collapsed into a convenient handful of buckets. Then the desired spending by bucket is determined: the '*what should be*'. This involves a consolidation of desired spending splits from the strategic allocation exercise above. Next comes a gap analysis. Existing projects are categorized by bucket and the total current spending by bucket is added up (the '*what is*'). Spending gaps are then identified between the '*what should be*' and '*what is*' for each bucket.

Finally, projects within each bucket are rank-ordered, using either a scoring model or financial criteria to do this ranking within buckets. Portfolio adjustments are then made, either via immediate pruning of projects, or by adjusting the approval process for future projects.

A somewhat simpler example is shown in Figure 8. The leadership team of the business begins with the business's strategy, and uses the Mercedes-Benz emblem (the three-point star) to help divide up the resources. There are three buckets: fundamental research and platform development projects which promise to yield major breakthroughs and new technology platforms; new product developments; and maintenance—technical support, product improvements and enhancements, etc. Management divides the

R&D funds into these three buckets, and then rates and ranks projects against each other within each bucket. In effect, three separate portfolios of projects are created and managed. And the spending breakdowns across projects mirror strategic priorities.

The major strength of the Strategic Buckets Model is that it firmly links spending to the business's strategy; further, it recognizes that all development projects that compete for the same resources should be considered in the portfolio approach. Finally, different criteria can be used for different types of projects. That is, one is not faced with comparing and ranking very different types of projects against each other.

Top Down Strategic Approach—Product Roadmap

A product roadmap⁶ is an effective way to map out a series of assaults in an attack plan. What is a roadmap? It is simply a management group's view of how to get where they want to go or to achieve their desired objective (Albright, 2001; Myer & Lehnerd, 1997). The roadmap is a useful tool that helps the group make sure that the capabilities to achieve their objective are in place when needed. Two useful types of roadmaps are the product roadmap and the technology roadmap:

- (1) The *product roadmap* defines the product and product releases along a timeline—how the product line will evolve over time, and what the next generations will be. It answers the question: what products? An example is shown in Figure 9. Here

⁶ This section is based on Lucent Technologies. See R. E. Albright (2001). For more on platforms and roadmaps, see Myer & Lehnerd (1997).

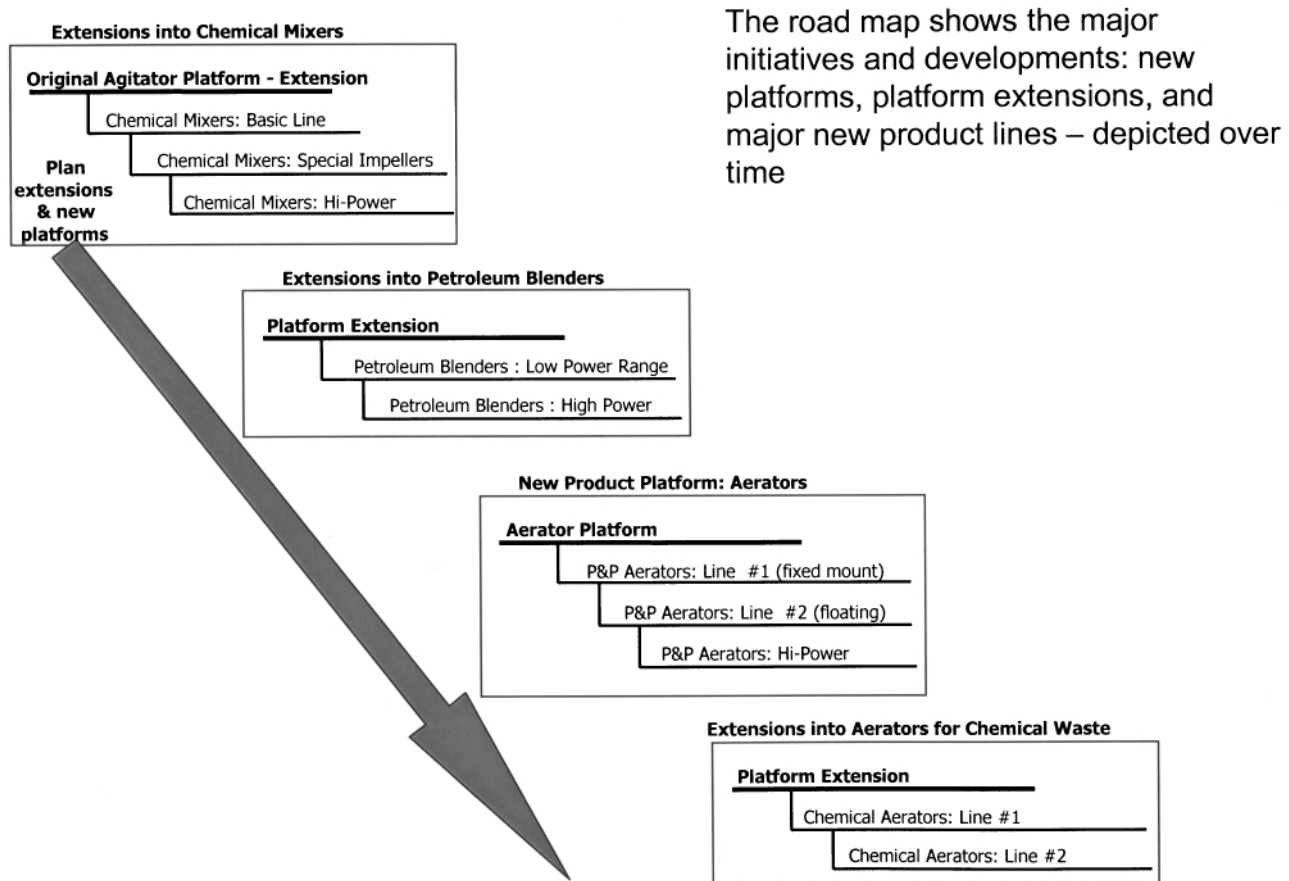

Figure 9. A product roadmap for a process equipment manufacturer.

Source: Cooper (2001).

the product roadmap for a process equipment manufacturer not only defines the platforms and platform extensions needed but also maps out the various product releases, specifies features or functionality that will be built into each new release, and indicates timing (launch date);

- (2) The *technology roadmap* is derived from the product roadmap, but also specifies how you will get there. That is, it lays out the technologies and technological competencies that are needed in order to implement (develop and source) the products in the product roadmap. The technology roadmap is a logical extension of the product roadmap and is closely linked to it.

Conclusion

Product innovation is a vital task for the modern corporation. The company's success at new product conception, development and launch may well decide the fate of the entire business. Many companies miss the mark when it comes to the 15 critical success factors outlined earlier in this chapter, and the results are predictable—a mediocre new product effort. Further, if the company lacks a systematic new product process, or if portfolio management for new products is a foreign concept, then best practices are missing. The effort to implement a robust Stage-Gate™ process coupled with effective portfolio management is significant: it may take a year or so of hard work. But those firms that have successfully implemented Stage-Gate and portfolio management methods for product innovation are reaping the benefits (Griffin, 1997; Menke, 1997).

Types of Innovations

Robert J. Sternberg¹, Jean E. Pretz¹ and James C. Kaufman²

¹ *Department of Psychology, Yale University, USA*

² *Department of Psychology, California State University, USA*

Abstract: Innovations can be of eight different types. Each represents a different kind of contribution. For example, a conceptual replication is a minimal innovation, repeating with minor variations an idea that already exists (e.g. Mercury's putting the 'Mercury' label on what is essentially an already-existing Ford car). Forward incrementations represent next steps forward along existing lines of progression (e.g. the 2001 version of a 2000 car). Redirections represent a totally different direction for products that diverge from the existing line of progress (e.g. electric cars). We will discuss the types of innovations and the circumstances leading to success.

Keywords: Innovation; Creativity; Incrementation; Propulsion; Redirection; Reinitiation; Replication.

Introduction

In the erstwhile television series, *All in the Family*, there was an episode in which a character created a novel invention: a remote-control doorbell ringer. One could ring someone's doorbell remotely, so that one actually did not have to go up to the door of the person in order to ring the bell. It quickly became obvious that, although the invention was novel, it somehow was not creative. What it lacked was a second property of creativity beyond novelty: usefulness. All inventions and, indeed, innovations of any kind, start with some kind of creative enterprise, and the enterprise must produce work that is not just novel, but useful.

Creativity is the ability flexibly to produce work that is novel (i.e. original, unexpected), high in quality, and useful, in that it meets task constraints (Lubart, 1994, this volume; Ochse, 1990; Sternberg, 1988, 1999b; Sternberg & Lubart, 1995, 1996). The remote-control doorbell ringer was novel, but not useful for any particular task anyone could think up—at least on the show. Creativity is a topic of wide scope that is important at both the individual and societal levels for a wide range of task domains. At an individual level, creativity is relevant, for example, when solving problems on the job and in daily life. At a societal level, creativity can lead to new scientific findings, new movements in art, new inventions, and new social programs. The economic importance of creativity is clear because new products or services create jobs. Furthermore, individuals, organizations, and societies

must adapt existing resources to changing task demands to remain competitive. *Innovation* is the channeling of creativity so as to produce a creative idea and/or product that people can and wish to use.

Creativity may be viewed as taking place in the interaction between a person and the person's environment (Amabile, 1996; Csikszentmihalyi, 1996, 1999; Feldman, 1999; Feldman, Csikszentmihalyi & Gardner, 1994; Sternberg, Kaufman & Pretz, 2002; Sternberg & Lubart, 1995). According to this view, the essence of creativity cannot be captured just as an intrapersonal variable. Thus, we can characterize a person's cognitive processes as more or less creative (Finke, Ward & Smith, 1992; Rubenson & Runco, 1992; Weisberg, 1986, this volume) or the person as having a more or less creative personality (Barron, 1988; Feist, 1999). We further can describe the person as having a motivational pattern that is more or less typical of creative individuals (Hennessey & Amabile, 1988), or even as having background variables that more or less dispose that person to think creatively (Simonton, 1984, 1994, this volume). But we cannot fully judge that person's creativity independent of the context in which the person works.

For example, a contemporary artist might have thought processes, personality, motivation, and even background variables similar to those of Monet, but that artist, painting today in the style of Monet, probably would not be judged to be creative in the way

Monet was. He or she was born too late. Artists, including Monet, have experimented with impressionism, and unless the contemporary artist introduces some new twist, he or she will likely be viewed as imitative rather than creative. To a large extent, creative innovation starts with a decision to be creative and to think intuitively and 'out of the box' (see Root-Bernstein & Root-Bernstein, this volume).

The Propulsion Model of Creative Contributions

Sternberg (1999c) has presented what he refers to as a propulsion model of creative contributions (see also Sternberg, Kaufman & Pretz, 2001, 2002). The idea is that creative contributions 'propel' a field forward in some way—they are the result of creative leadership on the part of their creators. The propulsion model is a descriptive taxonomy of eight types of creative contributions. Although the eight types of contributions may differ in the extent of creative contribution they make, there is no a priori way of evaluating *amount* of creativity on the basis of the *type* of creative contribution. Certain types of creative contributions probably tend, on average, to be greater in amounts of novelty than are others. For example, replications tend, on average, not to be highly novel. But creativity also involves quality of work, and the type of creative contribution a work makes does not necessarily predict the quality of that work.

The eight types of creative contributions are:

- (1) *Replication*. The creative contribution represents an effort to show that a given field is where it should be. The propulsion is intended to keep the field where it is rather than moving it;
- (2) *Redefinition*. The creative contribution represents an effort to redefine where the field currently is. The current status of the field thus is seen from a new point of view;
- (3) *Forward Incrementation*. The creative contribution represents an attempt to move the field forward in the direction in which it already is moving, and the contribution takes the field to a point to which others are ready to go;
- (4) *Advance Forward Incrementation*. The creative contribution represents an attempt to move the field forward in the direction it is already going, but the contribution moves beyond where others are ready for the field to go;
- (5) *Redirection*. The creative contribution represents an attempt to move the field from where it is currently headed toward a new and different direction;
- (6) *Reconstruction/Redirection*. The creative contribution represents an attempt to move the field back to where it once was (a reconstruction of the past) so that the field may move onward from that point, but in a direction different from the one it took in the past;

- (7) *Reinitiation*. The creative contribution represents an attempt to move the field to a different and as yet not reached starting point and then to move the field in a new direction from that point;
- (8) *Integration*. The creative contribution represents an attempt to move the field by putting together aspects of two or more past kinds of contributions that formerly were viewed as distinct or even opposed. This type of contribution shows particularly well the potentially dialectical nature of creative contributions, in that it merges into a new Hegelian type of synthesis two ideas that formerly may have been seen as opposed (Sternberg, 1999a).

The eight types of creative contributions described above are viewed as qualitatively distinct. However, within each type, there can be quantitative differences. For example, a forward incrementation may represent a fairly small step forward for a given field, or it may represent a substantial leap. A reinitiation may restart an entire field or just a small area of that field. Moreover, a given contribution may overlap categories. For example, a forward incrementation may be the result of an integration of somewhat closely related concepts in the field.

Thus, when people are creative, they can be creative in different ways. The exact nature of these ways depends upon the theory of types of creative contributions one accepts. What is a creative contribution and why do we need a taxonomy of types of creative contributions? A consensual definition of a creative contribution is of something that is: (a) relatively original; and (b) high in quality vis-à-vis some purpose (see Sternberg & Davidson, 1994; Sternberg & Lubart, 1995, 1996). Starting with creative contributions rather than creative contributors can have several advantages. First, a given contributor may make a variety of different types of contributions. The contributor thus is not limited to any one of the eight types of creative contributions described in this book. Contributions may be primarily of a given type, but creators may not be. For example, much, but certainly not all of Picasso's work, set off in strikingly original and bold directions. Through the proposed theory, one can evaluate individual works of a creator and not just the 'average' or typical type of work the creator produced. Second, even if contributors tend to have a type of contribution they make most often, observing differences in the types of contributions individuals make can help elucidate differences in the types of creativity the contributors typically tend to show. Third, the emphasis on contributions rather than creators underscores the point that people can modify the kinds of contributions they make. Someone early in a career may be afraid to depart too much from accepted ways of doing things, for fear that such a departure will put his or her career at risk of being derailed. Later in a

career, however, for example, after attaining tenure or, at least, financial security, the creator may be willing to take risks and make contributions that earlier he or she would not have felt comfortable making earlier. The creator's goals and purposes may change. Even from the days when composers had to compose music or artists had to paint works in order to please their royal patrons, creative individuals have always operated under societal constraints. Given the importance of purpose, creative contributions must always be defined in some context. If the creativity of an individual is always judged in a context, then it is important to understand how the context interacts with how people are judged. In particular, what are the types of creative contributions a person can make within a given context? Most theories of creativity concentrate on attributes of the individual (see Sternberg, 1988, 1999b). But to the extent that creativity is in the interaction of person with context, we would need as well to concentrate on the attributes of the individual and the individual's work relative to the environmental context.

How can one apply the propulsion model to invention? We consider this question next, reviewing inventions that represent each of the eight types of creative contributions listed above.

Examples of Each of the Types of Creative Propulsion

Replication

In replication, inventors essentially duplicate an existing product, sometimes, with improvements in pricing or in quality. Many people are familiar with Altoids™, which are a particularly strong kind of breath mint. When these mints first came onto the market, they were an immediate hit. People quickly started buying them up. As so often happens when a product is successful, other manufacturers see money to be made by imitating the original product. One of the authors recently went to a drug store to buy a tin of these mints, and was only a bit surprised to see that, where before the one brand had had this particular section of the drugstore counter to itself, now it was sharing space with three competitors. As far as the author could tell, the three competitors basically had replicated the Altoids™ formula for success, with minor variations.

Such copies are commonplace in industry. The success in IBM personal computers rapidly gave rise to large numbers of replications, which were so similar to the original IBMs that they actually were (and still are) referred to as 'clones'. Kleenex™ tissue paper gave rise to large numbers of imitators, as did bran cereals with raisins. Sometimes the replicators ultimately achieve a larger market share than did the originators, typically when the new products are either notably better in quality or notably less expensive than the original product.

Redefinition

Video games have become an integral part of American culture. Just as the invention of the television in the 1950s redefined entertainment and indirectly influenced many arenas of American life, the introduction of the video game in the 1970s has initiated a change in the nature of childhood play throughout society.

Where did video games come from? Who first had the idea to make television interactive, to give people the power to control the action on the screen? The origins can be found in one of the first video games, Pong. Video games actually stem from a very simple concept invented in the 1950s by an unsuspecting physicist working at Brookhaven National Laboratories in Upton, New York, Willy Higinbotham. Higinbotham's original 'video game' was designed to add some spice to a public tour of his instrumentation laboratory. Because Brookhaven was involved in nuclear research, these tours were organized to show visitors that the research was entirely peaceful and posed no risk to residents. Higinbotham knew that the tour of the facility was not very exciting, so he toiled around with an oscilloscope and a simple computer, built a few controls with buttons and knobs, and created what can be considered the first video game. The game was conceptually very similar to Pong: one player presses a button to launch a ball from the left side of the screen, adjusts a knob so the ball clears a barrier in the middle of the screen, and a second player hits the ball back over the 'net'. With these modest beginnings, the video game industry was born.

Little did Higinbotham know that not only would his simple tennis game relieve boredom on the tour of his laboratory, but that players would form lines, eager to try their hand at the novel challenge. Before Higinbotham understood the potential of the demand he had created, marketers seized hold of the idea. In fact, Pong is simply a redefinition of Higinbotham's basic tennis game. The originators of Pong did not seriously revamp the design, but they did bring to it a new perspective. Realizing the game's potential for fascination (and remuneration), they grabbed their opportunity to latch onto the public's interest. As almost every American child can attest, their fascination has not waned, and the video game industry continues to profit (Flatow, 1992). Redefinitions are not limited, of course, to video games.

A split-second decision can also represent an attempt to redefine a field. Jenò Paulucci was a businessman who had just purchased Chun King, a canned food company. Paulucci wanted to use this company to sell his own food inventions, Cantonese vegetables with Italian spices. Paulucci had a meeting with the main buyer for a top food chain, and he was trying to sell his Chun King cans to be distributed by this chain. If the businessman was able to make the sale, his company would surely take off and become profitable; if not, it

would be a difficult task to maintain financial solvency.

Demonstrating his product, Paulucci opened up a can of chop suey vegetables—and saw a cooked grasshopper sitting right in the middle of the can. Paulucci had one brief moment in which the grasshopper was hidden from the buyer by the open can lid. What could he do? If the buyer saw the grasshopper, the sale would surely not go through—and Chun King’s reputation would likely suffer. Think about what you might do in such a situation.

In those few seconds, Paulucci redefined his role as salesman. Not only was Paulucci responsible for presenting his product to a potential buyer, but his chances of making a sale would be increased if he could convince the customer that he was a consumer himself. A typical businessman might have either tried to surreptitiously remove the grasshopper from the can (and run a high risk of being caught) or tried to explain the many legitimate reasons why the dead grasshopper was not indicative of his company’s product. Paulucci decided to attempt neither of these two strategies. Instead, he looked the buyer in the eye and said that the vegetables looked so good that he wanted to have the first bite himself. Paulucci took a large forkful of vegetables—including the fateful grasshopper—and ate the large bite with a big smile. He got the sale (Hay, 1988).

Forward Incrementation

In forward incrementation, a new product is invented that moves an existing product line to the next step consumers are ready to take. The invention of the incandescent lamp is a good example of the forward incrementation typical of normal science (Kuhn, 1970). Although Americans strongly associate the name of Thomas Edison (1847–1931) with the invention of the light bulb, Joseph Swan (1828–1914) of England deserves equal scientific credit for his work on the problem, as do many others who also contributed small steps along the way toward the successful product.

The first attempts at creating a light bulb can be traced to 1838, when Jobart “sealed a carbon rod inside a vacuum and watched it glow as a current was passed through it” (Clark, 1985, p. 220). By 1847, progress had reached a point where the concept of an evacuated bulb with a carbon filament had been solidified. But specific problems remained. Incandescent lamps in the mid-1800s burned for a very short period of time due to a combination of two factors. First, the filaments were not durable, and second, there was too much air inside the bulb (Yarwood, 1983).

As the technology was not yet available to create a vacuum inside the bulb, experiments focused on perfecting the filament. Swan experimented with a carbon filament treated in various ways, whereas Edison believed that a platinum filament was the answer. Earlier, he had worked with carbon unsuccessful-

fully. In 1865, Hermann Sprengel introduced the mercury vacuum pump, and 14 years later, Edison devised and his group devised a vacuum pump combining the Sprengel and Geissler pumps. He finally met success with a carbon filament (Clark, 1985).

Step by step, scientists settled on the carbon filament and began to produce light bulbs in quantity by 1882. At that point, the only impediment to more widespread use of the bulbs was the lack of electrical wiring in homes and businesses. The next step of the path was cleared as Edison and his colleagues set out to create a system of electricity to bring power to cities. Even after Thomas Edison and Joseph Swan joined forces to create United Electric Company, experiments on metal filaments continued (Yarwood, 1983). Eventually, the tungsten filament became preferred because of its high melting point, and it remains the standard in the light bulbs of today.

Whereas some discoveries are characterized by distinct moments of insight that create a discontinuous path of progress, the light bulb is better viewed as the product of a scientific evolution directed by careful experimentation and simple trial and error. Such forward steps or incrementations are key to the progress of every scientific field.

Another example of a next step in science is Pasteur’s development of vaccine therapy following his germ theory of disease. After the germ theory had described how airborne bacteria are the mechanism for the cause of disease, the next step was to extend the theory’s implications for disease prevention, namely, vaccine therapy. The concept of vaccination did not originate with Pasteur (nor did pre-germ theory advances in sanitary practices in medical settings). For example, Edward Jenner had earlier discovered the effectiveness of using small amounts of cowpox to vaccinate humans against small pox.

Pasteur reasoned that the administration of similarly attenuated germs might prevent the development of bacterially caused diseases. His first attempt, using fowl cholera, proved a success. Although he at first did not realize that the attenuation was caused by prolonged exposure to warm air, later experiments with anthrax in cattle confirmed that time and heat did indeed sufficiently weaken the bacteria. Pasteur’s great triumph of vaccine therapy was in a dire case of a young boy attacked by a rabid dog. After administering a culture developed from the brains of dogs and rabbits, the boy’s survival was celebrated and the miraculous effectiveness of vaccination assured (Meadows, 1987).

Vaccine therapy was not a new idea to Pasteur, in that Jenner had already used it in the treatment of smallpox. In fact, ancient Chinese culture had already recognized this technique in the 10th century. Alchemists in China administered a smallpox vaccine by inserting slightly infected plugs of cotton into the noses of healthy individuals (James & Thorpe, 1994). But Pasteur extended this method to include new diseases

caused by germs he had identified, the logical next step, an increment forward on a path well chosen.

Advance Forward Incrementation

Advance forward incrementations can be found in products that, in essence, are ahead of their time. Consider, for example, the domain of computers. "If anyone was born out of his time it was Babbage; his ideas about the computer were only to find their rightful place by the middle years of the twentieth century" (Cardwell, 1994, p. 420).

In 1834, a British mathematician named Charles Babbage (1791–1871) envisioned the universal computer. Just over a century before the first modern computers were created, Babbage wrote up plans for a powerful analytical engine that had the capacity to perform diverse and complex functions. Babbage's analytical engine was a mechanical computer, complete with a memory store and the ability to operate conditional logic. Input and output were recorded in binary code on familiar punch cards. Although many engineers and scientists in the 19th century knew of Babbage's work, they did not pursue the potential of his ideas. They simply were not ready for them. Thus, Babbage's creative contribution can be viewed as an advanced forward incrementation.

The uniqueness of this example is not merely in its precocity, but also in its original emphasis on pure science. Whereas Babbage had hoped to create a universal computer, the demand for computers in businesses and the military did not require the flexibility of a universal engine, but instead was focused on creating specialized machines. The first computers that emerged around the turn of the twentieth century thus were business machines. One well-known early computer was Hermann Hollerith's business machine, which was designed to aid in calculating the census of 1890. During the wars, great progress was made in creating specialized computers that could make pointed calculations related to battle. Such computers were powerful, but suffered from severely limited memories. For example, in order for such a computer to change its specialty, it had to be completely reprogrammed, a process that required some parts of the computer to be modified and the machine rebuilt.

The concept of a universal computer, however, was not lost among scientists whose orientations were more basic. While computers were being developed to estimate ballistics during World War II, German engineer Konrad Zuse was aiming to create a universal computer, a scientific machine with great flexibility and less specificity. By 1941, he had built his Z3 computer. It was a mechanical universal machine that performed various tasks at the command of computer programs. Around the same time, from 1939 to 1944, International Business Machines (IBM) built a scientific universal computer according to specifications set

out by Howard Aitken of Harvard University. This machine was entirely mechanical, stretching 50 feet in length and run by a 4-horsepower motor. Although the first IBM computer did not have the capability of using conditional logic, its creators could be proud of their success in carrying out Babbage's vision of an analytical engine whose purpose was purely scientific. In fact, British mathematician Alan Turing took Babbage's concept of a universal computer to a hypothetical extreme with his invention of what has become known as the Turing machine. This machine exists only in an abstract sense, but it was instrumental in Turing's essay 'On computable numbers, with an application to the *Entscheidungsproblem*', proving that numbers existed whose precise value could not be computed.

Computers have had a revolutionary impact on many areas of modern life, from the first business machines to today's miniature day-planner computers. Charles Babbage's notion of the universal machine came a century before the first machines were built, a prototypical example of an idea ahead of its time. Perhaps the demands of the day dictated the path of progress on computer development, but Babbage's universal analytical engine was bound to return to the fore once the conditions were right. Incidentally, the revolution that has followed the advent of the computer age would not have been a surprise to the one who was there at its conception. Babbage has been quoted as predicting that "as soon as an analytical engine exists, it will necessarily guide the future course of science" (Cardwell, 1994, p. 483).

In the early 19th century, scientists were fascinated with understanding the relationship between magnetism and electricity. Michael Faraday (1791–1867) was a British chemist who had also become intrigued with the relationship between these two physical phenomena. In 1821, Faraday demonstrated that not only can electric current act like a magnet, but magnets can induce electrical current. Faraday's contributions to this line of investigation included the invention of several instruments, such as the electric motor, the electrical transformer, and the dynamo, devices that demonstrated the conversion of magnetism to electricity and of electricity to mechanical motion (Meadows, 1987).

Common theorizing about magnetic forces considered magnetism to be similar to gravity. Just as two bodies are attracted to one another, more or less depending on their distance from each other, two magnetic bodies also possess an amount of attraction. The strength of the attraction between two objects was thought to be a direct function of the distance between them. However, Faraday focused precisely on this distance, proposing that the space between two magnetic or electric objects was not uniform, but rather composed of 'lines of force'. These are the lines observed in the textbook example showing the position

of iron filings in the vicinity of two magnets. Faraday's field theory held that magnetic forces acted as fields between objects rather than as forces that lay within the objects themselves (Meadows, 1987).

Acceptance of this view of magnetism would necessitate a fundamental shift in scientific understanding at the time. Unfortunately, the import of Faraday's field theory was not appreciated by his contemporaries. These contemporaries were not satisfied with the theory and awaited a mathematical proof of it. The scientific world waited for this proof until 1873, when Scottish mathematician James Clerk Maxwell (1831–1879) published his *Treatise on Electricity and Magnetism*. This work not only proved the validity of Faraday's field theory, but also confirmed another prediction of Faraday's, which stated that light is actually a kind of electromagnetic wave (Meadows, 1987). Finally, the foresight of a great chemist was vindicated.

Some things that we take for granted today represented advance forward incrementations when they began. In the 1930s, with America mired in the Great Depression, Michael Cullen had a variety of ideas that changed the way that most people do their shopping. He saw a need for lower food prices. At that time, the predominant way that people bought food was through mom-and-pop grocery stores. These stores, however, were both slow (clerks completed a customer's order, resulting in long lines) and somewhat expensive (the quantities of food that the mom-and-pop stores could purchase would not be in large enough quantities to give them discounts). Cullen also noted that there were several other factors in place that made a new idea possible; most notable of these factors was the automobile, which enabled people to be able to travel farther to purchase food (Panati, 1991).

What Cullen did was to advance the field of food purchasing—and, by extension, shopping—drastically: He opened up the first supermarket. Cullen opened up huge stores that stocked enormous quantities of food. He chose low-rent locations that were not in the center of town. Yet they were locations that were suddenly accessible to people because of the automobile. Cullen even set aside paved lots for people to park their cars, an innovation by itself. He invented the art of balancing prices—by making a profit on one product, he could sell another product at cost. These bargains went a long way in attracting a large audience for the new supermarket. He introduced an early version of the shopping cart (an improvement over baskets). In addition, Cullen borrowed (from a different chain of stores) the idea of self-service, which helped cut down on his overhead (Panati, 1991).

Unlike many others who introduced advanced forward incrementation, Cullen's creation was immensely—and immediately—successful. One reason for this success was that while the field was not ready for his creation, the public was. Mom-and-pop

grocers tried to convince the government to make Cullen's price-cutting illegal. They also tried to get newspapers to reject advertisements for supermarkets. But the Great Depression had created a public that was eager to save money in any way possible, and the objections of the other grocers meant little. Indeed, many other supermarkets soon opened up in competition with Cullen's stores (Panati, 1991).

Redirection

Redirections are represented by products that are different in kind, in some way, from products that have existed before. Consider the concept of a 'custom-made' product. Almost any product ordered 'custom made' today will take longer to be produced and will likely be more expensive than off-the-shelf products. For the custom-made price, you are allowed to designate options according to your personal preferences and special needs. Americans living in the 19th century enjoyed the luxury (whether they wanted it or not) of custom-made everything, from kitchen cabinets to household machines. But with the introduction of mass production and assembly lines, the standards in industry were about to change, and with them, the standard of living of the average American citizen.

Eli Whitney in the U.S. as well as others in Europe had introduced mass-production techniques to the arms industry. However, a strong promoter of this industrial movement was the assembly line. The first notable assembly line in use during the 19th century was actually a *disassembly* line. Employees at a Midwest meat-packing company harvested cuts of meat from carcasses hanging from a trolley overhead. When the work at one station was done, the pieces were easily transported to the next point on the line (*History of the organization of work*, 2000).

It was in this context that Henry Ford first launched his constant motion assembly line for the manufacture of the Model T Ford in 1913. Whereas large machines had previously been mass-produced from a single location to which large stocks of components were hauled, Ford's innovation was to install a moving assembly line in which identical parts could be added to the car as it passed down the line (Cardwell, 1994). On the assembly line, one of Ford's Model T's could be produced in 93 minutes. This reduction in time led to a commensurate reduction in cost to the consumer. In particular, this unprecedented cost-effectiveness forced Ford's competitors to join him and play the new production game (*History*, 2000).

While his application of this technique to the automobile industry is no great feat of creative thinking, its impact on the field was strongly redirecive. Ford's promotion of the assembly line and of mass-production techniques was an impetus with wide-reaching impact. Whereas others had begun using these methods, Ford's introduction of the assembly line and mass production to the production of cars initiated a

change in manufacturing whose impact reached beyond the automobile industry to include a broad range of industrial domains.

The increased use of mass production has influenced the nature of the industrial workforce and the economies of countries through the world, and has led to related techniques such as automatization. For example, factories rely primarily on unskilled or semi-skilled labor while machines have taken over the technical difficulties of the job. As mass-production facilities have become more ambitious, more elaborate supervisory hierarchies have become necessary, and positions for management specialists as well as distributors and salespeople have been created. Although Ford himself did not conceive of this evolution of manufacturing industry, his introduction of the assembly line and the technique of mass production may be considered the crucial step which led to a complete redirection in the field of manufacturing.

An invention that had redirective effects on the field of communication as well as on the wider social and intellectual world is the printing press with movable type. The first printed book dates to 9th century China although the printing press did not appear in Europe until the mid-15th century. Whether these developments were independent or related is of less concern than is the impact of the printed word on Western society at the time of its introduction.

Prior to the invention of movable type and the printing press, books were laboriously copied by hand. This process resulted in books' being rare and precious. When Johannes Gutenberg (1394/99–1467) introduced the concept of movable type in 1448 in Mainz, Germany, a revolution followed. Especially in Europe, the 26-letter alphabet was particularly well suited to the use of movable type. Any book could be reproduced by mixing and matching many multiples of these 26 basic prototypes. (This was not the case in China. Given the large numbers of characters used in the Chinese language, movable type was simply not as practical in China as it turned out to be in Europe (Cardwell, 1994)). It has been estimated that there were more books published in Europe between 1450 and 1500 than had been published in the previous 1,000 years (Yarwood, 1983).

The immediate and lasting effect of Gutenberg's contribution can be summarized as the grand facilitation of the dissemination of ideas. Gutenberg's process affected many aspects of culture, including the dissemination of information about religion. Perhaps the best-known printed volume associated with Gutenberg's name is his version of the Latin Bible. As a case in point, greater public access directly to scripture had revolutionary (or, at least, reformatory) effects on the culture at the time. As Bibles became more available, lay people who were not proficient in Latin wished to read the text in their native language. As Bibles became

available in the vernacular, the theology of the Church was also in a parallel transition. Martin Luther (1483–1546) advocated direct access to the scripture by lay people, preaching a new Reformation theology that argued for a direct and personal relationship with God (Rubenstein, 2000).

One of the most popular products of early presses were indulgences, certificates that could be purchased from the Catholic Church in exchange for an absolution of sins. Appropriately, the presses also helped disseminate the famous 95 theses against the sale of indulgences first posted by Martin Luther in 1517. Although such heretical theological ideas would normally have been discussed among Luther's colleagues at the university in Wittenberg, the printed versions of his theses no doubt spread his controversial ideas to others, gaining subtle support for his call for reform.

The invention of the printing press greatly facilitated the spread of ideas in an age of great progress. From the careful molding and casting of movable metal type to the printing and binding of the illustrative Gutenberg Bibles, the printing press has been pivotal in redirecting the history of European culture.

Another redirection occurred in the field of telecommunications with the invention of the telephone in 1876. During the 19th century, people communicated with one another over long distances using the revolutionary telegraph network. However, as the technique became more popular, supply could no longer meet demand. The problem was that only one message could travel over a given wire at any given time, and there simply were not enough wires to carry all the messages that people wanted to send. In 1872, the race was on to find a way to send more than one message simultaneously over the same wire (Flatow, 1992).

Alexander Graham Bell (1847–1922), a teacher who enjoyed tinkering, believed he might have a solution to this problem. Based on his experience with tuning forks, Bell reasoned that it might be possible to send two messages over the same wire. He experimented with tuning-fork transmitters set at different pitches and receivers in the form of reeds set to vibrate at the same frequency as the tuning forks. Once Bell was able to tune the reeds to resonate with the forks, he was able to show that his hypothesis was correct: each fork caused a response in its respective reed, and the two frequencies did not interfere with one another! This was Bell's harmonic telegraph (Flatow, 1992).

Follow-up experiments with his new musical instrument revealed that when the tuning fork was plucked, its tone was transmitted to the receiver. Bell's suspicions that speech could be transmitted similarly over wire were beginning to become plausible. Bell knew that he only needed a transmitter that could convert speech into electrical signals, and the telephone then could become a reality. Meanwhile, Elisha Gray, a successful inventor, had been working on the same

telegraph problem, and had obtained similar results. However, Gray was discouraged by businessmen and others who believed that the telephone would never be profitable. Unfortunately, Gray listened to the short-sighted businessmen, and his design of the telephone was set aside (Flatow, 1992).

This is the point where Bell's daring to defy the crowd paid off. Bell's recent breakthrough with the harmonic telegraph propelled him forward. Flatow (1992) writes, "Bell could no longer ignore (opportunity's) knock. He would give up on the telegraph and concentrate on the telephone" (p. 81). Rather than follow the path of normal science, working to perfect the telegraph system, Bell saw an opportunity to make a new contribution, one that could redirect the field toward a communication system based not on dits and dahs, but rather on the authentic human voice.

The rest of the story is well known. Bell patented his telephone in 1876, just hours before Gray's application arrived at the patent office (Flatow, 1992). A few years later, the invention of the microphone by David Hughes (1831–1900) greatly improved the quality of telephone communication and spurred its more widespread use. The first telephone lines were installed shortly thereafter in 1878 in New Haven, Connecticut. By the 1920s telephones had become a standard mode of communication (Williams, 1987). Although the telegraph did not immediately fall into disuse, the addition of the telephone pushed our communicative repertoire in a new direction.

Reconstruction/Redirection

One relatively recent invention that is based on an old idea is the amateur photographer's one-use camera. The small unit is purchased pre-loaded with film, and the film is developed simply by dropping off the whole camera at a camera center. The film processors remove the film from the camera, develop it, and return the prints to the customer. This convenient service saves consumers the trouble of carrying a fragile, expensive camera with them on vacation. It also gives a second chance to those vacationers who forgot their personal cameras at home. And it even allows newlyweds to collect candid shots of their friends and relatives at their wedding reception without having to hire a professional. You think this is a wonderful example of an invention for modern convenience? Think again.

Actually, the one-use camera was invented in 1888, one of the original Kodaks to be marketed to amateurs (Flatow, 1992). The first cameras for personal use were marketed under the motto, "You press the button, we do the rest", a slogan which would certainly apply to many of today's automatic cameras (Flatow, 1992, p. 49). Whereas early photography was characterized by its reliance on cumbersome equipment and dangerous chemicals, this new Kodak was improved for amateur use. Kodak's first personal camera was small and lightweight. Its film was stored in a compact roll

that could be unwound with a key, and the operation of the camera required no special chemicals or setup. Consumers bought a camera that was preloaded with a roll of film of 100 exposures. When the roll was shot, the entire camera was shipped to Kodak for processing and returned fully reloaded and ready to go. By 1900, Eastman Kodak had perfected their concept of the personal-use camera with the introduction of the Brownie camera. The six-exposure Brownie was cheap and extremely simple to use, and caught the imaginations of many Americans (Flatow, 1992).

The reinvention of the original Kodak as a modern one-use, disposable camera is an example of a creative reconstruction/redirection. The Kodak company recognized the potential of this old idea to move the field in a new direction. Whereas the original camera first enabled non-professionals to try their hand at photography, the modern reconstruction contributes in a different way. In the field of modern photography, it is no new concept that amateurs have access to quality cameras, so the creative contribution of the new Kodak original is its convenience. Now there is an option for people who seek an inexpensive, temporary solution to their photography needs. Wouldn't they be surprised to learn that a similar convenience existed at the turn of the century?

Reinitiation

Reinitiations are represented by inventions that take off in an imaginative and wholly new way. An especially creative reinitiation lies in the field of written language. Imagine you were raised to communicate in a language that was only spoken and that had no written form. Suppose you wanted to create a system to represent the sounds and meanings of your native tongue. Where would you start? How many symbols would you need to sufficiently record the multitude of nuances in your oral tradition?

This is exactly the challenge that Cherokee Native American Sequoyah took upon himself in 1809. Sequoyah grew up in Alabama and spent time fighting the white settlers in the early 1800s. In 1809, when Sequoyah was approximately 35 years old, he realized that the Cherokee language might suffer under the effects of the social upheaval taking place at the time, so he decided he would do what he could to preserve the oral tradition with which he and his people had been raised. Unfamiliar with any particular written language, English or otherwise, Sequoyah began to create symbols to represent the sounds of Cherokee.

As he noted the many sounds that were part of his spoken words, he took symbols found in printed materials, including some from the English, Greek, and Arabic alphabets to represent these sounds. In 1821, after 12 years of hard work, Sequoyah had created a list of 85 syllables, the Cherokee syllabary. Based on this syllabary, Sequoyah began to read and write and to teach others to do the same. By 1828, the *Cherokee*

Phoenix became the first Native American newspaper to be published. The fact that this written language was created single-handedly and in such rapid time is a feat of genius and perseverance (Zahoor, 1999).

The contribution of Sequoyah to the written language may be viewed as a reinitiation through the alphabets he employed in creating it. Sequoyah took letters from English, Greek, and Arabic and assigned to them entirely new Cherokee phonemes without any regard to their sounds in the original languages. Although there is no reason to believe that Sequoyah did this with the intent to reject the source alphabets, his new syllabary is effectively a reinitiation of the alphabets he drew on in creating his Cherokee syllabary.

Reinitiative contributions are often bold and daring gestures. Such contributions are often found in inventive performance and artistic production. One prime example can be found in sculpture, with Marcel Duchamp's 1917 *Fountain*. Duchamp's Dada piece is simply a urinal turned on its back. The very act of entering such a piece in an art show is a statement about art—Duchamp's sculpture made art-making focus on the definition of exactly what art is and what art can be. Duchamp's urinal became a piece of art, and he and his fellow Dada creators set the stage for other modern art that exists, in part, to challenge our ideas of what 'art' encompasses (Hartt, 1993).

Another radical reinitiator is one of Duchamp's friends, the composer John Cage. He often employed unconventional sound materials and spent a period in which his compositional process (and often performance) was determined entirely by chance. The philosophy that led Cage to compose in this unorthodox manner can be considered essentially a rejection of some basic tenets of the Western musical tradition, including the definition of music itself. Cage declared music to be all sound, including the whispers and heartbeats we perceive while silent. Cage's affinity for Eastern philosophy caused him to focus on the importance of awareness in the human experience, and he used his music to foster awareness in his listeners.

An illustration of this point is his piece *4' 33"*. The performance of this piece consists of four minutes and 33 seconds of 'silence', or rather, in Cage's terminology, 'unintentional sound'. In performance, the instrumentalist approaches her instrument, prepares to play, and proceeds to sit, motionless and without sound, for four minutes and 33 seconds. The only pauses are those indicated to signal the change of movement. The music, therefore, is that sound which exists in the environment during that period of time. Cage's statement is that there is music being played around us all the time; we must reject the notion of music as organized melody, harmony and rhythm to include all intentional sound, even the rush of traffic beyond the door and the buzzing of the fluorescent lights above our heads (Cage, 1961; Hamm, 1980).

A reinitiation in science was Lavoisier's invention of a revolutionary new chemistry. This reinitiation had an immediate and lasting impact on the field. In the 18th century, the predominant view of combustion was that of the German chemist Georg Stahl (1660–1734). Stahl's model of combustion was founded on the premise that combustible matter was composed of water and a substance called phlogiston. According to this early view, burning a metal resulted in the loss of phlogiston. Support for this theory was demonstrated by combining the oxide of a metal with a material containing phlogiston (for example, charcoal). This experiment would yield a pure sample of the metal, consistent with the theory that the addition of phlogiston could restore the initial substance (Meadows, 1987).

However, it became clear that chemical reactions of combustion yielded slightly heavier products, despite the claim that the process of combustion required the loss of matter, namely, phlogiston. This apparent paradox led many chemists of the day to attempt to explain the result in the context of phlogiston theory. However, Antoine Lavoisier (1743–1794) was skeptical enough of the vague and sparse evidence for the actual existence of this mysterious substance called phlogiston that he dared to discard the concept altogether. Lavoisier proceeded to explain how combustion could take place in its absence. Based on careful analysis, Lavoisier confirmed through observation that metals actually did gain weight during combustion. This result was attributed to the presence of oxygen during combustion. When a metal burned, oxygen in the air was consumed and was captured in the resulting compound, an oxide (Cohen, 1985).

The key failure of phlogiston theory is its lack of an understanding of the gaseous state. Early chemists did not consider air to play a role in combustion reactions. At most, the air was a mere waste bin for the phlogiston lost in the reaction. Lavoisier discovered that elements could exist in solid, liquid, and gaseous states. It was this realization that became the foundation of Lavoisier's chemical revolution. Lavoisier pointed out that air is composed of many different substances, one of which is oxygen.

In contrast to many reinitiative contributions, Lavoisier's revolution in the field of chemistry made an impact almost immediately. Through the introduction of a standardized chemical language, a new periodical in 1788, a textbook in 1789, and a host of disciples, the new chemistry became respected by all but a few skeptical scientists (notably, Joseph Priestly) within a few decades (Meadows, 1987). This revolution is known as the triumph of the Antiphlogistians (Cohen, 1985).

Lavoisier's opposition to phlogiston theory was not wholly a radical leap from the normal science of his time. There was no dearth of results in studies of

combustion that did not fully support phlogiston theory. However, Lavoisier's confident declaration of his rejection of this long-held theory and his suggestion of a plausible alternative view reinitiated the field of chemistry. Especially notable are Lavoisier's subsequent contributions to the field in terms of developing a standardized chemical language and his laying out a textbook describing the new chemistry (Meadows, 1987). In this way, the contribution of a new chemical theory was not merely a next logical step, but a reinitiation from a new starting point that rejected what had been crucial assumptions of the field.

While a reinitiation can certainly be the result of a great and world-class innovator, unemployed advertising men can have reinitiative ideas as well, if on a different scale. In 1975, Gary Dahl listened to his friends talk about how expensive and time-consuming it was to own a pet. Dogs and cats are not a simple responsibility, and even lower-maintenance pets like fish or birds require some time, effort, and money. It was at this point that Dahl had the idea that a pet did not have to be a living creature. And, in fact, he proceeded along in that direction to create an entirely new idea: a pet rock (Panati, 1991).

While primarily (of course) a parody of pet owners, the pet rock does represent an entirely new way of looking at what it means to own a pet. Dahl took the idea and expanded on it. He wrote an owner's manual (which included instructions on how to train the pet rock to roll over or play dead). He packaged it in a box with air holes, and he also sold pet food, in the form of rock salt (Panati, 1991). The pet rock, as many people know, became an instant success; it is one of the few fads that is still remembered years later. Dahl may not have even been intending to make a creative statement, but he did. He conceptualized the field of pet ownership as being in a different place, and then he showed a new way for that field to go. And, indeed, perhaps the current feelings of possessiveness and ownership that some people feel for their cars is not that far removed from the odd tenderness one might feel for a pet rock.

Integration

An invention that is an integration is one that combines ideas from two distinct domains of invention. An example of an historical integration is the complex evolution of the Japanese written language. Originally, Japanese was strictly a spoken language, but around AD500, Japanese speakers began to use Chinese kanji (pictographs) to represent Japanese words. While written Japanese looked identical to the Chinese, any one character was pronounced in two different ways, one of which approximated the Chinese pronunciation, and the other of which corresponded to the Japanese word bearing the same meaning. Since 1945, close to 2,000 kanji have been designated as Kanji for Daily

Use in the Japanese language. These are the kanji that children learn in school today (Miyagawa, 2000).

By AD1000, however, the Japanese needed a supplemental system to represent Japanese words that had no Chinese counterpart. To meet this purpose, syllabaries called kana were derived from Chinese characters. Rather than representing the meaning of a whole word, a kana represents a syllable or sound. There are two systems of kana in modern Japanese. The first, called hiragana, originated with Buddhist priests. While they were translating Chinese works into Japanese, they began inserting syllables next to characters to designate a particular Japanese inflection or alternate meaning from the Chinese (Vogler, 1998). The second system of kana, katakana, is primarily used to represent foreign words.

The original use of Chinese characters to represent Japanese words may be viewed as a redefinition of sorts. That is, the meaning remained the same while the label, or way of reaching that meaning, changed. However, the entire Japanese language is best seen as an integration (and subsequent forward incrementation) of symbol systems. Specifically, the introduction of kana to modify kanji is a particularly good example of melding two representational systems into one entirely new system. The meanings of words with kanji and kana are not fully decipherable based solely on the kanji, evidence that a true integration has taken place.

An example of integration in science is Isaac Newton's (1642–1727) formulation of the universal law of gravity. In essence, this discovery was a synthesis of ideas proposed by thinkers such as Ptolemy, Copernicus, Kepler, Galileo, and Hooke. Newton succeeded in explaining how a singular concept of gravity could explain a variety of observations made by scientists past and contemporary. While Copernicus had dared to oppose the Ptolemaic notion that planets encircle the sun and Kepler had demonstrated that the orbits were elliptical, no one had been able to explain why such elliptical orbits would emerge. Newton discerned the mathematical rule by which elliptical orbits would result, thus explaining the relationship between planets and the sun. In his 1687 'The Mathematical Principles of Natural Philosophy', Newton described basic principles that could mathematically account for the diverse predictions made by Copernicus and Kepler.

This contribution is a grand synthesis. Not only did Newton bring together a variety of ideas to explain planetary motion. He also recognized the relationship of this phenomenon to another and essentially integrated the two problems by offering a single solution to both. Newton showed that his principles governing the movement of bodies in the sky could also account for a second, formerly unrelated, problem: that of the motion of objects on the earth. Essentially, Newton's universal law of gravity declared that matter attracts matter. That is, the sun attracts the planets just as the

Earth's gravity pulls on objects near its surface. By achieving this insight, Newton explained two major physical questions of his time with one universal law, an integrative contribution that has remained the basis of physics ever since.

Conclusion

When we think about inventions, we tend to think about their differing primarily in terms of their novelty, their usefulness, or perhaps their profitability. The propulsion model of creative contributions may lead us to think about them in terms of the type of innovation they represent. How is the propulsion model useful in understanding invention?

First, at a theoretical level, the model may be useful in understanding how inventions differ from one another, not just in their level of creativity, but in the type of creativity they demonstrate in the first place. Using the propulsion model, it may be possible even to trace historically how inventions of different kinds have influenced the development of various kinds of technologies.

Second, it may help us understand why certain types of inventions are less readily accepted than others. Advance forward incrementations, for example, may be beyond people's ready grasp. Reinitiations as well may be difficult for people to understand or accept. Forward incrementations may have the best shot for a ready market, on average. But they have to move far enough. For example, new editions of existing software that seem to be only minor variants and small improvements do not tend to sell well, unless manufacturers rig other software so that it will work only with the newer versions (and thereby risk consumer resentment and possibly government intervention!). At the same time, software that is beyond people's ready capabilities for use may be equally unappealing, simply because it is too complex for most people to handle.

Third, at a practical level, the model may be of use to organizations that specialize in invention. In order to maximize their profitability, they may wish purposely to distribute the kinds of inventions they produce across the various types in order to maximize both short-term and long-term investments in inventions.

In conclusion, we offer the propulsion model of creative contributions as a means for understanding different kinds of creative contributions, in general, and inventions, in particular. We believe the model may help all of us understand not only what the kinds of inventions are, but why some inventions are more or less successful than others, often independent of their quality or level of novelty.

Problem Generation and Innovation

Robert Root-Bernstein

Department of Physiology, Michigan State University, USA

Abstract: Most of the literature on innovation concerns fostering better solutions to existing problems. Many innovators in the sciences and engineering argue, however, that problem generation is far more critical to innovation than problem solution, involving not just a thorough grasp of what is known (epistemology), but of what is not known (nepistemology). The proper definition of a problem gets an innovator more than half way to its solution; poorly posed questions divert energy, resources, and ideas. This chapter explores how problem definition and evaluation act as catalysts for insight and examines strategies used by successful innovators to generate productive problems.

Keywords: Nepistemology; Ignorance; Problem generation; Problem evaluation; Types of innovation.

Introduction: The Nature of Ignorance

Most people believe that creativity and innovation, especially in the sciences and technology, are forms of effective problem-solving. I, however, believe, that creativity and innovation consist of effective problem-raising. People are creative only when they need to do something that cannot yet be done. Identifying, structuring, and evaluating problems in ways that allow their solution are therefore as important—arguably *more* important—than finding solutions. We must know what we do not know before we can effectively solve any problem.

One could, of course, argue that all of the important questions have already been asked, that ignorance is finite. One might believe that the number of questions that can be asked is limited so that ignorance decreases in direct correspondence to the increase in the volume of knowledge. One might, however, assert the opposite: that ignorance is infinite. The greater the volume of knowledge we accumulate, the greater the sphere of ignorance we can recognize around us. Every question breeds more questions without end. I favor the latter view. Every time someone in history has proclaimed that a field such as physics, medicine, philosophy or art has finally reached the end of its possible progress, a revolution has already been under way in that field, opening up unexpected vistas for exploration (Root-Bernstein, 1989, p. 45). For example, even as Lord Kelvin was preaching that physics was a closed book

with no new surprises to yield, Einstein was inventing relativity theory and Planck was creating the quantum revolution. Indeed, Einstein wrote that the very idea that physics could ever become a closed field was repugnant to a physicist in the twentieth century:

It would frighten him to think that the great adventure of research could be so soon finished, and an unexciting if infallible picture of the universe established for all time (Einstein et al., 1938, p. 58).

On the contrary, Einstein argued, in the struggle for every new solution,

new and deeper problems have been created. Our knowledge is now wider and more profound than that of the physicist of the nineteenth century, but so are our doubts and difficulties (Einstein et al., 1938, p. 126).

This is the situation in every fecund field. New explanations and new techniques always create unforeseen sets of new problems. In consequence, what drives progress is not the search for ultimate knowledge, but the search for ever more wondrous questions.

Creative people in every discipline recognize the importance of generating or discovering new problems. That which we cannot yet do impels us to invention. “Recognizing the need is the primary consideration for design”, said Charles Eames (Anon, 2000, p. 4). He and his wife Ray were the first designers to utilize

molded plywood, fiberglass, wire-mesh, and cast aluminum to make practical everyday objects such as furniture. Novelist Dick Francis says that whether you are trying to solve a mystery or write book, “You have to ask the right questions” (Francis, 1992, p. 288). Filmmaker Godfrey Reggio agrees. Commenting on his film ‘Koyaanisquatsi’ he cautioned viewers that it is not a solution to the world’s problems, but an unfolding question:

You know, the question is really more important than the answer. I can frame the question, but I don’t know the answer (Kostelanetz et al., 1997, p. 251).

In fact, the more important the question, the more important the ideas to which it will give rise. Sir Peter Medawar, whose research made possible medical transplant technologies, has written that scientists interested in important discoveries require important problems. “Dull or piffling problems”, he says, “yield dull or piffling answers” (Medawar, 1979, p. 13). And Werner Heisenberg, of uncertainty principle fame, stated another oft-repeated principle known to all scientists: “Asking the right question is frequently more than halfway to the solution of the problem” (Heisenberg, 1958, p. 35). One of the keys to creativity according to all of these people lies in the study of problem recognition and generation. It is not what we know, but what we do not know that drives inquiry in every discipline. Learning how to question deeply and well is therefore, as Socrates made clear 2,500 years ago, one of the most important keys for unlocking hidden knowledge and one that opens doors in every field of endeavor.

Nepistemology: The Types and Origins of Ignorance

The philosophical study of what we do not know falls under the heading of *nepistemology*. Epistemology, as many people will be aware, is the study of how knowledge comes into being. Its complement, nepistemology, is the study of how ignorance becomes manifest. Despite the extraordinary importance of nepistemology, the field has little literature and even fewer practitioners. For some unfathomable reason, the existence of problems is taken for granted and their nature and origins generally ignored. In a world in which education, business, and government are focused on problem-solving, it is worth remembering that problems must be invented just as surely as their solutions. Because good solutions can be generated only to well-defined problems, problem recognition and problem generation is arguably a critical step. Failure to ask questions results in the stagnation of knowledge. Asking the wrong question yields irrelevant information. Asking a poorly framed question yields confusion. Asking trivial questions yields trivial results. However, learning to recognize what we do not

know, developing the skills to transform ignorance into well-defined questions, and being able to identify the important problems among them, sparks innovation.

Few programs in history have been designed specifically to teach problem generation. Socrates, of course, asked questions but it is not clear that he taught his students how to ask their own. The Bauhaus, a design movement based in Germany during the 1920s and early 1930s, certainly incorporated problem generation as a fundamental part of its Foundation Course. When assigned to design a table or paint a painting students were challenged to begin not by seeking answers, but by seeking questions: “what is a table? . . . what is a painting?” (Lionni, 1997, p. 166) Only by questioning the assumptions they brought to their work, they were taught, was it possible to produce innovative answers. Similarly, English sculptors such as Henry Moore, Jacob Epstein, and Barbara Hepworth reinvented sculpture by “asking themselves the question: ‘What do we mean by sculpture?’” (Harrison, 1981, p. 217). By returning to so-called primitive techniques of direct carving and structural rather than realistic forms, they discovered new questions about the nature of art and thereby new answers. Learning to ask the right question always opens up new possibilities (Browne et al., 1986).

One of the very few contemporary questioning programs is ‘The Curriculum on Medical Ignorance’ founded by surgeons Marlys and Charles Witte and philosopher Anne Kerwin at the University of Arizona Medical School in Tucson, Arizona. The purpose of the program is to teach medical students how to recognize their own ignorance and that of other doctors in order to better define what still remains mysterious and take a first step towards enlightenment. The Wittes and Kerwin have identified six basic types of ignorance. (Witte et al., 1988, 1989). First, there are things we know we do not know (known unknowns, or explicit ignorance). A second type of ignorance consists of things we do not know we do not know (unknown unknowns, or hidden ignorance). The next kind of ignorance is that consisting of things we think we know but do not (misknowns, or ignorance masquerading as knowledge). Fourth, ignorance may be found among the things we think we do not know, but we really do (unknown knowns, or knowledge masquerading as ignorance). Next, some ignorance persists due to social conventions against asking certain types of questions in the first place (taboos, or off-limits ignorance). Ignorance may also persist due to refusal to look at some types of answers to perfectly legitimate questions (blinkers, or persistent ignorance).

Two essential points must be understood about this typology of ignorance. First, each distinct type of ignorance requires a different set of techniques in order to reveal itself clearly. Second, problem recognition and invention are active processes. Proficient questioners are those who can draw upon a wide

range of problem-finding tools and apply them appropriately to diverse questioning contexts. If nothing else, the Curriculum on Medical Ignorance reveals the poverty of simply asking 'why' or 'how' or 'what' for every observation one makes.

Explicit ignorance, the things we know we do not know, consists of questions and problems that experts in a field formally recognize because current explorations repeatedly fail to provide useful answers. Explicit problems from diverse fields include questions such as the following: How does the immune system differentiate 'self' from 'nonself'? Should animals have the same sorts of rights accorded to human beings? Does art progress or merely change to reflect the values of each new generation?

Explicit ignorance can be discovered using a wide range of proven approaches. One is to question the assumptions underlying the question. Some questions turn out to be unanswerable because they contain implicit concepts that are not valid. For example, what do we mean by 'progress' and how can we apply that term to art? What is a 'right'? Do 'rights' necessarily entail responsibilities? Can an animal that cannot understand or implement its obligations under the law be accorded 'rights' or must such rights reside in a legal guardian, as is the case for mentally incompetent human beings? Any problem, like these, that exists for any period of time demonstrates that the experts not only do not have the answer, but do not have the question. Persistence of questions implies a lack of proper question formulation. Questioning the question itself can often yield insight.

A second way to identify explicit ignorance is to focus on paradoxes. Paradoxes exist only where two or more well-formulated sets of knowledge come into conflict and thus represent the locus of the unknown. Such loci should be embraced, for where there are paradoxes, there is, as the physicist Neils Bohr repeatedly pointed out, hope of progress (Moore, 1966, p. 196).

A third method for recognizing explicit ignorance is to learn how to perceive the sublimity of the mundane. 'Sublimity of the mundane' refers to the inordinate beauty manifested in everyday things. Unfortunately, as practitioners of every discipline are all too well aware, that which is commonplace is easily overlooked or, in the terms of artist Jasper Johns, is recognized without being seen (Root-Bernstein et al., 1999, p. 32). Whether a person sets out to perceive what makes a flag flag-like, as Johns did in his art, or to ask why a banana turns brown but an orange does not, as biochemist Albert Szent-Gyorgyi did, such everyday problems, precisely because they are so commonplace, will also turn out to be fundamental. Johns's art has provided new insights into how we see, while Szent-Gyorgyi's researches on banana browning resulted in the discovery of vitamin C, for which he earned a Nobel Prize.

A final method for *revealing* explicit ignorance is to err. As Francis Bacon once wrote, truth comes out of error more rapidly than out of confusion. A clear mistake does far more good to any investigation by identifying the specific nature of the problem being addressed than any other method. Hence the trite (but true) aphorism that we learn best from our mistakes. People who never err not only never succeed, but have no mistakes (and hence generate no problems) from which to learn.

Hidden ignorance, the things we do not know we do not know, is perhaps the most difficult form of ignorance to discover precisely because it is not explicit. One of the most important characteristics of hidden ignorance stems from the fact that human beings tend to account for any phenomenon in any field in terms of what they already know. Thus, many forms of ignorance remain hidden simply because people are too proud to say the simple sentence, "I do not know". Instead, we tend to make up stories to hide our ignorance. For example, prior to the discovery of electricity, every culture attributed lightning to the wrath of the 'gods' rather than simply admitting ignorance. Similarly, prior to the discovery of germs, infectious diseases were attributed to bad air, bad water, and bad habits. No medical expert in any culture seems to have had the courage to simply admit that they did not really know how diseases spread.

To discover hidden ignorance requires very different methods than to address explicit ignorance. Hidden ignorance must be surprised. One way to surprise ignorance according to Sir Peter Medawar is to design research to challenge expectations. (Medawar, 1979, *passim*) His advice is predicated on the philosophy of science espoused by Sir Karl Popper, who maintains that theories can never be proven (because the observation you have not yet made may invalidate your position), but theories can always be *disproven*. The object of any research project in any discipline should therefore be to find the evidence that will disprove one's expectations. Physicians, for example, often call for tests to 'rule out' a possible but unlikely diagnosis. The specific way in which expectation is disproven will then reveal the nature of one's unsuspected ignorance.

Another method related to challenging expectation is to look for information where no reasonable person would look. There are many ways to implement this strategy but each entails to a greater or lesser degree the risk of appearing to be foolish or even crazy. The most acceptable method is to run many highly varied and even outrageous controls with any experiment. Winston Brill, a member of the National Academy of Sciences (USA), for example, recounts that his most important breakthrough occurred when he was designing a pesticide based on a particular theory of how its structure should look. He synthesized several versions of his compound in what he predicted to be active and inactive forms and also took a few chemicals off his

shelves at random to use as controls. None of the chemicals he had designed as a pesticide worked well, but one of his random choices was a stunning success, representing a new class of pesticides that no one could have predicted in advance (personal communication). Only by doing the unexpected can the unforeseen reveal surprises.

Another approach to revealing unknown unknowns is purposefully to turn things on their heads to yield a new perspective. The artist Wassily Kandinsky, for example, unthinkingly turned one of his early representational paintings upside-down and left it for several weeks. Re-entering his studio one evening, having forgotten about the painting, he suddenly became aware of it, illuminated by the setting sun, but did not recognize it or its content. All he saw was form and color. Suddenly he realized that it might be possible to create totally non-representational art, something that even the abstract painters of that time had not yet considered. By viewing his own work literally upside down he discovered that there was a whole realm of art that no one had realized was there, let alone begun to explore (Herbert, 1964, 32ff)

Playing contradictions (sometimes known as playing the devil's advocate) is another fecund source of unknown unknowns. Nothing reveals how little we know than to take a proposition such as 'the world is spherical' and assert instead that 'the world is flat'. As the novelist H. G. Wells pointed out a century ago, very few are the supposedly educated members of society who are able to produce evidence or experiments (especially ones that do not resort to the data gathered from space craft) that will clearly distinguish one of these possibilities from the other. (Wells, 1975, pp. 32–25) That which is obvious often becomes inobvious when its opposite is asserted, thereby raising questions and possibilities that would never otherwise come to light.

Finally, one can reveal hidden ignorance by drawing out the most absurd implications of any idea. Many children excel at this strategy, taking anything an adult says and applying it literally—too literally!—to any situation they meet. Much satirical literature ('Candide', Voltaire's send-up of rosy philosophical optimism as espoused by Leibnitz and Pope, is a good example) uses this strategy to reveal the limitations inherent in popular philosophies. What extrapolation of this sort reveals are the boundaries beyond which an otherwise quite reasonable proposition or method fails. The point at which it fails is often the point at which our ignorance begins.

Ignorance masquerading as knowledge, or mis-knowns, presents yet another class of problems. A classic example from medicine was the belief, rampant among physicians for most of the twentieth century, that stomach ulcers are due to mental stress or eating spicy foods or alcohol and can be treated only by a bland diet and relaxation techniques. Stomach ulcers

are, in fact, caused by the bacterium *Helicobacter pylori* and can be cured by a proper regimen of antibiotics. Stress, alcohol and spicy foods exacerbate the consequences of the bacterial infection. Thus, secondary factors were confused with primary causes.

Several methods exist for discovering that the king is wearing no clothes. One is to doubt all correlations. Everyone is taught that correlation is not causation, but in practice this warning is all too often ignored. In the case of ulcers, because spicy foods and alcohol exacerbated the symptoms, they appeared to be so highly correlated with the onset of ulcers that they were mistakenly identified as causative agents. Evidence that many people eat spicy foods and drink lots of alcohol without getting ulcers was ignored.

A second method for identifying mis-knowns is to question habit. For centuries, painters habitually propped their canvases up on easels in order to work on a surface perpendicular to their view. It took the courage of Jackson Pollock to take the canvas off of the easel and place it on the ground to experiment with the artistic possibilities of working in a new way.

Two additional methods also exist for identifying mis-knowns. Perhaps the most important is to doubt most those results or findings that accord best with our preconceptions. Those results or observations that best fit our preconceptions and expectations are the least interesting and yield the fewest questions and insights. Ignore them. They do not yield problems. The things that are the most interesting in terms of revealing ignorance are those that are the most disturbing or which conflict most clearly with strongly held beliefs or practices. Therefore, pay attention to the heretics, revolutionaries, and people stepping to their own drummer. Many of their ideas will be wrong, but many of the problems they reveal will be valid.

A related method for identifying mis-knowns is to collect anomalies. Anomalies are phenomena and observations that do not fit within the theoretical or explanatory structure of a field. They are the things that experts ignore as inconvenient nuisances. As philosopher Thomas Kuhn pointed out in his book *The Structure of Scientific Revolution* (1959) every great discovery has resulted from an individual paying attention to the anomalous results that most practitioners of a field have refused to countenance or have actively ignored because anomalies generate problems.

Finally, try doing the impossible. There are two kinds of impossible things: those that nature will not allow us to do (e.g. perpetual motion machines) and those that our predecessors have found beyond their means. The history of medicine is full of procedures that were declared to be 'impossible', such as blood transfusions and transplants, that are now part and parcel of everyday clinical practice. Indeed, the inventor of the instant camera and its Polaroid film, Edwin Land, advised innovators not to "do anything

that someone else can do. Don't undertake a project unless it is manifestly important and nearly impossible" (Root-Bernstein, 1989, p. 415).

Next we must deal with things we do not know that we know, or hidden knowledge. There is a story that one of the great eighteenth-century mathematicians sat down one day to try to calculate the perfect dimensions of a container for storing and shipping alcoholic beverages such as beer or wine. After taking into account the available materials, limitations imposed by the fact that the containers had to be carried by men from one place to another, and so forth, he generated his solution—only to find that he had described the wooden barrels already in use. Similarly, a recent study of medical treatments has found that many of the most 'innovative' are based on folk remedies that have been around for millennia. Just for example, honey pastes have been used since at least Babylonian times to treat severe wounds and burns and have recently been introduced in many hospitals to treat infections and ulcerations that are beyond the scope of current antiseptic, antibiotic, and surgical treatments. As both these cases show, the basic problem underlying hidden knowledge is that it exists either among people who are not considered to be valid sources of knowledge by disciplinary 'experts' or resides in historical documents bypassed by subsequent developments in the name of 'progress' (Root-Bernstein et al., 1997, Chapters 3 and 12).

The causes of hidden knowledge suggest solutions. The most obvious is to go outside the boundaries of acceptable disciplinary sources for information. Charles Darwin broke all of the standards of science in his day (not to mention social conventions) by writing to farmers, pigeon fanciers, horse breeders, and other non-scientists in order to discover the accumulated wisdom about artificial selection that existed outside of the academic community. The physicians who rediscovered the modern therapeutic uses of honey paid attention to non-traditional practitioners of their art such as family folk medical traditions or local traditional healers. Similarly, many innovators, such as the cubist artists Brach and Picasso and the modern composers Richard Reich and David Glass, having mastered formal Western techniques during their early training, then turned to non-academic sources of inspiration such as traditional African and Hindu arts.

Albert Szent-Gyorgyi, the Nobel laureate who discovered vitamin C, has suggested that another general way to reveal problems of unknown knowns is to go back and re-do classic experiments from 50 or 100 years ago using modern techniques (Root-Bernstein, 1989, p. 412). These re-creations, he says, almost always yield novel insights because the investigator brings to them different problems and theories that change their interpretation. Artists such as Henry Moore have similarly used ancient techniques such as direct carving, invented by Egyptian and Greek

sculptors, to revolutionize modern art by applying it to new materials.

Finally we reach persistent unknowns (taboos) and unacceptable or blinkered knowns. Both classes of ignorance are caused by the refusal to ask certain types of questions or to entertain certain types of answers. These classes of ignorance often result from social taboos or customs and sometimes from economic or political considerations as well. For example, many women living in underdeveloped nations (especially those dominated by Muslim sects) may not ask "How can I control my fertility?" Artists in the United States have met similar constraints on their ability to ask questions such as whether man has been formed in God's image or vice versa. And biomedical researchers studying AIDS have found it so unacceptable to ask whether the human immunodeficiency virus explains everything about AIDS that many have lost their funding and positions. The characteristic of taboo questions is that one risks one's career or even one's life by asking them.

Certain types of answers may also be avoided just as adamantly as certain kinds of questions. For example, alternative medical therapies are used by more than one third of European and American adults, but they are rarely subjected to the kind of double-blind controlled clinical trials that are required of pharmaceutical drugs. Both taboos and blinkered knowns help explain the situation. In the first place, it is not in the interest of purveyors of alternative medicines to have to meet the standards of either efficacy or purity set for pharmaceutical agents. In no case would meeting such standards increase their market share or profit margin and in many cases the standards might eliminate their product from the market. Thus, it is in the interest of these purveyors to foster the persistence of ignorance about their products. However, it is too expensive for Food and Drug Administrations or pharmaceutical companies to seek answers to issues of efficacy and safety. The only motive that these institutions have to test alternative medicines is to accredit them as prescription drugs. It costs, however, approximately one quarter to one half a billion U.S. dollars to obtain Food and Drug Administration approval for a new drug. In order to make such an investment worthwhile, a pharmaceutical company must be able to obtain patents on the drug and its manufacture so that other companies cannot take advantage of the work they have put into proving safety and efficacy. Unfortunately, alternative medicines are, by their nature, non-novel agents already in the public domain, and hence unpatentable. Thus, there is no business incentive to find answers to the problems posed by alternative medicine usage (Root-Bernstein, 1995, *passim*). We therefore persist in our ignorance about such therapies and will do so until other incentives make it worthwhile for us to seek answers.

Additional examples of blinkered answers can be found in various approaches to AIDS adopted around

the world. In Africa, for example, it is against the social mores of many men to use condoms, although they know that condoms are the most effective method of protecting themselves against AIDS. In some Muslim countries, AIDS-prevention counselors are not allowed to mention the fact that AIDS is spread most commonly by homosexual men and female prostitutes because neither group may be mentioned in conversation or print. Thus, programs that have proven to be very effective in controlling AIDS in some countries cannot be used in others because of such taboos.

Because the roots of taboo questions and blinkered answers are social, the methods for addressing it are also social—or, more accurately, anti-social. One of the most noteworthy aspects of many creative acts, whether in the sciences, humanities, social sciences or the arts, is that the people who carry them out are labeled heretics, provocateurs, misfits and worse. The greatest questioner of all time, Socrates, was put to death for the anti-social implications of his questions. Galileo was charged with heresy by the Catholic Church for daring to question the Ptolemaic view of the universe that underpinned Church doctrine. Darwin became a pariah among fundamentalists of many religions for questioning whether God had indeed created man in His image. Margaret Sanger and Marie Stopes, the revolutionaries who gave Western women contraceptive knowledge, each went to jail more than once. So did the many suffragettes who worked to give women the vote, simply for asking why women should not be able to do the things men do. One must have the courage of such people in order to break the taboos that prevent most of us from asking certain types of questions or facing the consequences of certain types of answers. The more dangerous the questions are to people in power, the greater the courage needed to ask them.

Problem Evaluation and Classification

Now, once problems have been recognized or generated, they must be evaluated. Just as there are different kinds of ignorance, they yield a great diversity of kinds of problems. Problems can be classified according to *type*, *class*, and *order*. *Type* refers to the technique necessary to *solve* a problem. *Class* refers to the *degree* to which the problem is solvable. And *order* refers to the placement of a problem within the context of the universe of other related problems. While each of these concepts may initially sound very abstract and academic, each is, in fact, extremely useful in practice. Classifying problems allows each to be linked to an appropriate method for achieving a solution and allows links between problems to be explored explicitly.

Just as it is true that not all forms of ignorance can be recognized or discovered in the same way, not all problems can be solved using the same methods. There are, in fact, at least ten types of problems, each distinguished by the manner in which it must be

addressed in order to achieve a solution. The ten basic problem types are: (1) problems of definition; (2) problems of theory; (3) problems of data; (4) problems of technique; (5) problems of evaluation; (6) problems of integration; (7) problems of extension; (8) problems of comparison; (9) problems of application; and (10) artificial problems (Root-Bernstein, 1982, *passim*; Root-Bernstein, 1989, p.61). Readers will immediately recognize a significant overlap in the terminology and concepts embedded in this typology of problems with the typology of innovation types proposed by Sternberg et al. in this volume. The type of problem an innovator chooses to address therefore determines the type of innovation she or he produces.

Problems of definition concern the purity of the language and its meaning as used by any given discipline. Representative issues include ‘what is velocity’ or ‘what is a legal right’ or ‘what is beauty’. Such questions cannot be addressed by experiment or observation or any form of research. Such definitions may be determined axiomatically in the same way that we accept definitions of basic concepts such as the numbers one, two, three, etc. or when we state that velocity is distance traveled divided by the time of travel. Definitions may also be addressed by means of a process, such as the legal system that determines whether something is a right.

Problems of theory or explanation involve any attempt to find or make sense of the relationships in existing data or observations that are currently incomprehensible or anomalous. Theory problems require the recognition or invention of a pattern that makes coherent sense of available information.

Problems of data involve the collection of experiences or information relevant to addressing some particular kind of ignorance. Relevant techniques include observation, experiment, and any kind of playing with materials that yields novel data.

Technique problems are those that concern the manner in which novel data, observations or effects are to be achieved. Such problems generally require the invention of instruments, methods of analysis or display, or techniques that allow new phenomena to be observed or created.

Evaluation problems arise when it is necessary to determine how adequate a definition, theory, observation or technique may be for any given application or situation. For example, is any particular observation an anomaly or an artifact of the way in which the observation was made? Evaluation problems require the invention of criteria and methods for evaluation. One might, for example, consider the entire field of statistics to be a set of solutions to evaluation problems.

Problems of integration often involve contradictory or paradoxical situations in which it is not obvious whether two theories, data sets, methods, or styles of research are compatible. For example, is there any

benefit to teaching art to science students and science to art students? If one were to do so, how would one go about it? Integration problems generally require the rethinking of existing definitions and theories to determine what hidden assumptions may provide bridges between apparently disparate concepts.

Extension problems concern the range of possible uses to which any method, technique, theory, or definition can be put. Ray and Charles Eames, for example, experimented widely with plywood to find out what its possibilities and limitations were as a design material. Such extensions require extrapolations from existing practices and ideas to unknown ones in the form of predictions, play, and testing. The object in addressing extension problems is to discover the boundaries limiting the valid use of any particular solution methodology.

Problems of comparison arise when more than one possible solution exists to a problem and one needs to determine which is the best. Explicit criteria must be generated to make such comparisons. Such criteria are embodied in logic and in the use of analogies. While it may be relatively obvious how to compare the relative merits of two types of glue, for example, it may be very difficult to determine whether glue, staples, screws, nails, or hooks are the best means for attaching any two objects together. Unless one has a good understanding of the nature of the problem to be solved, criteria for generating such comparisons cannot be made.

Problems of application attend any attempt to extend a solution from one problem instance to another. Chemical engineers, for example, are highly sensitive to the fact that reactions that occur quickly and nearly completely in a test tube may be disasters when scaled up to hundreds of gallons. Similarly, while the principles of flight are the same for a model airplane and a jumbo jet, the application of those principles differs in obvious ways. Thus, problems of application often involve modeling or scaling-up issues, or the transfer of a solution from one discipline to another.

The final type of problem is the artifactual problem. Artifactual problems arise from misunderstandings. Such misunderstandings can arise from inaccurate or misleading assumptions, as in the classic lawyer's question: "When did you stop beating your wife?" Or such misunderstandings can arise from ignorance. For example, I was once asked by a reviewer of a paper I had written to provide a correlation coefficient for a trait that had no variance: all of the members of one group had the trait; none of the members of the other group had it. By definition, no correlation coefficient can be calculated in such a case and I had to point out that the problem was not valid.

Just as there are many types of problems, there are many classes of problems defined by the degree to which a complete answer can be achieved. Problems can be classified by whether they are: (1) unsolvable; (2) solvable only by approximation; (3) exactly

solvable; (4) solvable as a class; or (5) solvable only for particular cases. Knowing the degree to which a problem can be solved is essential not only for evaluating the degree of precision that one can expect in an answer, but also for determining how important a problem may turn out to be.

Although practitioners of every field will recognize that some problems are amenable to more precise or general solutions than others, the only professionals who explicitly classify their problems according to such criteria are mathematicians (Wilf, 1986, pp. 178–221). In mathematics, problems are described as 'P', 'NP complete' and 'NP incomplete'. 'P' problems are those for which it can be demonstrated that the entire class of such problems can be solved using a common algorithm, or general problem-solving technique. An example of such a problem is whether any two numbers, x and y , are divisible by a common factor. It is possible to prove that any such problem can be solved. Thus, mathematicians can prove that 'P' problems are solvable even before addressing any particular manifestation of such a problem and before generating any particular solution. 'NP' problems, in contrast, are those for which it is impossible to solve the class of such problems, but for which individual solutions may be possible. One can always prove that any solution to an 'NP' problem is valid, but not whether such a solution exists in advance of actually finding it. An example is the classic traveling salesman problem in which a salesman must visit a large number of cities in a country and wants to do so in less than a certain number of days. There may or may not be a solution that satisfies the salesman's needs. Worse, there is no algorithm that will allow him to find out. He must generate possible solutions to the problem and hope that one satisfies his criteria. Worse yet, for most such traveling salesman problems, the number of possible solutions is too large to explore in any reasonable way, so that one can never prove that one has achieved the optimal solution to the problem, even if one finds a viable solution. The best one can do is to generate many solutions and compare them, looking for the one that is best of the batch of solutions on hand. Most real-life problems are of this NP type and require the generation of many possible solutions that are compared for their effectiveness. (See Root-Bernstein, 'The Art of Innovation', in this volume.)

Once an 'NP' problem has been solved, it may or may not yield general solutions to other such problems. In the case of the traveling salesman problem, each case must be solved individually within the entire class of such problems. Mathematicians call such 'NP' problems 'NP incomplete'. The class of problems that can be solved by the same algorithm as an already solved 'NP' problem is called the class of 'NP complete' problems. Such NP complete problems are not P problems because it is cannot be shown in advance that they have a solution—they must be found

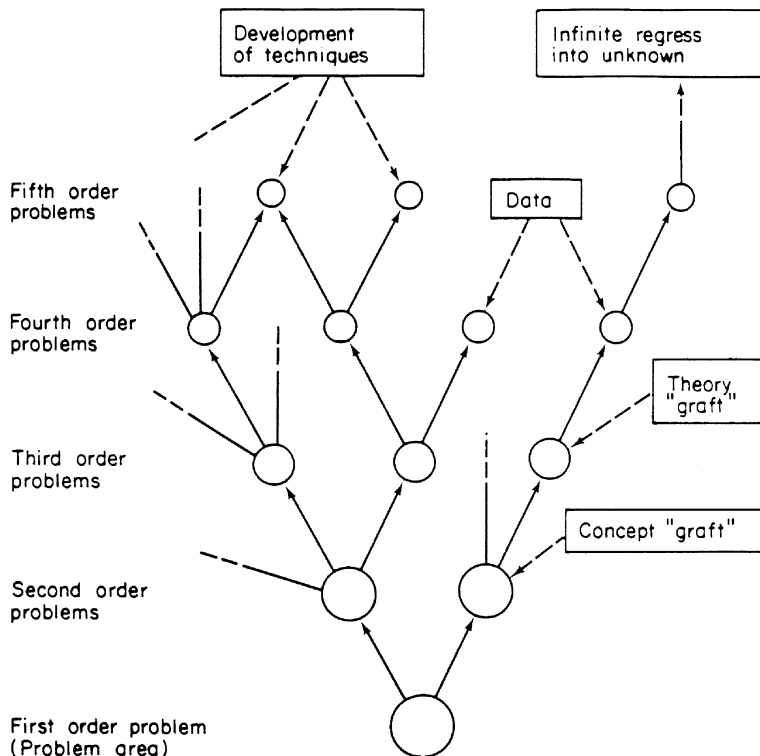

Figure 1. Caption copy not supplied.

one case at a time by trial and error. Moreover, as with NP problems in general, no one can ever prove that the optimal solution has been achieved for any member of an NP complete class. A better mouse trap might still be possible.

Mathematicians also recognize that there are problems that are neither 'P' nor 'NP', but are demonstrably unsolvable. This is the basis of Goedel's proof, which demonstrates that it is impossible to devise a mathematical system that has no unprovable assumptions. It has also been proven that it is impossible to trisect an angle using a compass and ruler. One might call such problems 'I', for impossible.

The existence of 'I' problems such as trisecting an angle raises another important point concerning the nature of problems. I have been stressing the principle that poorly defined problems yield confusing answers, whereas well-defined problems yield clear answers. One of the clearest possible answers to a well-defined problem is that it is not solvable at all. As astrophysicist Gregory Benford has cautioned, "The existence of a well-defined problem does not imply the existence of a solution" (Benford, 1989, p. 155). For example, many people have desired to create perpetual motion machines. The criteria defining the problem are

extremely well defined: such a machine must be capable of creating more energy than it uses. Stated as a question, the problem becomes: how does one create energy *de novo*? Anyone who has physics knowledge knows that, while this is structurally and logically a well-formulated question, it is not a reasonable question. To create energy *de novo* would violate the laws of thermodynamics. Thus, despite the fact that the problem can be stated exactly, it can also be shown that the problem has no solution. The question of whether God performs miracles is of the same class because miracles are, by definition, metaphysical or supernatural events beyond human comprehension, thereby placing any evidence beyond our ability to validate or replicate it. Such questions are therefore beyond rational discourse and belong, properly so, to questions of faith.

Finally, problems must be evaluated in terms of their order, which is to say with regard to their relationship to other problems. The most graphic and useful way of exploring the relationship between problems is to generate a hierarchical tree displaying their logical and methodological connections (Fig. 1). The logical problem tree was invented by biologist James Danielli to illustrate the fact that only very rarely is any problem addressed in isolation (Danielli, 1966, *passim*; Root-

Bernstein, 1989, p. 63). A problem of theory may require the invention of a new method for gathering relevant data and need to be solved in order to determine the feasibility of some practical application. An ordered problem tree allows investigators and inventors to determine which problems need to be solved in what order, using what methods. More importantly, a problem tree illustrates the degree to which any specific problem is more or less general and more or less connected to other problems of various types and classes.

Ordered problem trees are particularly useful for evaluating claims of significance. It is common for investors in new technologies and for funding agencies offering grants to require inventors to provide a justification of the utility of the work they propose to carry out. Thus, a cell biologist may justify the utility of his or her studies of cell division by the fact that cancer cells divide abnormally and therefore research on cell division may yield a cancer cure. Such claims may or may not be accurate, since the number of problems that need to be solved to link basic bench research with a clinical application may be so large as to be beyond reason. The degree of ignorance that must be addressed can only be evaluated when an ordered problem tree has been constructed to demonstrate the types, classes, and number of related problems that define the general problem area.

Problem Evaluation

An understanding of how problems are generated and the various types, classes, and orders into which they can be categorized provides useful information about how important or trivial any given problem is likely to be. Once again, there is virtually no formal research on this subject, but it is probably fair to say that what are called ‘important’ problems are those that are completely solvable for a large class of cases, and that this property of solvability is directly related to the ability to construct a very strongly connected problem tree that links many types of problems robustly. But the fact that problem evaluation requires a detailed understanding of where any given problem exists within a tree of other linked problems should warn us that there is nothing intrinsic to any given problem that makes it important or not. A seemingly trivial problem may provide the key to solving an entire problem tree of great significance; or a seemingly important problem may provide only a trivial answer because it can yield only a specific answer that connects with and informs no other problem. Many problems that may appear to be intrinsically interesting or worthy of attention (e.g. world peace) may be dependent on so many sub-problems of such an intractable nature (local economic conditions and resources, cultural habits, education, etc.) that there is no practical way to address them. Working directly on sub-problems may be a more practical goal.

However, the irresolvable nature of general or even specific problems should never be a barrier to problem-generating activities. The most important problems are always those that need to be solved and cannot be. Simply perceiving the detailed nature of such nested problems can be of practical value in and of itself. One of the strategies employed by creative people in every field is to construct a problem tree in order to identify the critical problems that cannot yet be addressed and, having identified and characterized these gaps in our knowledge, wait until answers are supplied by someone else. When these sub-problems are finally addressed, the problem tree becomes complete, and the importance of what may have appeared to be very trivial, individual problems suddenly takes on vast significance. One of the characteristics of the most innovative people is to discover the world in a grain of sand.

Another characteristic of great questions is that they are bold or even dangerous and it takes at least a modicum of bravery or bravado to pose them. Solving daring problems is of course important, but daring to pose them in the first place is still the key to making breakthroughs in any field. Many people are capable of solving well-defined problems, since solutions, as Einstein and his collaborator Leopold Infeld wrote,

may be merely a matter of mathematical or experimental skill. To raise new questions, new possibilities, to regard old problems from a new angle, requires creative imagination and works real advance in science (Einstein et al., 1938, p. 5).

Thus, learning how to pose the most insightful, provocative, and challenging questions is surely an art as much in need of training and practice as those arts devoted to problem-solving.

But in the end, the creative urge to generate problems comes down to motivation. What makes an explorer in any discipline is their attraction to the mysterious, the incomprehensible, the paradoxical, the unknown. As Albert Szent-Gyorgyi, a Nobel laureate in Medicine and Biology wrote,

A scientific researcher has to be attracted to these (blank) spots on the map of human knowledge, and if need be, be willing to give up his life for filling them in (Root-Bernstein, 1989, p. 407).

Fellow Nobel laureate and physicist I. I. Rabi agreed: “The only interesting fields of science are the ones where you still don’t know what you’re talking about” (Root-Bernstein, 1989, p. 407). Thus, the most creative people are always explorers quite literally in the way that Magellan, Columbus, or Lewis and Clark were explorers, aiming for the regions of our most manifest ignorance.

² *ESCP-EAP-European School of Management, France*

Abstract: Flexibility is the ability to change. Innovation involves different types of change. In this chapter we will examine the importance of flexibility for different aspects of innovation. Different types of flexibility will be considered throughout the chapter, such as adaptive flexibility (the ability to change as a function of task requirements) and spontaneous flexibility (the tendency to change for intrinsic reasons, to try out a variety of methods). Finally, we will discuss how different types of flexibility can be important at different stages in the innovation process.

Keywords: Innovation; Flexibility; Creativity.

Introduction

Have you ever wondered why the dinosaurs did not make it? According to recent evidence, dinosaurs' living conditions changed brutally after a comet hit the earth, putting a great deal of dust and debris in the atmosphere. Being unable to adapt to the new, darker and colder climatic conditions, they became extinct. Sometimes survival depends on flexibility. And what about the earliest human beings who made it through the Ice Age, populated the earth from Africa to Iceland and became a dominant species? Often prosperity also depends on flexibility.

Flexibility can be defined as the capacity to change (Thurston & Runco, 1999). This may be either a change in how one approaches a situation in the external environment (adaptive flexibility) or a natural tendency to change for intrinsic reasons (spontaneous flexibility).

Flexibility may vary from one species to another, or from one individual to another; some species are more flexible than others in general. Within each species, some individuals will be able to adapt to even the most difficult circumstances whereas others will not. This is true for organizations as well. Some organizations are like dinosaurs, slow to react to a changing environment, whereas others are, like our ancestors, able to adapt. Even Microsoft, one of the largest world corporations faced a threat to its survival when at one point, its management found out that a rival Netscape had 700 people working on Internet applications, while it had only four; Microsoft managed to rebound in this

case in six months. This ability to adapt quickly and effectively to the environment is particularly important nowadays given the speed of technological evolution and globalization. All this puts pressure on individuals, companies and societies to make changes and to be adaptable if they are to survive and prosper (Mumford & Simonton, 1997).

As important as flexibility is for survival and prosperity under pressure, it does not directly cause it. There are mediating behaviors involved. One candidate is innovation. Innovation is typically defined as the generation, acceptance and implementation of new ideas, processes, products or services (Kanter, 1983). It is through the implemented novel productions (economic, social or technological) that an individual or an organization can survive and prosper when the environment changes, through productions that are appropriate to the new environment (economic, social, or technological). In this chapter we suggest that flexibility influences innovation in several important ways, and research supporting this assertion will be presented. Three approaches to creativity and innovation will be presented successively: the creative person, the environmental press and the creative process. We start by examining flexibility as a characteristic of the innovator him- or herself, that is, the cognitive and conative factors that relate to flexible thinking and the creation of new ideas, new productions. (It is important to note that though we speak of the innovator, the discussion can refer to either a single person or a group of people

working together.) Then we will consider flexibility as a characteristic of the environment, the audience for innovations, the ways that individuals, embedded in cultural contexts, differ in their readiness to accept new ideas and innovations. Finally we will discuss how different types of flexibility (adaptive and spontaneous) can be important at different stages in the innovation process. We conclude by discussing several issues concerning the implications of the study of flexibility for individual and group innovation, but also for the organizational culture that can either facilitate or block innovation.

Before beginning an examination of flexibility and innovation, it is important to note that creativity, defined as an ability to produce work that is novel and appropriate (Amabile, 1996; Lubart, 1994), is a phenomenon closely related to innovation, and sometimes the terms are used interchangeably (West & Richards, 1999). Thus, in this chapter we do not draw a distinction between creativity and innovation.

Flexibility as a Characteristic of the Innovator

Cognitive Aspects

Flexibility is widely regarded as a cognitive ability important to creativity and innovation (Chi, 1997; Jausovec, 1991, 1994; Runco & Charles, 1997; Runco & Okuda, 1991; Thurston & Runco, 1999; Torrance, 1974). For example, for Thurston & Runco (1999), flexible cognition can facilitate creativity in several ways, such as helping to change strategies to solve a problem more effectively or to see a problem from a new perspective. It can also help one to switch easily between conceptual categories thus facilitating the production of diversified ideas. A flexible person can avoid getting stuck on one part of a problem, or can let go of the problem for a while when stuck and come back to it later. In discussing flexibility as a cognitive ability, research distinguishes adaptive flexibility and spontaneous flexibility, each facilitating creativity in a different way.

Adaptive flexibility involves changing perspectives on the problem, redefining it, or changing one's strategy to solve it when old perspectives or strategies have proven unsuccessful. For example, the candle task (Duncker, 1945), requires the participant to fix a candle on a wall without the wax dropping on the floor using only a candle, a box of matches and a box of tacks. Many people cannot find the solution to this problem because they try to attach the candle itself on the wall and consider the box as simply a recipient that holds the matches and/or the tacks provided. Once they change their perspective on the box, it becomes apparent that fixing a box on the wall with a few tacks and putting the candle in or on the box solves the problem perfectly. The change in perspective involves redefining the box as a support rather than a container, which then leads to an adaptive solution. Inflexibility in

one's conception of a common object, such as a box, is called 'functional fixedness' in the literature.

A number of authors have drawn attention to how adaptive flexibility in response to environmental constraints can lead to creative and innovative outcomes. For Barron (1988) an important ingredient of creativity is "seeing in new ways" (p. 78). According to Runco (1999) changes in perspective are related to both artistic and scientific creativity. Lipshitz & Waingortin (1995) call these changes in one's point of view on a problem 'reframing', which when applied to real-world problems, can lead to innovative solutions. For example, a hotel manager received frequent complaints about the elevators being too slow. He could follow the (very expensive) suggestion from an engineer to replace the elevators with a faster model, but decided to get a second opinion from an industrial psychologist. For the psychologist the problem was "not slow elevators but bored people" (Lipshitz & Waingortin, p. 153). He suggested installing large mirrors in front of the elevators so that people could pass the time watching themselves or others. The manager opted for this (much cheaper) solution and heard no more complaints about slow elevators. Thus, taking a different perspective on the problem led to an innovative and low-cost solution. The iMac from Macintosh is another example. In their design conception and publicity campaign, the computer is seen from a different point of view—as a decorative object rather than merely as an information-processing machine.

Flexible strategy use has also been found to characterize creative problem-solving as shown by gifted persons (Jausovec, 1991, 1994). Jausovec (1991) studied the relationship between flexible strategic thinking and problem-solving performance in two studies. In the first study, he compared the responses of gifted students to those of average and poor students on a number of tasks designed to provoke two types of rigid answers: response set and perceptual set. Response set is the inability to break a habit and use a different strategy to solve the task when there is a better way of solving it, and perceptual set is the tendency to see a problem just from one perspective. Gifted students showed fewer rigid answers than both average and poor students, who did not differ among themselves.

In the second study, the gifted and average students verbalized their strategies for solving both open and closed problems. Closed problems are stated in clear terms so that there is no need to redefine them, and they also have a single correct solution. Open problems are often less clearly stated, so clarifying what the goals are is part of the solution, and they do not usually have a single correct solution, but rather several solutions that work (Jausovec, 1994). Convergent thinking and logic are efficient strategies for solving closed problems, whereas divergent thinking and redefinition of the problem are more helpful for solving open

problems (Jausovec, 1994). Jausovec (1991) identified the following strategies from students' verbalizations: subgoals (breaking the problem into smaller problems), working backward, modeling (making a simplified representation of a complex information), inference, trial and error, goal discovery, memory recall (recalling relevant knowledge from memory), generating analogies, and finally intuition and insight. The results showed that gifted students used more varied strategies than average students when solving the problems, and they also used them more selectively, applying different strategies to different problems depending on the requirements of the task. Thus, gifted students were more flexible in their strategy use.

Kaizer & Shore (1995) found also a tendency for competence in mathematical problem-solving to be associated with flexible strategy use. When comparing the performance of more and less competent mathematics students on mathematical word problems, the more competent students alternated between appropriate strategies (verbal or visual) to solve the problems, whereas the less competent were as likely to resort to trial and error as to use one of the appropriate strategies. Taken together, these studies suggest that adaptive flexibility may play a key role in problem-solving because it facilitates the use of a variety of strategies in response to the requirements of the task.

Spontaneous flexibility is the capacity to find a variety of solutions to a problem when there is no external pressure to be flexible. For example, in divergent thinking tasks, a participant may be requested to find as many ideas as possible concerning an object or a situation. However, whether the ideas generated come from one or many different categories of use depends on the individuals' natural, spontaneous flexibility of thought. The tendency to change conceptual categories easily and to cover many different categories in the responses indicates spontaneous flexibility. It is integrated in the scoring system of Torrance's (1974) Test of Creative Thinking (TTCT).

For example, in one version of the 'unusual uses' task, participants are asked to indicate uses for a cardboard box. The (spontaneous) flexibility score corresponds to the number of conceptual categories from which the responses are drawn. A flexible answer to the box task would be, for example, three ideas (make a toy house, play kick the box and store old clothing) all belonging to different categories (the categories of construction, box as toy and box as container, respectively). A rigid answer would be three ideas (put shoes in a box, put pencils in a box, put toys in a box), all belonging to a single category (box as container).

One important question explored in research is how flexibility facilitates the generation of new ideas. Several authors have drawn attention to the flexibility of existing knowledge structures as a source of new ideas, and the rigidity of it as an obstacle to creativity (Chi, 1997; Mumford, Baughman, Maher, Costanza & Supinski, 1997; Mumford & Gustafson, 1988). Knowledge is structured into conceptual categories—in groups of entities (concepts or images) that people believe belong together. The facility by which people work with different categories is thus an indicator of the flexibility of their knowledge structures.

For Chi (1997), the essence of creativity is the flexibility with which people cross category boundaries. She represents knowledge as stored on distinct associative trees. These trees can be a barrier to creativity because it is difficult for many people to move from one tree to another—from one category to another. When a concept on one knowledge tree is re-represented in the context of another tree, the result can be a new idea. For example, when the sound of footsteps in the snow is re-represented in the context of pop music, the result can be an original song (Björk, 2001, see Fig. 1).

Similarly, for Perkins (1988), crossing significant boundaries is central to creativity. For example, the impressionists crossed paradigm boundaries in the arts

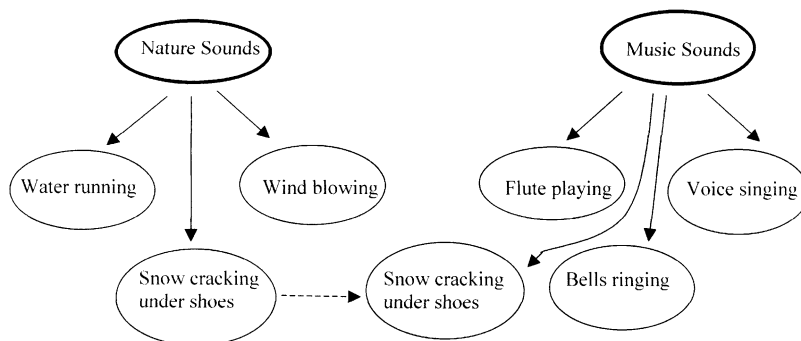

Figure 1. Example of two conceptual trees: nature sounds and music sounds. Flexibility involves considering (either spontaneously or purposefully) a knowledge element in a non-habitual conceptual tree, which may in turn lead to creative, innovative ideas.

when trying to capture the fleeting nature of light in their paintings, and Einstein crossed them in science when going against the traditional principles of electrodynamics. Operating on or across boundaries demands a profound change in perspective, as it involves questioning the limits of existing knowledge structures. By directly paying attention to boundaries, one can start operating explicitly on these boundaries, fiddling with them to experiment, or intentionally crossing them if one has reached an impasse.

According to Mumford et al. (1997), who also explored the flexibility of knowledge structures, combination and reorganization of existing knowledge play an important role in creating new ideas, but the processes underlying the combinations and reorganizations are not the same when working with similar concepts or distant ones. In their study, subjects combined and reorganized items from different unrelated categories in order to create a new concept that could account for all the items. They found that performance on this category combination task was related to the creativity of solutions of novel and ill-defined problems. Moreover, they found that instructions to use different methods for making connections between items (feature mapping or metaphors) contributed differently to performance for close categories and distant categories; when people were working with close (similar) categories, instructions to use feature mapping helped in finding connections between items, whereas when working with distant categories, instructions to use metaphors led to better performance.

In a similar vein, Mumford & Gustafson (1988) believe that the processes underlying major and minor creative contributions differ. According to them, integration and reorganization of cognitive (knowledge) structures is likely to underlie major creative contributions, but application of existing cognitive structures is likely to underlie minor contributions. These authors suggest that cognitive flexibility, whether it is due to outside requirements or to intrinsic reasons, is an important aspect of creative thought.

In order to implement a creative idea, however, flexible cognition is not enough. A number of recent models of creativity consider that in addition to flexibility, a combination of various cognitive factors, personality and motivational traits, emotional factors and environmental conditions is necessary in order to lead to creative, innovative productions (Getz & Lubart, 2000; Getz, Lubart & Biele, 1997; Lubart, 1994, 1999; Lubart & Sternberg, 1995; Mumford & Gustafson, 1988). In the next section we will examine the conative aspects of flexibility—personality traits and cognitive style—associated with innovation.

Conative Aspects

In this section we treat flexibility as a personality trait, a relatively stable, preferred way of behaving, rather

than as a cognitive ability discussed in the previous section. In the literature, the personality of highly creative, innovative individuals as compared to their less creative, less innovative counterparts has received a great deal of attention, and a number of personality traits have been identified as related to high creative achievement. We focus on the work that relates to flexibility.

According to Gough (1995), *flexibility as a personality trait* refers to having a preference for change and novelty. The trait of flexibility has been traditionally measured with self-report measures, questions concerning a person's reactions in various situations, whereas flexibility as a cognitive ability has been evaluated through performance on specific problems that tend to involve mental blocks and set effects.

The personality trait of flexibility has been associated with creative performance in several studies (Dellas & Gaier, 1970; Feist, 1998, 1999; McKinnon, 1962). For example, McKinnon (1962) found creative architects to be more flexible than their less creative peers. In a meta-analysis of the literature on personality and creative achievement, Feist (1998) found creative scientists to be more flexible than less creative scientists and that artists were more flexible than non-artists as measured by the California Psychological Inventory Flexibility scale.

In addition, other personality dimensions and traits, also associated with creativity, seem to have an important aspect of flexibility built into them. The Openness to experience factor in the Five-Factor Model of personality (Costa & McCrae, 1985b) relates to flexibility. The positive pole of Openness to experience is anchored with terms such as, 'flexible', 'need for change', 'open-minded' and 'wide interests', whereas the negative pole concerns rigidity of beliefs, opinions and behaviors. For example, in Feist's (1998) meta-analysis, creative scientists, compared to less creative scientists, scored higher on openness to experience. Artists, compared to non-artists, also were more open to experience. Furthermore, McCrae (1987) found that openness to experience correlated positively with the number of ideas generated on divergent thinking tests.

Another sign of conative flexibility linked with creativity is the capacity to integrate apparently conflicting or opposite personality traits. Some authors have suggested that creative persons often have a combination of personality traits that seem contradictory. Traits that normally do not go together, such as sensitivity and coldness (Feist, 1998) or introversion and dominance (Eysenck, 1997), co-occur in the creative individual. Creative people, it seems, are flexible enough to integrate very dissimilar traits in their personality without losing their integrity (Eysenck, 1997), and, in fact, complexity seems to be

a characteristic of creative people (Barron & Harrington, 1981; Eysenck, 1997).

Cognitive styles, at the interface between personality and cognition, refer to preferred ways of using one's cognitive abilities to approach a task. Lubart & Sternberg (1995) proposed that certain styles facilitate creativity and innovation more than others. For example, the legislative stylist prefers to invent his or her own rules and methods of doing things rather than to focus on implementation of these rules (executive style). The progressive stylist has a preference for novelty, welcoming change and innovation, whereas the conservative stylist prefers to do things the way they have always been done. Finally, the global stylist prefers working with a task in its large context, specially important for problem-finding and problem definition, whereas local stylists prefer to work with the details, on a narrower level.

Although specific styles have been associated with creativity, flexibility in shifting between different styles has received less attention (Martinsen, 1997). For example, the ability to shift between global and local levels of processing could be important for innovation, permitting the innovator to apply a different kind of treatment to different tasks or to different phases in the innovation process. It might be better to apply global processing in the beginning of a task, in order to identify the need for a new product in the marketplace. In contrast, during the elaboration of details of the particular product, local processing could be more helpful. Thus, in this view, flexibility may be due to an absence of a dominant cognitive style because a strong style would lead to preferential but sometimes non-optimal behavior in certain parts of a task or in certain tasks in general.

We have seen how flexibility contributes to creativity and innovation when viewed as a characteristic of individuals (both cognitive and conative). However, a possible downside of high flexibility could be that it could cause difficulties for the creative person to stick to a project and not to go from one thing to another. At this point it is important to distinguish between the *invention* or generation of an original idea and *innovation* or the project of converting it into a useful production (Roberts, 1988). In order to invent new ideas, flexibility is needed to see problems from a different perspective and come up with alternative ideas whereas perseverance is needed in order to stick to the project in spite of obstacles on the road of implementation. In this way other characteristics that play a role in creativity may balance any possible negative effects of flexibility.

However, in order to fully understand creativity, studying the individual is not enough (Csikszentmihalyi, 1988). No matter how creative the innovator, if the environment is not ready for creative, innovative ideas then original thinking will not flourish. In the next part of this chapter we will discuss the importance of the

social environment's willingness to accept innovations, and ways in which innovation can be facilitated through increased flexibility of the audience.

Flexibility as a Characteristic of the Audience for Innovations

Creativity takes place in a context, in a certain time and place that influence if the outcome will be seen as creative or not. For Csikszentmihalyi (1988), creativity is the result of an interaction between the environment (the cultural domain and the field) and the individual. Without a culturally defined domain and a group of peers to evaluate whether a proposal is original and useful, it is not possible to specify what is creative or not. Research on consumer behavior indicates that some people accept innovations more readily than others (Goldsmith & Foxall, this volume; Goldsmith & Hofacker, 1991; Goldsmith, d'Hauteville & Leisa, 1998). Some people will quickly try new products whereas others will continue to use well-known products well after innovative ones have been widely adopted in the marketplace. This phenomenon, called 'consumer innovativeness', has been shown to be related negatively to the age of consumers perhaps due to well-worn habits or risk aversiveness and is positively related to the trait of sensation-seeking. Thus some segments of the audience may be more rigid than others when considering potential innovations and adopting them. Beyond the level of individuals, organizational culture is a particular type of cultural environment that has been shown to play an important role in the destiny of new ideas. Consider now how one of its aspects—organizational flexibility—may influence innovation.

Flexibility in Organizational Climate and Culture

Organizational creativity is "deliberately changing procedures to make new, superior levels of quantity, quality, cost, and customer satisfaction possible" (Basadur & Hausdorf, 1996, p. 21). To achieve this goal, creative and innovative management is needed (Fernald, 1989).

A corporate climate refers to a coherent set of observable behaviors, attitudes and feelings in an organization (Ekvall, 1991). It is a manifestation of the deeper culture of the organization. According to Schein (1990), an organizational culture is a pattern of basic assumptions of a group, working to cope with problems of external adaptation and internal integration. These assumptions are considered valid, as they have worked in the past, and are therefore passed on to newcomers. Ekvall (1991) considers organizational climate as an intervening variable that affects the outcomes of the organization's actions through its effect on organizational and psychological processes like communication, decision-making and employee motivation. Together with the available resources, the organizational climate will have effects on outcomes

such as productivity, quality of products, innovation and job satisfaction. These outcomes in turn influence both the resources and the climate.

A number of authors have suggested that one of the hallmarks of corporate cultures that support creativity and innovation is their flexibility or, in other words, their lack of rigidity. For example, for Hisrich (1990), flexibility is one of the common characteristics of companies that have an excellent reputation, as they show the ability to adapt to changes in the marketplace. According to this author, traditional corporate climates emphasize cautiousness and avoiding risks; they favor conservative decisions, and are rigid in the sense that they are hierarchical with established lines of authority, instructions and working hours. Furthermore, short-term gains are preferred over long-term potential as each manager protects his or her own job. This emphasis on not making any mistakes hinders creativity and reduces flexibility. A climate that nurtures innovation tends to have a relatively flat (non-hierarchical) organization with teamwork, sponsors and mentors that facilitate communication, trust and cooperation. In addition, it has a long-term vision, goals and action plans to follow them up. Actions are rewarded, suggestions and experimentation are welcome, and creation and development in all areas is supported.

The willingness of managers and other employees to change their ways of doing things and thereby to take some risk is important in order for new ideas to be translated into action. For example, in interviews with research and development scientists focusing on qualities of the environment that either facilitate or inhibit creativity, Amabile (1988) found that an overemphasis on maintaining the status quo—the unwillingness to change anything—was a frequently mentioned obstacle to organizational creativity.

In two empirical studies, Ekvall (1991) identified features of a creative or innovative climate in organizations and in organizational departments. The first study compared the creative and innovative climate in 27 Swedish organizations, evaluated (by product innovation criteria) as being either innovative or stagnated. The second study compared the creative climate of organizational departments in an American industrial company that had been evaluated by independent judges as being either innovative or stagnant. The result of both studies went in the same direction. The innovative organizations and the innovative departments were rated higher on all aspects of creative climate measured (challenge, freedom, idea-support, trust, dynamism, playfulness, debates, risk-taking and idea-time) and had less conflict than the stagnated organizations and departments. In terms of organizational culture, three types of profiles were identified. These profiles reflected value orientations that were focused differentially on either structure, people or change. Of the three, the change-oriented cultures were the most flexible. Change-oriented cultures were

characterized by entrepreneurial and transformational management, in which the manager is more a leader who sets goals and makes tasks meaningful rather than one who gives instructions and makes decisions.

Furthermore, in a meta-analysis of organizational innovation, Damanpour (1991) found several potential determinants of innovation that relate to flexibility. The first was functional differentiation, or the existence of differentiated units of professionals, who work explicitly on elaborating, introducing, and influencing change. The second was lack of formalization with a low emphasis on strict rules. The third determinant was a positive managerial attitude toward change. A manager who is favorable toward change creates a good climate for innovation, especially useful during the implementation stage, when conflict resolution and coordination of efforts are important. Of these three determinants, a significant positive relationship to innovation was observed empirically for functional differentiation and positive managerial attitude towards change.

Large organizations in particular have rigidity problems that can be obstacles to innovation. According to Rosenfeld & Servo (1991) increasing size is related to depersonalization and decreased communication. Both invite the risk of becoming rigid as each individual has less impact and there is less interaction between divisions. Remaining open to change while maintaining organizational integration becomes more difficult with increased size. Innovation should be possible however, despite size, if an organization uses its human resources in a flexible manner. One approach to achieve this involves managing properly innovative individuals inside organizations, as well as other key players in the process of innovation, such as technological gatekeepers, sponsors and champions. Technological gatekeepers are experts on technology that will give their opinion on whether an innovation is cutting-edge technology or not. Champions are the advocates of the innovator when facing the organization, supporting the new idea (see also Hausschildt, this volume), and sponsors are senior, higher-status members of the organization, who dispose of material and human resources and use them to develop an idea. Flexibility is also a desirable characteristic for these different actors in the innovation process. For example, Howell & Shea (2001) found that the tendency to seek information from diverse sources was positively related to champion behavior. Breadth of interests or spontaneous preference for variety led people to scan diverse domains in search for information that could become critical to identify a promising innovation opportunity. Champions, thus, did not stick to subjects relevant to their own job, but showed interest in a variety of other topics. For organizations to identify people capable of facilitating innovation, it is important for them to have a flexible attitude towards the employee—to be able to set a formal job description aside for a while and see a

person from a different perspective. Finally, some authors (e.g. Hammer, 2001) point out that innovation that depends on exceptional persons identified as champions is *not* well managed. Rather, everyone in the company has to have the flexibility to adopt the role of innovation generator, champion and implementor within a well-described innovation process such as product development (see also a later discussion of the system for managing ideas). In a similar vein, observers of the creative and innovative practices in business (e.g. Hamel, 2000; Peters, 1999) point out that companies that have a large flexibility in terms of job contents independent of one's title or function are often the most innovative. Such organizational flexibility allows them to assemble teams for innovative projects based on employees' intrinsic motivation and not on the organizational rigidified role.

We have seen different ways in which flexibility and the willingness to change are important for innovations, but how can we help organizations to be more flexible, more open to change? We will now examine some of the efforts that have been made to stimulate innovation in organizations, in particular those pertaining to being flexible.

How Can We Facilitate Innovation Through Flexibility?

As important as it is for organizations to have creative individuals on board, going against the stream in a rigid, hierarchical and authoritarian structure can be difficult. In order to facilitate the task for innovators, several authors have suggested how flexibility could be increased, both at the organizational and at the individual level.

Burnside (1990) presents a model of how to improve organizational climates for creativity. Central to this model is goal clarity, both in the long term and in the short term, in order to channel employee's creativity. A clear long-term goal is a specific idea of where the organization is attempting to go in the future, whereas clear short-term goals are smaller concrete objectives in order to get there. After goal-setting, three important components in motivating an employee to be creative are challenge, freedom and encouragement. A challenging task is meaningful and interesting to the employee. Challenge suggests that the task will require the employee to go beyond established knowledge or known skills, moving the individual into his/her 'zone of proximal development'. The employee has freedom when he or she is given maximal autonomy to decide how to do the task, and encouragement is provided by the manager who helps the employee to build courage to come out with his or her ideas and to take risks. Part of encouragement is accepting mistakes when an employee is willing to learn a lesson from an error.

To help create these conditions in large organizations, some have adopted a decentralized structure called an 'office of innovation', first developed by the

Eastman Kodak Company. The office of innovation is not attached to a particular department, and also works independently from the human resource department, allowing for input from all departments and the flow of ideas between them. In the office of innovation, facilitators receive and look for individuals who play different roles in the innovation process (technological gatekeepers, sponsors and champions) in all departments of the organization (Rosenfeld & Servo, 1991). This decentralization increases flexibility in the organizational structure as it goes beyond department barriers in the conscious effort to innovate.

Fernald (1989) describes other examples of how different organizations have made an effort to stimulate creativity and innovation. At Intel, engineers are encouraged to meet with their engineer-peers to practice 'constructive confrontation' (p. 211), in order to eliminate bad ideas and make good ideas better. In these meetings, ideas are examined in a critical light, thus putting them in a different perspective. In this way, the engineers practice deliberately engaging their cognitive flexibility by changing their point of view on a problem in a group context.

Saturn Corporation illustrates an organization (General Motors) that considers flexibility and change necessary to be productive and innovative. In order to produce cars capable of competing on the world market, Saturn departs considerably from the traditional, hierarchical corporate structure. First, it considers its employees as creative and innovative people, capable of taking well-considered risks. Second, it keeps the bureaucratic structure as lightweight and flat as possible. For example, all employees contribute to the decision-making process, all are salaried personnel with a part of their earnings tied to the company's profit, and job classifications are limited and simple (Fernald, 1989). In 2001, however, General Motors made a decision to bring its Saturn division closer to its other divisions which lead many industry observers to question if its culture could survive in the long run.

A more global approach to achieve innovation through both specific organizational processes and flexible management of human resources is proposed in the *System for Managing Ideas* (SMI, Getz & Robinson, in preparation). SMI—a set of idea management processes and of human resource management practices aimed to encourage, act upon and recognize employees' ideas—is increasingly found in excellent companies known for the creativity and innovation of their employees. The essential belief on which SMI is founded is that if employees are not creative, it is not their fault (lack of necessary personal traits and abilities), but the company's which does not manage its employees' creative potential properly. According to the SMI, every employee is viewed as potentially creative, each to a different degree. Thus, SMI's set of practices aims to make every one's potential a reality—

through encouraging employees' ideas, providing all the necessary support for their implementation, and recognizing their innovative productions appropriately. In this sense, the SMI approach is contrary to the earlier mentioned approach of flexibly managing particular individuals—innovators, gatekeepers, sponsors and champions. Although doing the latter is better than doing nothing, relying on particular extraordinary individuals in any organizational process, be it product development or innovation, is generally viewed as a sign of non-systematic management. For innovation, this approach may be less reliable than the systematic idea management that involves flexibility in managing all company employees' creative potential.

Manager's attitudes towards creativity and innovation are important for the future of new ideas, as they must often introduce potential changes, at least on the middle and lower levels of organizations (Damanpour, 1991). According to Basadur & Hausdorf (1996), manager's attitudes towards creativity can be influenced through experience. In their study, managers who received training in using flexibly different modes of thought (alternatively using divergent and convergent thinking) in order to be more creative had more positive attitudes towards creativity after the training than before it. A manager who has positive attitudes towards creativity is more likely to be creative him or herself and encourage creativity in employees.

Thus, flexibility of the audience and, more generally, the environment is important for both stimulating innovation and appreciating it. In the next section, we will look at the process of innovation and how different types of flexibility can become important at different moments in the process.

Different Types of Flexibility at Different Stages in the Innovation Process

According to creativity research, the creative process is not viewed as a homogeneous phenomenon. It involves different stages or sub-processes that probably call for different approaches. We will start by briefly reviewing the different stages and sub-processes of the creative process before turning to how different types of flexibility are relevant for the different parts of the innovative process.

The creative process is frequently regarded as a special case of problem-solving, with the problem-solving process described in sequential stages (Lubart, 2000–2001). The best-known stage model was proposed by Wallas (1926), and includes four stages. The first is preparation, followed by incubation, illumination and finally verification. During the preparation stage, relevant knowledge and skills are used to analyze and define the problem. Next the problem is set aside for awhile, at least consciously, allowing different associations to the problem to be formed unconsciously, and impasses to be rejected. Illumination is a sudden insight into the solution of the problem that

then needs to be tested during the verification stage. In addition, some authors consider problem-finding, the realization that there exists a problem to be solved, as a separate stage, preceding the preparation stage (Amabile, 1996; Ducec & Côté, 1994; Runco & Chand, 1994).

In a similar vein, Amabile (1988, 1996) proposed a stage model for the creative and innovative process in organizations including the following stages: (1) identifying the problem to be solved; (2) preparing by assembling the relevant information; (3) generating the response after searching possible solutions; (4) (critically) evaluating and communicating the response; and finally (5) making a decision to go through with the idea or not. At any point in this process the person or group may need to return to a previous phase to rework problems that become apparent as the work progresses.

Flexibility could play a role at different points in the creative process. Both adaptive and spontaneous flexibility are important, but the two do not function in the same way. Adaptive flexibility is applied when there is a pressure from the outside to change, whereas spontaneous flexibility reflects change for intrinsic reasons. For example, in the preparation phase, spontaneous flexibility may be useful for gathering information from diverse domains that might be relevant to solve the problem, avoiding a limited search in a few domains that seem directly relevant. Also in the preparation stage, defining the problem may call for adaptive flexibility, to see the problem from a different perspective, which may result in an insightful approach. For example, in a study by Getzels & Csikszentmihalyi (1976), a group of art students were observed while making still-life drawings, and the originality of these drawings was then evaluated by expert judges. They observed a range of behaviors during the preparation phase. Some students examined only a few objects before moving on to drawing them, whereas others examined many different objects in detail, and sometimes changed the original arrangement they had made, after having started the drawing. These latter students demonstrated flexibility (changing their original approach to the problem and adopting a new one). This attitude was also positively related to the rated originality of the final drawings. Amabile (1996) separates problem-finding from the other stages in her model. Problem-finding calls for flexibility in order to identify a problem others did not see. In working through the process, flexibility can also facilitate moving with ease from one stage to another, depending on the sub-problems that may arise in the process.

The fact that incubation is postulated to take place mostly on an unconscious level limits what we can say about flexibility at that stage. Nevertheless, the ability to set the problem aside for a while can be regarded as an act of flexibility in itself instead of stubbornly

struggling with it when the present approach is clearly not effective. A different act of flexibility in the incubation stage can occur in preconscious emotional processing. A series of studies by Getz & Lubart (1998, 2000) and Lubart & Getz (1997) have shown that when individuals rely on emotional processing of their experiential memory representations they produce more creative associations than individuals relying on the cognitive processing of their conceptual memory representations. Thus spontaneous flexibility could be involved during incubation if an individual switches from cognitive to emotional processing. These findings are also corroborated in the well-known organizational practice of fostering the production of creative ideas by going and experiencing (feeling) directly the problems. Indeed, within the Japanese Kaizen (continuous improvement) approach, recognizing both the importance of 'feeling' the problem and the cultural reluctance (rigidity) to do so encourages a problem-solver to 'become' flexible and to go and experience the problem before trying to look for its solutions (Robinson, 1991).

The illumination stage is the moment where the different elements of the problem suddenly 'click' into place and the solution becomes clear. Adaptive flexibility could be essential at this stage, allowing one to change one's approach to the problem or to rearrange its different elements in a new way, which can result in a new insight. The verification stage involves testing the solution produced—determining if it solves the problem or not. This is perhaps the stage where convergent thinking is the most important—verifying if a particular solution is right for the particular problem. The facility to switch from divergent thinking to convergent thinking involves adaptive flexibility, as each mode is best suited to different portions of the problem-solving process.

The idea of a sequential stage-based process has been recently questioned, as some authors find it too simplistic to describe what really takes place during creative problem-solving (Lubart, 2000–2001). Many sub-processes that play a role in creativity have been studied independently of stage models of creativity, some of which involve flexibility, such as definition of the problem, divergent thinking, reorganization of information and remote association. For example, remote association is a process that is hypothesized to involve spreading activation in memory (Mednick, 1962). A spontaneously flexible person, able to search in many varied categories, should have more chance of finding varied associations in response to a given problem and thus a greater capacity for remote association. Lubart & Mouchiroud (in press) propose an alternative, dynamic view in which the creative process is made up of different sub-processes that are mutually reinforcing. This approach does not postulate a fixed sequential order of the different processes but rather an interaction of different processes, or their

simultaneous activation. In this type of approach to the creative process, the importance of flexibility to jump back and forth between different modes of thought or sub-processes, or to apply them at the same time, is evident.

Conclusion

In this chapter we have seen how flexibility is important for innovation. The innovator needs it in order to identify new problems and to get away from the traditional ways of solving them, and the audience needs it in order to give new and unusual ideas a chance to exist and show their value. Finally, the process of innovating involves flexibility in numerous ways.

These have several implications, both for the functioning of organizations and for future research on creativity and innovation. For example, in modern organizations, innovation often depends on a group of individuals being able to work as a team. In the beginning of the chapter we specified that our discussion of individual flexibility could also apply to a group of people working together. In a team, having a flexible personality is probably important for the individual members to work well together, but additionally, having a group of individuals with different perspectives on the problem could also contribute to a creative and innovative solution. This would be especially true if team members voluntarily confront their different point of views in order to solve the problem better.

Moreover, innovative individuals and teams need a flexible environment if their ideas are to become real products. Organizational creativity involves deliberately changing established procedures, which implies that managers at all levels in organizations can contribute to flexibility. It is important that managers be flexible enough to give the employees space to be innovative, for example by being willing to take well-considered risks, having low emphasis on rules and offering the possibility of flexible working hours. While all these things are important to create a more flexible corporate culture, the System for Managing Ideas (Getz & Robinson, in preparation) offers an alternative approach. Organizational innovation is placed in a new perspective by redefining the problem. In the System for Managing Ideas, innovation is not about exceptional individuals innovating against all odds under traditional management, but about exceptional management practices that enable the creative potential of ordinary individuals. This approach could encourage interest for the employees' efforts to be innovative, and tolerance towards these employees who just cannot seem to fit nicely into their job descriptions, instead of interpreting their behavior as a simple defiance against authority.

Organizations today need to be ready to change without much notice and to prepare as well as they can

for the unpredictable hazards of the organizational environment: economic crises, smart competitors, changes in consumer behavior and a workforce that is evolving as well. Awareness of why and how flexibility is important for organizations can help them take action towards more adaptability and thereby be less vulnerable if the environment suddenly changes. As for the innovative process itself, we have seen how the process of creating and innovating can be seen as an essentially flexible one. For example, in the sequential stage-based approach, flexibility seems to be important at each stage. However, with more recent, non-sequential approaches to the creative process, new venues open up for research on flexibility. In this non-sequential and interactive view of the creative process, the role of flexibility to synchronize the use of different sub-processes becomes a central issue.

The Effect of Mood On Creativity in the Innovative Process

Geir Kaufmann

Norwegian School of Economics and Business Administration, Bergen, Norway

Abstract: The division of labor between the concepts of creativity and innovation is discussed. The effect of mood states on creative problem-solving as part of the process of innovation is then addressed. The prevailing notion that there exists an unconditional positive causal link between positive mood and creativity is criticized. Evidence is reviewed that shows that under certain, important conditions, positive mood may actually impair creativity, while negative and neutral moods may facilitate finding insightful and highly creative solutions to problems. A new theory of mood and creative problem-solving is developed.

Keywords: Innovation; Innovative process; Creativity; Mood; Creative problem-solving.

The Conceptual Terrain of Creativity, Innovation and Mood

We have previously argued that there is a string of concepts in the innovation domain that, put together, form a fairly tight and coherent conceptual equation (Kaufmann, 1993). At the base, there is *originality* that is characterized by novelty of ideas, which is a necessary, but not sufficient condition for *creativity*, which, in addition requires the concept of value or usefulness. Creativity, in turn, is a necessary, but not sufficient condition for *invention*, which in turn requires *incremental* novelty, in the sense that the novelty in question must be objective, and not only subjectively novel to its originator. In the last piece of the conceptual equation, invention is a necessary but not sufficient condition for *innovation*, which in addition requires that the condition of realizability be fulfilled.

In the present discussion we will concentrate mainly on the creativity space of the innovation domain, and discuss the status and implications of a recent stream of new research that has sparked considerable attention and controversy. In this new line of research, the functional significance of mood and affect in the process of creativity has been addressed.

Affect and Mood—Figure and Ground

According to Morris (1989), we can distinguish between the ‘figure’ and ‘ground’ of mood. As ground,

mood is the backdrop against which a person experiences and evaluates events; as figure, mood comes into the forefront of attention, which may result in attempts to explain why a particular mood is present and, if it is negative, attempts to ‘repair’ or replace the current mood state. Moods are seen to be pervasive and global and have the capability to influence a broad range of thought processes and behaviors.

Vosburg & Kaufmann (1999) argued that a more precise conceptual outlook would be to regard mood as the background state, and affect as its corresponding, overt manifestation. Thus positive mood may be manifested in the affective state of elation, and negative mood, in the overt state of depression or anger. By definition, then, mood is a background state not consciously articulated by the individual. This is a matter of practical importance, in the sense that, at least on some theories, mood effects are only obtainable when not consciously experienced and articulated in an explicit way by the individual (cf. Forgas, 2000a).

Roadmap of the Chapter

In the present chapter we will review and critically discuss the current status of research and theories on mood and creativity. We will argue that a premature closure on a certain bottom line conclusion has been taken, and plead for a more nuanced perspective on the complex interrelationships between mood states and different aspects of the process of creativity, and present our perspective in the form of a new theory of

mood effects on creative problem-solving. Last, but not least, we will place the discussion of mood effects on creativity in the larger context of process of innovation.

From ‘Cold’ to ‘Hot’ Cognition

In psychology, there has always been a tendency to drive a wedge between cognition and emotion, in the sense that they are seen as two distinct, separate systems, that may run exclusively on their own wheels, but sometimes may interact in different ways (e.g. Forgas, 2000a).

The ‘Cold’ Approach

This general position has, to a large degree, dominated traditional cognitive approaches to the study of creativity, and cognitive theories of creativity are consequently largely focused on elucidating ‘cold’ cognitive mechanisms and strategies involved in creative thinking. In Newell, Shaw and Simon’s classical work on creativity conceptualized from a cognitive information processing perspective, there is a passing mention of the importance of ‘motivation’ and ‘persistence’ as one of the important defining criteria. However, the remainder of the treatment of the subject is almost entirely concentrated on identifying the most relevant heuristic strategies that are used by problem-solvers in handling the creativity aspect of problem solving (Newell, Shaw & Simon, 1979). Along similar lines, Weisberg (this volume), argues uncompromisingly that the traditional, well-known mechanics of ordinary problem-solving is the only road that takes us to the peak levels of creativity, excluding any privileged role of affect in the process of creativity that other theorists would like to grant (e.g. Getz & Lubart, 1999; Getz & Lubart, 2000; see also Root-Bernstein & Root-Bernstein, this volume).

Also in the most recent, sophisticated ‘creative cognition’ approach launched by Finke, Ward & Smith (1992) and Smith, Ward & Finke (1995), where the concepts, theories and methods of cognitive science are applied as a platform for a rigorous study of creativity, the focus is exclusively on identifying the kind of cognitive mechanisms that are at work when people are engaged in creative endeavours. No place in their theories has been given to the ‘hot’ dimension of cognition, that is fueled by desires, affect and mood.

Indeed, as Forgas (2000a) points out, in the classical cognitive tradition there has generally been a tendency to think of affect as a ‘subtractive’ factor that is ‘dangerous’ in the sense of having the potential to subvert efficient cognitive processing. More recently, we see this perspective expressed in theories espoused by Ellis & Ashbrook (1988) and Mackie & Worth (1991), where both positive and negative affect are regarded as states that take up scarce processing capacity.

Cognition is Heating Up

During the last 20 years, however, we also have seen an increasing interest in embracing the concepts of emotion, affect and mood within more integrated cognitive theories, like the associative network theory (Bower, 1981). Here affective content is also granted a potentially positive function, in providing extra cues in memory. On this perspective, openness to feelings may become a useful adjunct to the machinery of effective, rational thinking. This perspective is also adopted specifically with regard to creativity by Getz & Lubart (1999), in their elegant Emotional Resonance Model of Creativity.

Of particular relevance to the area of creativity is also the view put forward in one of the most prominent theories in the field advocated by Forgas (1995, 2000b). In his Affect Infusion Model (AIM), a core thesis is that tasks that require elaborate and constructive processing—exactly what is likely to be needed in the open and unstructured problem spaces that require creative thinking—there will be more reliance on affectively primed information, and greater influence of affect and mood states on performance. Such effects are held to be both detrimental and facilitative of performance, partly due to the kind of information processing that is triggered by the particular affective state in question with regard to the task at hand.

Following Forgas (2000a) we may regard the division of labor between the different emotion concepts in the way that affect is a general, superordinate concept, where mood refers to long-term, relatively stable affective states, and emotions constitute more short-lived, specific affective episodes.

Research on affect and creativity has been focused largely on the effect of positive and negative mood, compared to a neutral state on a large variety of creative task performances (Russ, 1993, 1999).

Mood and Creativity: A Straight or a Crooked Relationship?

We may start out by asking if the research done so far gives us a fairly clear and consistent picture of the impact of mood and creativity, or if moderating contingencies is the rule rather than the exception.

In spite of many differences regarding the theoretical interpretations of mood effects on cognitive performance in general (Forgas, 2000a; Hirt, 1999; Hirt, McDonald & Melton, 1996; Martin & Stoner, 1996), a specific position has frequently been cited as a valid general conclusion on the relationship between mood and creative problem-solving. This is the conclusion that *positive mood facilitates creative problem-solving* (e.g. Benjafield, 1996; Hirt, 1999; Hirt, McDonald & Melton, 1996; Isen, 1993, 1999; Isen & Baron, 1991; Shapiro & Weisberg, 1999; Shapiro, Weisberg & Alloy, 2000).

Hirt (1999) is a representative voice of these views when he claims that "Individuals in positive mood states have been reliably shown to be more creative on a range of tasks than are individuals in other mood states" (p. 242). Not only that, but "the effects of (positive) mood on creativity appear to be remarkably robust both in terms of the mood induction procedure used and the range of possible creativity tasks that have been measured" (p. 242). Isen (1999) agrees, and claims that "... positive affect is associated with greater cognitive flexibility and improved creative problem-solving across a broad range of settings" (p. 3).

The Supporting Evidence

It is true that findings from a large number of studies seem to support this general conclusion (Hirt, 1999; Russ, 1993, 1999). In a classical, and frequently cited study, Isen and her coworkers have shown positive mood to facilitate performance on standard indicators of creative problem-solving ability, such as insight problems (Isen, Daubman & Nowicki, 1987; see also Greene & Noice, 1988), and the Remote Associates Test (RAT) (Isen, Daubman & Nowicki, 1987; cf. Estrada, Isen & Young, 1994 for a replication and extension). Unfortunately, a serious flaw exists in all these studies, in the form of lack of discriminant validation of the findings. No control tasks, *not* presumed to be affected by mood, or to be affected to a lesser degree than creativity tasks, were included. Thus, we do not know if these effects are constrained to creative problem-solving specifically, or if they reflect a general, positive performance effect of positive mood, for instance through reducing test anxiety. However, in further studies it has also been shown that positive mood promotes more original responses to a word association task, and encourages broader and more inclusive categorization performance (Isen & Daubman, 1984; Isen, Johnson, Mertz & Robinson, 1985; cf. Greene & Noice, 1988). Such findings are taken to mean that positive mood selectively facilitates the kind of basic cognitive, associative mechanisms that may lie behind creative performances. These are interesting findings, but a direct demonstration that the kinds of associations primed by positive mood do indeed significantly impact on creative problem-solving performance would have been desirable. Thus, we are left with interesting hints as to a facilitative effect of positive mood on creative problem-solving, but by no means with conclusive evidence.

Consistent with the positive mood-creativity hypothesis, Bowden (1994), in a review of psychometric studies of cognitive characteristics associated with elevated positive mood, reported that this state of mind was associated with tendencies toward over-inclusion and loose conceptual boundaries. Similar results were reported by Jamison (1993) when highly creative individuals were observed by monitoring their mood

systematically and recording reports of creativity, a mild hypomanic state was observed to significantly coincide with high levels of ideational fluency, speed of association, combinatorial thinking (including incongruent combinations and metaphors) and 'loose' processing involving irrelevant intrusions in thought (cf. Schulberg, 1990, 1999; Shapiro & Weisberg, 1999; Shapiro, Weisberg & Alloy, 2000). In a positive sense, this cluster of cognitive characteristics may tend to facilitate originality and creativity in problem-solving.

Recent experimental research adds further support to these findings (Hirt, McDonald & Melton, 1996; Murray, Sujun, Hirt & Sujun, 1990; Showers & Cantor, 1985). In these experiments, positive mood subjects, compared to controls, were found to be better able to generate and use broader categories when identifying similarities, and also more able to shift to narrower categories when focusing on differences. Such findings have been linked to creative problem-solving by the argument that subjects in whom positive mood had been induced gained access to more unusual and diverse information, and were also more flexible when categorizing (Hirt, McDonald & Melton, 1996; Isen & Baron, 1991).

These findings are consistent with results from other studies showing positive mood to increase fluency in divergent thinking tasks. Abele (1992a) induced positive, negative and neutral mood by way of autobiographical recall, and demonstrated that positive mood resulted in superior performance on ideational fluency tasks. Vosburg (1998a) recorded mood at arrival through an adjective checklist immediately prior to task performance and found that positive mood facilitated and negative mood inhibited fluency of idea production.

Related to these findings are results showing facilitative effects of positive mood on heuristic problem-solving tasks, like the Means End Problem Solving Test (Mitchell & Madigan, 1984; cf. Abele, 1992b). Similarly, Carnevale & Isen (1986) examined the effect of mood on the quality of problem-solving in negotiation behavior. They focused on the ability to find a creative integration from which both parties gain. Again, positive mood was found to yield superior performance. Staw & Barsade (1993) examined the relationship between positive affectivity and performance in a complex managerial In-Basket task. Positive affectivity was found to be significantly positively related to all important problem-solving attributes, including flexibility and originality.

The Explaining Models

The conclusion that positive mood facilitates creative problem-solving is reached from different theoretical premises. Isen (1984, 1987, 1993, 1999) posits that positive, compared to negative and neutral, material is more extensively connected and better integrated in

memory. This is held to promote spreading activation and increase the likelihood of making remote associations conducive to creative thought. However, no direct and independent evidence in support of this general principle has ever been offered. The idea that positive mood promotes spreading activation is largely gratuitous and used in a *post hoc* manner to explain observed, empirical findings.

According to the cognitive tuning theory originally proposed by Schwarz (1990), and further developed by Schwarz & Bless (1991) and Clore, Schwarz & Conway (1994) (see also Schwarz, 2000), the essential function of emotional states is to inform the individual about the state of the current task environment (cf. Frijda, 1988). Negative mood indicates a problematic situation, whereas positive mood signals a satisfactory state of affairs. Consequently, individuals in negative mood will be tuned to an analytic, 'tight' mode of processing (cf. Fiedler, 1988, 2000), where the situation is treated carefully and systematically. Positive mood individuals relax on the processing requirements, and are more prone to use simplifying heuristics and 'loose' processing (cf. Fiedler, 1988, 2000). As such, they may be more willing to explore novel procedures and possibilities that could increase the likelihood of finding creative solutions (cf. Russ, 1993).

Much evidence does exist, in fact, that lends support to the general thesis that positive mood promotes a heuristic style of problem-solving (e.g. Abele, 1992b; Forgas, 2000a, 2000b).

However, the idea that positive mood tends to promote a 'no problem' attitude to the task at hand, whereas negative mood leads to perceiving the (same) task as problematic, and in need of careful scrutiny, may just as well be used as an argument in favor of the notion that negative mood may put the individual on higher alert. This may facilitate new interpretations and reframing of a task. Conversely, positive mood may put people's cognition on automatic and may lead them to overlook important new features in a task that is superficially disguised as a traditional, well-handled one. This is an interesting type of problem that has tended to be overlooked in the problem-solving literature. Such tasks are described and classified as 'deceptive problems' by Kaufmann (1988).

In a similar theoretical approach, which is gaining in popularity, Fiedler (2000) and Bless (2000) link the effects of positive and negative mood, respectively, to the processes of assimilation and accommodation. In a strange twist, they argue, however, that somehow assimilation promotes creativity and accommodation does not. But accommodation involves reorganizations of established schema into new, more adaptable ones, and is, in fact, the mechanism that normally is seen as most closely linked to creative thinking in the classical theory of Piaget (e.g. Furth, 1969). How do we reconcile the view specifically adopted by Bless (2000) that a happy mood tends to make people rely on

stereotypes and prior judgment in the face of the frequently held definitional criterion of creativity to the effect that one of its essentials involves rejecting or seriously modifying conventional perspectives and solutions? (cf. Kaufmann, 1988; Newell, Shaw & Simon, 1979; Sternberg & Lubart, 1995.)

All in all, theories supposed to explain the positive-mood creativity link are either ad hoc rationalizations, or problematic as clearcut interpretations of the posited relationship, and may even be internally inconsistent.

Some Cause for Alarm

Several studies suggest that positive mood may also significantly impair problem-solving performance. Mackie & Worth (1989, 1991) argued that mood states will activate task-irrelevant material in memory and promote cognitive overload. They demonstrated that positive mood subjects showed reduced processing when shown stimuli for the same amount of time as neutral mood subjects. Increased exposure times were needed for positive mood subjects to systematically process information to the same level as negative mood subjects. It is unclear, however, why this reduction of capacity in processing is particularly marked in the case of positive mood, since the argument made by Mackie and Worth makes no provisions for an asymmetrical decrement, and should, in principle, also be obtained under negative mood. In line with the observation that positive mood may lead to reduced processing efforts, however, Martin, Ward, Achee & Wyer (1993) demonstrated that subjects stopped searching for task-relevant information sooner under positive as compared with negative mood conditions when asked to stop when they thought they had enough information.

Other findings also are consistent with the hypothesis that positive mood leads to less effort being spent in problem-solving. Sinclair & Mark (1995) found happy subjects to be less accurate than neutral and sad subjects in judging the magnitude and direction of correlation coefficients associated with each of nine scatterplots. Melton (1995) found subjects in a positive mood to be more prone than negative mood subjects to select unqualified solutions in solving linear syllogisms, and also to be more influenced by atmosphere effects in their problem-solving performance. In this study, Melton also threw doubts on the robustness of some key findings in the mood and creativity field. Positive mood subjects were not more adept than negative mood subjects in solving RAT tasks. As noted above, several studies also indicate that positive mood leaves people more open to biases in thinking and judgments. In contrast, negative (mildly depressed) mood seems to encourage more realistic perceptions and judgments, and decreases the tendency to be subject to biases (Alloy, 1986; Alloy & Abramson, 1979; Alloy, Abramson & Viscuti, 1981; Forgas, 1998, 2000a, 2000b; Tabachnik, Crocker & Alloy, 1989).

This is particularly alarming, since lack of creativity is often linked to what we may term ‘strategy bias’, where the subject carries on using a procedure that is no longer apt for solving the problem. This is the case in the classical Einstellung experiments reported by Luchins (Luchins & Luchins, 1950; cf. Kaufmann, 1979, 1988). Here the experimental procedures were varied in such a way that a previously successful procedure was no longer adequate (or possible) for solving subsequent tasks with some new twists.

It may, however, be argued that most of the studies demonstrating processing decrements for positive mood are not specifically carried out in the context of creative problem-solving tasks, and that somehow what is bad for systematic, logical thinking may be good for creativity.

Some Reasons Why Negative May Be Positive

Researchers in the creativity field (e.g. Boden, 1991; Mumford & Gustafson, 1988; Mumford, in press; Rothenberg, 1990; Weisberg, 1986, 1993) often emphasize the need for rational and ‘tight’ processing modes in high-level creative problem-solving. There are also good theoretical reasons to expect facilitating effects of negative mood on creative problem-solving. Virtually by definition, creative problem-solving entails a *modification* or *rejection* of conventional solutions (Boden, 1991; Kaufmann, 1993; Newell, Shaw & Simon, 1979)—processes that might well be prompted by negative mood. Runco (1994, 1999a) has argued convincingly that ‘tension’ and ‘dissatisfaction’ appear to be important prerequisites for creative problem-solving. In accordance with such a view, Mraz and Runco (1994) reported that an indicator of strongly negative mood (frequency of suicidal thoughts) was, indeed, significantly *positively* related to problem finding ability, indicative of an ability to imagine new and interesting problems. More recently, Zhou & George (2001) have demonstrated that workers who reported the strongest job dissatisfaction were rated as the most creative. This relationship was contingent on a high continuance commitment to the organization. It is true that we lack direct evidence on the mediating role of negative mood here. Yet the results may be reasonably interpreted as consistent with a theory like the one proposed by Runco above, to the effect that negative mood may promote a ‘creative tension’ and may lead people more easily to question the status quo. ‘Defying the crowd’ is, as Sternberg & Lubart (1995) argue, close to the essence of creativity. At least it may be a necessary prerequisite for creative problem-solving.

In line with such arguments, we find that problem *finding* has been seen as a key element in creativity, in the sense that it is often a necessary antecedent to creative problem-solving (cf. Getzels & Csikszentmihalyi, 1976; Runco, 1994; see also Root-Bernstein, this volume). Thus, there is a need for expanding studies in

the field to also include tasks of problem finding as well as problem-solving. If we take seriously the idea that creative thinking is more than a happy-go-lucky idea excursion, then the processing decrements demonstrated for positive mood above do seem to present a problem for the general assumption of a straightforward positive causal link between positive mood and creativity.

Inconsistent Evidence on the Positive Mood–Creativity Link

Even if we keep strictly within the specific task domain of creative problem-solving, however, several findings anomalous to the positive mood-enhance-creativity theory have been reported. Jausovec (1989), comparing the effects of positive, negative and neutral mood on analogical transfer in insight problems, reported a complex set of findings. In one task, a facilitating effect of positive mood on an analogical transfer task was obtained. In another task, positive mood was detrimental to performance, whereas in a third task, no significant differences between the different moods appeared. It is interesting to note that the task where positive mood was found to be detrimental is a typical insight problem (the Radiation Problem; Duncker, 1945), held in the classical literature to be a representative indicator of core creative processes in creative problem-solving (e.g. restructuring; cf. Wertheimer, 1958). Weisberg (1994) pointed to an important distinction between productivity and creativity. With reference to the evidence indicating a significant relationship between hypomania and creativity cited above, Weisberg conducted an interesting case study of Schumann’s mood bipolarity. The results suggested that the relationship demonstrated between elevated positive mood and creativity may reflect increased productivity, in the sense of quantity of products, but it did *not* generalize to a higher *quality* of creativity. Vosburg (1998b) made similar observations. In her study, positive mood significantly enhanced ideational fluency, compared to negative mood, but no significant differences between positive and negative mood were obtained on scores of originality and usefulness of ideas.

Evidence to the Contrary

Even more serious evidence against the hypothesis of a general positive effect of positive mood on creative problem-solving has recently been reported by Kaufmann & Vosburg (1997). They demonstrated a *reversal* of the standard finding that positive mood facilitates creative problem-solving. In the first study, subjects were given the task of solving two insight problems (the Hatrack and the Two String problem), as well as two control tasks (standard reasoning problems; Sentence Completion and Analogies). Mood was measured immediately prior to task performance by way of Russell’s Adjective Check List (Russell, 1979). The

results showed that positive mood was significantly *negatively* related to task performance. In a second study, subjects were given the same insight tasks. Positive and negative mood, as well as arousal, were measured by way of the Russell scale, as in the first study. In addition, positive, negative and neutral mood were experimentally induced by way of short video-clips. Both error rates and solution latencies were recorded as measures of performance. Natural positive mood measured by the adjective checklist was again found to be significantly negatively related to task performance. Moreover, experimentally induced positive mood subjects were found to be the poorest problem solvers compared to control, neutral and negative mood subjects, in that particular rank order. These findings argue strongly against any simple and unconditional proposition stating that positive mood facilitates creative problem-solving. Interestingly, no mood effects were observed on the control tasks, indicating that the mood selectively operated in the creative problem-solving tasks, in general line with Affect Infusion Theory (Forgas, 1995, 2000a).

Closely related, in a series of experiments, Gasper (in press) was able to empirically cash in on the hypothesis originally proposed by Kaufmann & Vosburg (1997), to the effect that induced positive mood, as compared to induced negative mood, promotes the Einstellung effect in problem-solving in selected tasks in the Luchins tradition.

A key task in the new 'creative cognition' tradition explored by Finke & Slayton (1988), Finke, Ward & Smith (1993) and Smith, Ward & Finke (1995), is the so called 'creative mental synthesis' task. Here the subject is presented with randomly generated shapes and alphanumeric figures, such as a line, a square, or the capital letters L, D, and X. The task is to combine a given number of such elements into a recognizable pattern. An example of a very easy task is giving the subjects a J and a D, and asking them to combine them into a meaningful figure. No doubt, you have already constructed the umbrella that most people easily can visualize. This task can be made very difficult by adding the number of elements to three and five, and can be scored on both correspondence (how well integrated the different constituent elements are), and creativity (how original and ingenious the configuration of the elements are).

Anderson, Arlett & Tarrant (1995) directly investigated the effect of mood on performance in this task by way of comparing induced positive, negative and neutral mood to various indicators of problem-solving performance. The Velten (1968) mood induction procedure was employed, where the subjects were given 60 statements, happy or sad, and asked to experience each statement fully. The results showed that positive mood had a significantly negative effect on performance, in particular compared to the neutral mood condition. Anderson, Arlett & Tarrant (1995) claim that the results

show positive mood to have a detrimental effect on the constraining of elements into a whole pattern, by settling for solutions with poor correspondence and lower creativity.

In line with such findings, in a recent experiment, Kaufmann & Vosburg (2002) found a crossed interaction between mood and early vs. late idea production. Positive mood subjects scored significantly higher in early production, whereas negative and neutral mood subjects significantly outperformed the positive mood subjects in late production. Indeed, the positive mood condition seemed to produce a steep response gradient held by Mednick (1962) to be characteristic of non-creative individuals (cf. Martindale, 1990; Fasko, Jr., 1999), whereas the negative/neutral conditions were closer to the flat association gradient typical of creatives.

Recently, Szymanski & Repetto (2000) also reported that induced negative mood facilitated creative problem-solving, measured by a story-telling task. In a fresh study conducted in a field situation, George & Zhou (2001), in close line with our arguments above, make the observation that "people in positive moods . . . may evaluate the status quo positively as well as their own ideas which may cause them not to put forth high levels of effort to make suggestions for significant improvements that are, in fact useful" (p. 3). They base their study primarily on the contextual Mood-as-Input Model advocated by Martin & Stoner (1996, 2000). From this vantage point they suggest that under important contextual conditions conducive to creativity and conducive to facilitating the effects of mood states, such as perceived recognition and rewards for creativity as well as clarity of feelings, negative mood will tend to facilitate, whereas positive mood will be detrimental to, creativity. Creativity was measured by supervisory ratings. The negative mood hypothesis was supported but only weakly. However, there was a clearly significant detrimental effect for positive mood on creativity, in support of the theoretically derived hypothesis. Such findings, at the very least, clearly warn against any general and straightforward conclusion to be drawn from such findings as reported in the frequently cited study by Isen, Daubman & Nowicki (1987).

Among the results referred above, the Kaufmann and Vosburg findings seem particularly difficult to reconcile with the classical findings reported by Isen, Daubman & Nowicki (1987), where performance on a task strongly similar to the ones used in Kaufmann and Vosburg experiments was facilitated by positive mood. There is, however, one potentially critical difference between the Isen et al. and Kaufmann and Vosburg study that may account for the discrepant findings. In the Isen et al. experiments, the task was solved in a practical setting that allowed the subjects continuous feedback on their solution attempts. In the Kaufmann and Vosburg studies, the tasks were performed in

writing with no external feedback on solution ideas. Thus, the subjects were left to set their own subjective standards for acceptable solutions. Kaufmann & Vosburg (1997) and Vosburg & Kaufmann (1999) suggested that the existing theories are insufficient to account for all of the available evidence on the effect of mood on creative problem-solving performance. Specifically, they argued that there is a need to take account of the task-solution requirements in predicting mood effects. We will return to this important point as a means of reconciling seemingly contradictory findings when we present our general theory of mood effects in creative problem-solving in the last section of this chapter.

Moving Away from the Singular Positive Mood-Enhance-Creativity Myth

We can now clearly see that we have come far away from the simple positive mood-enhance-creativity hypothesis. The functional relationship between mood and creativity seems to be as complex as the phenomenon of creativity itself. We should not be surprised. The fabric of creativity is made up from a large number of constituent psychological and contextual components, and is not likely to be captured by simple formulas, and neither is its relationship to such broad variables as mood. We have seen that there is good reason to think that some important aspect of creativity, such as an easy flow of ideas, may indeed be facilitated by positive mood, and inhibited by negative mood. This is, indeed, a very important part of the total creative problem-solving process, particularly in the early 'lift off' stage of creative thinking. However, other critically important aspects of creativity, such as reframing, and striving hard to find insightful and original solutions, may, indeed be prevented by positive mood and facilitated by negative mood. It seems clear that we need a more complex theory to account for the large number of seemingly inconsistent and even paradoxical findings in this area. In the last section, we will sketch the essential elements and structure of a general theory of mood and creative problem-solving that is based on independently verified empirical premises and may do the job of integrating the bewildering array of findings in the mood and creativity area.

A Theory of Mood Effects on Creative Problem Solving

A theory of mood effects on creative problem-solving needs to be anchored in a more general theoretical perspective on the functions of emotions, particularly with respect to their role in cognition.

In general, we agree with Frijda's functionalist account of emotions (Frijda, 1986), where emotions are seen as basically having a signal, or heuristic cue function (cf. Kaufmann, 1996; Vosburg & Kaufmann,

1999). More specifically, we agree with the basic premise behind the cognitive tuning theory developed by Clore, Schwarz & Conway (1994) (see also Schwarz (1990, 2000)). Here a positive emotional state signals a satisfactory state in the task environment, whereas a negative emotional state signals that the task environment is problematic. Thus, mood may induce a 'frame of mind' (cf. Morris, 1989) that serves as a mental backdrop for choosing a particular strategy to deal with the task at hand.

We do, however, believe that this is only *half* the story, and that the theory needs to be supplemented by a second premise to the effect that mood also signals a state in the 'internal environment' of the information processor. According to Bandura (1997), self-efficacy may be defined as the "belief in one's capabilities to organize and execute the courses of action required to produce given attainments" (p. 3). Thus, we postulate that positive mood will lead to enhanced confidence in one's own ability to solve the problem at hand, and thus promote a higher level of self-efficacy. Conversely, negative mood is thought to lower confidence, promote pessimism, increase susceptibility to fear of failure and thus decrease the individual's level of self-efficacy. Such a relationship between mood and self-efficacy has in fact previously been empirically established in a study by Kavanagh & Bower (1985).

Why this second premise? Without it, we believe it will be difficult to reconcile some of the seemingly discrepant findings reported in the literature, such as the diametrically opposed findings on the solution of insight problems discussed above. We will return to this important point after we have presented our theory in more detail.

Mood and Its Influence on Different Aspects of Problem Solving

The principles stated above may now be applied more specifically to different aspects of problem-solving, and testable hypotheses may be derived. Different levels of abstraction may be chosen for the development of a theory in this field. For the present purpose, we will focus on four general dimensions of problem-solving. These are: (1) *Problem perception*, i.e. how the problem is represented to the individual in general terms; (2) *Solution requirements*, i.e. what are the criteria for an adequate solution to the problem; (3) *Process*, i.e. what type of processing of problem information is most adequate to deal with the problem at hand; and (4) *Strategy*, i.e. what kind of general method or tactic of solving the problem is required.

We do not claim that these dimensions are exhaustive. There are additional dimensions that might be considered, such as problem ownership, importance of the problem, reversibility/irreversibility of solutions, etc. (cf. Mitchell & Larson, 1988). But we do think that the four dimensions chosen here are all of primary

importance whereas creative problem-solving is concerned, and that a limitation in variables to be dealt with at this stage of the inquiry is needed. This caveat also applies to the further examination of variables within the four dimensions.

Mood and Problem Perception

The issue of problem perception (or problem representation) is thought to be highly important in the study of problem-solving. What happens at this stage may to a strong degree determine the further processing of the problem and, ultimately, the success of solving the problem (cf. Simon, 1979), particularly with regard to *creative* problem-solving (Getzels & Csikszentmihalyi, 1976; Hayes, 1978; Kaufmann, 1988; Unsworth, 2001). There are many important sub-issues in this regard (cf. Runco, 1994), but here we will concentrate on the more general level of perception of the problem. A highly important aspect of problem representation that may be intimately linked to affect and mood states is the so-called 'valence' of the problem, in the sense of classifying the problem as an 'opportunity' or as a 'threat' (e.g. Jackson & Dutton, 1988; cf. Ginsberg & Venkatraman, 1992; Thomas et al., 1993).

A problem perceived as an opportunity is seen as positive, controllable and involving a potential gain, whereas a problem perceived as a threat is seen as negative, uncontrollable and involving a potential loss. A number of studies have demonstrated predictable differences in information processing as a consequence of defining the problem as threats or opportunities (e.g. Thomas et al., 1993). Seeing the problem as an opportunity results in more open information processing and stronger belief in one's own ability to solve the problem. In contrast, a threat representation leads to more restricted information search and to a more pessimistic outlook on one's ability to solve the problem (Jackson & Dutton, 1988).

From the theory presented above, it follows that positive mood should promote a frame of mind that is conducive to perceiving a problem as an opportunity, whereas negative mood should increase the likelihood of perceiving the problem as a threat. Jackson & Dutton (1988) make this assumption on a more intuitive basis. In a recent study by Mittal & Ross (1998), this posited link between mood states and the valence in categorizing the problem has been directly tested.

Mittal & Ross used business scenarios as problem situations, where the demographics of the customer base of a company was changing significantly. Mood was manipulated by presenting half of the subjects with a sad story and the other half with a happy story. Among the many interesting findings observed in this study, significant differences in issue interpretation in a strategic decision context were observed in the two mood groups. Subjects in a positive mood were more

likely to interpret the strategic issue as an opportunity compared to negative mood subjects.

Mood and Solution Requirements

Again it should be emphasized that there are many different issues that are important in this category. A cardinal consideration may, however, be said to reside in the distinction between optimizing vs. satisficing criteria originally proposed by Simon (e.g. 1956) and further developed by Simon (1977) and March (1994). Rather than viewing these criteria as distinct categories, we have previously argued that it is more convenient to regard them as opposite, extreme points on a continuum (Kaufmann, 1996; Kaufmann & Vosburg, 1997, 2002; Vosburg & Kaufmann, 1999). At the satisficing end of this continuum, the individual is held to construct a very simplified mental model of the solution space and accept the first solution that meets the corresponding aspiration level for an adequate solution. At the optimizing end of the continuum, the individual will attempt to perform an exhaustive search and rational evaluation of the expected utilities of all alternative solutions available. Kaufmann & Vosburg (1997) and Vosburg & Kaufmann (1999) posited that positive mood will promote a satisficing strategy of solution finding, whereas negative mood will be more appropriate under optimizing conditions. In their experiments, the tasks employed ranked extremely high in solution requirements (highly ingenious and unconventional solutions were required to fulfill all the solution requirements). They explained their findings that positive mood was detrimental and negative mood facilitative of finding the ingenious, 'ideal' solutions with reference to the hypothesis that positive mood promotes a satisficing and negative mood an optimizing solution strategy.

One important determinant of solution criteria along this continuum is the degree to which the task environment is perceived as satisfactory or problematic. Carrying this argument a step further, we may also argue that satisficing vs. optimizing criteria will be applied in the course of solving a problem, and that different individuals may settle for solutions of highly different quality. From the theory presented above, it follows that being in a positive mood would lead to perceiving a task as less requiring of high-quality solutions than when being in a negative mood, where a stricter criterion for an acceptable solution is more likely to be upheld. We argued above that this mechanism is the likely explanation for the 'paradoxical' mood effects observed in the Kaufmann and Vosburg study cited above. Also, we have seen above that Anderson, Arlett & Tarrant (1995) made similar observations and interpretations of a significant negative effect of positive mood on performance in the creative mental synthesis task.

We may now posit the general principle that positive mood will promote a satisficing strategy of solution

finding, whereas negative mood will be more appropriate under optimizing conditions.

We would, however, like to add that, concerning our theory, availability of *feedback* on solution attempts may significantly change the postulated pattern. It is expected that positive mood subjects, when continuously informed of their success, and lack of success at the task, may be more persistent in pursuing the tasks, and may, under such circumstances, possibly also more be more flexible in shifting strategies, than negative mood subjects. The latter may be expected to have their lower confidence in eventually being able to solve the task confirmed, and their performance may more easily 'freeze' and deteriorate correspondingly. These important qualifications follow from the postulated effect of mood on the 'inner environment', where differences in self-efficacy are held to be the crucial mediating variable. We have seen that making this distinction in mood effects may serve to reconcile the findings of Isen et al. (1987) and Kaufmann & Vosburg (1997). With no feedback on a self-set criterion for solution, positive mood subjects will more likely settle for solutions that have a lower quality, or, indeed, do not qualify as solutions at all. With negative performance on solution attempts, our theory leads us to expect that the situation may change significantly. Here the positive effect of self-efficacy may kick in among the positive mood subjects, and lead to more persistent and vigilant information processing in reaching out for the ideal solution of the task (cf. Phillips & Gully, 1997).

Such important contingencies are in line with the thrust of the argument in the Mood-as-Input Model developed by Martin & Stoner (1996) and Martin (2000), also advocated in the context of creativity by George & Zhou (2001).

Mood and Type of Process

In cognitive information processing theory, the kind of process is often distinguished in terms of the level of processing and breadth of processing (Anderson, 1990).

The level of processing refers to the question of whether processing occurs at a surface level, such as the sensory level, or at a deeper level, such as the semantic level, where information is further processed in terms of meaning and organizational structure in memory. Breadth of processing refers to the distance between informational units that are related during processing.

As we have seen above, the breadth dimension has been particularly targeted by mood theories (e.g. Isen & Daubman, 1984; Isen, Johnson, Mertz & Robinson, 1985). One possible explanation is that positive material is more richly interconnected than negative material, and that positive mood may provide a retrieval cue for linking information at a broader level, as suggested by Isen & Daubman (1984). This hypothesis also entails, however, that positive material

is better organized than negative material. We should then expect that positive mood promotes both a higher level and a broader information processing than negative mood. In our theory, however, positive mood is linked to broader information processing on the premise that positive mood promotes a less problematic perception of the task, and possibly also to overconfidence in ability to handle the task in question. Thus, positive mood may lead to a less cautious approach to the task than negative mood, promoting a broader but also a more superficial processing. More concisely, positive mood promotes broad and shallow processing, whereas negative mood leads to more constricted but deeper processing. This may be an advantage in a task that requires the generation of new ideas, but may be detrimental when the task requires careful considerations and deeper processing. In a recent experimental study, Elsbach & Barr (1999) observed the effect of induced positive and negative mood on the cognitive processing of information in a structured decision protocol. Here the subjects were given the task of assessing and weighing information in a complex case involving the core issue of whether a racing team should participate in an upcoming race. Negative mood subjects made much more careful and elaborate considerations than the positive mood subjects that were more prone to thrust superficial, 'holistic' judgment without going into the depth and details of the available information.

Mood and Strategy

This is probably the dimension that has received the most attention in discussion of the effects of mood on problem-solving behavior. As stated above, several theorists claim that positive mood increases the likelihood of employing heuristic-intuitive strategies whereas negative mood promotes the use of controlled, systematic and analytic information processing methods (e.g. Abele, 1992a).

A hallmark of a heuristic strategy is, of course, simplification. Analytic strategies are costly in terms of cognitive economy, and often the problem-solver has to resort to cruder and more general strategies in dealing with a fairly complex task. The choice of strategy may, however, also be determined by the general assessment of the structure of the task, and the individual's confidence in his or her ability to solve the problem. It follows, then, that positive mood would increase the likelihood of employing heuristic, short-cut strategies, whereas negative mood should lead to more cautious, analytic and systematic methods of dealing with the task at hand. As argued above, the available evidence tends to support this contention (cf. Forgas, 2000a, 2000b).

Task or Mood?

A highly pertinent problem in mood research is the question of how much of an effect mood really has on

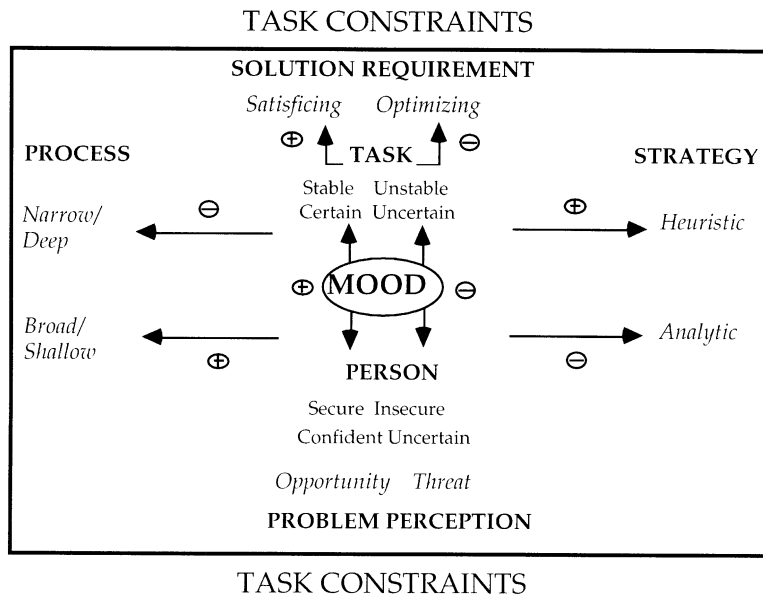

Figure 1. A theory of mood effects on creative problem solving.

performance, compared to the requirements of the task. Is mood a very significant factor with pervasive and persistent effects on task performance, or is mood a much more ephemeral factor that fairly easily yields to the requirements of the task? Is positive mood more fleeting than is negative mood, or vice versa? Are there individual differences in the reliance of mood as a heuristic cue to information processing? Is it possible, for example, that people with an 'intuitive' cognitive style rely more on mood in their choice of strategy and process, than individuals with an 'analytic' cognitive style, who are barely affected by mood as a heuristic cue for choice of mode of information processing? Indeed, in a recent study by Kuvaas, Kaufmann & Helstrup (2002), the typical, and normally robust mood dependency effect in memory and judgment was obtained only for subjects with little need for cognition.

These are important questions to consider, and very little is known about what the answers may be. So far, we have seen that mood effects seem to have their strongest effect in ill structured tasks, where an open and constructive information processing is required. Much more research is, however, needed to validate this general claim. A possible limitation of this principle may be that the conditions postulated by Forgas (2000a) may selectively open the door for positive mood effects to operate, whereas structured problem spaces, like that employed by Elsbach & Barr (1999), may be selectively favoring the operation of negative mood effects.

To take account of these considerations in our model, we have added task constraint as an external

boundary variable, which may significantly moderate the effect of mood as shown in Fig. 1, where the full model is graphically illustrated.

How wide or narrow this boundary is, if it varies for tasks and/or individuals, are important questions to consider to further our understanding of the functional importance of mood not only in creativity in the process of innovation, but also more generally in information processing and cognitive performances.

Concluding Comments on the Effect of Mood on Creativity in the Process of Innovation

Contrary to some bold statements made from adherents of the mainstream position to the effect that there is a straightforward, unconditional facilitative effect of positive mood on creativity, we have seen that the road from mood to creativity is far more crooked and full of twists and turns, often where we least expect them. The picture is one of complexity, not simplicity as the mainstream view would like to present it. Yet we have seen that a broad, general model enables us to view the differential effects of positive and negative mood as forming a meaningful and coherent pattern.

The complexity is apparent when we consider the relationship between mood and creativity per se. When we expand the equation to include creativity in the process of innovation, we may expect the picture to become even more complicated. As argued above, creativity may be seen as a necessary, but not sufficient, condition for innovation. Conceptually, innovation also requires that a creative product may be exploitable and possible to implement and diffuse in its market place, broadly conceived. Often this process is more difficult

than the process of invention in the first place. There are important and careful considerations to be made before a decision is made to launch the effort and resources that go with the attempts at trying to capture a productive niche for a novel product, procedure or policies. From what we have learned so far, a positive mood would not be facilitative of the cognitive processes behind such deliberations and decisions. Quite to the contrary, we have seen consistently that the kind of nuanced, fine tuned and critical thinking that will enter into this stage of thinking in the process of innovation, would more likely be disrupted by positive mood, and facilitated by negative mood. Or we may even find that, in the total, complex process of innovation, there is a place for an ahedonic, cool mind too!

Case Studies of Innovation: Ordinary Thinking, Extraordinary Outcomes

Robert W. Weisberg

Department of Psychology, Temple University, USA

Abstract: Researchers studying the creative process have been faced with the issue of how to study the thought processes of individuals at the highest levels of accomplishment. Much research in this area uses qualitative case studies. The present chapter uses what can be called quasi-experimental quantitative methods to examine case studies, which make possible rigorous testing of hypotheses concerning the creative process. Examples discussed include Picasso's development of his painting *Guernica* and Edison's electric light. Results from the case studies serve as the basis for conclusions concerning the thought processes underlying innovation at the highest levels.

Keywords: Innovation; Creativity; Thought processes; Thinking; Case studies; Creative process.

Introduction

In my work, I use the term 'creative' to refer to the production of goal-directed novelty (Weisberg, 1993, chap. 8). Thus, the creative process consists of the cognitive processes that result in production of goal-directed novelty, a creative individual is one who intentionally produces such, and a creative work is a novel product produced intentionally by some individual. In this chapter I will use *innovation* as synonymous with *creative product*. This definition differs from that used by most researchers who study creativity, who usually include as a criterion for calling something creative that it be *of value* (see chapters in this volume). That is, a proposed solution to a problem must actually solve the problem in order to be called creative; an invention must carry out the task for which it was designed; a work of art must find an audience. For reasons discussed elsewhere (Weisberg, 1993, chap. 8), I believe that including *value* in the definition of creative and related concepts significantly clouds several important issues. However, in the present context the specifics of the definition are irrelevant, since all the innovations to be discussed in this chapter are undoubtedly of the highest value. Therefore, no one would argue that the conclusions drawn are irrelevant because they are drawn from analyses of products which are not creative.

Methods for Studying Creative Thinking

Laboratory Investigations and Their Limitations

Researchers who study creative thinking usually have approached the subject matter from one of two directions. On the one hand, investigators have carried out experimental studies, typically centering on the study of undergraduates working on laboratory problems (e.g. Gick & Holyoak, 1980; Glucksberg & Weisberg, 1966; Weisberg, 1995, 1999; Weisberg & Alba, 1981; Weisberg & Suls, 1973). Successful problem solving, *per se*, requires creative thinking, so such investigations have face validity as studies of creative processes. However, one can raise a question concerning their external validity: To what population can one generalize conclusions drawn from such studies? On the basis of controlled investigations of undergraduates working on small-scale laboratory problems, one may not be able to make inferences about such individuals as Picasso, Mozart, Edison, and Einstein, who are also part of the population of creative thinkers one wishes to understand. Indeed, it could be argued that those latter individuals, and others like them, are the most important component of that population. If we wish to be able to claim at some point that we truly understand creative thinking, we will have to be able to explain how innovations at the highest level are produced. Examining undergraduates working

on laboratory exercises may not provide an understanding of the thought processes underlying the achievements of the most eminent among us. Of course, one could simply assume that laboratory investigations can illuminate aspects of the creative process that are relevant to all creative thinkers. However, such an assumption, if made without empirical support, seems to beg a basic question which motivates the study of creative thinking: What are the thought processes which bring about the greatest advances?

Studying High-Level Creativity

Thus, there is a potential limitation in our understanding of the creative process if we rely solely on results from experimental studies of undergraduates. Researchers have therefore also attempted to investigate directly the creative process in individuals of the first rank. First, researchers have observed such individuals at work (e.g. Dunbar, 2001). Second, researchers have collected autobiographical reports concerning how individuals of great accomplishment carried out their work (e.g. Ghiselin, 1952). A third method has been to carry out biographical studies of eminent creators, hoping thereby to illuminate the creative process (e.g. Gardner, 1993). Fourth, researchers have used archival information to try to reconstruct the processes underlying significant creative advances (e.g. Gruber, 1981). Finally, researchers have used historiometric methods to carry out quantitative analysis of historical data (e.g. Martindale, 1990; Simonton, this volume). After a brief review of these various methods, I will describe another method, which I call the 'quantitative historical case study'. This method centers on quantitative analysis of the work of individuals, based on archival records, and in some circumstances allows us to carry out rigorous tests of predictions concerning the creative process in eminent individuals for whom laboratory data are not available (Ramey & Weisberg, 2002; Weisberg, 1994, 1999, 2002; Weisberg & Buonomano, 2002).

Studying High-Level Creativity in Real Time: 'In Vivo' Investigations

One way to overcome the limitations inherent in using results from studies of undergraduates to draw conclusions concerning creative thinking in people of the highest rank is to try to observe such people directly. Dunbar (e.g. 1995, 2001) over several years observed the ongoing activities in four high-level research laboratories in molecular biology. He was given complete access to the laboratory activities by the directors, who in each case was a scientist of high repute, with numerous publications and grants, and who had been awarded prizes based on the quality of the research carried out in his or her laboratory. Dunbar regularly attended and recorded laboratory meetings, discussed ongoing work with the scientists involved,

and was given copies of research papers in various stages of completion. He became so integral a part of those various laboratories that he was informed several times when discoveries were imminent, so that he could be present.

These observations enabled Dunbar to make several discoveries concerning the processes underlying creative work in those laboratories (2001). As one example, he found that scientists' use of analogies in theorizing is relatively limited, and that a scientist may not move far afield when trying to think of a situation analogous to some poorly understood phenomenon that he or she is facing. Any analogies produced will usually come from domains closely related to the one in which the scientist is working. This finding indicates that creative scientists do not rely on far-ranging leaps of thought, based on remote analogies, when trying to understand a recalcitrant phenomenon. Also, Dunbar (1995) has found that a scientist's conception of his or her own work is sometimes changed radically as the result of input from colleagues during laboratory meetings in which data and analyses are discussed. The scientist alone is less likely to try to deal with recalcitrant data. Thus, the scientist may not experience a sudden insight into some phenomenon, based on a concomitant restructuring of understanding, without help from people who may be reluctant to accept the scientist's perspective on the phenomenon. Dunbar has also found that, perhaps surprisingly, senior scientists are more likely than their junior colleagues to change their analysis of some phenomenon in light of disconfirming data. One might have thought that senior scientists, being more set in their ways, would be more likely to cling to old ways of looking at things, but this was not the case in the laboratories studied by Dunbar. It seems that senior scientists, because of experience with being mistaken, are less likely to hold strongly to a hypothesis when it is contradicted by data.

In sum, Dunbar's research has shown how scientific research can be studied *in vivo*, and has produced a number of important results. However, although the laboratories studied by Dunbar are directed by scientists of strong reputation, those individuals and their research groups are as yet nowhere near the significance of Einstein, Darwin, and the like, and so there is still the issue of how the conclusions from Dunbar's research would illuminate the latter. In addition, taking Dunbar's tack leaves us without a way of gaining an understanding of historically significant figures who are not available to provide access to their laboratories. Thus we are led to other options, which deal with historically significant individuals *per se*.

Subjective Reports of the Creative Process

A number of investigators have used personal reports of individuals of extraordinary accomplishment to provide entrée into the creative process (e.g. Ghiselin, 1952). These reports, coming from individuals from

across the spectrum of creative fields, including poetry, literature, music, visual arts, and the sciences, are in the form of letters, addresses before scientific societies or other groups, responses to questionnaires, and in-depth interviews. Ghiselin made clear the motivation for use of such reports as the basis for theorizing concerning creativity.

(A) large amount of comment and description of individual processes and insights has accumulated, most of it fragmentary, some of it not perfectly reliable. Among these materials the most illuminating and entertaining are the more full and systematic descriptions of invention and the reflections upon it made by the men and women most in position to observe and understand, the thinkers and artists themselves (1952, p. 11).

Ghiselin's enthusiasm notwithstanding, first-hand reports concerning the creative process suffer from several shortcomings. They are usually made long after the fact, which raises questions about their accuracy (Perkins, 1981; Weisberg, 1986, 1993). For example, the well-known report by Poincaré (excerpted in Ghiselin, 1952, pp. 33–42), concerning how several of his most important mathematical discoveries came about, was made many years after the fact (Miller, 1996). Similarly Kekulé's often-cited report of his 'dream' of a snake grasping its tail and dancing before his eyes, which served as the basis for his formulation of the circular structure of the benzene ring, was presented some 25 years after it occurred, as part of an address he gave at a Festschrift commemorating his discovery (Rocke, 1985). Long lags between an event and the report of that event raise questions about the accuracy of the report. Dunbar (2001) has found that the investigators in the laboratories that he studied were likely to forget how advances in their thinking came about. Because Dunbar had taped laboratory meetings, he was able to check the accuracy of the investigators' recollections of events in the meeting that had resulted in changes in conceptions of some phenomenon. Even after as short a period as 6 months, people were able to remember the outcome of the lab meeting—e.g. a new way of conceptualizing some phenomenon—but were not able to remember how that change had been brought about. Thus, subjective reports given years after the fact are of questionable value as data for theories of creative thinking.

Even if the subjective report were given very soon after the events in question, which might reduce potential memory problems, in most cases we have no way of verifying the accuracy of the report, because usually there is no objective evidence to support it. Indeed, given the subject matter of many of these autobiographical reports—they are presented to give us insight into what the isolated person was thinking when he or she made some creative advance—it is not clear that there could be information that could serve to

verify them. The difficulty verifying subjective reports is particularly troubling in the face of evidence that some often-cited published reports are not true, including 'Mozart's letter' (in Ghiselin, 1952, pp. 44–45) concerning his process of musical composition, and Coleridge's description of how the poem 'Kubla Kahn' came to be (in Ghiselin, 1952, pp. 84–85; see Weisberg, 1986, for further discussion).

Furthermore, the individuals providing those reports, although of undeniable eminence in their fields, have no training as behavioral scientists, which may limit their ability to provide valuable data, even if such are available. That is, contrary to Ghiselin's belief quoted above, the creative individual—painter, poet, or physicist—may *not* be in the best position to observe and understand the processes underlying his or her achievements. The position taken in this chapter is that the cognitive scientist, equipped with tools to analyze objective data, is the individual most likely to make valid observations about the creative process. Finally, subjective reports describe autobiographical events and as such provide no information directly amenable to quantitative analysis. This limits their usefulness as the basis for development of scientific theories, the goal of which is to understand creative thinking.

Biographical Case Studies

In a move away from the problems inherent in using autobiographical reports as the basis for theories of creative thinking, Gardner (1993) carried out biographical studies of seven of the most eminent creative individuals of the 20th century, Freud, Einstein, Picasso, Stravinsky, Martha Graham, T. S. Eliot, and Gandhi, each of whom exemplifies one of Gardner's proposed multiple intelligences. He used these biographies to derive a number of conclusions concerning how each individual brought about his or her groundbreaking work. For example, Gardner emphasizes the role of a support group in providing a sympathetic arena in which the individual can introduce radical ideas. Gardner's approach is a significant step toward an objective basis for a theory of creative thinking, because it relies on historical data. However, a quantitatively oriented psychologist is left unsatisfied with biographies as the basis for an analysis of creative thinking, because there is very little in the way of a unique psychological contribution to the analysis. As one example of this lack, biographies, although undoubtedly informative, provide little in the way of quantitative data to serve as the basis for scientific theorizing; e.g. there are no data tables or graphs in the 400-plus pages of Gardner's book.

Historical Case Studies: Archival Data and Reconstruction of Process

A number of investigators have examined individual cases of the highest level of creative achievement, such as Gruber's (1981) analysis of Darwin's development

of the theory of evolution through natural selection (see also Holmes (1980) and Tweney (1989)). Gruber's ground-breaking study was based on archival data, i.e. Darwin's notebooks, and his work stimulated interest in case studies of creative thinking (e.g. Perkins, 1981; Weisberg, 1986). One difference between Gruber's case study of Darwin and Gardner's (1993) biographical case studies is Gruber's concentration on Darwin's development of his theory. That is, one could contrast Gruber's and Gardner's perspectives by saying that Gruber presented a biography, not of Darwin, but of the theory of natural selection. In the case-study perspective, the emphasis is less on the creator than on the work. Inferences about the creative process are made on the basis of changes that occurred in the work, as evidenced by objective data in notebooks, laboratory records, and the like.

Gruber (1981) has proposed on the basis of his analysis of Darwin that the creative process may be unique in each individual, and that there may be no generalizations to be made about the creative process or the creative person, because each creative accomplishment is carried out by a unique individual in a unique set of circumstances. Such a conclusion, however intriguing it may be, must be supported or rejected through the analysis of other case studies. Furthermore, Gruber's method of analysis may make it difficult to discover generalizations about the creative process, even the generalization that no generalizations can be made about the creative process, because the qualitative and descriptive slant of his method provides little in the way of data to be analyzed in the search for generalizations. As in Gardner's (1993) biographical studies, there are no data tables in Gruber's study of Darwin. Gruber may be correct in his claim that no strong generalizations will come out of case studies of creative thinking, but the only way to know is to carry out more of them, in a form which allows latent generalizations to become manifest.

A sub-genre of case studies has centered on computer modeling of the creative processes that led to significant innovations (e.g. Kulkarni & Simon, 1988; Langley, Simon, Bradshaw & Zytkow, 1987). In these studies, computer programs are given data comparable to those presumed available to the investigator whose case study is being analyzed. The computer program is usually minimally structured, so that the only methods available to it are general-purpose heuristics, and the question of main interest is whether a program so structured will produce the discovery that the researcher produced. It has been concluded by a number of investigators that such programs have been successful, which supports the claim that a number of innovations in science have been brought about using very general methods (Klahr & Simon, 1999; Langley et al., 1987). The case studies to be discussed in the present chapter can be seen as being influenced by the overall conception behind the computer-simulation

studies, that is, the idea that it is possible to analyze in relatively straightforward terms the cognitive processes that produced innovations of the highest order. One basic difference between the present chapter and computer simulation studies is that I have made no attempt to model any case studies using computers.

Historiometric Methods

Simonton (e.g. this volume) and Martindale (e.g. 1990) have applied quantitative methods to historical data in order to formulate and test hypotheses concerning creative thinking. For example, Simonton has investigated the influence of war and other social upheaval on creativity, by breaking the last two millennia into 20-year 'epochs', and determining for each the frequency of social unrest and of creative accomplishment, based on such measures as years in which active war was carried out, and numbers of creative individuals who flourished. Using methods such as time-lagged coefficients of correlation, Simonton has attempted to distill causal relations from historical data, and has concluded, for example, that occurrence of war involving a nation results in a decrease in creative accomplishment in that nation in the following epoch. Also, the occurrence of a significant number of individuals of high levels of accomplishment during one epoch is positively related to the level of accomplishment in the next generation, which Simonton takes as supporting the idea that one generation serves as role models for the next. These methods have thus produced sometimes striking findings, but they have usually been applied to the analysis of groups of individuals, over relatively long periods of time. This method does not preclude the study of the creative process in individuals, however, and the studies I will discuss can be looked upon as based on the philosophy behind these historiometric methods.

Quantitative Historical Case Studies

Methods used heretofore to attempt to come to grips with the production of innovation have not for the most part provided quantifiable data concerning the creative process in individuals of great renown. In an attempt to apply quantitative analyses to data from individual cases of creativity at the highest level, I and my students have recently carried out a number of what could be called quantitative historical case studies (Ramey & Weisberg, 2002; Weisberg, 1994, 1999, 2002; Weisberg & Buonanno, 2002). The specific antecedent for those studies was the work of Hayes (1981, 1989), who examined the role of experience—what Hayes called 'preparation'—in the production of creative masterpieces. Hayes measured the amount of time that elapsed between an individual's beginning a career in the fields of musical composition, painting, and poetry, and the production of that individual's first 'masterpiece'. Hayes defined a masterpiece in objective terms as, e.g. a musical composition that had been

recorded at least five times, a painting that was cited in reference works, or a poem that was included in compendia. There was a regular relationship between time in a career and production of the first masterpiece: all of the individuals in all of the domains required significant periods of time—approximately 10 years—before production of their first masterpiece. Thus, Hayes provided quantitative evidence for the claim that immersion in a discipline is necessary before an individual can produce world-class work (see Weisberg (1999) for further discussion).

Several of the case studies that I will discuss in this chapter have been carried out using methods similar to those of Hayes. Although the ‘data’ from case studies of innovations are not always amenable to rigorous quantitative analysis, we will see that bringing a quantitative orientation to case studies sometimes results in discoveries that would not have been apparent using only qualitative presentations of historical information. I will now examine the question of whether ordinary processes could serve as the basis for innovation, and whenever possible, case studies will be presented as evidence. Before discussing ordinary processes in innovative thinking, it is first necessary to briefly examine the opposite view, which has a long history in psychology, i.e. the idea that great innovative advances are the result of extraordinary thought processes.

Innovation and Extraordinary Thinking

Because creative thinking brings about innovations that most of us are not capable of producing, many researchers who study creativity have assumed that there is something extraordinary about the creative process. That is, extraordinary outcomes must be the result of extraordinary processes. Two examples of such processes are the Gestalt psychologists’ notion of productive—as opposed to reproductive—thinking (e.g. Scheerer, 1963; Wertheimer, 1982) and Guilford’s notion of divergent—as opposed to convergent—thinking (e.g. Guilford, 1950).

Extraordinary Processes

According to the Gestalt psychologists, true creative advances require that the person use productive thinking to go beyond what had been done before (staying with what had been done before was mere reproductive thinking). Furthermore, if one relied on the past and ‘mechanically’ reproduced habitual responses, one would not be able to deal with the particular demands of the novel situation that one faced, and would therefore be doomed to failure. Similarly, Guilford (1950) reasoned that the first step in the creative process must be a breaking away from the past, which is the function of divergent thinking. As the name implies, this type of thinking *diverged* from the old, and produced numerous novel ideas, which could serve as the basis for a creative product. The highly

creative individual is assumed to be high in divergent-thinking ability (e.g. Csikszentmihalyi, 1996). Once divergent thinking has served to produce multiple new ideas, then convergent thinking can be used to narrow down the alternatives to the best one. Current theoretical analyses of creative thinking sometimes assume that it is based on divergent thinking, even if that term is not explicitly used. As an example, Simonton (1999, p. 26) proposes that the creative process must begin with “the production of many diverse ideational variants”. These multiple and varied ideas, produced presumably as a result of divergent thinking, provide the basis for the thinker’s ability to deal with the new situation that he or she is facing.

Although there are differences between the concepts of productive/reproductive thinking and divergent/convergent thinking, there is a basic underlying similarity: the first step in the creative process is breaking away from the past, and there is a special kind of thought process that brings this about (see Weisberg (1999) for further discussion). This idea has become part of our culture, as evidenced in the often-heard comment about the need for ‘out-of-the-box’ thinking in situations demanding creativity. This instruction is a direct extension of the Gestalt idea that true creativity requires productive thinking, and the related idea that reliance on experience can interfere with dealing with the demands of the present. The well-known work by Luchins and Luchins (e.g. 1959) on problem-solving set is often brought forth as a graphic example of the dangers that can arise from a too-strong (and unthinking) reliance on the past.

Innovation as the Expression of Ordinary Processes

The view to be presented in this chapter, in contrast to those just discussed, assumes that innovation comes about through the use of ordinary thinking processes; creative thinking is simply ordinary thinking that has produced an extraordinary outcome—ordinary thinking writ large (Weisburg, 1986, 1993, 1999). Variations of this view have been presented by Simon and colleagues (e.g. Simon, 1976, pp. 144–174; Simon, 1986) and Perkins (1981). When one says of someone that he or she is ‘thinking creatively’, one is commenting on the *outcome* of the process, not on the process itself. Although the impact of innovations can be profound—as when a scientific theory changes the way we conceive the world, or when an invention produces changes in the way we live, or when an artistic product can arouse a strong emotional response in all of us—the mechanism through which the innovation comes about, as I will show, can be very ordinary.

The view that ordinary thought processes serve in creative endeavors has several facets. The most striking aspect of ordinary thinking is that it is based strongly on experience: ordinary thinking is based on *continuity* with the past. We build on the old to produce the new. Ordinary thinking is also *structured*: we are usually

able to understand why one thought follows another in our consciousness. Third, ordinary thinking consists of a family of related activities (Perkins, 1981). We use the term *thinking* to refer to a number of specific activities, such as remembering, imagining, reasoning, and so forth. Finally, ordinary thinking is sensitive to environmental events. All these components of ordinary thinking are important in innovative thinking as well.

Continuity in Thinking

Consider the processes involved in an activity that would *not* be labeled creative, such as preparing dinner from a recipe. Perhaps the most striking aspect of this activity is that the more we carry it out, the better we get; we take it for granted that we will show learning. If you watched the first time I followed that recipe, and then came back and watched me do it a tenth time, presumably I would be better at it. I would not have to check the directions in the cookbook, I could do it from memory; I would carry out each of the components faster; and there would be less wasted effort. Thus, the basic component of thinking as expressed in our day-to-day activities is that it builds on what has come before; it is based on *continuity* with the past.

If creative thinking is ordinary thinking, then it too should demonstrate continuity with the past. Several different sorts of evidence would demonstrate continuity in creative thinking. First, there should be a learning curve in creative disciplines: people who work in creative disciplines should require a significant amount of time to become good at what they do. Specific data that would demonstrate the development of skill within a discipline would be increasing productivity and increasing quality of a person's work. We have already seen some evidence to support this general perspective from Hayes's (1989) study of preparation in creative fields—10 years are needed before a masterwork is produced—and additional evidence will be adduced shortly. A second aspect of continuity with the past is that we build on our experiences. If creative work also builds on the past, then it should be possible to discern connections between innovations and what came before. That is, there should be antecedents for creative works (Weisberg, 1986, 1993). Another way of expressing this aspect of continuity—antecedents for creative works—is to say that we move incrementally away from the past as we go on to something new; we do not reject the past, we use it. If innovations are based on continuity with the past, rather than rejection of it, we should see incremental movement beyond what has been done before.

Structure in Thinking

As has been argued for millennia, at least from Aristotle, our ordinary thinking is structured: one thought follows another in a comprehensible manner as

we carry out our ordinary activities. There are several components to the structure of our ordinary thinking activities. Sometimes our thoughts are linked through associative bonds, which are the result of links between events in our past. This is expressed in Hobbes's familiar statement concerning the stream of associations in ordinary thinking (reprinted in Humphrey, 1963, p. 2).

The *cause* of the *coherence* or consequence of one conception to another is their first *coherence* or consequence at that *time* when they are produced by sense: as for example, from St. Andrew the mind runneth to St. Peter, because their names are read together; from St. Peter to a *stone* for the same cause; from *stone* to *foundation*, because we see them together; and for the same cause from *foundation* to *church*, from church to *people*, and from people to *tumult*: and according to this example the mind may run from almost anything to anything (emphases in original).

A second basis for one thought following another is *similarity*; as Aristotle noted, common content will tend to make one thought call forth another (Humphrey, 1963, pp. 3–4). So, for example, thinking about your team's last game may bring to mind earlier games you attended. Similarly, an environmental event can remind one of a similar event from one's past.

Ordinary thinking also possesses structure because sometimes we use reasoning processes of various sorts in our ordinary activities, and this provides a basis for moving from one thought to the next. As an example, a friend says to you: 'If it rains tomorrow morning, I am not coming'. The next morning, you look out the window, see that it is raining, and think 'She is not coming'. That thought arises from the logic of what your friend said. If innovative thinking depends on ordinary thinking, it too should possess structure of these sorts; we should be able to understand the succession of thoughts as a creator brings a product into existence.

Thinking is a Family of Activities

Ordinary thinking is made up of a family of cognitive activities. The phrase 'I'm thinking', can refer to any of a large group of activities, some of which are the following: trying to remember something; imagining some event that you witnessed; planning how to carry out some activity before doing it; anticipating the outcome of some action; judging whether the outcome of an anticipated action will be acceptable; deciding between two alternative plans of action; determining the consequences of some events that have occurred (through deductive reasoning); perceiving a general pattern in a set of specific experiences (through inductive reasoning); comprehending a message; determining if two statements are contradictory. Creative

thinking should also be constructed from these sorts of basic cognitive activities (Perkins, 1981).

Creative Thinking and Environmental Events

Ordinary thinking is sensitive to environmental events, which often change the direction of thought and action. For example, you might change your beliefs about someone by witnessing their behavior in some situation. You might observe someone, who you thought was kind, behaving cruelly toward someone without any reason that you can see. That might change your opinion of the person's character. Creative thinking also should be sensitive to external events.

We now turn to an examination of evidence supporting the hypothesis that each of these facets of ordinary thinking is also seen in creative thinking. In each of these areas, much of the evidence will be drawn from case studies.

Continuity in Creative Thinking

Several sorts of evidence would support the idea that creative thinking depends on continuity with the past. First, if individuals must learn to be creative, there should be a significant amount of time before an individual puts a distinctive stamp on his or her work. Second, during this time period, one should see an increase in an individual's productivity, as he or she learns the skills relevant to the domain; and in the quality of that individual's work, as he or she begins to put a distinctive stamp on the work. Third, one should be able to find antecedents for creative works, which is another way of saying that creative works should be the result of small-scale, or incremental, advances beyond the past, rather than being the result of wholesale rejection of the past.

Learning to be Creative: The 10-Year Rule

The work of Hayes (1981, chap. 10; 1989), already briefly reviewed, provides evidence that creative work requires a significant period of development. If production of a masterpiece in Hayes's terms can be taken as evidence for having mastered the discipline, then a significant period of time is required before this level of accomplishment is reached. Hayes's work was based on earlier research on what has become known as the '10-Year Rule' in the development of expertise in problem solving. The 10-Year Rule was postulated by Chase and Simon (1973) on the basis of their study of chess-masters' skills. In an extension of work by de Groot (1965), Chase and Simon examined, among other things, the ability of chess masters to recall almost perfectly, after an exposure of only 5 seconds, the positions of the 25–30 pieces from the middle of a typical master-level game. They concluded that the basis for this skill was a database of familiar groups of pieces, or 'chunks', acquired through years of intensive study and play, which are applied to any new board position which the master faces. The master uses this

database to perceive the board position upon initial exposure, choose the next move from that position, and remember the position at a later time. Thus, the memory for the board position was based on the same information that served in the master's choice of the next move in the game, which can be considered a component in a creative act at the highest level (i.e. playing master-level chess). In estimating how many chunks had to be available in order for the master to be able to recall 25–30 pieces from a brief exposure, Chase and Simon concluded that approximately 50,000 chunks of 3–6 pieces each were needed, and that 10 years or so of intense study of chess was required to store these chunks in memory (hence, the '10-Year Rule').

As we have already seen, Hayes (1981, Chapter 10; 1989) extended Chase & Simon's analysis to creative production in the domains of musical composition, painting, and poetry, and provided quantitative evidence to support the need for immersion in the discipline as a necessary condition for the production of world-class work. In addition, this relationship was seen for even the most extraordinarily precocious individuals, such as Mozart. Mozart began his musical career at age six, under the tutelage of his father, a professional musician of some renown. His first masterpiece by Hayes's criterion was the Piano Concerto #9 (K. 271), written in 1786, when Mozart was 21, some 15 years into his career. Gardner's (1993) biographical studies of seven eminent 20th-century individuals also supported the 10-Year Rule: each of those individuals needed a significant amount of time before carrying out his or her first major accomplishment. Furthermore, those of Gardner's subjects who produced more than one major work required significant amounts of time before each of them.

In conclusion, research on the 10-Year Rule supports the idea that even great individuals need a significant period of time to gradually perfect their skills (Weisberg, 1999). However, the research discussed so far does not tell us in any detail what happens during the period of time when the individual is developing. Based on the notion of continuity in thinking, one would expect that there would be increases in an individual's productivity and in the quality of his or her work during that time.

Learning to Write Great Music. 1: Mozart

Productivity

As we just saw, Mozart's first masterwork was composed some 15 years into his career. There were, of course, compositions produced during Mozart's earlier years, as shown in Fig. 1A, and those data support the hypothesis that Mozart's production would increase with his experience as a composer. Over the first few years of his career, production gradually increased, until after about 12 years it more or less leveled off,

Figure 1A. Number of compositions per year of Mozart's career.

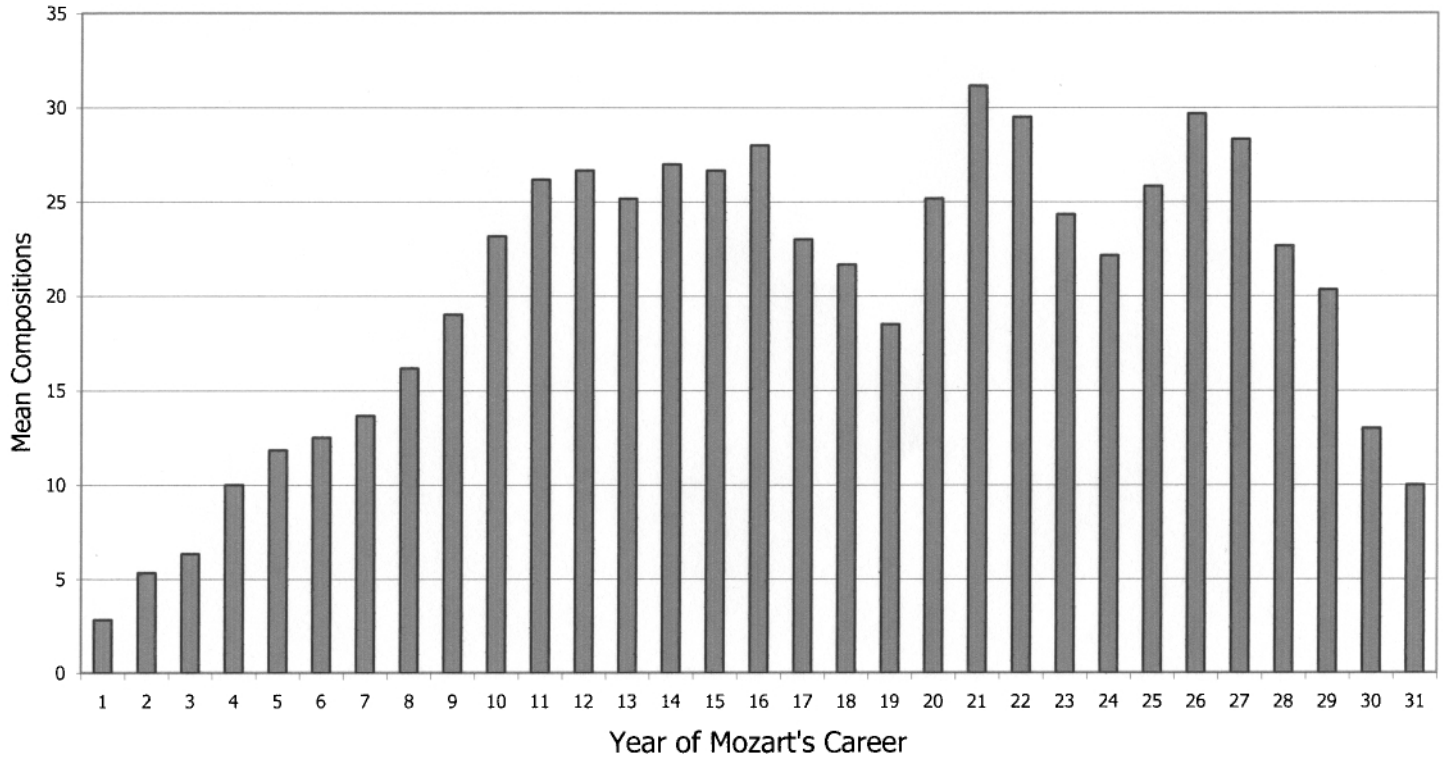

Figure 1B. Mozart's productivity—three-year running averages.

Figure 1C. Productivity of fifths of Mozart's career.

although there is considerable variability in productivity from year to year. The increase in Mozart's productivity can be seen more clearly in Figs 1B and C, which present, respectively, the average numbers of his compositions grouped over three-year segments (a three-year running average of his productivity), and grouped by fifths of his career. Here we see relatively clearly that the number of compositions increased over the first 12 years or so. The increase over the first three fifths of Mozart's career in Fig. 1C is significant.

Quality

Based on the notion of continuity in creative thinking, one would also expect an increase in the quality of Mozart's compositions over time. Possible changes in the quality of Mozart's early compositions can be seen if we use the number of recordings of each of his compositions as a continuous measure of quality, which allows one to include 'pre-masterworks' in the analysis. This measure differs from Hayes's 5-recording criterion for masterworks, which is an all-or-none measure. Figure 2A presents the average number of recordings for each of the compositions for each year of Mozart's career, and three interesting points emerge. First, similarly to Mozart's productivity, there is much variability in quality from year to year. Second, consistent with the notion of continuity, there is an overall increase in the quality of compositions over time; compositions later in Mozart's career are recorded on average more than early compositions. However, in contrast with productivity (Fig. 1), the increase in the quality of Mozart's compositions as indexed by the average number of recordings is much less gradual. This is seen more clearly in Figs 2B and C, which present three-year running averages and average numbers of recordings per composition for the fifths of Mozart's career, respectively, and the contrast with Mozart's productivity is striking. The data in Fig. 2 indicate that Mozart seems to have languished in what one could call mediocrity until he moved up to a new level of quality, approximately 10 years into his career. The overall difference in numbers of recordings for the fifths of Mozart's career shown in Fig. 2C is significant, with the first and second fifths being significantly lower than the others. The first and second fifths do not differ, nor do the last three fifths.

This analysis of Mozart's development as a composer has provided support for two aspects of the notion of continuity in creative thinking: we have seen an increase in Mozart's productivity and in the quality of his compositions over the first portion of his career. However, we have also seen possible differences in the pattern of development of these two aspects of Mozart's production, with quantity increasing gradually over time, and quality increasing more suddenly. One interesting point to be taken away from the quantitative analysis in Figs 1 and 2 is that one may become aware of patterns in a creator's work that are

not apparent when one simply presents a qualitative discussion of the same phenomenon.

The Question of Originality

The finding that Mozart's earliest compositions are of lower quality than his later ones leads to the question of what differences between early vs. late compositions might account for the differences in quality. Assume that at least part of the process of becoming a 'world-class' composer involves developing a distinctive voice or style—producing music that leads listeners to say 'That is by Mozart'. In general terms, reaching world-class level in any artistic field requires development of some originality, i.e. one's own style, so that one's work is recognizable. One might extend this view to creative work in the sciences and technology, where one also must establish a 'distinctive voice' before one's work can be considered innovative. There are at least two possibilities concerning how this distinctive voice might develop. On the one hand, the young person might produce distinctive work from the beginning of his or her career, but the quality of those early innovations might be low, so they make no impression, or even a negative impression, and are not acknowledged as masterworks. On the other hand, the young artist might not be particularly innovative in his or her early works, and that is why modern-day audiences find them of less interest than later works. Coming back to Mozart, his earliest works might not be 'Mozartian'.

Evidence to support the latter view comes from examination of some of Mozart's earliest compositions, which turn out to be little more than reworkings of compositions of other composers (Weisberg, 1999). Table 1A summarizes Mozart's first seven works in the genre of the piano concerto, and one sees that those works contain almost nothing original: the music was composed by others. Mozart arranged it for piano and other instruments. So Mozart seems to have begun learning his skill through study and small-scale modification of the works of others; Mozart's earliest works, which perhaps should not even be labeled as being by Mozart, contained little that was original and have been of little lasting musical interest.

Even when Mozart began to write music of his own, those pieces seem to have been based relatively closely on works by other composers, as can be seen in his production of symphonies (Zaslav, 1989; see Table 1B). Mozart's final three symphonies (#39–41), usually acknowledged as his greatest, are those with which listeners are most familiar. They comprise four large-scale movements, and require approximately 30–40 minutes to perform. In addition, each contains innovative elements, which places it on a high plane of artistic achievement in the history of music. As one example, the final movement of Mozart's last symphony (K. 551, the *Jupiter*) is structured to a degree of complexity never before seen in a symphonic work. Mozart's early

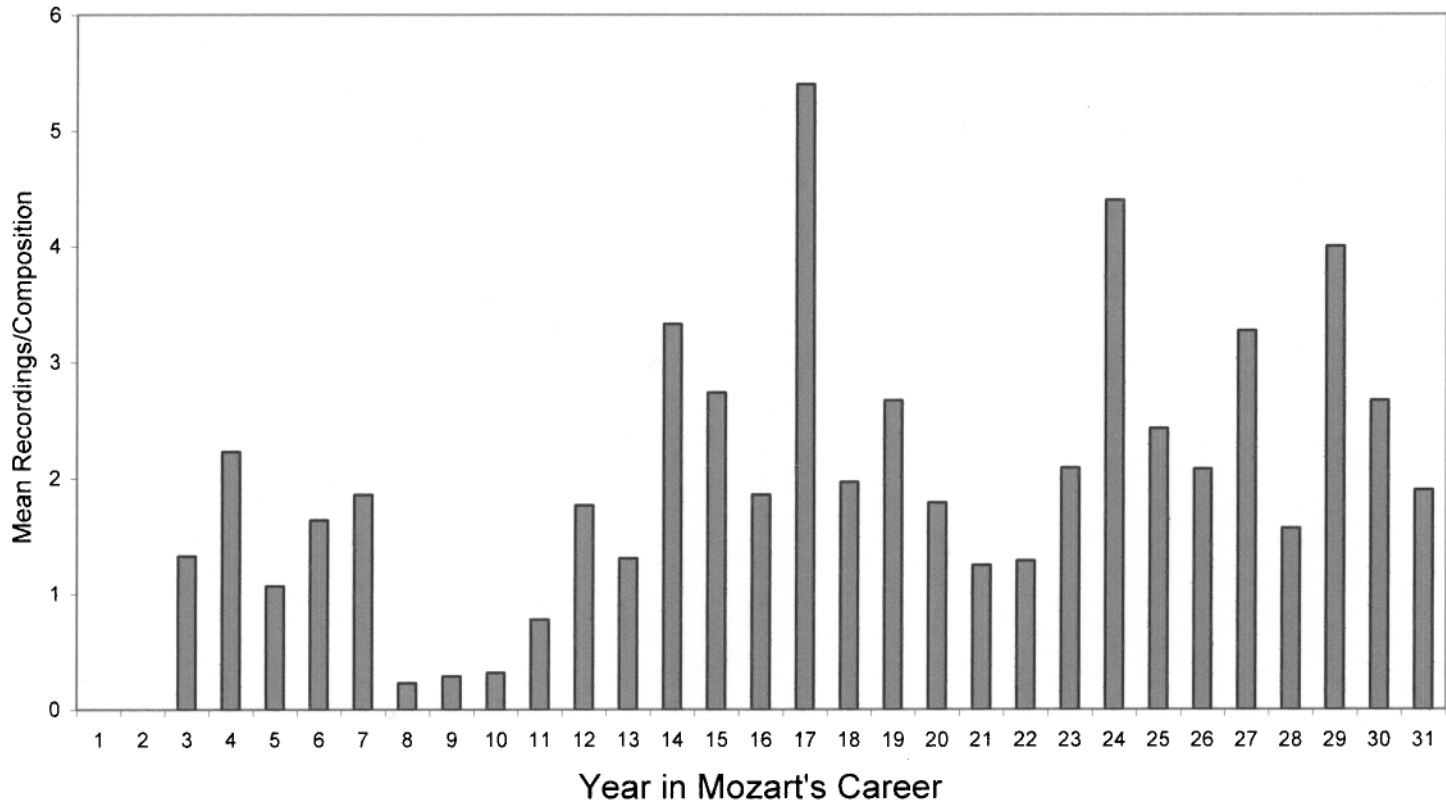

Figure 2A. Mozart's development—mean recordings/composition over the years of Mozart's career.

	Op. 7, #5	1764, London	3	F, S, F	8'
	Op. 7, #6	1764, London	3	F, S, F	14'
Mozart	1 (K16)	1764, London	3	F, S, F	10'
	– (K19a)	1765, London	3	F, S, F	12'
	4 (K19)	1765/6, Holland	3	F, S, F	12'
	5 (K22)	1765, Holland	3	F, S, F	7'
	– (K45a)	1765/6, Holland	3	F, S, F	11'
	39 (K543)	1788, Vienna	4	(S intro) F, S, Men., F	33'
	40 (K550)	1788, Vienna	4	F, S, Men., F	33'
	41 (K551)	1788, Vienna	4	F, S, Men, F	38'

symphonies are very different from the later ones in structure, emotional scale, and innovation. His first symphony (K. 16) was produced in London in 1764, when he was eight; several others were produced in the next two years. All those very early symphonies were composed when Mozart and his father were visiting London and Holland, as part of a 'grand tour' of Europe, which afforded the young composer opportunities to meet important musical figures and members of the nobility.

While the Mozarts were in London, young Wolfgang became close to Johann Christian Bach (youngest son of J. S. Bach), who had established himself in England as a composer. Bach had composed a number of symphonies for use in concerts which he promoted in London in partnership with W. F. Abel, another German composer who had also written symphonies for their concerts. Those early symphonies almost always were composed of three short movements, usually in tempos of fast, slow, fast, and were built with

a simple harmonic structure. Mozart's first symphonies closely parallel those of Bach and Abel in structure and substance (see Table 1B). They consist of three short movements, usually in tempos of fast, slow, fast. In addition, the harmonic structure of Mozart's early symphonies does not go beyond the structure of those models. Thus, Mozart's earliest works are not very original, which supports the hypothesis that the ten years of 'apprenticeship' provide the basis for later originality.

Mozart's Development: Conclusions

The analysis of Mozart's career development supports the notion of continuity in creative innovation, as we found the developmental sequence expected on the basis of continuity. A significant amount of time passed before a unique contribution was made, and there was evidence for the development of Mozart's skill as a composer during this time: his productivity increased with experience, as did the quality of his compositions.

In addition, there was evidence that his early works were based relatively directly on those of others.

Learning to Write Great Music. 2: The Beatles

Further evidence for this developmental sequence—immersion in the works of others before producing innovations of one's own, with early works being of lower quality than later ones—can be seen in the career of the Beatles, specifically, the Lennon–McCartney songwriting team (Weisberg, 1999). I analyzed the development of the Lennon–McCartney songwriting team to examine the hypotheses that: (1) Lennon and McCartney developed their skill as songwriters through long-term immersion in the works of others; and (2) their skill as songwriters improved over their years together. The first step in the analysis was to demonstrate a long period of immersion in the works of others before the production of significant works of their own. I used records of the Beatles' performances (Lewisohn, 1992) to determine how often they played together before they became world-famous in 1964. As shown in Fig. 3, before becoming well known, the Beatles had spent more than five years performing, and were on stage on average more than once a day during those years. The results in Fig. 3 are evidence for a long period of development, but we also have to consider the content of those performances, in order to show that they involved immersion in the works of others. As expected, during those early performances, the Beatles were mainly playing songs written by others. Table 2A presents, for each year of the Beatles' performing career, the proportion of new songs in their performance repertoire that were Lennon–McCartney songs. Only in the last three years of their career did they add significant numbers of their own works to their repertoire. Thus, Lennon and McCartney began their careers as composers with a long apprenticeship of immersion in the works of others; at the very least, they were playing the works of others much more than they were playing their own.

The fact that the Beatles were playing few Lennon–McCartney songs early in their careers says nothing directly about the relative quality of those early songs. Those early Lennon–McCartney works, in contrast to Mozart's early works, might have been high in quality. Table 2B displays the proportion of early and late Beatles' compositions from their performance repertoire that were released on records at any time during their time together (which extended beyond their performing career). Assuming again that probability of recording is a measure of a song's quality, then it is clear that early Beatles' songs were of a lower quality, because many of them were not released while the Beatles were together. Many of those early songs were released on recordings in significant numbers only relatively recently, when numerous anthologies of early Beatles' material have been produced. Similar conclu-

sions can be drawn concerning the development of originality in the music of Lennon and McCartney. Critics are in agreement that their originality became manifest most strongly in such works as *Rubber Soul*, *Revolver*, and *Sergeant Pepper's Lonely Hearts Club Band* (e.g. Kozinn, 1995; Lewisohn, 1992). These works were produced several years into their career.

Development of Musical Creativity: Conclusions

Analysis of the development of musical creativity in two cases from very different domains—18th-century classical music and 20th-century popular music—supports the same conclusions: composers begin by getting to know well the works of other composers. It is only after a significant period of immersion in others' music that the composer's own identity begins to emerge. At the beginning of a composer's career, the music of others seems to serve relatively directly as the basis for new compositions. Over a period of time, the composer's distinctive voice develops. Later works are of higher quality than early works according to objective measures, such as the number of recordings made of each composition; they are more original as well, according to the opinions of critics. We can now examine the generality of this view, looking beyond the domain of music to two examples of scientific innovation.

Continuity in Scientific Innovation

One aspect of continuity of thought that is particularly clear in scientific innovation is the presence of antecedents to many ground-breaking works. Antecedents to a seminal scientific innovation can be seen in the development of Darwin's theory of evolution (Gruber, 1981). One can analyze Darwin's work into two stages: his theory based on natural selection with which we are all familiar is the second of those stages. The first stage in Darwin's theorizing was based very directly on Lamarckian evolution (i.e. the idea that evolution of species depended on the transmission of acquired characteristics from one generation to the next) and on the concept of the monad (the idea that each species sprang from a single living form—the monad—that appeared spontaneously from nonliving matter and then evolved in response to environmental conditions). These two ideas had been advocated earlier by other theorists, one of whom was Darwin's grandfather, Erasmus Darwin, who had, independently of Lamarck, proposed a theory of evolution based on acquired characteristics. Darwin went on to reject those earlier views and develop the theory which revolutionized scientific thinking about the development of species, but he began with his feet firmly planted in the work that came before him. Furthermore, it is interesting to note that at least part of the basis for

Proportion recorded	0.13	0.54	1.00

Darwin's rejection of previous work was his acquisition of new pieces of information, which raised problems for his first theory. This sensitivity to environmental events, already noted as a characteristic of ordinary thinking, will be discussed in more detail later.

Another example of antecedents in scientific innovation is seen in the development of Watson and Crick's double-helix model of DNA. Watson and Crick's work can also be divided into two phases, with the double helix being the second phase. Their initial work centered on the possibility that DNA was a three-stranded or triple helix. Their general orientation, that is, the working assumption that DNA was probably helical in shape, was based on then-recent work by Pauling, who had proposed a helical model for the structure of the protein alpha-keratin (Olby, 1994; Watson, 1968; Weisberg, 1993). As with Darwin, Watson and Crick's final product went considerably beyond the earlier work, but that work was crucial in setting the direction that ultimately proved successful. Watson and Crick were pushed to reject their earlier work and to go beyond it at least in part by new pieces of information that became available to them, in a further example of sensitivity to environmental events in innovative thinking.

We see here examples from science of two aspects of continuity in innovation, specifically, the use of the past as the foundation for the development of the new, and the role of environmental events in pushing the thinker to go beyond the past. In neither of these cases

did the innovation come about through a leap away from the past.

Hidden Continuities in Apparent Discontinuities

When examining case studies of innovation, one sometimes finds radical breaks—what seem to be *discontinuities*—in thinking; i.e. a shift in thinking leads to the development of a new line of work. A central thesis of the present viewpoint is that such radical breaks are more apparent than real, and that they are still based on the processes that underlie ordinary thinking. Sometimes what seems to an observer to be a discontinuity occurs because the individual's database is not known in detail. Therefore, the individual in actuality produces an innovation that is built on the past, but the ignorance of the observer results in the mistaken belief that the innovation has come out of nothing. An example of such a 'hidden antecedent' can be seen in the development of Jackson Pollock's 'poured paintings', which were critical in making New York City the capital of the art world around 1950 (Landau, 1989). Pollock's works, with their swirls of paint and a complete lack of recognizable objects, were totally different from anything he or anyone else in American painting had produced until that time (see Weisberg, 1993). Perhaps the singular revolutionary aspect of Pollock's technique was his complete rejection of traditional methods of applying paint to canvas. Rather than using a brush or palette-knife to apply paint, Pollock poured the paint directly from a can, or used a stick to fling the paint on the

canvas, which was laid out on the floor, rather than hung on an easel.

Although many people today are still struck by the seeming radicalness of Pollock's innovative technique and subject matter, if we examine Pollock's background, we can find a likely source for his developments (Landau, 1989, pp. 94–96). In 1935, as part of the WPA, a number of artist's workshops were organized in New York. One of these workshops was directed by David Alfaro Siqueiros, an avant-garde painter from Mexico who, along with his compatriots Diego Rivera and José Clemente Orozco, had established a presence in the New York art scene. These painters had as part of their agenda a bringing down of art from what they saw as its elitist position in society, and making it more accessible to the masses. One aspect of that agenda was incorporating modern materials and techniques into painting, including industrial paints, available in cans, in place of traditional tubes of oil paint. There was also experimentation with new ways of applying paint, such as air-brushing, rather than the traditional brush. In the Siqueiros workshop, there also was experimentation with such techniques as throwing paint directly on the canvas, thereby avoiding use of the brush, which one of Pollock's friends who attended the workshop derided as "the stick with hair on its end". In 1936, Siqueiros himself created a painting, *Collective Suicide*, for which he poured paint directly from a can on the painting, which was flat on the floor, and he also flicked paint on it with a stick. Although Siqueiros did not create that painting at the workshop, it is reasonable to assume that similar techniques were demonstrated there. The attendees of the workshop collaborated on projects involving these new materials and methods, and one of those attendees was Pollock, who worked on a project with two other young artists involving applying paint using pouring and spilling, among other methods. In addition, there is evidence that in the early 1940s, several years before his 'breakthrough' works, Pollock had produced at least one painting in which paint is used in a nonrepresentational manner. Interestingly, in the context of the earlier discussion of the 10-Year Rule, the structural complexity of that painting and of Pollock's technique are very primitive compared to his mature works.

Thus, Pollock's advances, when placed in context, are seen to have come out of his experiences. We (and artists and critics in the late 1940s) were surprised by Pollock's work because we (and they) were not familiar with his history. This is not to say that Pollock's work was not highly innovative and of singular importance in the history of mid-20th century art; rather, it is simply to point out that even what seem to be the most radical innovations in any domain may have direct antecedents within the experience of the creator. Simply because some innovation appears as if it came out of nowhere, one must not assume that that

is how it came about. Looking below the surface can sometimes reveal direct sources for what seem to be the most radical of innovations.

Continuity in Innovative Thinking: Conclusions

We have examined evidence that supports several expectations arising from the idea that creative thinking is based on continuity. First, there is a learning curve in creative disciplines: people who reach the highest levels of accomplishment in the arts and sciences do so after a long period of immersion in their discipline (the 10-Year Rule). During this period of time, there is an increase in the individual's productivity and also in the quality of his or her work. This increase in quality of work is accompanied by an increase in originality as well. In the cases discussed, it has been possible to point out antecedents for innovations, and to show that innovations build on the past rather than reject it. We now turn to an examination of the structure of the thought processes that bring forth innovations. Specifically, we will examine the claim that creative thinking is structured in much the same way as ordinary thinking.

Structure in the Creative Process: Picasso's Development of *Guernica*

I have recently completed a quantitative case study of Picasso's creation of his great painting *Guernica* (Weisberg, 2002; see Fig. 4), which provides information concerning several aspects of Picasso's thinking. First, the study examined the preliminary sketches that Picasso produced in the process of creating *Guernica*, which allowed inferences concerning structure in Picasso's thought processes. Second, the study also examined the relationship between *Guernica* and what came before, which provided further evidence concerning antecedents in artistic innovation, and evidence concerning factors that link ideas in creative thinking.

Guernica, a landmark of 20th century art, was painted in response to the bombing, on April 26, 1937, of the Basque town of Guernica, in northern Spain, by the German air force (Chipp, 1988, chap. 3). The destruction of the town and killing of innocent people horrified the world, and Picasso's painting quickly became a great anti-war document. *Guernica* is massive in scale, measuring approximately 12' × 26', and is painted in monochrome: black, white, and shades of gray. In the left-hand portion of the painting, a bull stands over a mother whose head is thrown back in an open-mouthed scream, holding a dead baby whose head lolls backward. Below them, a broken statue of a warrior holds a broken sword and a flower. Next to the bull, a bird flies up toward a light. In the center of the painting, a horse, stabbed by a lance, raises its head in a scream of agony. In the upper center, a woman leans out of the window of a burning building, holding a light to illuminate the scene. Beneath the light-bearing woman, another woman with

Figure 4. *Guernica*. © 2002 Estate of Pablo Picasso/Artists Rights Society (ARS), New York.

bared breasts hurriedly enters the scene. At the far right, a burning woman falls from a burning building.

The Preliminary Sketches

At the time of the bombing of Guernica, Picasso had been working on a painting of an artist's studio that was to be displayed in the pavilion of the Spanish Loyalist government in a World's Fair opening in Paris in June, 1937 (see Fig. 5). When news of the bombing reached Paris, Picasso dropped work on the studio painting and began work on *Guernica*, producing his first sketches on May 1; the last sketch is dated June 4. He began painting on approximately May 11; the completed work was put on display early in June. Picasso dated and numbered all the preliminary works for *Guernica*, a total of 45 sketches. There are several different types of preliminary works. Seven *composition studies* present overviews of the whole painting; the remaining sketches, *character studies*, examine characters individually or in small groups. Samples of preliminary sketches are shown in Fig. 6.

The preliminary sketches provide us the opportunity to get inside Picasso's creative process, and can serve to answer several questions:

- (1) We can determine through analysis of the sketches whether or not Picasso systematically worked out the structure of *Guernica*. Do we see a pattern in how Picasso worked, for example, concentrating first on composition sketches and then on character sketches, or did he simply jump from one type of sketch to another, without any logic or pattern? If we find that Picasso worked first on composition sketches, say, before spending much time on individual characters, it would be evidence that he worked out the structure of the painting—the overall idea—before fleshing it out by considering the individual characters.
- (2) After determining whether or not Picasso was systematic in working out the overall structure of the painting, we can investigate the specifics of how Picasso decided on that structure. Did he experiment with several different possible structures for the painting, or did he have one structure in mind when he began to work? If we find that there was a common core to all the composition sketches, it would be evidence for the hypothesis that Picasso had a basic idea in mind in response to the news of the bombing, and this idea structured the process whereby the painting was produced.
- (3) The next question we can examine is where the structure for *Guernica* came from. That is, can we relate the overall structure of *Guernica*, as seen in the composition sketches and in the painting itself, to any antecedents, in Picasso's work or in the work of other artists?
- (4) We can also use the sketches to examine the question of whether or not Picasso's thought

process was structured when he worked on individual characters. For example, if we look at all the sketches that contained one particular character, say, the horse, do we find that aspects of that character are randomly varied from one sketch to the next, or is Picasso systematic in his explorations of the characters?

- (5) Finally, parallel to the question of possible antecedents for the overall structure of *Guernica*, we can examine the question of antecedents for the individual characters in the painting. Was *Guernica* constructed out of components that we can trace to other works?

Systematicity in the Sketches?

Picasso worked on the sketches for *Guernica* over a period of a little more than a month; for ease of exposition, this period can be summarized into three phases of work: the first two days (May 1–2); an additional six days, commencing about a week later (May 8–13); and a final two weeks of work, which began about a week later (May 20–June 4). As can be seen in Table 3A, there was structure in Picasso's thinking as exemplified in the sketches: the first two days resulted in composition studies and studies of the horse, arguably the central character in the painting. In the second phase, the composition studies are fewer, and other characters are examined. In the last phase, there are no composition studies, and peripheral characters (e.g. the falling person) are seen for the first time. This pattern can be made clearer by combining categories of sketches, as shown in Tables 3B and 3C. These results support the conclusion that Picasso spent the bulk of his early time working on the overall structure of the painting and on the main character, and then moved on to other aspects of the painting. There is a significant decrease over the three periods in the frequency of composition sketches. Thus, analysis of the temporal pattern in the whole set of sketches has provided an affirmative answer to the first question outlined above: Picasso was systematic in working out the structure of *Guernica*.

Deciding on an Idea: Analysis of the Composition Studies

The next question focuses on how Picasso decided on the final structure of the painting. Examination of the content of the composition studies can show us the specific path through over which he traveled. As can be seen in Table 4, the structure of the painting is apparent in the composition studies produced on the first day of work. In seven of the eight composition studies, including the very first one, the light-bearing woman is in the center, overlooking the horse. In addition, each of the central characters (horse, bull, light-bearing woman) is present in almost all of the composition sketches, with other characters appearing less frequently. This pattern supports the view that Picasso had

A. All Preliminary Works Tabulated by Three Periods of Work

Period	Comp.	Horse	Bull	Mother & Child	Woman	Hand	Falling Person	Man	Total
1 (May 1–2)	6	5	0	0	0	0	0	0	11
2 (May 8–13)	2	4	2	5	1	1	0	0	15
3 (May 20–June 4)	0	2	2	2	8	1	3	1	19

B. Composition Sketches vs. All Others

Period	Composition	All Others	Total
1 (May 1–2)	6	5	11
2 (May 8–13)	2	13	15
3 (May 20–June 4)	0	19	19
Total	8	37	45

C. Composition Sketches + Horse + Bull vs. All Others

Period	Composition + Horse + Bull	All Others	Total
1 (May 1–2)	11	0	11
2 (May 8–13)	8	7	15
3 (May 20–June 4)	4	15	19
Total	23	22	45

at least the 'skeleton' or 'kernel' of *Guernica* in mind when he began to work: *Guernica* is the result of Picasso's working out of this kernel idea. We see here further evidence for structure in Picasso's thought process: news of the bombing stimulated him to paint, and his thought process was relatively constrained from the beginning. Indeed, if the sketches can be taken at face value as the record of Picasso's thought processes concerning the painting, then from the very beginning there was only one idea that he considered.

Antecedents to the Structure of Guernica?

Analysis of *Guernica* as arising from a kernel idea that Picasso had available from the beginning of his work immediately raises another question: Whence did the kernel idea arise? Chipp (1988), in his extensive analysis of *Guernica*, was struck by the quick gestation of the painting. Based on the discussion so far, one might expect that the structure of *Guernica* was based on works that came before, and this could help account

for the speed with which the painting took shape. When Picasso painted *Guernica*, he was in his mid-50s and had been an artist for most of that time. Therefore, he had available a history of his own to draw on, and that history played a significant role in the creation of *Guernica*, which is closely related to many of Picasso's works from the 1930s. One striking example of a work that presages *Guernica* is *Minotauromachy*, an etching made by Picasso in 1935 (see Fig. 7). In this composition, a dead woman in a matador's costume, holding a sword in one hand, is draped over the back of a rearing horse. A minotaur (the mythological half-man half-bull) raises a hand in front of his eyes to shield them from the light from a candle held by a young woman who is observing the scene. Two other women observe the scene from a window above, where two birds also stand. On the far left, a man is climbing a ladder.

Table 5 summarizes a number of correspondences between *Guernica* and *Minotauromachy*, and indicates that *Minotauromachy* contains the same kernel idea,

Table 4. Guernica Composition studies: presence of characters. (From Weisburg, in press).

and may have served as a source for *Guernica*. In order to demonstrate that those correspondences in Table 5 reflect more than chance, however, one needs a 'control' painting to compare with *Guernica*. As indicated earlier, just before the bombing of *Guernica*, Picasso was working on a painting of an artist's studio. He never got beyond sketches for that work, one of which was shown in Fig. 5. If one compares that work with *Guernica*, as shown in Table 6, one finds very little overlap in subject matter, especially as regards major characters and structure.

One can carry out a statistical test of the degree of correspondence between *Guernica* and the *Artist's Studio* vs. *Minotauromachy*. One can count the number of rows in Tables 5 and 6, and use each of those numbers as the denominator of a fraction, the numerator of which is the number of lines which correspond in the respective tables. Based on this measure, the degree of correspondence of *Guernica* and the *Artist's Studio* is 0.13 (2/16), and the degree of correspondence of *Guernica* and *Minotauromachy* is 0.67 (8/12). The proportion of correspondence is significantly higher for the latter than the former. Furthermore, the strong

correspondence between *Minotauromachy* and *Guernica* shown in Table 5 is actually an underestimation of the true correspondence. *Minotauromachy*, an etching, was printed from a drawing made by Picasso on a printing plate, so the scene Picasso drew on the plate was actually reversed from left to right in comparison with the print shown in Fig. 7. The 'vertical person' was drawn on the right, and the bull was on the far left. The light-bearing female also faces in the same direction as the corresponding character in *Guernica*. In conclusion, not only does *Minotauromachy* contain many characters similar to those in *Guernica*, but the absolute spatial organization of the two works is also similar. One might raise questions about the specific entries in Tables 5 and 6, but it seems clear that there is a much higher degree of similarity between *Guernica* and *Minotauromachy* than between *Guernica* and the *Artist's Studio*.

This analysis of the composition studies for *Guernica* has supported the claim that the kernel idea for the painting was in Picasso's mind from the beginning. Further, examination of similarities between *Guernica* and *Minotauromachy* indicates that that idea was one

which can be found in earlier works in Picasso's career. Thus, at the time of its creation, *Guernica* was the most recent variation on a theme present in Picasso's work. So at least part of the reason why Picasso was able to create *Guernica* so quickly was that it was related to ideas that he had used before.

The Link Between *Minotauromachy* and *Guernica*

Assume for the sake of discussion that when Picasso began to paint *Guernica*, he had *Minotauromachy* in mind and used it as a model for the new work. This raises the question of why the bombing of Guernica caused Picasso to think of *Minotauromachy*. There are several links that can be traced between the bombing and *Minotauromachy* and *Guernica* which can help us understand why Picasso's thinking might have taken the direction that it did. First, the bombing took place in Spain, Picasso's native land, and *Minotauromachy* is a representation of a bullfight, which obviously has deep connections to Spain and to Picasso, who painted bullfight scenes from his very earliest years (Chipp, 1988). In addition, the emotionality of the bombing might have provided a further link to the bullfight, an event of great emotional significance for a Spaniard. *Guernica* also contains the skeleton of a bullfight: a bull and horse, a person with a sword (the statue), and 'spectators' overlooking the scene. It may also be of potential importance that when Picasso was growing up in Spain, the bull was not the only victim in a typical bullfight. The horse that carried the *picador* (the lance-carrier, whose task is to drive the lance into the shoulders of the charging bull) was not padded, and was often an innocent victim of the bull's charge. Based on this reasoning, the horse in the center of *Guernica*, whose head is raised in a scream of agony, can be seen as a representation of an innocent victim, and one can understand how that symbolization might have arisen in Picasso's mind. Thus, *Guernica* and *Minotauromachy* are linked by a web of interrelationships, and it is not hard to understand why the bombing might have stimulated Picasso to think of *Minotauromachy*, which then played a role in directing his further thinking. It is also notable that this web of relations does not seem different than those discussed centuries ago by philosophers interested in the structure of ordinary thinking.

Structure in Development of Individual Characters

We can also use the sketches of individual characters to examine the question of structure in Picasso's thought process. First, did he tend to concentrate on only one character at any given time, and second, did he examine systematically the characteristics of each character? As with the development of the overall structure of the painting, Picasso was systematic in his development of the individual characters.

Attention to One Character at a Time

In order to determine whether Picasso tended to concentrate on a given character at a given point in time, we can analyze the sequential pattern over all the sketches (see Table 3A). As can be seen, the sketches for the horse were concentrated in the first two periods, the mother and child were most frequent in the second period, and the isolated woman and the falling person were most frequent in the third. Thus, Picasso seems to have been systematic in his working on the individual characters over time.

Development of Individual Characters

If we consider the development of individual characters over the series of sketches, we can also find evidence for structure in Picasso's thought. For several of the individual characters, one can focus on elements which Picasso varied separately. As one example, in the sketches of the horse, Picasso varied the position of the head: up vs. down. Another example is in the sketches of the woman: whether her eyes are dry or tearing. A third is whether the woman is alone or with another individual (usually the baby). We can examine each of those components, in order to uncover structure in Picasso's thinking as he worked on each character.

Including composition studies, the horse was sketched a total of 19 times in the first two periods of Picasso's work. The position of the head of the horse in those periods is summarized in Table 7A, and a clear differentiation is seen: in the earlier sketches, the head is predominantly down, which changes in the later sketches. A similar pattern is seen in the sketches containing women. Tables 7B–7D summarize all 20 sketches, composition sketches and character studies, in which there was at least one woman participating in the action (the light-bearing woman was ignored, as were any dead women). Once again there is a pattern in the presence of the various elements of the women over the two periods of work in which women appeared in sketches. In the early sketches, the woman usually is holding a dead person, whereas in the later sketches she is usually alone (Table 7B). Similarly, in the early sketches, she is screaming without tears; in the later sketches, tears are almost always present (Table 7C). Finally, Table 7D summarizes for all the sketches the relationship between the facial expression of the woman and whether she is presented alone or with a dead person. When she is alone, she is almost always weeping; when she is holding the dead person, she sheds no tears. In conclusion, analysis of the character sketches supports the conclusions drawn from analysis of the composition studies: Picasso was systematic in his working out of the elements of *Guernica*.

Antecedents to Characters in *Guernica*

The final question to be examined is whether there were antecedents to specific characters in *Guernica*, and one can find what seem to be specific connections

Table 7. Summaries of presentation of the horse and of women in the sketches for *Guernica*. (From Weisberg, in press).

A. Position of Head of Horse Summarized Over Periods 1 and 2

to characters in *Guernica* from works of other artists. Two examples will serve to make the point that Picasso's thought process was structured in various ways by art with which he was familiar and which was relevant to the theme of *Guernica*. One particularly distinctive character in the sketches is the falling man in sketch 35 (see Fig. 8A). Picasso included no men among the actors in *Guernica* (the only male is the broken statue), so the content of this sketch is intriguing. This distinctive individual, with sharply drawn profile, striking facial expression, facial hair, and placement of eyes, as well as the falling posture with outstretched arms, bears striking resemblance to the man shown on the right in Fig. 8B. The latter drawing is from an etching in a series by Goya (1746–1828), called *Disasters of War*, which was created more than 100 years before *Guernica*. Picasso had great respect for and knowledge of Goya's works (Chipp, 1988), and it would not be surprising if the events that stimulated Picasso's painting of *Guernica* also resulted in his recollection and use of Goya's work as the basis for his own, especially given the commonality of theme. Picasso changed the man into a woman in the painting, but the falling woman in *Guernica*

bears residue of the Goya etching from which she began: her profile is similar to that of Goya's man, and her outstretched hands with exaggeratedly splayed fingers echo those of the Goya.

A second example of a correspondence between one of Picasso's characters and another work from Goya's *Disasters of War* is shown in Figs 8C and D. Picasso's sketch 14 contains a mother and child, with the woman distinctive in her sharply profiled head thrown back; her pose, with her outstretched left leg producing a distinctive overall triangular shape; and her skirt folding between her legs. The woman in Goya's etching is similar in facial profile and expression, and in her posture, with an outstretched left leg producing an overall triangular shape, and her skirt folded between her legs.

Structure in Creative Thinking—Conclusions

Examination of the content of the sketches for *Guernica* indicated that Picasso's thought process was structured in several ways during his creation of this great work. First, he considered a relatively narrow range of subject matter when he began to work; the creation of *Guernica* can be looked upon as the

elaboration of a kernel idea, which is seen clearly at the very beginning of Picasso's work on the painting. Furthermore, this idea was a straightforward extension of earlier work done by Picasso, perhaps in conjunction with his knowledge of Goya's *Disasters of War*. Second, he worked systematically over time, beginning work with the overall structure of the painting, and then spending time on the specific representations of the individual characters. Third, the development of the individual characters showed a similar pattern. For the representation of the horse, as well as of the woman, Picasso examined a very limited set of possibilities, and those limited possibilities were examined systematically. Further evidence for structure in the creative process will be presented in a later section, as part of the discussion of Edison's invention of the light bulb.

This case study of *Guernica* also has provided further evidence for continuity in thinking; specifically, we have seen much evidence for antecedents for Picasso's great painting, both in his own work and in that of others, although I have concentrated only on the work of Goya. (For further analysis, see Chipp (1988).) This analysis has provided evidence for what one could call layers of antecedents to *Guernica*. The overall structure, based on the kernel idea seen in *Minoatour-machy*, is one level of structure. Within that structure or framework, specific characters are based on other antecedents, meaning that one can trace antecedents nested within antecedents in *Guernica*. If the present analysis is accepted as valid, it means that it has been possible to trace the origins of some microscopic aspects of *Guernica*, for example, the facial expressions and postures of some characters, as well as the appearances of the characters' hands. Thus, the present analysis supports the proposal that creative works may be closely linked to previous works, although how often this occurs and how close the links are remain to be answered, through the analysis of other works, in painting as well as in other domains (for further discussion, see Weisberg (1993)). We now turn to consideration of the question of the cognitive components which comprise innovative thinking (Perkins, 1981).

Cognitive Components of the Creative Process

Ordinary thinking is built out of a family of cognitive processes, which includes deductive reasoning, both formal and informal, as well as induction; processes of comprehension; evaluation; imagination; and so forth. We now examine the notion that the creative process is built out of those same sorts of cognitive components.

Ordinary Thinking in Creative Problem-Solving

On the basis of laboratory research examining problem-solving, Perkins (1981) proposed that we could understand creative leaps, or Aha! experiences in problem-solving, as being the result of ordinary cognitive processes, such as recognizing or realizing

that something is true or false, without assuming the operation of extraordinary thought processes. He presented the Fake-Coin problem (see Table 8A), and when the participant solved it, he or she was to report immediately on the thought processes that had led up to solution. Perkins took precautions to ensure that those reports would be as accurate as possible: his participants were given some training and practice in producing verbal reports, and the reports were collected immediately after solving the problem, which kept potential difficulties to a minimum.

Two of Perkins's reports are presented in Table 8B. The two people solved the problem differently, with one (whom Perkins called Abbott) reporting that the solution 'just snapped' together in a leap of insight; the other (Binet) worked out the solution in a logical series of steps. When Perkins examined the reports further, however, he concluded that the thought processes carried out by Abbott and Binet were in actuality very similar. First, both Abbott and Binet focused on, or *recognized*, the date as the crucial piece of information. Second, Abbott's 'leap' turns out to have required only a couple of steps of reasoning on Binet's part; that is, the insight process turns out not to have done much in the way of cognitive work. Most importantly, the 'leap of insight' could be explained by our understanding of ordinary cognitive processes: what was required was that the thinker *realize* the contradiction in the coin-maker's knowing that Christ would be born at some later date. Perkins pointed out that we often experience such realizations in our ordinary cognitive activities. As one example, we constantly fill in information when we comprehend sentences as part of our ordinary language activities, and in so doing we can come to realize that two statements are contradictory. Thus, one can understand Abbott's 'leap of insight' as an example of the ordinary process of realizing that something was impossible. Perkins concluded that it was not necessary to assume that leaps of insight are brought about by anything in the way of extraordinary mental processes. Rather, sometimes we use *reasoning* in order to work out the consequences of some state of affairs, and other times we can realize the consequences directly, without reasoning anything out. As a parallel situation, Perkins points to our understanding of jokes: sometimes we can 'get' a joke directly, as we hear the punch-line, while other times we have to have the logic of the joke explained to us. Getting a joke as we hear it involves realization of the same sort that plays a role in leaps of insight.

In conclusion, Perkins showed that the 'insights' involved in solving some sorts of problems might consist of very small steps, rather than large leaps, and that whatever leaps occurred might be brought about by ordinary cognitive processes. One might argue that Perkins's results depended on the specific problem he studied, i.e. the Fake Coin, which is not particularly complex. Perhaps really important advances, such as

Table 8. Perkins's study of insight in problem solving.

A. Fake Coin Problem.

A museum curator is approached by man offering to sell him an ancient coin. The coin is made of metal of the typical sort, and on one side it has an engraving of an ancient emperor with the date 44 B.C. barely readable. The curator has had dealings with the man before, but this time he immediately calls the police and accuses him of fraud. Why?

B. Perkins's two protocols on Fake Coin Problem (Perkins, 1981)

Abbott

1. Couldn't figure out what was wrong after reading through once.
2. Decided to read problem over again
3. Asked himself, do architects dig up coins? Decided yes.
4. Asked himself, could the problem have something to do with bronze? Decided no.
5. Saw the word 'marked'. This was suspicious. Marked could mean many different things.
6. Decided to see what followed in the text.
7. Saw 544 B.C. (Imagined grungy coin ion the dirt; had an impression of ancient times.)
8. Immediately realized—"it snapped"—that B.C. was the flaw.

Binet

1. Thought perhaps they didn't mark coins with the date then.
2. Thought they didn't date at all—too early for calendar. (Image of backwards man hammering 544 on each little bronze coin.)
3. Focused on 544 B.C.
4. Looked at B.C.
5. Realized 'B.C.—that means Before Christ'.
6. Rationalized that it couldn't be before Christ since Christ wasn't born yet.
7. Saw no possible way to anticipate when Christ was going to be born.
8. Concluded 'Fake!'

those involved in high-level innovations, might involve larger leaps and extraordinary thought processes. In response to this objection, we now turn to Edison's invention of the light bulb, an innovation at the highest level from a domain very different from those discussed so far, and here too we will see numerous examples of the role of ordinary cognitive processes in furthering innovative work. In addition, development of the light bulb will provide us with further evidence for structure in innovative thinking, the role of antecedents in innovation, and the incremental nature of innovative advances.

*Cognitive Components in High-Level Innovation:
Edison's Invention of the Light Bulb*

Edison invented the light bulb in October, 1879. The invention looks very similar to today's light bulbs. Electric current is passed through a thin filament of carbon ('the burner'), which is enclosed inside a glass bulb, in a vacuum. The current flowing through the carbon causes it to heat to the point of glowing or 'incandescence', thereby producing light.

The Myth

Edison's invention of the electric light is part of American mythology. Here is a description from the *New York Herald* of the process through which the light bulb was invented, published around the time of Edison's demonstration of the successful light bulb.

Sitting one night in his laboratory reflecting on some of the unfinished details, Edison began abstractly rolling between his fingers a piece of compressed lampblack (carbon obtained from the soot deposited on the glass flues of gas lamps) until it had become a slender filament. Happening to glance at it, the idea occurred to him that it might give good results as a burner if made incandescent. A few minutes later the experiment was tried, and to the inventor's gratification, satisfactory, although not surprising results were obtained (*New York Herald*, December, 21, 1879; quoted in Friedel & Israel, 1986, p. 94).

The invention of the light bulb is a story which many of us think we know. Edison, who is famous for saying that genius is 1% inspiration and 99% perspiration (Friedel, 1986), is legendary for working through innumerable possibilities before finding just the right material that would serve in his bulb. And if the *Herald* report is accurate, he just stumbled across that material. From that story, one gets the impression that Edison had not thought about the usefulness of carbon before 'absently' rolling the piece of lampblack in his fingers. If all Edison did was try one material after another, until he stumbled on one that worked, we have little reason to look more deeply into his accomplishment. In reality, however, the story is different (Friedel, 1986; Friedel et al., 1986; see also Jehl, 1937; Weisberg & Buonanno, 2002), and examination of Edison's accom-

plishment will enable us to consider in a different context the cognitive components of innovative thinking, as well as the role of antecedents in innovation. I will present this case historically, to provide a context for understanding Edison's achievement and analyzing the thought processes involved. Sternberg, Pretz and Kaufman (this volume) discuss Edison's light bulb in the context of their system of classification of innovations. Their overall conclusion is supported by the present study.

Antecedents to Edison

As one might expect, based on the discussion thus far, there had been numerous attempts to produce a working incandescent electric light bulb in the years before Edison began to tackle the problem, and he was aware of what had been done before (Freidel & Israel, 1986). Table 9 summarizes some of these earlier attempts, almost all of which used either carbon or platinum as the burner in the bulb. However, there were

difficulties with each of those elements, which earlier investigators had been unable to overcome. At the heat needed to produce light, carbon would quickly oxidize (burn up), rendering the bulb useless. In order to eliminate oxidation, it was necessary to remove the carbon burner from the presence of oxygen, and most early attempts placed the carbon either in a vacuum or surrounded by an inert gas. However, the vacuum pumps available before Edison's work could not produce a sufficient vacuum to save the burner. Platinum presented a different problem: when used as a burner, its temperature had to be controlled very carefully, because if it got too hot, it would melt and crack, thereby rendering the bulb useless. Thus, when Edison began his work, perfection of the vacuum was crucial to the carbon-burner light bulb; control of the temperature was crucial in utilizing platinum.

In analyzing Edison's innovation, we shall examine what we can call the phases of Edison's work (Weisberg & Buonanno, 2002). For each phase, we

shall consider any new developments and how they came about. The question to be asked about each phase is whether it is necessary to assume anything beyond ordinary thought processes in attempting to understand how the new developments came about.

Edison's Early Phases: Beginning with the Past

Edison began the first phase of his electric-light work in 1877, with a bulb comprising a burner of carbon in a vacuum (see the left-hand column in Table 10). This work, built directly on the past, was, like earlier work with carbon burners, not successful: the burner oxidized. Since, at the time, there was no way available to improve the vacuum, due to limitations in technology, Edison dropped the carbon burner. About a year later, he carried out a second phase of work on the light bulb, in which platinum served as the burner (see Table 10).

Here too the work was built directly on what had been done in the past. In order to try to stop the platinum from melting, the platinum bulbs contained 'regulators', devices like thermostats in modern heating systems, designed to regulate the temperature of the platinum, and thereby keep it from melting. Edison and his staff in his laboratory in Menlo Park, New Jersey developed regulators of many different types, but it proved impossible to control the temperature of the platinum burner. Thus, Edison's first two phases of work were based directly on work from the past with which he was familiar. Furthermore, the initial attempts using carbon, the rejection of carbon and the switch to platinum, and the incorporation of regulators in the platinum bulbs, can all be understood on the basis of ordinary thought processes. Carbon was rejected because it kept burning up; platinum was used because

Table 10. Summary of Phases of Edison's Invention of the Electric Light. (From Weisburg & Buonanno, 2002).

Phase and Activity	Basis for New Developments
A. Phase 1 (early 1877; Autumn, 1877)	
A1. Carbon burner A2. Vacuum	A1. Continuity: previous work by others A2. Continuity: previous work by others
B. Phase 2 (August–early October, 1878)	
B1. Platinum burner B2. Regulators	B1. Failure of carbon; continuity B2. Need to control burner temperature
C. Phase 3 (October, 1878–February, 1879)	
C1. Analysis of broken platinum burners C2. Escaping hydrogen ⇒ need for vacuum	C1. Consistent failures of platinum C2. Deduced from observation of burners
D. Phase 4 (early spring, 1879)	
D1. Platinum in vacuum	D1. Deduced from analysis of platinum's reaction to heating
Analysis of Requirements of Electrical System	
E. Phase 5 (Spring, 1879)	
E1. High-resistance platinum E2. Search for insulating material	E1. Deduced from system requirements E2. Problems with long platinum spirals
F. Phase 6 (July–August, 1879)	
F1. Improved vacuum pumps	F1. Failures with platinum ⇒ need better pumps; hiring of Boehm; article by de la Rue and Muller
G. Phase 7 (September–early October, 1879)	
G1. Platinum in high vacuum	G1. New pumps available
H. Phase 8 (mid-October, 1879)	
H1. Return to carbon, now in high vacuum	H1. Failure of platinum; new pumps overcame problems with carbon

it did not burn (and because it had been tried in the past). The regulators in the platinum bulbs were necessary in order to control the temperature of the platinum burner.

Systematic Analysis of Platinum

After the consistent failures with platinum, Edison looked carefully at why the platinum burners failed (Phase 3 in Table 10). He observed the broken burners under a microscope, and he and his staff thought they found evidence that the melting and cracking were caused by escaping hydrogen gas, which platinum under normal conditions had absorbed from the atmosphere. The hydrogen escaped when the platinum was heated, causing holes to form, which facilitated melting and cracking of the burner. Edison reasoned that the platinum might be stopped from cracking if the hydrogen could be removed slowly. In order to bring this about, he reasoned further that the platinum would first have to be heated slowly in a vacuum, which would allow the hydrogen to escape without destruction of the platinum. These Phase 3 advances came about as a result of information gained from the observations of the failed burners under the microscope, and Edison's reasoning from those observations. Edison turned to the systematic analysis of platinum because of the consistent failures with platinum-burner lamps in Phase 2.

Platinum in a Vacuum

Based on the new Phase 3 information and the deductions from it, Phase 4 of Edison's work involved a platinum burner being heated slowly in a vacuum and then sealed. The removal of the hydrogen from the platinum burner made it last longer and burn brighter, but it did not eliminate the basic problem: the burners still overheated and melted (Friedel & Israel, 1986, pp. 56–57, 78). In the spring of 1879, Edison and the staff at his laboratory attempted to extend the life of the platinum burner through the use of more efficient vacuum pumps and through a variety of coating techniques. Edison was able to obtain a state-of-the-art Geissler vacuum pump in late March (Friedel & Israel, 1986, p. 78), but even with this device, it was still very difficult to achieve near-complete vacuums that lasted for the time needed to heat the platinum to remove the hydrogen. Phase 4 of Edison's work, arising directly from the new information in Phase 3, brought some improvement, but overall the work was still a failure. As far as cognitive processes are concerned, nothing extraordinary is seen in this phase.

The Light Bulb in Context: Edison's Analysis of the Electrical System and Its Needs

So far we have been analyzing Edison's work on the light bulb in isolation from any other activities. However, Edison had strong entrepreneurial interests, and he was developing the electric light bulb as part of

a *system* of electric lighting, which he hoped would replace the gas lighting then in use (Israel, 1998). Consideration of the light within the context of a lighting system put certain constraints on its characteristics, and by the late fall of 1878, Edison began to realize that the light would need to be highly resistant to the passage of the electrical current if it were to operate efficiently as part of a larger system (Friedel & Israel, 1986, p. 56; see Weisberg & Buonanno (2002) for further discussion).

Electrical resistance (measured in ohms) refers to how easily an electrical current passes through some material. Some substances, such as many metals, are low in resistance, so that electrical current passes easily through them. In contrast, materials such as glass and rubber are high in resistance, and thus are poor electrical conductors. The actual resistance of any given material when it is placed in an electrical circuit depends upon its physical configuration, e.g. for a wire, its diameter and length. Resistance of an electric wire decreases as the diameter of the wire increases. That is, all other things equal, a wire of small diameter is more resistant than one of larger diameter. In addition, the resistance of any material increases as its length increases: a 2-foot length of wire is twice as resistant as a 1-foot length of the same wire.

In the system as envisioned by Edison, there were to be many individual lamps, each receiving electricity through copper feeder wires from a central generating station. In order for each lamp to receive enough electrical energy, there would have to be either a large current or a high voltage, because energy = (voltage) × (current) (Friedel, 1986). Sending large amounts of current through the feeder wires raised another problem: much of the energy would be given off in the form of heat, as the current flowed to the individual user. This would reduce the energy available to light the bulb. Because the amount of heat given off by a flowing electrical current depends on the resistance of the material through which it flows, in theory this problem could be solved by decreasing the resistance of the feeder lines. This would mean increasing their diameter, which would result in spending an enormous amount of money on copper lines; this additional expense would have made electrical lighting economically unfeasible. Alternatively, one could increase voltage and reduce the current in order to ensure that each lamp received enough energy. Because voltage = (current) × (resistance), Edison reasoned that if he were to use a low current in his system, then it would be necessary for each lamp to have a high-resistance burner. Thus, Edison concluded that the use of high-resistance lamps was necessary for electrical lighting to become a commercially viable alternative to gas lighting. This conclusion, which had important ramifications on Edison's work on the light bulb, came about through logical/mathematical analysis of the requirements of the lighting system.

High-Resistance Platinum and Insulation

In Phase 5 of his work, Edison was concerned with the dimensions of the burner, in response to the requirement that the lamp be of high resistance. He concluded that there would have to be a very thin and long platinum wire, wound into a spiral, packed inside the evacuated glass bulb (Friedel & Israel, 1986, p. 79). However, as a result of the tight packing of the burner, the turns in the wire would often come into contact with one another, resulting in a short-circuiting of the lamp. To solve this problem, Edison tried to coat the platinum spirals with an insulating material that would prevent them from coming into direct contact with one another. During the spring of 1879, Edison and the staff devoted much of their time to finding an insulating material that would adhere to the platinum wire under high-temperature conditions (Friedel & Israel, 1986, p. 79), but by the end of April 1879, such material had yet to be found. The work in Phase 5 arose from the requirements of the electrical system and the resulting problems with packing the high-resistance platinum burner inside the bulb.

Improved Vacuum Pumps

Work on the electric lamp did not resume until the summer of 1879. Edison at this time made substantial progress in designing a more efficient vacuum pump. In August, he hired Ludwig Boehm, a full-time glass-blower who had apprenticed under Heinrich Geissler (the creator of the Geissler vacuum pump that had been used in Edison's earlier work). The hiring of Boehm was an indication of Edison's belief that a more efficient vacuum pump would be an indispensable component of a successful platinum lamp (Friedel & Israel, 1986, p. 82). Edison and his staff spent much of August attempting to develop more efficient pumps. They eventually produced a vacuum pump that was a combination of two pumps—a Geissler pump and a Sprengel pump, another type of advanced vacuum pump. The idea of combining two vacuum pumps was first presented in an article by de la Rue and Muller (Friedel & Israel, 1986, pp. 61–62). Using this new pump, Edison was able to reduce the pressure inside the bulb to one-hundred-thousandth of normal atmospheric pressure, which was the most nearly complete vacuum then in existence (Friedel & Israel, 1986, pp. 62, 82). Further work in the autumn of 1879 produced pumps that were even more efficient. Edison's work in Phase 6 is summarized in Table 10; the advances in vacuum pump technology benefited from the new expertise brought by Boehm, as well as information from the article by de la Rue and Muller.

Platinum in a High Vacuum

Edison used the new vacuum pump with a platinum-burner bulb, and in early October 1879, Edison's light consisted of a highly resistant filament of tightly wound platinum inside a glass bulb that was evacuated

to approximately one 1-millionth of normal atmospheric pressure (Friedel & Israel, 1986, pp. 87–88). However, this advance had not solved the basic problems: even after being heated in the vacuum, the platinum filaments would last for only a few hours and would tolerate only a minimal amount of electrical current, making it very difficult to generate light of useful brightness. Also, the platinum burners had a resistance that was far too low to be of any use in the system Edison had envisioned. Edison had calculated that it would be desirable to obtain lights that had a resistance of 100 ohms or greater, but the lights constructed in early October at Menlo Park had a resistance of only 3 or 4 ohms. Phase 7 of Edison's work is summarized in Table 10, and the work in that phase was a straightforward application of the advances in Phase 6.

Return to Carbon and Success

In early October, 1879, Edison began to experiment once again with carbon as an incandescent substance. This goes against the *Herald* story quoted above, which makes no mention of the fact that Edison's successful use of carbon was his second attempt with that element. The return to carbon follows directly from the situation at the end of Phase 7: (1) the platinum bulb was still not successful; (2) an improved vacuum pump was available; and (3) Edison knew that earlier attempts with carbon had failed due to problems with the vacuum. Experiments with carbon continued through October. On October 19th, Edison's assistant Francis Upton experimented with raising a stick of carbon to incandescence in a vacuum. The results were encouraging, producing a light that was the equivalent of 40 candles. On October 21st, Upton recorded that he had raised a half-inch stick of carbon that had a diameter of 0.020 inches to 'very good light'; however, the stick had a resistance of 2.3 ohms when heated, much too low to be useful (Friedel & Israel, 1986, p. 100). On October 22nd, another assistant, Charles Batchelor, conducted experiments using a 'carbonized' piece of cotton thread placed inside of an evacuated bulb. The thread had been baked in an oven until it turned into pure carbon. This filament initially had a resistance of 113 ohms, which increased to 140 ohms as it was being heated. Although this was encouraging, the filament yielded a weak light that was the equivalent of only half a candle. Batchelor continued to experiment with a variety of carbon materials throughout the day, and at 1:30 a.m. the next morning he attempted once again to raise a carbonized cotton thread to incandescence (Friedel & Israel, 1986, p. 104). This light burned for a total of 14.5 hours, with an intensity of 30 candles.

With hindsight, we can see that Edison had produced a successful light bulb, and the date of October 22, 1879 is generally given as the date of the invention of the light bulb. However, from Edison's viewpoint, there

was no sudden point when it was obvious that everything was in place. The cotton-thread experiments were an undeniable success, but Edison still did not consider the lamp to be a completed invention (Friedel & Israel, 1986, p. 103). One problem was that the cotton filament was extremely fragile. The staff spent much of late October, 1879 continuing to search for another carbon material. (Here may be part of the basis for the *Herald* story.) Carbonized cardboard filaments in the shape of a horseshoe seemed to produce especially promising results. By early November, 1879, Edison felt sufficiently confident in the success of the carbon lamp that he filed for an electric light patent with the U.S. patent office. On New Year's Eve, 1879, Edison opened the lab, illuminated by interior electric lights and electric streetlights, to the public, and crowds came to view and marvel at what the wizardry of Edison had accomplished (Friedel & Israel, 1986, p. 112).

Invention of the Light Bulb: Summary and Conclusions

This analysis of Edison's seminal invention is consistent with the other case studies presented: his work provides further evidence for continuity and structure in innovative thinking, as well as providing evidence that innovative thinking is made up of a family of components. There has been no need to assume anything beyond ordinary thinking in order to understand Edison's accomplishment. Edison's first attempts were based directly on what had been done in the past. He moved beyond past work first by trying to determine the reasons for his consistent failures. In addition, his logical/mathematical analysis of the requirements of the electrical system that he hoped to build led to the conclusion that the lamp had to be of high resistance. Improvements in vacuum-pump technology and the need for a high-resistance lamp in turn led back to carbon and ultimate success. All these developments can be understood as being the outgrowth of ordinary thought processes, and we can see how innovation comes about as an orchestration of a family of cognitive processes.

Critical Analysis and Discontinuity in Thinking

The invention of the light bulb has provided an example of a discontinuity in Edison's thinking—use of a platinum burner in a vacuum. Edison began his work believing that a platinum burner could be exposed to air, but later the vacuum became a crucial component of the platinum-burner bulb. This discontinuity, which was critical in Edison's success, was brought about by ordinary cognitive processes: in Phase 3 Edison examined under the microscope the condition of the broken platinum burners, which led him to conclude that escaping hydrogen had contributed to their destruction. (At least one earlier investigator had

placed the platinum burner in a vacuum (see Table 10). I am assuming that Edison was not aware of that attempt, although if he was, it would mean that platinum in a vacuum would be a further example of continuity.) In considering how to remove the hydrogen without destroying the burner and how to keep the burner isolated from hydrogen, placing it in a vacuum was a logical conclusion. Edison's critical analysis in Phase 3 of the difficulties that arose in Phase 2 led to the realization of the need for the vacuum: nothing new is needed for us to understand Edison's thinking.

A discontinuity arising in a similar way can be seen in James Watt's development of the steam engine (Basalla, 1988; Weisberg, 1993, pp. 126–130). Although Watt is usually given credit for inventing *the* steam engine, Watt's invention was in fact a modification of an extant engine—the Newcomen engine, a steam-powered engine invented by Newcomen a generation earlier. Watt was employed as a laboratory technician at the University of Glasgow, and he was preparing a small-scale Newcomen engine for a lecture demonstration. He was struck by the difficulty he had in getting it to run; it would carry out a few cycles and then would stop, due to lack of steam because all the coal had been quickly consumed. Watt then modified the Newcomen engine so that it ran more efficiently. Thus, Watt's innovation was driven by his critical analysis of the poor performance of the Newcomen engine; again, ordinary cognitive processes are central in this innovation. Discontinuity based on critical analysis of one's own earlier work can also be seen in Watson and Crick's development of the double-helix model of DNA. They originally proposed a triple-helix model of the structure (based in part on Pauling's alpha-helix, as noted above). When this model was found to be inadequate on empirical and logical grounds (Olby, 1994; Watson, 1968; Weisberg, 1993), they modified it, producing the double helix. It is also important to note that some of the inadequacies in the triple-helix model of DNA were pointed out by other researchers, with whom Watson and Crick discussed their model. This parallels Dunbar's (1995) finding, cited earlier, of the importance of input from others in changing a scientist's analysis of a phenomenon.

Cognitive Processes in Innovation: Conclusions

This section has centered on analysis of Edison's invention of the light bulb to provide support for the claim that creative thinking is constructed out of the same family of cognitive processes that are seen in ordinary thinking (Perkins, 1981). It was concluded that it was possible to understand each phase in Edison's thinking without introducing processes beyond those found in ordinary thinking (see Table 10). In addition, several other cases, presented more briefly, also support the idea that radical innovation can be stimulated by such mundane processes as critically examining deficiencies in an extant product, either

one's own or someone else's. This section also provided further evidence for continuity in innovation, specifically the role of antecedents in the development of new products.

Sensitivity to External Events

Ordinary thinking is sensitive to outside events, which can serve to trigger new directions in thinking. This is a second way in which discontinuity in thinking can occur: an external stimulus may suddenly change the direction of a person's work. An example of a triggering event can be seen in Alexander Calder's development of mobiles in the 1930s in Paris (Calder, 1966, p. 113). These abstract moving sculptures, which depended on the wind to provide motion, were different than anything Calder had produced before (see Fig. 9A). For the present discussion, we will examine only the abstract or non-representational nature of these sculptures, which was in itself a significant breakthrough (for further discussion, see Weisberg, 1993). Figure 9B reproduces an exhibit from 1931 in Paris of Calder's then-recent work, and one can see graphic evidence that his work took a radical shift in subject matter around 1930, moving relatively suddenly away from representation. In this exhibit, one sees representational and abstract works together.

In examining Calder's work before this point (e.g. the wire sculptures hanging near the ceiling in the exhibit in Fig. 9B), one finds little or nothing in the way of non-representation. Calder himself (1966) provides the clue to why his style changed relatively suddenly. In the late 1920s, Calder had made a name in avant-garde art circles in Paris, through his performances of his *Circus*, a miniature big-top, complete with multiple rings, a high-wire act, animals, acrobats, jugglers, clowns, music, a chariot race, a sword-swallower, etc., and grandstands for the spectators. Many of the most well-known of the modern artists in Paris witnessed Calder's circus performances, which resulted in his establishing connections to many artists. One of the artists who attended a circus performance was Piet Mondrian, whose work at that time involved highly abstract geometrical paintings, built out of blocks of primary colors. Calder reported that in 1930 he visited Mondrian's studio, which was painted white, with blocks of primary colors on the walls and examples of his latest work also present (see Fig. 9C). Very soon thereafter, Calder began to paint in a style much like Mondrian's, but he then adapted that style to sculpture, with which he felt more comfortable. One can see that at least one of the abstract sculptures in Fig. 9B has a base painted in the style of Mondrian. So the radical change in Calder's style came about at least in part as a result of his adoption of the style of Mondrian, which means that the radical change within Calder's style was not radical at all in the modern-art milieu of Paris around 1930. The change seems radical only in the context of Calder's work until that point.

Another example of a discontinuity triggered by an external event occurred during Picasso's production, in 1906–1907, of his seminal painting *Les Femmes d'Alger*, arguably the most important painting of the 20th century (Rubin, 1984). The style of this painting was radically different from anything that he or any other artist had produced before, and this radical stylistic shift has been attributed to Picasso's exposure to non-Western art (Rubin, 1984; Weisberg, 1993, pp. 197–198).

External events can also play a role in the development of innovation in domains beyond art. A similar process may have occurred in the Wright brothers' development of the 'wing-warping' control system for their early glider, which became a crucial component of their successful powered airplane. This system, which is the direct ancestor of the ailerons seen on modern aircraft, was designed so that the tips of the trailing edges of the two wings on the Wrights' machine could be made to lift or drop by the operator. The mechanism was constructed so that the two sets of wing tips moved in opposition; i.e. when the left wing tips were lifted, the right ones dropped, and vice versa. This caused the plane to turn in one direction or the other. This control system, which differed radically from those developed by other would-be airplane inventors, may have been stimulated, at least in part, by Wilbur Wright's observations of birds' movements of their wing tips when gliding (Weisberg, 1993, pp. 139–140).

It is also interesting to note that one difference between the Wright brothers and other researchers working on the problem of flight was that the Wrights were from the beginning very concerned with how they would control their flying machine once they got it into the air. Most of the other would-be inventors assumed that the machine could be made inherently stable with a few simple passive design components, such as a V-shaped wing (Crouch, 1992). It was assumed that such components would serve to automatically keep the plane stable in flight. The Wrights, in contrast, assumed from the beginning that the human operator would have to play an active role in controlling the machine in the air. A possible reason for the Wrights' concern about control (besides the fact that more than one person had been killed investigating possibilities of flight) is that they came to the problem from a background of designing and building bicycles, which have problems of stability remarkably like those seen with flying machines. Most of the other people working on the problem of flight approached it with the belief that movement in the air would be like a boat's movement on the surface of a body of water, which turned out to be an incorrect analogy. The Wrights' adopting this overall perspective is further support for the notion of continuity in thinking: the general orientation of their work on controlling the flying machine was based on their experience with bicycles.

External triggers have also played important roles in innovation in science. Darwin's final synthesis of the theory of evolution based on natural selection may have been stimulated by his reading a passage in Malthus's well-known essay *On Population*, which discussed the competition among organisms for limited supplies of food (Gruber, 1981; for further discussion see Weisberg, 1993). In this example, the external stimulus provided the capstone on a process that had gone on for more than 20 years for Darwin. External events can also serve to start the process of innovation. As an example, the collaboration between Watson and Crick may have come about in part as the result of an external trigger. Watson's initial desire to work on the problem of the structure of DNA at the Cavendish Laboratory at Cambridge University—where he met Crick—was stimulated in part by his exposure to an X-ray photograph of crystalline DNA which he saw at a conference in Naples (Watson, 1968). This external event played a role in initiating the whole process. In addition, comparable to Malthus's influence on Darwin, Watson and Crick's thinking at several places was pushed in a critical direction as a result of their exposure to new experimental results which allowed them to draw conclusions about important features of the DNA structure (Olby, 1994; for further discussion see Weisberg, 1993).

Innovation and External Events—Conclusions

Examples from a broad range of domains—the arts, invention, and science—support the hypothesis that new directions in innovative thinking are sometimes the result of external events. External events can play a role at every point in the creative process, from initiation of interest in some phenomenon to the final piece of information that results in things coming together. These examples are further evidence that innovation comes about through processes no different than those underlying our day-to-day activities.

The Ordinary Basis for Creative Thinking: Conclusions and a Remaining Question

Conclusions

At the beginning of the chapter, several facets of ordinary thinking were outlined, and the discussion has presented support for the hypothesis that each of those facets is also seen in innovative thinking. We can summarize the discussion in the chapter by examining those facets once again (see Table 11).

Continuity in Thinking

Continuity in innovative thinking is supported first by the learning curve that has been found in creative disciplines: people who work in creative disciplines

Table 11. Summary of case studies.

*Continuity in Thinking**Learning to be Creative*

- 10-Year Rule (Hayes, 1981)
 - Gardener's (1993) biographical studies
- Mozart
 - 10-Year Rule
 - Increasing productivity
 - Increasing quality of works
 - Increasing originality
- Lennon & McCartney
 - 10-Year Rule (although fewer years)
 - Increasing quality of works
 - Increasing originality

Antecedents to Innovation

- Mozart
 - Early piano concertos constructed out of those of others
 - Early symphonies modeled on those of others
- Lennon & McCartney
 - Immersion in early rock & roll
- Darwin
 - First stage: Lamarckian evolution and the monad
- Watson & Crick
 - Pauling and helical structures
- Picasso
 - Guernica* and *Minotauromachy*
 - Characters based on Goya
- Pollock
 - Stylistic innovation: Siqueros workshop
- Edison
 - First attempts: Carbon and platinum burners; based on earlier work
- Wright brothers
 - Controlling bicycle to controlling a flying machine

Structure in Innovative Thinking

- Picasso's *Guernica*
 - Antecedents related in content
 - Worked on overall composition first, then characters
 - Systematic working out of overall composition
 - Systematic working out of individual characters
- Edison
 - Analysis of problems with platinum burners; based on failures
 - Analysis of needs of electrical system

Cognitive Components in Innovative Thinking

- Perkins—experimental studies of insight in problem-solving
- Edison
 - Logical/mathematical thinking
 - Analysis of failed platinum burners
 - Analysis of requirements of electrical system
 - Need for high-resistance burner
 - Evaluation of consequences
- Watt
 - Critical analysis of problems with Newcomen engine
- Watson & Crick
 - Critical analysis in rejection of triple-helix model

External Triggers to Innovation

- Watson & Crick
 - Criticism by others of the triple-helix model of DNA
 - Information from others' research that pointed the way to the double helix
- Calder
 - Mondrian's studio and abstraction
- Picasso
 - 'Primitive' art and *Les Femmes d'Alger*
- Wright brothers
 - Bird flight and 'wing warping'

require a significant amount of time to get good at what they do, as we have seen from studies of the 10-Year Rule (Hayes, 1989). Gardener's (1993) biographical studies supported the same conclusion. There was also evidence from case studies in music for increasing productivity and increasing quality of work during this learning period. A further aspect of continuity, that in producing innovations we build on our experiences, was supported by the finding of antecedents for innovations in a wide variety of areas (Weisberg, 1986, 1993). Similarly, based on a consideration of the relationship between creators' early works and works produced by those around them, we saw incremental movement beyond what had been done before, rather than wholesale rejection of the past.

Structure in Thinking

Ordinary thinking is structured in several ways: (1) our thoughts are linked through associative bonds, which are the result of links between events in our past, and on the basis of similarity of content; (2) we use reasoning processes of various sorts, which provide a basis for moving from one thought to the next. The analysis of Picasso's creation of *Guernica* and Edison's invention of the light bulb provided evidence for the structured nature of innovative thinking.

Thinking is a Family of Activities

Ordinary thinking is made up of a large family of cognitive activities, some of which are: planning how to carry out some activity before doing it; anticipating the outcome of some action; judging whether the outcome of an anticipated action will be acceptable; deciding between two alternative plans of action; determining the consequences of some events that have occurred (through deductive reasoning); perceiving a general pattern in a set of specific experiences (through inductive reasoning). Several sorts of evidence support the claim that creative thinking is also constructed from those sorts of basic cognitive activities (Perkins, 1981). Analysis of the thought processes underlying Edison's invention of the light bulb indicated that the phase-to-phase transitions could be understood as being the result of ordinary processes. For example, Edison's decision in Phase 4 to put the platinum burner in a vacuum came about as a consequence of his analysis in Phase 3 of the failed platinum burners. Similarly, his decision to return to carbon in Phase 8 was the result of the consistent failures with platinum, the still-existing need for a burner of high resistance, and the availability of the newly developed high-efficiency vacuum pump.

Thinking is Responsive to Environmental Events

Ordinary thinking and innovative thinking are both sensitive to environmental events: radical changes in thinking are sometimes based on the innovator's exposure to what could be called external triggers. Support for this conclusion comes from the arts

(Calder's radical style shift in his sculpture around 1930, Picasso's radical style shift in painting *Les Femmes d'Alger*); science (Darwin's reading of Malthus; Watson & Crick's collaboration); and invention (the Wright brothers' control system based on bird flight).

A Remaining Question: What then is the Basis for Innovation?

If one assumes for the sake of discussion that innovation is indeed the result of ordinary thinking processes, we are still left with one important question: What are the differences between the great innovators and the rest of us? If innovation at all levels, including the highest, is brought about through thought processes which are available to essentially all of us, then why do very few of us produce seminal advances? In response to this question, one should note that, even if we all possess the same basic set of cognitive processes, there are still ways in which we could be different which might bring about the differences among us in innovative achievement. Let us take the hypothetical case of two individuals who are researchers in the same field—why might one produce ground-breaking work while the other does little or nothing in the way of innovation? One crucial element of difference could be disparities among individuals in information-processing capacities. As one example, it was noted earlier that Mozart's last symphony was different in complexity than earlier symphonies, those by Mozart and by others. That advance leads us to the question of how Mozart was able to produce a greater degree of complexity than others had (and than even he had previously produced). One possibility is that Mozart might have had a larger working-memory capacity than others (Baddeley, 1990). That is, Mozart might have been better able to keep track of multiple strands of music, which might have contributed to more complexity in his compositions. However, it should also be noted that an individual's ability to process and remember information is based on the person's expertise in the domain. Therefore, Mozart's 'larger working-memory span' might not have been some innate characteristic of his information-processing system. Rather, it might be a secondary result of his long immersion in music. In addition, on this view, the fact that Mozart's last symphony is the most complex of all of his works in that genre is because his ever-increasing expertise might have paved the way for works of greater and greater complexity.

This leads to a second possible difference between people who produce notable innovations and those who do not: the different databases that different individuals bring to their work. If one individual has broader and deeper knowledge than the other, such a difference could affect the chances of one individual rather than the other producing innovation. Related to the issue of the size of the database is how it is acquired—all other

things equal, a larger database would be the result of more intense and/or longer-lasting immersion in the discipline. This difference in immersion might in turn be the result of differences in the motivation with which individuals approach their work. Motivation might be crucial in another way as well. It has been proposed that one crucial element in producing innovative work at the highest level ('genius-level' work) is the motivation to persist in an activity even when it seems unlikely that success will be obtained (see Howe, in press). Although innovation may ultimately come about from the application of one's knowledge to the situation that one is facing, and this application may come about as the result of structured processes of thinking that we all can carry out, having the information to work with only comes through years of immersion in the discipline. Not everyone is equipped with the motivation to stay the course.

Innovation and Evolution: Managing Tensions Within and Between the Domains of Theory and Practice

James R. Bailey¹ and Cameron M. Ford²

¹ *Department of Management & Technology, School of Business and Public Management, George Washington University, USA*

² *Management Department, College of Business Administration, University of Central Florida, USA*

Abstract: Innovation occurs when individuals produce *novel* solutions, and members of the relevant domain adopt it as a *valuable* variation of current practice. At the individual level, creative or innovative actions are adoptive responses to tensions between the *person* and *situation*. In domains such as the arts or sciences, person–situation tensions are best resolved by favoring novelty, whereas in domains such as business, the same tensions are best resolved by favoring value. We employ a neo-evolutionary view of creativity to propose that these *within* domains tensions create intractable tensions *between* domains.

Keywords: Innovation; Creativity; Evolution; Domain; Tensions.

Introduction

That progress is the progeny of diverging and converging forces is true in innovation as in all endeavors. Such operative forces, or *tensions*, are not new as explanatory frameworks. At a planetary level, geological history is best understood as long-grinding terrestrial and atmospheric pressures that shaped modern topography. Even the origin of a species can be viewed as friction between which variation is best suited to environmental demands—a logic to which we will soon return. And in human affairs, societies advance when social equilibrium is upset by countervailing movements as diverse as immigration and technology.

The common theme in all these tensions is *change* and *stability*—a contrast inherent in virtually all discussions of creativity and innovation. Other parallel and analogous polar anchors include subjective vs. objective, emotion vs. logic, conceiving vs. organizing and, in our minds the one most indicative of creativity and innovation, *novelty* vs. *value*. A truly innovative idea, process, service or product achieves both, and can thereby be said to have successfully resolved the tension. But how, exactly, is that accomplished?

In the pages that follow we make two interrelated arguments. The first is that innovation begins when an individual presents a novel proposal. But because proposed variations are evaluated in specific contexts or domains—replete with idiosyncratic expectations and reinforcements—novel proposals will be more compatible with and frequently adopted in some domains rather than others. Hence, explaining creative action in a given context requires appeal to the classic *person–situation* debate. By conceiving individuals as goal-oriented, future thinking and feedback-seeking entities, we advocate a neo-evolutionary approach wherein individual creativity introduces variations that are subsequently selected or rejected by the demands and predilections of the domain environment. In domains where novelty holds intrinsic value (e.g. the arts, science), creative behavior is an adaptive response that mitigates person–situation tensions. Alternatively, in domains where ‘new’ doesn’t necessarily mean ‘improved’ (business management—cf. Ford & Gioia, 2000), person–situation tensions are best addressed by adherence to established practices.

Our second argument is trans-application in nature, based on the premise that innovations achieve their

greatest impact when they are adapted across interdependent domains. Reciprocal adaptation is especially valuable in the worlds of *theory* and *practice*. We hold that in theoretical domains such as organizational studies, selection processes favor novelty, whereas in practical domains such as business, selection processes favor demonstrated value. Hence, over time theoretical structures have become increasingly complex, jargon-laden, pluralistic and unproven, whereas application concentrates on easily apprehended, broadly diffused 'best practices' whose value has been benchmarked.

In an ironic twist, the very evolutionary forces that engender innovation within these domains drive a divide between them. That is, a consequence of individuals' striving to resolve the person–situation tensions imposed by selection processes *within* their domains is exacerbated misalignment *between* them. Hope for maximally integrating theory and practice, then, lies in a recognizing that innovation reflects both novelty *and* value, and thus deploying intermediaries and designing institutional resource dependencies capable of sustaining divergent and convergent variations.

A Fork in the Road: Person–Situation Tensions

If tensions are critical in all endeavors, what is the one most representative of innovation? On the one hand lies the stark realization that innovation, in the final and fundamental analysis, is the spawn of individual imagination. To be sure, findings from academic journals build to novel theses and companies bring new products to market. But in every case, if enough layers are peeled or the shrouds of history are lifted, some clever, brave, or just plain lucky individual stands at the center. On the other hand, though, innovation does not unfold in a vacuum. The germination of an idea in one's mind stems from thousands of diverse threads, and the execution of that idea is the product of many minds and hands. In these ways, innovation is social in nature. Furthermore, there is ample evidence that throughout history some societies have been more progressive than others, and some firms have managed to sustain inventive cultures better than others. In these ways, innovation is institutional in nature. The oft-repeated aphorism that 'necessity is the mother of invention' is testimony to the creative potential of collective will.

All of this brings us to the much traveled *person–situation* debate, which is itself a variant of the grand nature–nurture debate, writ small. This is the tension most characteristic of innovation, garnering enormous examination over the last half century. The literature is too vast to review here, but the polar structure is easy to grasp.

At one end of the continuum is the hardcore 'individual differences' camp that dates back to Allport (1937) and draws heavily from research into dispositions, personality, traits, values, needs and attitudes. This approach assumes that individuals possess meas-

urably stable and enduring qualities that determine behavior across a wide variety of situations. Although seldom explicitly stated, the intellectual commitment is that too many variables comprise a given situation at a given moment, making them a fragile foundation for useful prediction. Situations, then, are a proverbial goose chase. And although people do change, they still constitute the most stable factor in the equation, and hence should be focus of analysis.

The other end of the continuum is anchored, predictably, by the 'situationalists'. Chief among them is Walter Mischel, whose 1968 tome, *Personality and Assessment*, built the case that situations vary in strength, depending on extant mores, norms, reward structures, supervision, tightly scripted roles and the like. In strong situations, the behavioral patterns imbedded in personality would be trumped by contextual cues. In this way, Mischel showed the Behaviorist tendency to assume that the conditions of one's life determine one's behavior. Change the conditions (via public policy and programs) and the behavior will follow. Behavior, then, is the flotsam and jetsam of the situation's ebb and flow. (For an instructive, recent exchange on the manifestation of this debate in organizational studies, see Davis-Blake & Pfeffer, 1989 and House, 1996.)

Of course, any reasonable person—including those that staked claim in this debate—recognizes that behavior is the function of both the person and the situation. For this reason, a strong contingent of 'interactionists' has emerged who examine motivational and creativity processes associated with innovation (Amabile, 1996; Ford, 1996; Woodman, Sawyer & Griffin, 1993). To encapsulate, the person–situation tension is enacted when individuals' choose from a range of alternative behaviors in a particular circumstance. That choice is a coping behavior that either facilitates or constrains personally appealing courses of action.

With this as a background, we will distinguish between two broad options for coping with person–situation tensions—*novel behavior* and *routine behavior*—that together represent a 'fork in the road' (Ford, 1996). Whether consciously or not, in any given situation individuals are presented with a choice between new and routine behavioral options that instigate change or reinforce the status quo respectively. To support this view, we focus on three interactionist theories that treat individuals as goal-oriented, future-thinking and feedback-seeking entities attempting to resolve the person–situation tensions they face on a day-to-day basis.

Goals Model

This model assumes that individuals are goal-directed, summarized nicely with its founder's own words:

(B)ehavior is the expression of the interplay among many goals, and there is a complex relation between

goals and behaviors, such that the same behavior may express different goals and the same goal may lead to different behaviors, according to the demands of the situation (Pervin, 1989, p. 355).

Pervin is asserting that individuals' action is organized to advance the achievement of a variety of personally desired outcomes, the saliency of which varies depending on the availability of particular outcomes in particular situations. Thus, individuals 'read' a situation to determine its operative goals, its reward structure, and their own ability to behave according to those demands. Such internal (i.e. goals) and external (i.e. situations) canvassing becomes the basis for choosing among alternative behavioral options. Elected behaviors address the person–situation tension by attaining desired outcomes or avoiding unpleasant ones.

Social Cognitive Model

This model focuses on individual adaptability to situations as a function of social intelligence (Cantor & Kihlstrom, 1987). Social intelligence is not necessarily that typically associated with the raw problem-solving ability reflected in IQ. One can have a high IQ and be woefully socially inept. Rather, it refers to having readily accessible memory structures of the concepts, rules, dynamics and skills that were operative in previous situations. This is a 'social-cognitive' model because individuals draw on the knowledge of what did or did not work in previous situations to formulate strategies for handling new ones. This *feed-forward* process creates the expectancies and instrumentalities underlying individual motivation, as well as specific performance strategies designed to attain personally desired outcomes. Adaptability, then, becomes a competency that turns on seamless rehearsal of relevant past experience and careful assessment of current circumstances to organically integrate behavior. Evidence shows that: (a) strategies can be considered effective only to the extent that the person using them, and the situation in which they are used, are considered; (b) effective strategies do not necessarily generalize across contexts; and (c) individuals who are inflexible in strategic deployment run into a whole host of problems.

Self-Appraisal Model

This school of thought is based on the notion that individuals strive to reduce uncertainty about their abilities in relation to environmental demands (Bailey, Strube, Yost & Merbaum, 1994). What distinguishes it from the two previous models is the notion that self-knowledge is predicated by one's willingness to seek out feedback. People can be arranged on a continuum from those low in self-appraisal motivation (meaning they tend to shy away from diagnostic feedback, favoring instead that which is skewed toward enhancing

their self-image) to those high in self-appraisal (meaning a keen desire for accurate and complete feedback, regardless of its self-esteem implications).

This is a theory of ego operation that examines how the very human and hedonistic urge to feel good about oneself is manifested. Those low in self-appraisal do so by choosing tasks and eliciting feedback that reflects positively on them. In contrast, those high in self-appraisal take the lumps that negative feedback might inflict on their ego in order to understand better what they do well and what they do poorly. This, subsequently, puts them in a better position to select or create environments where their abilities are well matched to the demands, which ultimately would lead to positive feedback via successful performance, and hence serve the ego well. The Self-Appraisal model goes beyond the others by emphasizing the possibility of enacting or creating environments to discover the 'fitness' of specific behaviors—that is, the extent to which they accomplished desired outcomes.

These three models provide a robust foundation for understanding the person–situation tension as it relates to creativity and innovation. The Goals Model highlights how objectives are made salient and pursued depending on extant circumstances, and thus involves *direction*. The Social Cognitive Model looks at how future contingencies could help or hinder alternative course of action. Imagining possible consequences is an anticipatory *feedforward* activity that forms and shapes expectations. The Self-Appraisal Model poses that the ego strength to face *feedback* regarding abilities in relation to demands is the path to self-regard and, although threatening, could lead ultimately to placing oneself in a complimentary environment. These three elements are illustrated in Fig. 1 as a framework for illustrating multifaceted person–situation tensions.

A Neo-Evolutionary Resolution of Person-Situation Tensions

The evolutionary metaphor of the person–situation tension would be that between *variation* and *selection*. At a surface level, variation represents individual creative action and selection the environment (referred to interchangeably as the domain) in which that action takes place. Although accurate so far as it goes, as with all metaphors, these parallels break down when extended. Standard evolution theory holds that the cycles of production—that which produces variation—are causally distinct from cycles of maintenance—the environmental demands which select or reject variation. So, for example, the environment did not cause the giraffe's neck to be long. Rather, the giraffe's neck is long because of tendencies toward spontaneous genetic variation. The environment did, however, select for that neck inasmuch as it was a 'fit' adaptation that increased the likelihood of procreation (see Bailey, 1994, for a review).

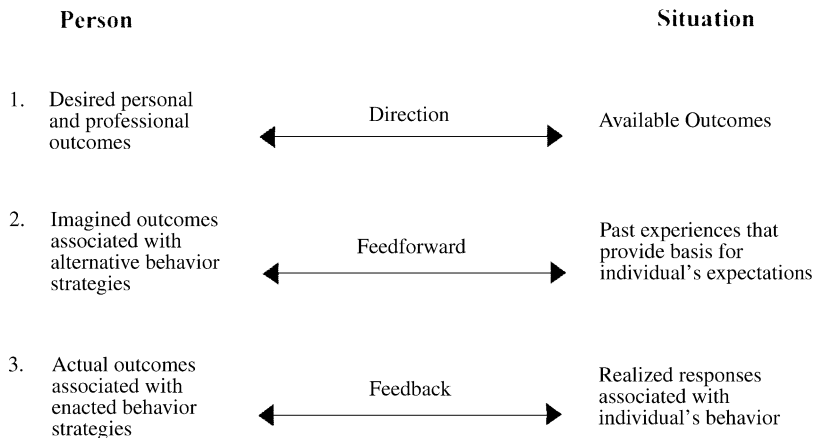

Figure 1. Managing person-situation tensions.

Casual separation of variation and selection may hold true in biology, but it is untenable in the social psychology of creativity and innovation. Individual creative action is not merely an accidental, spontaneous variation, and the domain in which individuals live and work is not merely a removed, disinterested, passive environment that selects after the fact. Rather, as our previous discussion demonstrates, the person and the situation are reciprocal and interdependent. Thus, we appeal instead to neo-evolutionary theory as an optimal framework to describe person-situation resolution. Originally described at the individual level by Campbell (1960) and later elaborated on and organized by Weick (1979), this perspective contends that each level of analysis has three sequentially ordered process categories, *enactment*, *selection*, and *retention* (E-S-R).

An E-S-R approach is especially useful for understanding how creativity and innovation unfold in social settings because it explicitly depicts the tension between divergence and convergence, change and stability, novelty and value, and creating and organizing. An 'enactment' refers to an individual choice that is, in our parlance, either new or routine and sensitive to the demands of the domain. That is, individuals' operative goals and expectations are conditioned by past and current environmental features such as resources dependencies that acknowledge, allocate and reward. Assuming that individuals seek to achieve desired outcomes and avoid undesired ones, it makes perfect logical and hedonistic sense that they would choose enactments that are likely to be well received in their domains. In this fashion, either new *or* routine behaviors can be labeled adaptive.

A neo-evolutionary approach also recognizes that domains change as a result of enactments that are selected and retained as a legitimate practice. That is, once an idea, process or product is accepted, it is now

available for further adoption within the domain. Individual creative actions represent novel enactments that may instigate a commensurate E-S-R cycle at the next highest level (e.g. a team or department). This kind of analytic scheme better depicts how individual dispositions and interpretations are expressed in organizational settings, and how patterns of social interaction at various levels of analysis impact on creative outcomes (Weick, 1979). Just as the introduction of a new species alters the floral and faunal equilibrium of an ecosystem, so it is with innovation.

With this background, creativity and innovation are defined from the perspective of those working within a particular domain. Thus, an idea, process or product is considered 'creative' to the extent that informed judgments by knowledgeable players in a given domain deem it to have merit. In this way, selection processes are determined by those individuals who enjoy influence, authority or expertise. Creativity is a domain-specific, subjective judgment of the novelty and value of a particular action (Ford, 1996).

The E-S-R approach illustrates the person-situation interaction that leads individual actors to choose new or routing behavioral options. It also helps to surface the priorities that drive selection processes between domains. The next sections show how innovating (i.e. enactments, variations) and organizing (i.e. selection, retention) are differentially prized in theory and practice. Equally apparent, however, is that these processes are reciprocal; the former cannot proceed in the absence of the knowledge and purpose that results from latter, and if the latter becomes too narrowly focused and rigid, it will stagnate creating. Innovating and organizing are like rival siblings who constantly squabble but who are nevertheless intimately linked. The following section will employ this neo-evolutionary perspective to describe how individuals' efforts to reduce person-situation tensions within domains can

increase tensions between related domains with different methods of ascribing value. We focus specifically on the tension between theory and practice created by the processes illustrated in Fig. 2.

Tensions within the Domain of Organizational Studies

The primary tension facing tenure-track faculty in organizational studies is simple yet profound: publish or perish. The old axiom is overstated perhaps, but few would disagree with its essence. Bedeian (1996) described the road to professional success in organizational studies by saying:

In economic analogy, publications are the major currency of the realm. Whereas there may be diversity in academic reward structures at the institutional level (e.g. teaching, research, service), the reward structure at the national and international level is monolithic rather than plural. Thus, whereas scholars may draw their paychecks locally, academic recognition and the rewards that follow (e.g. editorial appointments, professional board memberships, fellow designations) are conferred elsewhere as a consequence of judgments made by the larger academic community . . . Publications mean visibility, esteem, and career mobility (p. 6).

Recent research supports this characterization. Gomez-Mejia & Balkin's (1992) analysis of determinants of faculty pay in organizational studies found that the correlation between the number of top-tier publications (defined as the top 21 organizational studies journals as judged by a sample of department chairs) and 9-month faculty pay was 0.61. The authors of this study suggest that given the nonprogrammable nature of faculty's work, incentive systems are used in lieu of monitoring as a means of directing behavior (i.e. selecting desired, and rejecting undesired, behavior). Of course, this environmental demand is a source of person-situation tension only to the extent that it is poorly aligned with individual aspirations. If one wants to do nothing but publish, academe provides an exceptional fit. But such is not the case. Gomez-Majia and Balkin found strong evidence that most faculty not only are resigned to a singular and narrow path toward career success, but do not like it:

Of the respondents to our survey, 11% were 'strongly satisfied' and 58% were either 'dissatisfied' or 'strongly dissatisfied' with the statement that 'when it come down to it, publishing is the overwhelming criterion for faculty pay decisions'; in contrast, 80% agreed that this statement was true (p. 948).

Thus, the adaptive strategy for organizational scholars who seek tenure and high pay is, like it or not, to publish research in top-tier journals. In order to thrive, one must become savvy about the criterion used by

journal editors and reviewers to evaluate submissions. From the neo-evolutionary perspective we employ to describe person-situation interactions related to creativity, this is akin to understanding the selection processes that favor one type of variation over another, and enacting accordingly.

Recent empirical research sheds further light on the selection processes employed by top-tier journals. Beyer, Chanove & Fox (1995) found that submitted papers were likely to be viewed as more significant to the field, and therefore more likely to be published, if they made explicit claims regarding novelty. Mone & McKinley (1993) found evidence that a 'uniqueness value' is held by organizational scholars that influences their conception and execution of research programs. Specifically, they found that the dialogue between researchers submitting papers and editors deciding the papers' fate was defined by explorations and identification of novelty. The key question reviewers ask to gauge the worth of a submitted paper is 'what's new here?' Locke & Golden-Biddle (1997) went so far as to analyze specific gambits that researchers use to convince reviewers of the novelty of their work because, "... what counts as a contribution is that which is perceived as unique or novel in light of the extant literature" (p. 1024). The rhetorical devices they identified include specifying gaps in current theory and knowledge, noting oversights or neglected issues and advocating alternative theoretical approaches.

Taken together, our neo-evolutionary view suggests that resolving the person-situation tension facing those in the domain of organizational studies involves publishing novel theoretical proposals in top-tier journals. This strategy leads to job security, high pay, recognition and mobility, and therefore constitutes an adaptive response that advances personally desired outcomes. Given the selection processes imposed by the domain and the nature of adaptive responses most likely to be retained, what are the implications for theory in organization studies?

We believe that the description offered by Astley (1985) remains valid, perhaps more so now than when originally presented more than 15 years ago. Astley argued that organizational studies value iconoclasm over truth, and that creative theorists were much more likely to be successful than those who sought to verify the validity of existing theories, catalog the success rates of current practices or the like. Because novelty is assessed relative to existing theory rather than current practice (Locke & Golden-Biddle, 1997), most research tends to be literature-driven rather than problem-driven. Consequently, organizational studies continue to evolve as a fragmented discipline addressing loosely related topics. Astley's conclusion that "New theoretical advances do not seem to build cumulatively on previous findings; instead they add to the bewildering variety of perspectives within the field" (p. 504) still rings true.

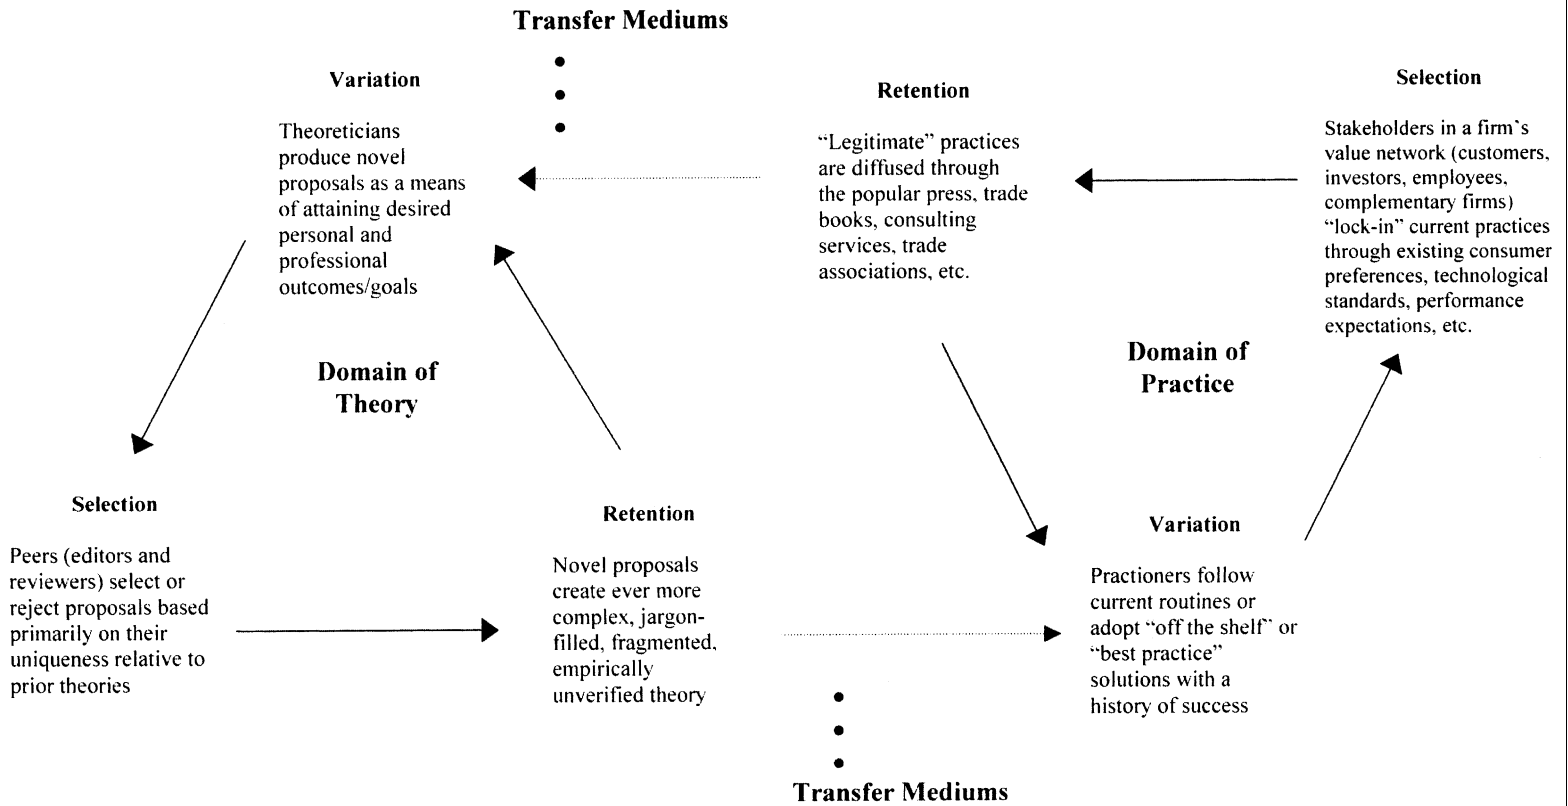

Figure 2. A neo-evolutionary view of tensions within and between the domains of theory and practice.

Our description leads to the disheartening conclusion that theoretical novelty is more important than practical value to those seeking to advance their careers in the discipline. The resulting ‘management theory jungle’ (cf. Koontz, 1961) should come as no surprise. Our stance is that optimism with respect to theoretical pluralism lies in changing the selection processes in a manner that more closely aligns the values facing scholars with those affecting management practitioners. But first we examine the tensions faced by practitioners.

Tensions Within the Domain of Management Practice

Despite wide recognition of its importance, few organizations can claim to have mastered the challenges associated with managing creativity. Why is this so? We maintain that the primary characteristic of firms is the presence of normative cues, emanating from various sources, that describe and reinforce adherence to routine or habitual behaviors (Ford, 1996). Organizations primarily exist to align the collective efforts of diverse individuals toward common goals. Formal aspects such as structural alignment, operational procedures and rules, stated objectives and compensation systems, as well as informal aspects such as roles, norms and culture, all serve to induce conformity in the thoughts and actions of organization members. Industrial and professional identifications carry equally as defined notions of appropriate and inappropriate behavior. The comportment expected of a financial officer in a bank, say, can be as constricted as an actor in a play.

These processes are the functional equivalent of environmental pressures that form the dynamics of selection processes. All are very important and even indispensable means of aligning collective behavior and empowering individuals to act on behalf of organizational interests. Shared interpretive frameworks held by participants encourage reliance on well-understood, previously tested solutions, but they also discourage the generation or consideration of new possibilities. As a consequence, the benefits of reliability and efficiency associated with normative processes come at the cost of low creativity. This is especially problematic in large organizations where innovation may even be considered ‘illegitimate’ (Dougherty & Heller, 1994).

On the whole, there is every reason to believe that the domain of practice privileges value over novelty, organization over innovation. March & Simon (1958) described firms as collections of routines wherein innovation resulted only when the repertoire of habitual responses failed. Burns & Stalker (1961) saw firms as ranging between routine-laden and mechanistic vs. innovation-oriented and organic archetypes. Thompson (1967) partitioned organizations into a technical core that maintained stable routines surrounded and pro-

ected by an institutional domain that addressed novel, potentially threatening demands and circumstances. In a similar vein, Weick (1979) illustrated an organizational antimony whereby firms address conflicting requirements for flexibility and stability. March (1991) argued that organizations comprise incommensurate activities related to either exploiting current routines or exploring novel alternatives. Christensen’s (1997) research on ‘the innovator’s dilemma’ presents compelling evidence that the operational configurations necessary to dominate existing technologies or markets make it impossible for firms to participate in highly creative departures from the status quo, and vice versa. Decades of research suggest that organizing is the antithesis of innovating, where the former promotes routines and the latter disrupts them.

As previously argued, the person–situation tension means that individuals must choose between new and routine behavioral options. Unfortunately, the paradox between conforming and creating looks rather one-sided to most employees. Especially in ‘strong’ organizational settings—characterized by detailed job descriptions, rigid reporting relationships, close supervision and persuasive cultures—powerful normative processes furnish an environment where thought and behavior become routine-driven. Therefore, firms become unreceptive to creative enactments because they run counter to potent forces toward convergence. Given a choice between time-tested routines that produce relatively certain, near-term consequences, and creative alternatives that are typically disruptive, uncertain, and prone to failure, most individuals opt for the safe haven of sanctioned routines. This is true at the organizational level as well; corporations tend to adopt industry ‘best practices’, avoiding risks associated with ‘re-inventing the wheel’, but promoting look-alike strategies and operations that doom an industry to competition based solely on price (Porter, 1996). It is hardly surprising, then, that corporations have trouble harnessing employees’ creative potential. Evolutionary tensions between enactments and selection commonly follow a trajectory that favors known value over novelty.

Tension Between Theory and Practice

The connection between theory and practice—in this case, organization studies and management practice—is readily apparent and much lauded. Indeed, academic research can and should serve the business community through careful examination of processes and practices that improve implementation. Rigorous research can identify trends, refine procedures and instigate change. In every way, successful enterprise management is inextricably linked to the scholarship that informs and directs it (see Bailey & Eastman, 1996, for a detailed treatment of the interdependent benefits).

However, in reality these domains are only loosely coupled, represented by different sets of stakeholders

with different preferences with respect to novelty and value. As we have shown, novelty is intrinsically valuable in academe, whereas it is eschewed in practice, which gravitates toward demonstrated value instead. Consequently, academics and practitioners are motivated by quite dissimilar and even competing interests embedded in their domains. As basic testimony to this tensions, knowledge that defines theoretical domains is well documented, archived and easily accessible, whereas knowledge that defines practice is often proprietary, and tends to be documented in a haphazard fashion (even within firms).

Not surprisingly, then, attempts to enhance and manage innovation often encounter a paradox between the respective benefits of aligning collective effort—which promotes individual routine choices that emphasize organization—and empowering creativity—which embraces new choices that emphasize innovation. Conformity to current practices, values and norms can indeed direct the collective energies of employees toward realizing desired organizational outcomes, and thus is a critical component of success. However, individual creativity allows companies to resolve intransigent and strategically critical problems and develop new market offerings and technologies. This is especially important in the long term because creative actions contribute to learning and competitive differentiation; the heart and soul of sustained vitality. Ultimately, business success requires capitalizing on advantages associated with both creating and organizing. The squabbling children must be reconciled.

Resolving Between Domain Tensions

How, then, can these inherent tensions between the highly interdependent domains of theory and practice be resolved? We offer two broad strategies, arranged around intermediaries and aligning interests.

Intermediary Roles

Fortunately, there are several avenues through which innovative theories are communicated to practitioners, and best practices are noticed by professors. The extraordinary growth of the ‘guru business’ demonstrates the economic value provided by those who fulfill intermediary roles between professors and business people. The central problem with such boundary spanners is that they do not enjoy full acceptance in either domain. Professors often shun gurus for their simplistic treatment of complex issues. Practitioners just as often dismiss them as ‘witch doctors’ who have renamed and reframed last year’s fashion, angling for personal profit over firm performance. Despite this, popular management books are perennial bestsellers, testimony to their influence.

Although there is unquestionable value in the guru, there are other ways to structure an intermediary role. We believe there is enormous value in business schools appointing ‘practitioner’ or ‘professional’ professors,

drawn from the ranks of business people. Such individuals do not need to possess doctorates, and their role could be defined specifically to facilitate interaction between faculty and practitioners, novelty and value. That is, in addition to teaching elective courses, these professional faculty could be paired with more traditionally academic faculty to explore ways in which novel ideas could be framed and communicated to a practitioner audience. This might include arranging meetings and presentations with corporate counterparts or pursuing publication in trade publications as well as highly respected outlets like the *Harvard Business Review*. Further on-site action research opportunities could be brokered by such professional professors. Their general role would be to help connect the world of theory to the world of practice.

An inverse strategy for developing intermediaries is the ‘professional sabbatical’. In this scenario, professors are encouraged, and perhaps even required, to spend a percentage of their sabbaticals as ‘professors in residence’ of a firm. Finance professors could reside in banks, entrepreneurship professors in small business, organizational behavior professors in consulting firms, and so on. Because they are paid by the school, this option is low-cost for firms, involving only an office and minimum support. The idea here is for professors to work side by side with those who apply, in some way, shape or form, academic principles. Their role would be to encourage further the value of novelty, to push practitioners to question assumptions of best practices, the processes that are erected around institutional innovation and the championing of new ideas. That is, by bringing fresh perspectives and recent research to bear, professors could add value to the apprehension and resolution of real organizational issues.

Aligning Interests

The primary means available for resolving the domain tensions between theory and practice is to alter the selection process of the domains themselves. Specifically, the world of theory would have to encourage, reward and embrace practical value as much as it does novelty. Conversely, the world of practice would have to encourage, reward and embrace novelty as much as it does value.

How could this ever be accomplished? The answer is deceptively simple in conception but extremely difficult in implementation. Frankly stated, it involved introducing resource dependencies that reward academics for value and practitioners for novelty. That is, universities should alter their current reward system to encourage publications in trade magazines and popular managerial outlets. Right now, the correlation between faculty salary and publication records in top-tier academic journals is skewed and should be balanced. Further, activities such as designing practicum and supervising internships, all of which foster a keener

sense of appreciation for the challenges faced by businesses, should be explicitly acknowledged and rewarded.

For firms, the answer lies less in promoting creativity than in not punishing it. Organizations will always reward those who control costs and oversee smooth operations. Such is to be expected whenever large-scale strategic directions require careful administrative support. The problem is that those who do take risks or recommend novel processes are discouraged by red-tape and territorial defenses, and can even be shunned or marginalized. As a result, a kind of organizational level ‘groupthink’ occurs where those who have truly creative ideas do not even bother advancing them. This kind of creativity malaise is not uncommon; how many executives tell tales of shelving great ideas because of the resistance they engendered? Firms need to offer mechanisms by which such individuals can advance their ideas in a non-threatening forum and, if adopted, enable their quick and fluid implementation.

Conclusion

The same processes that alter the selection mechanisms of a domain can also create a different path, one where creative action is central to the interests and identity of employees and the organization. Neo-evolutionary processes related to creativity have been described by both Ford’s (1996) and Drazin, Glynn & Kazanjian’s (1999) theories of organizational creativity. These theories adhere to the requirements of *co-evolution* research by describing multilevel processes, multidirectional causality, nonlinear processes, positive feedback processes, and path and history dependence (Lewin & Volberda, 1999).

Thinking of creative action in this light raises an interesting ‘chicken and egg’ problem. Which comes first: a creativity-friendly environment that nurtures the talents of would-be creators, or creative actions that test the boundaries of legitimate behavior and reveal the true character of the environment? Co-evolution theory suggests that one must consider recursive influences that are path-dependent and prone to rapid escalation. In the context of creativity research, one must simultaneously consider how individual behavior shapes proximal and distal features of the work environment, and how the environment shapes individual behavior, and how these reciprocal influences evolve over time.

The final hope for resolving between domain tensions so as to harmonize the interdependent advantages of theory and practice, novelty and value, lies, paradoxically, in macro-managing the environmental selection pressures. We say paradoxically because we built this paper around the premise that innovation begins with an act of individual creativity. However, we also argued that that creativity does not occur in a

vacuum, but rather is intimately linked with the context in which it takes place. The creation of that context, and thus the triggering of the co-evolutionary processes described above, is a matter of organizational structure, policy, reward systems and culture. Unlike in the biological realm, organizational environments can be consciously managed. And they must be, if innovation is the objective.

E-Creativity and E-Innovation

Keng Siau

College of Business Administration, University of Nebraska-Lincoln, USA

Abstract: Creativity, most people tend to assume, is inborn, mysterious, unanalyzable, and unteachable. Psychologists have been trying to understand this phenomenon for decades. The literature is overwhelmed with inconsistent theories and hypotheses. Lately, development in artificial intelligence has provided researchers with another means of analyzing the creative process. In this chapter, we review some of the work in this area and discuss some approaches for e-creativity.

Keywords: Creativity; Innovation; E-Creativity; E-Innovation.

Introduction

May 11, 1997 is a milestone in computer evolution. On that day, Garry Kasparov, who had never lost a chess match, conceded defeat for the first time ever to a chess-playing computer—IBM's Deep Blue computer. After losing the first game in the match, the Deep Blue IBM computer won in game two, and managed draws in games three, four, and five. In game six, a game lasting only an hour, Deep Blue won the game by dominating on the board and capturing Kasparov's queen. The final score was 3.5 points for Deep Blue and 2.5 for Kasparov. The match drew worldwide attention, not only because 34-year-old Kasparov was widely considered the greatest chess player ever, but also because of its compelling man-vs.-machine theme.

With the win by Deep Blue, a few age-old questions are popping up again. Are computers good enough to substitute for human beings? Can computers be creative? In this chapter, we look at the quest for electronic-creativity, e-creativity or e-innovation. E-creativity relies on Artificial Intelligence (AI), which emphasizes defined operations that can yield the same sorts of ideas that are produced by creative human beings. Some of the e-creativity efforts and projects are reviewed in this chapter, and some criteria that are necessary for e-creativity are discussed.

What is Creativity?

Creativity is an important, but elusive, phenomenon (Siau, 1995, 1996, 1999, 2000). Different writers have different expressions for this moment of insight and for

the process leading to it. Gestalt psychologists named it the 'Aha' experience. Pearce (1971) called it 'the crack in the cosmic egg'. Bruner initially referred to it as the 'empty category' (1956) and later as 'thinking with the left brain' (1962). Guilford (1959) and de Bono (1970) have used the broader terms 'divergent thinking' and 'lateral thinking', respectively, to refer to the process by which new ideas are generated.

Since the beginning of civilization, people have been amazed by one of our most precious abilities—creativity. Greek philosophers, such as Plato, Socrates, and Aristotle, occasionally discussed creativity in their philosophical account. For instance, Plato valued creative creation as a result of inspiration, which can only be activated by divine power. Plato saw creative activity as a topic that cannot be subjected to rational analysis.

The word 'creativity' has long been associated with mysticism. Koestler (1975) wrote about creativity:

The moment of truth, the sudden emergence of a new insight, is an act of intuition. Such intuitions give the appearance of miraculous flashes, or short-circuit of reasoning. In fact they may be likened to an immersed chain, of which only the beginning and the end are visible above the surface of consciousness.

Creativity is also defined in many other different ways. For example, Torrance (1970) defined creativity as the process of sensing gaps or missing elements, and forming ideas or hypotheses concerning them. Boden (1996) identified two senses of being 'creative'. One is psychological creative (P-creative) and the other is

historical creative (H-creative). The psychological sense refers to ideas that are fundamentally novel with respect to the individual that has the idea. For example, if John comes up with the idea of the wheel for the first time (he has not heard or seen a wheel before), his idea is P-creative—no matter how many people had the same idea before him. The historical sense applies to ideas that are fundamentally novel with respect to the whole human history. In this case, John's invention is H-creative only if no one has ever had that idea before him. By definition, all H-creative ideas are P-creative too.

Boden (1996) also defined two types of creativity—the *improbabilist* and the *impossibilist*—and further summarized how creativity works along this dimension. The *improbabilist* creativity involves combinations of familiar ideas to give a 'statistically surprising', or improbable, new idea. Several AI models that fit into this framework of *improbabilist creativity* are the analogy-based model, the associative-based model, and the induction-based model. *Impossibilist* creativity, however, centers on the formation of new ideas that could not have emerged in the current state of the domain. According to Boden, *impossibilist* creativity involves the transformation of conceptual spaces (paradigm-shifting creativity).

The Birth of E-Creativity

Cognitive psychologists did not start to explore the internal realm of mind and the operations involved in creative thinking until the invention of the von Neumann machine. Researchers in artificial intelligence (AI), especially Herbert Simon and Allan Newell, pushed forward these explorations. Newell (1990) proposed *the unified theory of cognition*. Langley et al. (1987) used the process-tracing technique to access the thought process of individuals involved in creative thinking to formulate hypotheses and to write computer programs to mimic the related process for problem-solving in various domains. Boden (1989, p. 2) described the computational psychologists as people who:

adopt a functionalist approach to the mind ... conceive of the mind as a representational system, and see psychology as the study of the various computational processes whereby mental representation are constructed, organized, interpreted, and transformed ... think about neuroscience ... in a broadly computational way, asking what sorts of logical operations or functional relations might be embodied in neural networks ...

The computational concepts developed by AI-researchers are now influencing more traditional disciplines such as psychology. The next section introduces AI and some of its approaches.

AI—An Enabling Technology

AI studies how the computer can be programmed to achieve intelligent attributes of human beings. With a goal to explain what the mind is and how it works, AI is closely related to cognitive psychology. It has created new approaches for creativity studies, and its computational concepts have shifted the fundamental focus from the external measurements of creativity to the internal description of processes involved in creative activities. Three of the popular approaches in AI are: classical/symbol-system AI, neural networks, and genetic algorithms.

Classical/Symbol-System AI

The central assumption that leads to classical AI is *the physical symbol system hypothesis* proposed by Newell and Simon (1976, p. 116):

A physical system consists ... symbols ... contains a collection of processes that operate on expressions to produce other expressions ... A physical symbol system is a machine that produces through time an evolving collection of symbol structures ... has the necessary and sufficient means for general intelligent action.

Classical AI has a diverse research scope and application domains. They vary from planning, game-playing (e.g. chess), general or expert problem-solving to theorem-proving, perception, and natural language understanding. Because knowledge is essential for intelligent reasoning, and processes are required to manipulate the knowledge, knowledge representation and processes are the two issues in classical AI systems. A number of techniques for knowledge representation are available in AI. They include semantic networks, scripts, frames, rule-based systems, and several others.

The most successful and widely used classical AI architecture is the rule-based production system. Most of the existing e-creativity programs are based on this technique. A production rule typically takes the form of:

```
IF conditions are true
THEN some actions
ELSE some other actions
```

An inference engine is used to realize the reasoning of the production-rule systems. It employs two approaches in the reasoning process: backward chaining and forward chaining. In backward chaining, a specified goal is used to select rules in the knowledge base, which will in turn call for additional information and eventually work backward to information that is available to the system. Forward chaining, however, is an inference method in which known facts are used to select rules, which will provide additional facts and thus, eventually, the solution to the problem.

Neural Networks

Neural networks, or connectionist systems, are parallel processing systems with computational properties that are modeled after the human brain. They are based on a theory of association (pattern recognition) among cognitive elements (Baer, 1993). To mimic the human cognitive processes, connectionist systems are not programmed, but are designed to learn from experience by 'self-organization'. The connectionist paradigm maintains that what appears to be lawful cognitive behavior may in fact be produced by a mechanism in which symbolic representations are unnecessary—no rules are "written in explicit form anywhere in the mechanism" (Rumelhart & McClelland, 1986). An example of simple connectionist architecture is shown in Fig. 1.

The key to understanding connectionist architecture is the 'hidden units'—units that are neither input nor output. Unlike the intermediate states of computation in symbolic accounts, these units represent uninterpretable states of the system. That is, the patterns of connections and interactions between the hidden units cannot be expressed in the form of rules or propositions. In other words, the 'meaning' of these units and their various combinations cannot be stated in words.

Connectionism can be approached in two ways. First, it can be considered simply as a way to implement production systems. The learning that takes place in a connectionist system is an induction of rules, which, although not stated formally as rules, operates on inputs in the same way that rules in a production system operate on symbols. The set of weights that the system derived, in this 'weak' connectionist scenario, would simply be the program's coding of the 'explicit inaccessible rules' (Rumelhart & McClelland, 1986).

Second, the connectionist model may be used to replace existing symbolic-processing models as the explanations of cognitive processing. This is an extreme claim made by many connectionists, and it is this claim ('strong' connectionism) that caused the most interest and controversy (Churchland, 1988, 1989; Pinker & Prince, 1988; Smolensky, 1988).

Figure 1. A simple connectionist architecture.

Figure 2. The genetic algorithm cycle.

Pinker and Prince termed this strong connectionist claim 'eliminative connectionism'.

Genetic Algorithms

Genetic algorithms are general-purpose search algorithms that use principles inspired by natural population genetics to evolve solutions to problems. The basic idea is that over time, evolution will select the 'fittest species'. In this sense, genetic algorithms emulate biological evolutionary theories to solve optimization problems. The central loop of the genetic algorithm is depicted in Fig. 2.

- Select pairs from the set of classifiers according to their strengths—the stronger a classifier is, the more likely it is to be selected.
- Apply genetic operators to the pairs, creating 'children' or 'offspring'. These genetic operators perform the role of variation. Chief among the genetic operators is crossover, which simply exchanges a randomly selected segment between the pairs. The other operators, such as mutation and inversion, have lesser roles, mainly providing 'insurance' against overemphasis on any given kind of schema.
- Replace the weakest classifiers with new offspring.

Attempts at E-Creativity

Several approaches have been attempted to implement e-creativity. Some of them are discussed below.

- Generative grammars:** Generative grammar systems use a predefined grammar to specify the way the output is to be generated. The grammar is specified as a set of production rules. For example, Rumelhart (Rowe & Patridge, 1993; Rumelhart, 1975) used the following for a story grammar:

Story → setting, episode
 Setting → time, place, characters
 Episode → event, reaction

Then the story is built in a top-down fashion by replacing story with setting and episode, replacing setting with time, place, and characters until everything becomes irreplaceable, or terminals (in

this case, words and phrases). The system can use random selection for the replacement to produce different stories each time the system is executed. The weakness of this system, according to Rowe & Patridge (1993), is the rigidity of the grammar. For example, the stories generated using the grammar described above always have a fixed structure of story line. Other examples of generative-grammar systems are Rumelhart's story-writer (Rumelhart, 1975), TALE-SPIN (Meehan, 1981), Johnson-Laird's jazz improviser (Johnson-Laird, 1987), AARON (McCorduck, 1991), MINSTREL (Turner, 1992), and EMI (Cope, 1991).

- (b) *Analogy-based systems*: Koestler (1964) asserted that most of the so-called creative scientific progress sometimes is a discovery of novel analogy with another unrelated domain. Gentner's Structure Mapping Theory (SMT) (1989) proposed that an analogy could be formed by mapping objects/concepts and their relations to one another. A computer model, called the Structure-Mapping Engine (SME) (Falkenhainer et al., 1989) was constructed to prove Gentner's theory. Other examples of analogical problem-solver include processes of induction (PI) (Holyoak & Thagard, 1989a, 1989b, 1994), and Copycat (Mitchell, 1993).
- (c) *Meta-rules*: Meta-rules are 'rules to control rules'. In other words, they are used to create, delete, or modify rules in a system. The reason for using meta-rules is that the rules in a rule-based system are often so rigid that they constrain the behavior of the system. Meta-rules can be used to provide variations to the governing rules of the system so that new behavior can emerge. For example, the grammar rules in a story-generator limit the possible story lines that the generator can produce. Meta-rules can be introduced to modify some of these rules to provide new variations of storylines. For example, Meta-DENDRAL is an add-on module to an expert system DENDRAL (Lindsay et al., 1993). DENDRAL is an expert system used to assist the chemists in molecule decomposition analysis. The purpose of Meta-DENDRAL is to find possible decomposable molecules. Although Meta-DENDRAL has been very successful in its domain (i.e. it H-created some new rules in molecule decomposition), Boden (1996) argued that its success comes from the highly sophisticated chemical knowledge of DENDRAL. Other systems that make use of meta-rules are MU.S.CA-DET (Paestre, 1989), and DAY-DREAMER (Muller, 1987).
- (d) *Discovery systems*: A discovery system works to discover new information from a given input. Examples of such systems are BACON (Langley et al., 1987) and AM (Davis & Lenat, 1982). BACON is able to find a theory (formula) to explain a set of

data. Given a set of measurements of several properties, BACON can find relationships of these properties and produce a formula that fulfills the measurements. For example, Kepler's laws are rediscovered when measurements of planetary coordinates and trajectories are given to BACON as input. Other laws rediscovered by BACON are Boyle's law and Ohm's law. Rowe & Patridge (1993) described this as an "ad hoc curve-fitting exercise" because BACON never uses any semantic constructs like models or structures to achieve its goal. Langley's (1987) team developed GALUDER, STAHL, and DALTON based on BACON concepts.

AM works to form new mathematical concepts given a set of initial mathematical concepts and heuristic rules to discover and judge the importance of the concepts. In AM, a mathematical concept is represented as a frame with slots such as definition, examples, domain, and range. A concept can be another concept's example. Some slots in the initial concepts are purposely left blank for AM to fill in appropriate items. AM will occasionally create some new concepts in the process of filling these slots. New concepts are then added into its concepts pool and the process goes on until AM finds 'nothing interesting'. With the initial set of concepts like sets, lists, ordered pairs, intersection, union, and canonization, AM discovers natural numbers, addition, multiplication, primes, prime factorization, and Goldbach's conjecture.

- (e) *Decentralized systems*: A decentralized system is generally defined as a system without a central control mechanism. It might contain several independent (homogeneous or heterogeneous) modules/agents interacting with each other to achieve global-level behavior (emergent behavior). An example of such a system is Copycat (Mitchell, 1993). Copycat generates an analogy for strings of alphabets. For example, given an input such as:

If $abc \rightarrow bca$, then $def \rightarrow ??$

Copycat can produce strings that will fulfill the analogy. The internal mechanism of Copycat is quite complicated. It uses a network of permanent concepts (slipnet), such as leftmost, rightmost, middle, same, group, alphabetic successor, and alphabetic predecessor to create a relationship map of the input structure. Weights are assigned to the links of the network of permanent concepts and used to determine the possible solutions. Then parallel processing among structuring agents (codelets) determines the final solution(s). Another example of this approach is Letter Spirit (Hofstadter & McGraw, 1993).

- (f) *Induction-based systems*: Induction includes inferential processes that expand knowledge in the face

of uncertainty. The study of induction-based machines in computational creativity assumes that the key to creativity lies in the ability to learn (i.e. see Shank & Childers, 1988). Thus, induction-based systems are intimately associated with learning and self-improving machines. Examples of such systems are PI (Holyoak & Thagard, 1989a, 1989b, 1994) and Copycat (Mitchell, 1993).

Criteria for E-Creativity

The formal study of creativity as a science started under the name of cognitive psychology. Guilford's theory of divergent thinking (1950) was probably one of the most influential theories on creativity. Guilford claimed that there is no such thing as general intelligence that enables 'general creativity' in any domain. He proposed four criteria that are considered important to divergent thinking: fluency, flexibility, originality, and elaboration.

- (a) Fluency—the ability to produce a large number of ideas
- (b) Flexibility—the ability to produce a wide variety of ideas
- (c) Originality—the ability to produce unusual ideas
- (d) Elaboration—the ability to develop/embellish ideas, and to produce detail

In his quest for a general, domain-transcending theory that would account equally well for creativity irrespective of the task domain, Mednick (1962) proposed five factors that are critical for creativity to occur:

- (a) Domain-specific knowledge
- (b) Numbers of associations generated, not generation speed
- (c) Differences in cognitive or personality styles
- (d) Selection of creative combinations
- (e) Associative hierarchy—how associations are organized

In their attempts to move from general creativity to computational creativity, Rowe & Partridge (1993) surveyed psychological theories of human creative behavior and proposed five characteristics required for e-creativity to occur:

- (a) Organize knowledge in such a way that the number of possible associations (the creative potential) is maximized.
- (b) Allow for ambiguity in representations. The programs should, under appropriate circumstances, accept the generation of seemingly incorrect associations in order to build connections between concepts.
- (c) Enable multiple representations. A single concept should not just be appropriate in one situation. Rather, a concept should be indexed to many

situations. This would help to avoid the problem of functional fixity.

- (d) Evaluate new combinations. New combinations should be examined and their usefulness assessed.
- (e) Elaborate new combinations to elicit their consequences.

Discussion

Based on prior studies and a literature review, we categorized the criteria for e-creativity into knowledge representation, randomness, and learning.

- (a) *Knowledge representation*: Knowledge representation refers to the way knowledge is represented so that it can be processed efficiently and effectively by the functioning system. Most of the researchers in computational creativity agree that knowledge must be represented in the most flexible way for the functioning system to manipulate it efficiently. Boden (1990) argued that a creative system needs a multilevel internal map of its 'conceptual space' (knowledge schema), so that the system can explore the map in a flexible and efficient manner or even transform the 'conceptual space' to enable *impossibilist* creativity. Minsky (1990), however, suggested using several different representations in a system to compensate for deficiencies in each of the knowledge representation schemes.
- (b) *Randomness*: Randomness can be used to produce ambiguous behaviors and to provide a certain level of novelty in the output of the system. Racter is an example of such a system. Racter constructs sentences, poems or stories using 'syntax directives' and random selections from words and phrases. Such systems, however, might surprise the reader by its creation only for the first time. The 'creative' impression of Racter does not last long. Rowe & Partridge (1993) argued that randomness is not *sufficient* for creative behavior. Yazdani (1989) also reported that pure randomness will only produce interesting output by chance, with all other output being useless. He claimed that randomness should be used by artists and scientists as a starting point for generating a large decision space. Boden (1990) reported that if a random process happens to produce creative output, it can only result in 'first-time curiosity'. Other examples of systems that use randomness are Johnson-Laird's jazz improviser (Johnson-Laird, 1987) and TALE-SPIN (Meehan, 1981). In short, randomness helps to 'think outside the box' but is not sufficient, by itself, to produce sustain creative behavior.
- (c) *Learning*: Learning is viewed as an important criterion in computational creativity. Systems that are capable of making changes in and by themselves over time, with the goal of improving their performance on the tasks in a particular environment, are more interesting than systems that are

not capable of such changes. Neural networks and genetic algorithms are two popular approaches for achieving learning. Most of the existing learning systems, however, based their performance on factors such as minimizing costs and maximizing profits. For computational creativity, we are more interested in generating new and unpredictable outcomes.

Conclusion

To attribute creativity to divine inspiration, or to some unanalyzable power of intuition, is to suffer from a paucity of ideas. Even to describe it as the work of the unconscious or subconscious mind, or as a combination of old concepts in new ways, does not get us very far. But, surprising as it may seem, we can build creative programs and study their characteristics. E-creativity has the potential to shape the future of innovation.

The Art of Innovation: Polymaths and Universality of the Creative Process

Robert Root-Bernstein

Department of Physiology, Michigan State University, USA

Abstract: Many people view arts and sciences as being different because sciences yield objective answers to problems whereas arts produce subjective experiences I argue that art and science are on a continuum in which artists work with *possible* worlds whereas scientists are constrained to working in *this* world. But sometimes perceiving this world differently is the key to making discoveries. Thus, arts and sciences are on a continuum in which artistic thinking produces possibilities that scientists can evaluate for efficacy here and now. Not surprisingly, then, many of the most innovative scientists have had avocations in the arts, and some of the most innovative artists have had avocations in the sciences. These polymaths have often written or spoken about how their arts involvements have benefitted their scientific creativity and may provide a model for fostering a more innovative education.

Keywords: Innovation; Polymathy; Arts/science; Creative process; Avocations; Hobbies.

Introduction: The Universality of Creative Thinking

Innovation in science and engineering is often portrayed as if it were distinct from that in the fine arts, perhaps because most definitions of innovation center on the idea of *effective problem-solving*. Science and engineering are supposed to be objective, intellectual, analytical, and reproducible so that it is clear when an effective solution has been achieved to a problem. The arts, literature, and music, by contrast, are portrayed as being subjective, sensual, empathic, and unique, so that it is often unclear whether a specific problem is being addressed, let alone whether a solution is achieved. It therefore comes as a considerable surprise to find that many scientists and engineers employ the arts as scientific tools, and that various artistic insights have actually preceded and made possible subsequent scientific discoveries and their practical applications. These trans-disciplinary interactions must cause us to reconsider how we think about innovation.

There are four important ways in which innovative ideas flow between the professions. One is through problem generation (see Root-Bernstein, 'Problem Generation and Innovation' in this volume). The arts often invent or discover phenomena and observations unknown to the sciences. A second role that the arts

play is to provide scientists and engineers with non-traditional physical and mental tools, analogies and models that can be used to solve problems. More on this below. Third, the arts often provide scientists with the tools necessary to communicate their results—with the considered use of words, images, and modeling techniques necessary to reify ideas as theories and explanations. The aesthetic portrayal of results in the sciences is just as important as in the arts and relies upon the same tools. And finally, the arts contribute to scientific innovation through *fantasy*, that is to say, through *the generation of possible worlds* that scientists can test according to the constraints of what is known about the real world. This fourth type of sciences–arts interactions is the one most often overlooked and of the widest application to understanding innovative thinking in general.

All real-world innovation is a process that involves the elaboration through fantasy (sometimes called imagination) of many possible solutions to any given problem, and the use of the widest range of mental and physical tools to constrain and evaluate which of these possibilities is most adequate to any given need. In this sense, all innovation is a process of survival of the fittest in which multiple variations of ideas are selected by social, economic, cultural and other factors

(Nickles, this volume; Root-Bernstein, 1989). What the arts provide the sciences is the ability to imagine possibilities—possible problems, possible tools, possible solutions—through synthetic and sensual forms of thinking to which analytical and logical forms of thinking can later be applied as part of the selection process. In short, I maintain that effective solutions to problems (i.e. innovation or creativity itself) can only be achieved if a *range* of possible solutions have been elaborated that can be examined for their relative effectiveness. Arts foster sciences and technology by elaborating possible worlds that can be evaluated for the insights they provide to the real world.

Note at the outset that I am not claiming that art is science or science, art. A painting is not usually a scientific diagram; each has distinct purposes and goals. A short story is not usually a scientific paper and no intelligent person could confuse them under most circumstances. A sculpture is not usually equivalent to a molecular model, nor do they have the same functions. But sometimes they do.

Sometimes what an artist imagines might be possible turns out to be what actually is. Unexpectedly, a painting can sometimes be a way to generate scientific ideas; fiction can explore and even propose new scientific theories; and sculptures can be scientific or mathematical models. The purpose of this essay is to argue that there exist fundamental connections between sciences and arts that provide non-trivial windows onto the gardens of the mind where innovative thinking is cultivated.

The key to understanding my approach to innovative thinking in the arts and sciences is to distinguish clearly between disciplinary products and trans-disciplinary processes. I believe, along with Koestler (1964), Bronowski (1967), and many others including Weisberg in this volume, that no distinction exists between the arts and sciences at the level of the creative process itself (Root-Bernstein, 1984, 1989). The ways in which artists and scientists discover and invent problems, experiment with ways to come to grips with them, and generate and test possible solutions is universal. In fact, most of the greatest innovators in every discipline have been polymaths—Renaissance people like Leonardo da Vinci—who demonstrated their creative abilities in several fields of endeavor. Thus, I propose that creative people are generally creative, and their general creative ability comes from mastering a common set of thinking tools (see Root-Bernstein & Root-Bernstein, 'Intuitive Tools for Innovative Thinking' in this volume) and a creative process that is similar across all disciplines. This point can be made particularly effectively through examples of artists who have made scientific discoveries, scientists who have made artistic contributions, and those who bridge both sets of disciplines without claiming allegiance to one or another. As rare as such examples may be (I will argue that they are unexpectedly

common), the very fact that polymaths make trans-disciplinary discoveries should warn us against making too-easy distinctions between disciplines or cognitive domains. On the contrary, I will argue that those people who incorporate (in a quite literally visceral way) modes of thinking belonging to many cognitive domains are those most likely to become innovators.

Polymathy as a Predictor of Success

Santiago Ramon y Cajal, one of the first Nobel Prize Winners in Physiology or Medicine, is remembered today for his ground-breaking work on neuroanatomy. He was also a talented artist and photographer who attributed much of his scientific success to these avocations. Not only did he proclaim that, "it is not without reason that all great observers are skillful in sketching", but he also avowed that only through neuroanatomical studies were his strong "aesthetic instincts" satisfied by the "incomparable artistic emotions" he experienced. Ramon y Cajal recognized that his polymathic tendencies were unusual, but asserted in his autobiography that the most successful scientists were, like him, "endowed with an abundance of restless imagination spend(ing) their energy in the pursuit of literature, art, philosophy, and all the recreations of mind and body. To him who observes them from afar, it appears as though they are scattering and dissipating their energies, while in reality they are channeling and strengthening them" (Ramon y Cajal, 1951, p. 171). To be creative, Ramon y Cajal said, one had to have wide experience with the process of creating.

A surprising number of his contemporaries agreed. Charles Richet, another Nobel laureate and a celebrated playwright, wrote: "Generally those who later become illustrious (in science) have shown from the first, by their aptitude for history, science, literature, languages, that they were superior to their contemporaries" (Richet, 1927, p. 128). Similarly, J. H. van't Hoff, the first Nobel laureate in Chemistry (1901) and himself a musician and poet, proposed that the development of the scientific imagination requires the development of artistic, musical, and poetic talents. In a famous address on 'Imagination in Science' (van't Hoff, 1878), he listed dozens of examples of eminent scientists who were multiply talented, including such notables as Kepler (a musician), Galileo (an artist), Davy (a poet), and Pasteur (another artist). He concluded his address by arguing that often the poetic vision outstrips the scientific showing the latter the way to the truth. This is a point to which I shall return below.

Many of van't Hoff's contemporaries saw the same connections between artistic proclivities and scientific success that he did. Van't Hoff's friend and colleague Wilhelm Ostwald produced a large body of work on scientific genius that validated the polymathy hypothesis (Ostwald, 1909). The English polymath, Francis Galton found that polymathy was unusually common

among members of the British Royal Society (Galton, 1874). Botanist P. J. Moebius, the grandson of the famous mathematician, and the Frenchman Henri Fehr both noted independently the unusually high incidence of artistic and musical proclivities among two large groups of mathematicians (Fehr, 1912; Moebius, 1900). Jacques Hadamard confirmed these findings several decades later in his classic, *The Psychology of Invention in the Mathematical Field* (Hadamard, 1945). All of these studies were summarized by the Nobel laureate and pianist Max Planck when he suggested that scientific success depends upon the use of an 'artistic imagination' (his emphasis; Planck, 1949, p. 14).

When so many successful scientists all say that artistic imagination fosters good science, one must wonder whether it might not be true. In fact, a large body of psychological literature supports the hypothesis that polymathy is correlated with career success. For example, Stanford psychologist Lewis Terman, the father of the Stanford Binet IQ test and one of the foremost investigators of high achievers, wrote in 1941 that: "While the versatility of geniuses has long been stressed by biographers (e.g. of Da Vinci), the less spectacular cases are usually overlooked. People prefer to believe that the genius, as a rule, is no better than the rest of us except in one particular. The facts are very different . . . there are few persons who achieved great eminence in one field without displaying more than average ability in one or more other fields" (Seagoe, 1975, p. 221). His conclusion was based upon decades of study of high achievers followed from their school days well into their careers, much of it published by his collaborator Catherine Cox. He also drew on studies of historical figures carried out by his colleague R. K. White. Analyzing hundreds of historical figures, White had found that "the typical genius surpasses the typical college graduate in range of interests and . . . he surpasses him in range of ability" (White, 1931, p. 489). Similarly, historian of science Paul Cranefield found that there was a direct correlation between the eminence a scientist achieved and his range of activities. The number of avocations practiced by a scientist correlated with the number of different scientific areas in which he worked. The number of different areas in which each scientist worked correlated with the number of significant discoveries they made. And the range and nature of the subjects that a scientist addressed in their research correlated with their cultural and philosophical avocations (Cranefield, 1966).

Subsequent cognitive studies have tended to validate the notion that the versatility of genius provides useful mental skills. For example, studies by Rauscher et al. and Gardiner et al. have suggested that direct relationships may exist between art and musical skills and improved spatial and mathematical reasoning in children (Graziana, Peterson & Shaw, 1999; Gardiner et

al., 1996, p. 284; Rauscher, Shaw & Ky, 1997). Similar results exist for adults. An 11-year follow-up of participants in Project TALENT by Humphreys et al. (1993) has shown that in college students neither high grades nor high scores on verbal and mathematics tests are predictive of future participation or success in engineering and physical sciences. High scores on spatial and mechanical comprehension tests were, however, predictive, especially when combined with high mathematics scores. Schaer et al. (1985), Woody Flowers at MIT, and various other investigators (Stewart, 1985) have shown that it is possible to train scientists and engineers through explicit visualization and drawing exercises to improve their imaging and modeling skills, thus bringing the arts–sciences connection full circle.

Avocations can be as useful in training the creative mind as can formal classwork. Students who develop artistic skills through natural inclination tend to have much improved success in all careers according to a huge, long-term study of Israeli professions carried out by Milgram et al. (1993). They found that high IQ, standardized test scores, and high school grades were not good predictors of career success either independently or as aggregate measures. The best single predictor of success in any field, including the sciences, was participation as an adolescent in what Milgram calls "challenging leisure-time activities", i.e. avocations that require significant intellectual and time commitments. These include music performance and composition, painting, drawing, photography, chess, electronics, programming as a hobby, and creative writing, among others. These activities appear to be surrogate measures not only of intellectual ability, but energy, self-motivation, task commitment, cognitive breadth, and other attributes that strongly influence success.

Continued participation in the arts as an adult is also highly predictive of success as a scientist. A convenience sample of 40 scientists recruited by Bernice Eiduson in 1955 for a psychological study was analyzed by Root-Bernstein et al. in 1988 (Root-Bernstein, Bernstein & Garnier, 1993). By then, the group included four Nobel laureates, 11 members of the National Academy of Sciences (USA), many typical university professors, as well as several individuals who left academia for industry. Two measures of success were employed: impact (the ratio of citations to publications) and citation cluster (people with one or more papers having more than 100 citations over a 15 year period; people with one or more papers having between 10 and 100 citations in a single year; people with one or more papers having between 10 and 100 citations over 15 years; and people who met none of the previous criteria). The Nobel laureates were all in the top impact group and citation cluster, as were most of the National Academy members. Statistically significant correlations were found between success as

measured by impact ratio and participation as an adult in painting, drawing, and sculpting. Significant correlations were found between success as measured by citation cluster and painting, collecting art, writing poetry, photography, crafts, singing, and most strongly with the sum of all hobbies. In short, these correlations validated the anecdotal evidence collected by Ramon y Cajal, Richet, van't Hoff and so many other Nobel laureates (Root-Bernstein et al., 1995).

Root-Bernstein et al. (1995) also found that statistically significant correlations existed between various hobbies and the modes of thinking that the scientists reported using during their scientific work. Artistic scientists tended to be visual and imageless-nonverbal thinkers whereas musicians were predominately visual thinkers. The link found between music training and improved visualization by Graziano et al. (1999), Gardiner et al. (1996) and Rauscher et al. (1997), therefore seems to extend into adulthood. Sculptor-scientists were mainly imageless-nonverbal and kinesthetic thinkers. Writer-scientists, not surprisingly, were mainly verbal thinkers; and those who participated in electronics-related hobbies tended to use the widest range of modes of thinking. How we think about problems therefore seems to be a function of what mental skills we develop through practice. Moreover, modes of thinking were independently correlated with measures of scientific success. Success as measured by impact ratio correlated significantly with visual thinking, use of verbal/auditory patterns, kinesthetic thinking, and other unusual forms of thinking such as use of word images, acoustic images, and talking to oneself. Success as measured by citation clusters, however, correlated most strongly with use of visual images, and visualized symbols and words.

These results do not distinguish between three non-exclusive possibilities. First, the most successful scientists may simply be very bright people who could succeed at anything. Second, innate talents are expressed in both scientific style and avocations. And third, practice using certain modes of thinking leads to skill development that is trans-disciplinary. Interviews with the scientists lead me to favor the latter hypotheses. The most successful scientists all perceived the sciences and arts to be complementary or compatible, as opposed to the less successful, who saw them in conflict. Some of the most successful went on to describe, like Ramon y Cajal, ways in which their avocations stimulated their scientific acumen.

I am not claiming that to become a successful scientist one *must* cultivate the arts, music, or literature. There are many ways of learning how to think visually, kinesthetically, and by analogies, including the practice of science itself. In fact, until recently, both free-hand and mechanical drawing, model building, and writing were integral parts of many science and engineering curricula. But due to larger classes, fewer labs, and monetary restrictions, arts and crafts programs now

retain almost exclusive hegemony over such skills. Still, their continued necessity in science and engineering training has been urged in books as varied as Eugene Ferguson's *Engineering and the Mind's Eye* (Ferguson, 1992), Cyril Stanley Smith's *A Search for Structure* (Smith, 1981), Geri Berg's *The Visual Arts and Medical Education* (Berg, 1983), Phillip Ritterbush's *The Art of Organic Forms* (Ritterbush, 1968), and my own *Discovering* (Root-Bernstein, 1989). All of these studies tell us that artistic scientists and engineers have more image-ination, musically talented ones duet (do it) better, and the verbally inclined have the skills to become pundits. Seriously. Being cultured is still a prerequisite to being educated, and education is still a requirement for being successful.

The Uses of Arts by Scientists

The fact is that scientists and inventors not only explore the arts as avocations, but use them in their professional work (Root-Bernstein, 1985, 1987, 1990, 1997, 2001). Astrophysicist and novelist Gregory Benford points out, "Many believe that science fiction (SF) writers get their ideas from science and often this is so. Fewer recall that ideas have also flowed the opposite way" (Benford, 2001, p. 1). The Russian rocket pioneer Konstantin Tsiolkovsky was inspired to begin inventing by the works of Jules Verne; Leo Szilard took out the first patent on nuclear reactors after reading a short story by H. G. Wells about the potential for unlocking the energy stored within the nucleus of atoms; and Benford himself explores in his fiction the ideas that he cannot carry out as a scientist.

The use of fiction to explore novel scientific ideas is hardly rare. Robert L. Forward, an astrophysicist and inventor who is also an award-winning science fiction writer, says of his work: "Those of (my) far-out ideas which can be accomplished using present technology (I) do as research projects. Those that are too far out (I) write about in speculative science articles or develop in (my) short stories and novels" (Forward, 1985, book-jacket). Forward insists that his science and his fiction are on a continuum, his fiction simply consisting of the ideas that are currently beyond his means to implement. That does not mean that these ideas are any less valuable or insightful. As science fiction writer Jeff Hecht notes, "Fictional inventions take real skill and some prove truly prescient" (Hecht, 1999, p. 59). Recognition that important innovations are foreseen by scientific novelists has now become so explicit that the European Space Agency recently announced that they are scouring science fiction for new space propulsion technologies (Anon., 2000, p. 41). Similarly, corporations such as Global Business Network hire scientist-novelists such as computer innovator Vernor Vinge because they provide "an unbelievably fertile perspective from which to look back at and reunderstand the present. It's that ability to conceptualize whole new ways of framing issues He has

contributed to the turnarounds of at least two well-known technology companies” (Hafner, 2001, D9).

Poetic scientists find similar connections between their poetry and their science. Words are scientific tools just as much as they are artistic ones, and therefore the exercise of words can be as enlightening to a scientist as to a writer. Thus, Nobel-prize-winning chemist Roald Hoffmann says that, “I begin with a vision of unity of creative work in science and in the humanities and arts . . . I have no problem doing (or trying to do) both science and poetry. Both emerge from my attempt to understand the universe around me, from my own personal affection for communicating, teaching what I’ve learned, and from my infatuation with language . . . It seems obvious to me to use words as best I can in teaching myself and my coworkers. Some call that research . . . The words are important in science” (Hoffmann, 1988, p. 10). Similarly, physician and poet Jack Coulehan maintains that writing poetry makes him a better physician: “Both disciplines require careful observation. Both focus on the concrete—an illness, an event, a feeling—over the abstract. In fact, William Carlos Williams’ famous aphorism about poetry, ‘No ideas but in things’, is also a good prescription for medical practice . . . Moreover, a physician’s ability to empathize with a patient is a creative act analogous to the poet’s act of exploring the subject of a poem . . . (And), like poetry, medicine achieves much of its powerful effect through the use of symbol and metaphor” (Coulehan, 1993, p. 57). To learn how to manipulate images and feelings through the words of a poem is therefore, according to Hoffmann and Coulehan, to learn how to manipulate the images and feelings that are expressed in scientific symbols as well. Equally important, learning to manipulate language teaches verbal imagination without which great science is not possible.

Ethologist and Surrealist painter Desmond Morris has said that he uses his art for the same reasons that scientific fiction writers and poetic scientists practice theirs. “Being a biologist and a student of evolution, I attempted to evolve my own world of biomorphic shapes, influenced by but not directly related to the flora and fauna of our planet. From canvas to canvas I have tried to let them grow and develop in a natural way, without ever crudely borrowing specific elements from known animals or plants” (Morris, 1987, p. 17). He says that his biomorphic shapes undergo the same evolutionary stages that real organisms do so that his art becomes a mental laboratory for exploring the nature of evolutionary processes in the abstract. He realizes explicitly that his “paintings are very biomorphic, very preoccupied with biological shapes, and that my biological writings are largely concerned with visual patterns of behaviour. I have never resisted that kind of leakage . . .” (Remy, 1991, p. 18). In fact, he has made that leakage the source of fertile studies of the biological origins of art and of the evolution of

primitive arts among humans, an interest he shared with another evolutionary pioneer, Mary Leakey, who began her scientific career as an illustrator for other anthropologists (Leakey, 1984, pp. 39–43).

Many evolutionary and ethological studies have been influenced by artistic biologists. Thomas Henry Huxley, Alfred Russel Wallace (Nelson, 2001, p. 1260), and Ernst Haeckel are only a few of the pioneers of evolutionary theory who were also artists. Haeckel, whose prints (Haeckel, 1905) had a significant impact on the artists of his day (Kockerbeck, 1986), was the first to fully realize Darwin’s concept of an evolutionary tree as an articulated image. Huxley for his part claimed that accurate scientific observation was impossible without a facility for drawing and argued that art classes should be required for all scientists: “I should make it absolutely necessary for everybody, for a longer or shorter period, to learn to draw . . . I do not think its value can be exaggerated, because it gives you the means of training the young in attention and accuracy, which are the two things in which all mankind are more deficient than in any other mental quality whatever” (T. H. Huxley, 1900, vol III, pp. 183–184).

Contemporary artistic scientists include ethologist Jonathan Kingdon (Gautier-Hion et al., 1988) and paleontologist-novelist Robert Bakker (Bakker, 1995), both of whom draw their own specimens and create three-dimensional models from their sketches in order to better understand with their material. Bert Holldobler, a professor of entomology and an amateur painter, also draws the illustrations for all of his publications. He says that, “It is my urge that I make every paper I write as crystal clear as I can in words and illustrations. A scientific publication should be a piece of art” (personal communication). His success is proven by the fact that he won a Pulitzer Prize for his collaboration with E. O. Wilson on their book, *The Ants*, of which Holldobler says, “It was our first intention to write a scholarly book, but we were also driven to show the beauty of the life of our subjects, both in our writing and in the illustrations of the book” (personal communication). For these men, an illustration is therefore both art and science.

Another example of art having a scientific component and science having an intrinsic artistic element can be found in the subject of moiré patterns. Moiré patterns are created when figures with periodic patterns are made to overlap so that both patterns are still visible. The word ‘moiré’ comes from the French word for ‘watered’ and has classically been used to describe the particular type of silk fabric that has the shimmer of water waves. This shimmer results from folding the silk onto itself at a slight bias and then pressing it under high pressure and heat to imprint the slightly offset pattern of one fold of the fabric onto the other. Similar patterns can be created by overlapping two or more screens or meshes, or by drawing overlapping patterns

on paper. Physicist Gerald Oster demonstrated that moiré patterns have many interesting mathematical properties, including the potential to perform analogue computations, thereby calculating by visual means (Oster & Nishijima, 1963). Oster not only published widely on the scientific uses of moiré patterns, but also exhibited them as art in several well-known galleries (Mueller, 1967, pp. 197–198).

In a similar way, music has played its role in scientific developments. Musical analogies are so commonly used by scientists that historian of science Jamie Kassler has written a book describing their many problem-solving functions (Kassler, 2001). Not only did Johannes Kepler derive many of his astronomical discoveries from attempts to optimize the ‘harmony of the spheres’ (which he wrote out literally as music!) but physicist-musician Louis de Broglie earned himself a Nobel prize by comparing atoms to tiny stringed instruments and then showing that they would have the same kinds of harmonics and overtones, but with frequencies proportionally smaller. In these cases, the links between music and science are apparent and often describable as mathematics. Sometimes scientists therefore take advantage of the music–mathematics equation to convert quantitative results into music! Many university professors and corporations, including Bell Labs, Exxon Research and Engineering Corporation, and Xerox have experimented with transforming complex quantitative data into sound. They have discovered that the ear has powers of pattern recognition that extend far beyond the discriminatory abilities of the eye, and therefore that turning data into music rather than into graphs or charts often aids analysis. Applications of this technique have included exploring the patterns within the human genome, chemical analyses, complex physiological data, and multivariate economic indicators (Peterson, 1985a).

Sometimes scientists use music less analytically and more inspirationally, raising interesting issues about what stimulates creative thinking. Cardiology researcher Richard Bing, for example, is also a composer. He says that, “Writing music enriches me to look at science in a different way. It helps me emotionally to feel more about science. You see, I am a romanticist. I perceive science as an emotional exercise of searching the unknown” (Root-Bernstein, 1987, p. 2). Bing believes, as did Einstein, that “both (music and science) are born of the same source and complement each other through the satisfaction they bestow” (Clark, 1981, p. 106). This may explain why scientists from Darwin to Einstein and inventors such as Charles Martin Hall have all turned to music when faced by an apparently unresolvable problem. Somehow music frees the analytical mind allowing intuition to yield its fruits (Root-Bernstein, 2001).

Even dance has placed its footprints in scientific innovation. Berkeley physicist Marvin Cohen has collaborated with choreographer David Wood and his

dancers to explore forms of dynamic symmetry that inform the theory of super-conductivity. Cohen describes the dance not only as a novel way to communicate his otherwise inaccessible mathematical theories, but also as a form of ‘research’. He hopes that the dancers will invent forms of dynamic interactions that physicists have yet to have considered as possible models for electron interactions (NOVA, 1988). Dance notations are playing a similar role in elucidating the visualization problems that plague neurology and other areas of medicine. Describing and accurately communicating the nature of the motor impairments that characterize particular neurological lesions and various genetic diseases has always been extremely difficult. How does one explain to someone that multiple sclerosis is typified by this type of gait, but amyotrophic lateral sclerosis presents a different set of motor impairments that look quite different? That problem was first solved about 20 years ago by neurologists Ilan Golani and Philip Teitelbaum, when they applied Eshkol–Wachman movement notation, a well-known tool for recording dance movements, to the description of laboratory animal and human movement diseases (Golani & Teitelbaum, 1979). Since that time, Labanotation and Benesh Movement Notation have also been applied to the recording and analysis of physical actions. Someday, they may inform our design and control of robots as well.

The arts, in short, often supply scientists with ways of looking at the world that complement purely logical and analytic modes. This cross-fertilization is common enough, and the insights yielded by applying artistic methods to scientific problems useful enough, that an increasing number of investigators are suggesting that for exploring the human dimensions and implications of science and technology, artistic methods may even be superior to scientific ones. Chemist Carl Djerassi, for instance, the inventor of the birth control pill, has begun writing ‘science-in-fiction’ in order to explore the ethical and social implications of the latest biomedical innovations in meaningful ways impossible through purely analytical discourse (Djerassi, 1990, p. 16). For the same reasons, Nobel-prize-winning economist John Kenneth Galbraith said of his novel *The Triumph* that it “is a story I have tried to tell before in articles and lectures. But it has occurred to me that maybe there are truths that best emerge from fiction” (Galbraith, 1968, p. 7). Physicist/musician Victor Weisskopf has suggested that, “Especially in human relations, a piece of art or a well-written novel could be much more revealing than any scientific study. In many respects, *Madame Bovary* is a piece of sociology—in fact, better sociology than much of what is done by aping the techniques and language of the natural sciences” (Weisskopf, 1977, p. 410). And chemist/poet Roald Hoffmann has warned scientists to beware of chavinism in their dealings with the arts: “One thing is certainly not true: that scientists have some greater

insight into the workings of nature than poets” (Hoffmann, 1988, p.10). In sum, these men are arguing that the analytical methods of the sciences are not the only possible methods for revealing truth, and that particularly in the human sciences, but perhaps in all sciences, the artist’s approach may be more insightful than that of the mathematician. This is an interesting and potentially revolutionary message that bears serious consideration, especially when it comes from such accomplished scientists.

Arts Advance the Sciences

The thesis that the arts may provide insights beyond the methodological capabilities of the sciences comes from the fact that the artistic innovations often precede and make possible subsequent scientific ones. Examples are legion.

Alexander Graham Bell’s first invention, multiplex telegraphy, resulted from his avocation as a pianist. He was playing a well-known parlor game of striking an ‘A’ and showing his party that only the harmonics of ‘A’ resonated; and similarly for ‘B’ and ‘C’, and so on, when it suddenly struck him that one could design a telegraph along similar lines. One could send multiple messages along a single telegraph wire if one sent one metaphorically in the key of ‘A’, another in the key of ‘B’, and so forth. His work on multiplex telegraphy was what led him to the telephone (Mackay, 1997, 9ff).

In an intellectually related innovation, professional musician George Antheil and actress Hedy Lamarr collaborated to create one of the most influential inventions of the last century: frequency hopping. Lamarr was married to a major munitions manufacturer in Germany before divorcing him and moving to the United States. She was aware that munitions such as torpedos were usually radio-controlled, but that it was relatively easy to jam the radio frequency by which control was maintained. She discussed this problem with Antheil, a polymath who not only wrote some of the most revolutionary music of the twentieth century (e.g. ‘Ballet mecanique’), but also wrote about endocrinology, crime, and war. They realized that radio signals are like music: if one changes the radio frequency at which one sends a message, one keeps the same ‘notes’ within a message, just as one retains the musical message when one alters the key. But if one changes the ‘key’ (radio frequency) on a random basis, then the person trying to intercept or jam the message will have a very hard time doing so. Their invention is the basis for almost all secure communications, control systems, and anti-jamming devices currently in use worldwide (Braun, 1997).

A musical device also inspired one of the first heart pacemakers. Engineer Earl Bakken was looking for a way to create miniaturized regulators for the electrical output of apparatuses being designed to steady heart rhythms. Bakken found the answer in an already

existing device, the electronic metronome that musicians had been using for years. Instead of generating a sound, as musical metronomes do, Bakken reconfigured his device to generate regular pulses of electricity to stimulate the heart. His company, Medtronic, became a leader in the development of the implantable pacemakers that are used today (Jeffrey, 1997).

Visual arts have also stimulated many scientific innovations. Hermann Rorschach, the Swiss psychiatrist who invented the well-known Rorschach ink blot tests, was also an amateur artist. The idea for ink blot tests came to him from a popular party game based on decalomania, an artistic technique in which an image is transferred from one piece of paper to another, or within a piece of paper by folding it. For entertainment, people would drip a variety of colored inks or paints onto paper that was then folded and pressed. When the paper was unfolded, unexpected images were revealed. Rorschach noticed not only that people had a tendency to comment on what they saw in the ink blots, but that different people saw very different things that were suggestive of their personalities and problems (Larson, 1958). Thus, Rorschach’s innovation resulted from taking advantage of a technique invented and popularized by professional and amateur artists.

Perceptual psychologists also owe many debts to artists. Those studying motion perception, for example, often rely upon the rotoreliefs of Marcel Duchamp. Rotoreliefs are a form of artwork based upon tops. If a spiral is painted on a top, it appears to move continuously, even though it actually has a finite length. A similar effect can be observed if a spiral is painted on a round platen and rotated on a record player. Duchamp invented very large platens that he painted with extraordinary patterns that create effects that still puzzle perceptual psychologists and are therefore useful in their research. One of the most intriguing is a double spiral that appears to spiral both in and out simultaneously (Sekuler & Levinson, 1977, p. 61). Another set of perceptual phenomena that have become a major focus of psychological research are the size and space illusions invented by Adelbert Ames, a lawyer and artist. The most famous of Ames’ innovations is the so-called ‘Ames room’ that creates the illusion that a person standing at one side of the room is a dwarf and a person standing at the other side of the room is a giant, when in fact they are the same size (Behrens, 1994).

Sometimes artists and scientists collaborate in an intricate dance of images. One example of such a dance was initiated by M. C. Escher, the famous graphic artist. Escher specialized in drawing impossible things, such as hands emerging out of a flat piece of paper drawing themselves. Roger Penrose, a mathematical physicist and amateur artist, visited an exhibition of Escher’s work in 1954 and was stimulated to invent his own impossible objects. The result of his

experimentation is the famous ‘impossible tribar’ a two-dimensional rendering of a three-dimensional triangle that appears to twist both forwards and backwards simultaneously. Roger Penrose showed his tribar to his father L. S. Penrose, a biologist who also dabbled in art, and L. S. Penrose soon invented the ‘impossible staircase’, in which the stairs appear to spiral both up and down simultaneously. The Penroses’ published their ‘discoveries’ in 1956 the *British Journal of Psychology* and sent Escher a copy of the publication as thanks. Escher then developed the artistic possibilities of the impossible tribar and staircase in ways that have since become famous not only in artistic circles, but as fodder for psychological experimentation (Ernst, 1992, pp. 71–80).

The impossible tribar was only one of Roger Penrose’s artistic forays. Another was his invention of aperiodic tilings, which also owe a debt to Escher. A tiling is a pattern made out of repeating visual or design elements that covers a surface such as a plane or a sphere. A periodic tiling is one that does so using a regularly repeating pattern. Much of Escher’s graphic work involved periodic tilings interpreted as birds, fish, and other animals. Penrose spent many years mastering the techniques of making periodic tilings like those popularized by Escher. But he tired of the regularity of the patterns and began searching for new possibilities (personal communication). One of these was aperiodic tiling. Aperiodic tilings are composed of a limited number of invariant shapes that nonetheless result in a pattern that never repeats. Penrose was one of the pioneers of this field. He says he created them mainly as an artistic puzzle. He later investigated the mathematical properties of them. Even more recently, after his artistic renderings were popularized by Martin Gardner in his mathematics column in *Scientific American* (Gardner, 1977), crystallographers realized that many metal alloys have structures that are described as aperiodic tilings (Peterson, 1985b, p. 188). Thus, an artistic hobby resulted in the discovery of novel structures that subsequently shed light on the nature of previously mysterious properties of metals.

Artists often invent novel structures that subsequently reveal unexpected properties of nature. R. Buckminster Fuller, working as an artist and architect, laid out an entire theory of structural stability based on tetrahedral forms that eventually led to his invention of the geodesic dome. Fuller claimed that this structure combined the least material to encapsulate the greatest space with the greatest stability. As such, he suggested that it would turn out to be a fundamental construct of nature. In fact, when virologists began to study the structures of spherical viruses, they turned to Fuller for help in solving the possible structures and soon discovered that most spherical viruses are geodesic domes, as Fuller had predicted (Fuller, 1965, p. 72). More recently, chemists have discovered that extremely

stable carbon compounds, appropriately called ‘buckminsterfullerenes’, can be made that have geodesic structures, and similar structures are beginning to be discovered among biological macromolecules.

Almost as well known as Fuller’s geodesic concept is his student Kenneth Snelson’s concept of tensegrity, in which stable structures result from a juxtaposition of rigid pieces and elastic tensions to yield structures with great structural integrity. Snelson’s tensegrity sculptures exist in major collections (e.g. the Smithsonian) all over the world and attracted a great deal of attention during the 1970s. Among those who became enamoured enough with tensegrity sculptures to build some of their own were biologists Steve Hiedemann and Donald Ingber (personal communications), who more than a decade later were to realize that the structures within cells that maintain their shapes have many similarities to tensegrity structures (Brookes, 1999, p. 43). The tensegrity theory of cell structure has captured the cover of *Scientific American* (Ingber, 1998, p. 48), and the new mathematics of tensegrity captured the cover of *American Scientist* (Connelly & Back, 1998, p. 142), once again demonstrating that artistic inventiveness can provide basic scientific insights.

Artist Wallace Walker has similarly galvanized solid geometry. While a student at the Cranbrook Academy in the 1960s, he was asked to make a three-dimensional object out of a sheet of paper only by folding and gluing it. The result was a complex donut that could be folded through its center hole to take on a kaleidoscopic variety of shapes. Walker’s invention not only earned him a patent but also attracted the attention of Doris Schattschneider, a mathematician specializing in geometric objects. Schattschneider determined that Walker’s paper sculpture was the first of a novel class of geometric objects, now called kaleidocycles (Schattschneider & Walker, 1977).

Another version of paper folding has also become the source of major mathematical innovations in recent years, and that is the ancient oriental art of origami. Mathematicians have recently discovered that the rules of origami embody (literally) a set of mathematical algorithms that determine whether an object can be created by folding, or whether it must be cut. This observation has opened an entirely new field of research into what is being called ‘plication’ that is now yielding unexpected benefits (Hayes, 1995). A set of engineers at the Lawrence Livermore National Laboratory in Berkeley, California have recently invented a huge, foldable lens, many times larger than any lens heretofore created, for use in space laboratories (Anon., 2001). Other scientists have discovered links between origami and logic that may transform the way computers are designed and programmed (Cipra, 1998).

Novel structures are not the only ways in which artists contribute to scientific innovation. Some

contributions stem from artistic observations. Since artists are trained to observe what other people overlook, they sometimes think about what other people never see. Leonardo da Vinci, for example, was the first to observe that a cross-section through the branches of a tree from the twigs down to the trunk will always conserve the same total area of wood. ‘Leonardo’s principle’ as this observation is now known, is still a viable area of research in botany and engineering. The invention of the concept of camouflage provides another, more modern example. Ever since people began hunting, they undoubtedly noticed that animals tend to blend into their environments, but it was not until the 1880s, when a professional painter of portraits and angels named Abbott Thayer looked carefully at nature through the eyes of an amateur evolutionist that anyone thought to question how this blending came to be. After more than a decade of visual experimentation, Thayer described the entire range of possible mechanisms by which camouflage might be expressed in nature (Maryman, 1999, 116ff).

Artistic techniques have also been the basis for scientific developments. One such technique is anamorphosis, meaning ‘shape change’, which derived historically from the discovery of perspective. Perspective drawing involves the mapping of a three-dimensional object onto a flat surface. Renaissance artists quickly realized that two-dimensional objects could also be mapped onto three-dimensional surfaces, including spheres, cones, and rods (Gardner, 1975). Such transformations became central to D’Arcy Thompson’s *On Growth and Form* (Thompson, 1930, Ch. 17). and Julian Huxley’s *Problems of Relative Growth* (J. Huxley, 1932, Ch. 4), both of which describe evolutionary and embryological processes as anamorphic distortions. Anamorphosis also underlies Wilder Penfield’s and neurologist-artist C. N. Woolsey’s studies of the motor and sensory mappings of primates onto the cortex of their brains, which yield the familiar ‘homunculi’ with their huge lips, hands and feet, and tiny bodies (Woolsey, 1978).

Another striking example of how artistic techniques inform science is the reification of logic in modern computer chips. The logic embedded in computer chips is actually a pattern directing electron flow. This pattern is drawn using techniques as old as drafting architectural plans and then shrunk using photographic techniques to produce a tiny template. This template is then used to transfer the pattern to silica wafers using methods adapted directly from silk screening and etching. Thus, the physical embodiment of logic as a functional image on a chip contains within it hundreds of years of artistic experience (Root-Bernstein, 2000).

Finally, the arts can foster scientific advances through the development of new aesthetics (Root-Bernstein, 1996). The use of pixels, false coloring, and abstractions provide three cases. The process of breaking a picture into discrete areas of color (pixels)

was invented by pointillist painters such as Seurat. The technique of falsely coloring objects was invented by Fauvist painters. And abstract art, in which a single element of a complex phenomenon, such as its pattern, structure, or color, is chosen for selective description, was pioneered by Picasso, Braque and Kandinsky during the 1920s. Examine any scientific illustration carefully and you are likely to find one or more of these artistic techniques being employed to focus attention on one particular aspect of data. Without an excellent sense of history, it is too easy to overlook the artistic origins of many of the scientific tools we use for analyzing our results (Root-Bernstein, 2001).

Arts and Innovation: The Future of Polymathy

Fortunately, there is growing understanding that art fosters science. Mitchell Feigenbaum, one of the pioneers of chaos theory, believes that understanding how artists paint will provide the cognitive insights necessary to do better science: “It’s abundantly obvious that one doesn’t know the world about us in detail. What artists have accomplished is realizing there’s only a small amount of this stuff that’s important, and then seeing what it was. So they can do some of my research for me” (Gleick, 1984, p. 71). Similarly, C. S. Smith, of MIT spent a lifetime studying oriental arts and crafts for the insight they gave him into metallurgy: “I have slowly come to realize that the analytic, quantitative approach I had been taught to regard as the only respectable one for a scientist is insufficient . . . The richest aspects of any large and complicated system arise from factors that cannot be measured easily, if at all. For these, the artist’s approach, uncertain though it inevitably is, seems to find and convey more meaning” (Smith, 1978, p. 9).

In fact, some scientists are formally inviting artists to help them perceive new realities. Milton Halem, chief of the Space Data and Computing Division at NASA’s Goddard Space Flight Center in the early 1990s, invited Sara Tweedie, a design instructor in the Corcoran School of Art, to help his engineers invent new ways to visualize the huge amounts of data being generated from satellite sources. “Visualizing that data, coloring that data, enables the mind to more quickly assimilate the information and the image”, he noted. He says he needs artists such as Tweedie to push “modeling a step beyond where it’s gone in the past” (Mercier, 1990, p. 28). The National Supercomputing Facility and Bell Laboratories (now Lucent Technologies) have hired artists for similar reasons.

But the real future of sciences–arts interactions must be within the minds of individuals. Artists and scientists too often speak different languages and use different tools. In order for them to collaborate effectively, to perceive in each others’ problems and methods opportunities for insight, we must have a large cadre of artist-scientists and scientist-artists. Some of

these people already exist. Desmond Morris for his part refuses to be labeled as a scientist or an artist: “If my paintings do nothing else, they will serve to demonstrate that such titles are misleading. In reality, people today are not scientists or artists . . . they are explorers or non-explorers, and the context of their explorations is of secondary importance. Painting is no longer merely a craft, it is a form of personal research . . . So, in the end, I do not think of myself as being part scientist and part artist, but simply as being an explorer, part objective and part subjective” (Morris, 1987, p. 27). He adds that, “perhaps the time will come when we will give up the folly of separating sub-adults into the imaginative and the analytical—artists and scientists—and encourage them to be both at once” (Remy, 1991, p. 18).

This melding of the artistic and scientific mind within a single individual may even have benefits for both since, as the art critic Kenneth Clark has suggested, art and science emerge from the same imaginative sources: “Art and science . . . are not, as used to be supposed, two contrary activities, but in fact draw on many of the same capacities of the human mind. In the last resort, each depends on the imagination. Artist and scientist alike are both trying to give concrete form to dimly apprehended ideas” (Clark, 1981, p. 24). Rather than forcing individuals to choose a scientific approach to problems or an artistic one, thereby devaluing the other, Clark admonishes us, to “wait patiently for our faculties to be reunited” (Clark, 1981, p. 29).

Clearly, the arts and sciences are as capable of full integration today as they were in the Renaissance, and there is every reason to expect their union to be as fruitful. But to derive the fruits of their union, we must foster the connections and the people who can make them. Richard Mueller, an MIT-trained engineer, novelist and artist agrees with Clark. He writes in his stimulating book, *The Science of Art*, “In many ways, I think, the scientist is delaying his own understanding and development in science by discouraging, not only the artistically inclined members of his clan, but also the artistic urges within himself . . . Art may be a necessary condition for constructing the new consciousness from which future science gets its structural realities to match nature, in which case it is more important than we generally admit . . .” (Mueller, 1967, p. 320).

Thus, we need a new kind of education that fosters interactions between disciplines rather than divisions between them and which trains people who can bridge C. P. Snow’s ‘Two-Cultures’ divide. We need such curricula and people not only because of the fragmentation of knowledge that must result in their absence, but more importantly as a stimulus to the highest forms of innovation. For specialization can never suffice. As General Electric engineer, Charles Steinmetz, pointed out nearly a century ago, “technical training alone is

not enough to fit a man for an interesting and useful life” (Seymour, 1966, p. 119). He urged his students to study languages, literature, philosophy, art, music and history, arguing that if an engineer failed to produce a workable invention, it was his own fault for not understanding the greater needs of society and the factors that control its manufacturing and economic functions. Similarly, composer-architect-engineer Iannis Xenakis argues today that “the artist-conceptor will have to be knowledgeable and inventive in such varied domains as mathematics, logic, physics, chemistry, biology, genetics, paleontology . . . the human sciences and history; in short, a sort of universality, but one based upon, guided by and oriented towards forms and architecture” (Xenakis, 1985, p. 3). All this is necessary so that we can address the truly important problems of the world, added embryologist and art historian C. H. Waddington: “The acute problems of the world can be solved only by whole men (and women), not by people who refuse to be, publicly, anything more than a technologist, or a pure scientist, or an artist. In the world of today, you have got to be everything or you are going to be nothing” (Waddington, 1972, p. 360). Buckminster Fuller agreed: “Overspecialization leads to extinction. We need the philosopher-scientist-artist—the comprehensivist, not merely more deluxe quality technician mechanics” (Fuller, 1979, p. 104).

To invent and to create requires an understanding that incorporates all that is known sensually and abstractly, subjectively and objectively, imaginatively and concretely. And because of their wide disciplinary training in the imaginative skills, handicrafts and expressive languages, only polymaths will have the tools necessary to do so. Thus, the future of innovation will reside, as it always has resided, in the minds of multiply talented people who transcend disciplinary boundaries and methods. We can recognize this phenomenon by fostering artsience—a term promoted by artist-inventor-psychologist Todd Siler (Siler, 1990)—or we can retard it by creating educational and workplace systems that prevent arts and sciences from meeting. As Siler has pointed out, artsience is both the past and future of innovation because innovators cannot help drawing upon any form of thinking that will spur their imagination. We ignore this profound truth at our peril.

Young Inventors

Nicholas Colangelo, Susan Assouline, Laurie Croft, Clar Baldus
and Damien Ihrig

*The Connie Belin & Jacqueline N. Blank International Center for Gifted Education and Talent
Development, The University of Iowa, USA*

Abstract: This chapter focuses on young inventors—children and adolescents. A brief review of the history and documentation of young inventors is presented. Research is presented on the young inventors who were part of the Invent Iowa program and who have been evaluated as meritorious inventors at local and regional invention competitions qualifying for the State of Iowa Invention Convention. This research includes perceptions of young inventors about the inventiveness process, their attitudes toward school and toward students, and an analysis of their inventions. Boys and girls have equally strong interest and equal participation in inventiveness programs.

Keywords: Innovation; Inventiveness; Flexibility; Originality; Invent Iowa; Iowa Inventiveness Inventory.

Introduction

When we think of inventors, we typically form the image of a Thomas Edison or a Henry Ford: adults who made fame and fortune through their inventions. We also have more ambiguous images of adults who had clever ideas but for one reason or another achieved neither fame nor fortune. These adults may get the moniker of tinkerer, oddball, or ‘ahead of his time’. Regardless of whether the adult was successful or not, the constant in the image is the adult (typically a male adult). It is rare that our image of the inventor is a child. Yet children and adolescents do invent. We know little about the young inventor in terms of both the person and the invention. The focus of this chapter is to ‘look’ at young inventors, their inventions, and their attitudes and perceptions.

Early in the 1980s, the United States Patent and Trade Office committed to a comprehensive effort to introduce thinking at all levels of school curricula. Project XL was initiated in 1985 as a national effort to create and disseminate new programs and materials to promote critical and creative thinking and problem-solving skills fundamental to innovation and invention (United States Patent and Trade Office, 1997). The program reflected the emerging belief among leaders in business and science and technology, as well as in education, that schools could nurture the creative and

innovative spirit essential for future leaders (Treffinger, 1989). In spite of widespread support for the cultivation of inventiveness among children, however, little comprehensive research explores the behaviors, thoughts, and attitudes of school-age inventors. The literature on inventiveness and invention programs for children emphasizes thinking skills and creativity and this makes inventiveness ‘invisible’.

Westberg (1996) called inventiveness a “manifestation of creativity” (p. 265), and she suggested (Westberg, 1998), for example, “to stimulate children’s creative thinking abilities, consider teaching them how to develop inventions” (p. 18). Rossbach (1999) suggested that through the invention process, “students of all levels work toward the common goal of realizing their creative potential” (p. 8). In addition to creative thinking, other specific skills associated with teaching children about the inventive process include critical thinking, problem-finding, problem-solving, decision-making, and the development of enhanced research skills (Perkins, 1986; Rossbach, 1999; Treffinger, 1989). Gorman and Plucker (n.d.) found that a structured inventiveness course enables secondary students to develop their abilities to collaborate with team members and to better understand the collaboration, politics, patience and persistence required in the invention and patent processes.

Invention programs for children share attributes that parallel recommendations for stimulating children's creative thinking. Perkins (1986) suggested that educators focus on intrinsic motivation, minimizing evaluative feedback in favor of more informative feedback. Treffinger (1989) emphasized establishing challenging but appropriate expectations and standards, as well as delineating criteria to help students identify their strengths and weaknesses. Treffinger also explored the invention-evaluation process, encouraging formative evaluations that were respectful of the diversity of student processes as well as outcomes.

Inventiveness programs for school-age children share organizational features. Young inventors are typically introduced to:

- the definitions, goals, and purpose related to inventing;
- the societal contributions made by inventions and inventors, frequently including examples of school-age inventors;
- experiences creating Rube-Goldberg kinds of inventions with random available materials;
- the importance of journals or logs;
- activities to help them identify needs or wants;
- skills to research relevant content areas and to evaluate proposed solutions;
- ways to design prototypes or models;
- general strategies for naming inventions;
- audiences for sharing their inventions (Gorman & Plucker, n.d.; Plucker & Gorman, 1995; Shlesinger, Jr., 1982; Treffinger, 1989; Westberg, 1996, 1998).

McCormick (1984) and Gorman and Plucker (n.d.) structured the exploration of inventiveness around historical immersion in the lives of inventors and their inventions. Gorman and Plucker developed online interactive models (Gorman, 1994), enabling students to simulate the 19th century competition between Alexander Graham Bell and Elisha Gray as they pursued different strategies to develop the telegraph. Structured explorations of the invention process allowed children to develop significantly greater numbers of inventions (Westberg, 1996). Also, inventiveness activities have often been evaluated for outcomes related to academic subjects rather than enhanced inventiveness. Shlesinger, Jr. (1982) reported that teaching an inventiveness process enhanced students' general interest in social science and history. McCormick (1984) also found that teaching inventiveness improved student attitudes toward science as well as inspiring student flexibility and originality.

As implied earlier, inventiveness programs for children are submerged under the more familiar school concepts of critical thinking and creativity. Inventiveness (and invention curriculum), while viewed positively in schools, has not become a major part of school and school curriculum. It is viewed as a special or extra-curricular unit. Where it does appear, it seems

to be more 'justified' in how it positively affects more typically used school concepts such as creativity. Inventiveness is not well researched among children and adolescents because it is not part of the tradition of school. The State of Iowa has a unique situation whereby its statewide Invent Iowa program and the Invent Iowa curriculum offered to schools allow an opportunity to better understand young inventors and the inventiveness process with this age group. (Note: while some other states have State invention programs, Iowa's is extensive and has been in existence over 15 years.)

The remainder of the chapter provides a brief description of the Invent Iowa program and the research done with young inventors in this program. The research focuses on attitudes about school, and the types of inventions they produce.

Invent Iowa

Invent Iowa is a comprehensive, statewide program developed to assist Iowa's educators in promoting the invention process as part of their regular kindergarten through high school curriculum. The program was initiated in 1987 through the support of state political, business, and educational leaders in response to the future of rapidly expanding technology and the decline in American inventiveness in relation to other nations. Since 1989, Invent Iowa has been administrated through The Connie Belin and Jacqueline N. Blank International Center for Gifted Education and Talent Development at The University of Iowa (Belin-Blank Center).

Invent Iowa supports educators in teaching creative-thinking and problem-solving skills associated with the invention process. As a means of teaching these skills, students are encouraged to identify real-world problems and develop their own inventions that successfully solve these problems. This multidisciplinary process enables students to use several academic skills in combination: reading, library and field research, science and technology, creative and critical thinking, writing, art, and persuasive speaking. Students who participate in the program have the opportunity to display their inventions at their local, regional, and state invention conventions. Each year an estimated 30,000 students in grades K-12 participate in the Invent Iowa program. Invent Iowa sponsors a series of 'invention conventions' at the local, regional, and state levels. At each level, inventions are evaluated, and students are recognized for their achievements. The *Invent Iowa State Invention Convention*, organized by the Belin-Blank Center, is the pinnacle of inventiveness competitions in Iowa. Over 300 students qualify and are invited to the *State Invention Convention* each spring.

Invent Iowa is not limited by gender, race, class, academic standing, or any other classification. Invent Iowa helps students gain the sense of accomplishment

and purpose vital to the development of a creative, competent, and involved workforce.

The Invent Iowa Evaluation Rubric

Students participating in Invent Iowa must submit their invention and a detailed and structured journal of this invention. Additionally, a student must be able to articulate the purpose and process employed in completing his or her invention. The inventor's journal is also signed by a school representative and a family member, confirming that the invention is the idea and work of the student.

Students are evaluated at the local, regional, and state level according to the criteria of the Invent Iowa Evaluation Rubric (Rubric) (See Appendix A). The Rubric is used by the judges to evaluate the actual invention in terms of the dimensions of appeal, usefulness, and novelty (criteria for invention).

Each of the criteria dimensions is evaluated according to four levels of mastery, from Expert Inventor (highest rating) to Beginner Inventor (lowest rating). The other part of the Rubric (criteria for Entry) guides judges in evaluating the visual, written and oral presentation by a student of his or her invention.

The Rubric is designed to provide subscores, as well as a total score. The subscores are particularly useful in providing the young inventor specific feedback on the various aspects of the invention and the presentation. Judges provide oral and written feedback to the inventor. The total score is used to determine the local and regional qualifiers for State, and at the State Invention Convention to determine the special Merit Awards.

Research with Young Inventors

Much of what we know about young inventors has to do with whether or not they 'win' an invention contest. While success in such competitions tells us something useful about the skill of the young inventor, it does not inform us about the psychological profile of the inventor including his or her attitudes, feelings, interest, motivation, etc. The research reported in this study informs on some of the perceptions and attitudes of young students who have demonstrated their inventiveness in major competitions.

A unique feature of this chapter is its focus on young inventors and research with young inventors. The research is based on those students, grades 3–8, who qualified for the Iowa State Invention Convention in the year 2001. Each of these students had to receive merit recognition at the local and regional level in order to be selected for State. Also, all competitors were part of the Invent Iowa program. In the year 2001, approximately 30,000 students in K-8 participated in local and regional conventions. Of this group 364 were selected for the State Convention in grades 3–8. (Note: Students in grades K-2 can only participate in local and regional conventions. Students are not eligible for state com-

petition until they reach 3rd grade. Students in grades 9–12 did not participate in the research.)

For the remainder of this chapter the term 'young inventors' will refer to those students from grades 3–8 who were selected for the Iowa State Invention Convention. They met the criterion for 'inventor' in that they had to compete against a large number of students in order for their inventions to qualify for State.

The Invent Iowa Survey—2001

The students in grades 3–8 who qualified for the Iowa State Invention Convention in 2001 were asked to complete the Invent Iowa Survey (IIS). The IIS is a self-report instrument developed at the Belin-Blank Center, which assesses the perceptions of young inventors in the following:

- (a) perceptions about the inventiveness process;
- (b) attitudes about school;
- (c) attitudes about status of being a young inventor.

Of the 364 students who qualified for the Iowa State Invention Convention, 294 (81%) completed the IIS. Table 1 indicates by grade and gender those who qualified for the State Convention and who completed the IIS.

Stereotypically, inventing and entering invention contests have been associated more with boys than with girls. Of the 364 students who qualified for the State Convention ($N=207$ girls; $N=157$ boys), girls are very much part of the Invent Iowa program and have been very successful in making it to the State Convention. (Note: The minority population of the State of Iowa is about 6% of the general population. Of those who participated in 2001, 6% minorities qualified for the State Convention. Since the numbers were small, we did not do any separate analyses by ethnicity, only by gender.)

Table 1. Young inventors who completed the Invent Iowa Survey in 2001.

Grade	Gender		
	Males (Response Rate)	Females (Response Rate)	Total (Response Rate)
3	14 (93%)	14 (78%)	28 (85%)
4	26 (76%)	41 (75%)	67 (75%)
5	45 (78%)	43 (78%)	88 (78%)
6	21 (84%)	45 (83%)	66 (84%)
7	13 (100%)	16 (89%)	29 (94%)
8	11 (92%)	5 (71%)	16 (84%)
Total	130 (83%)	164 (79%)	294 (81%)

The Inventiveness Process

In 1992, Colangelo, Kerr, Huesman, Hallowell and Gaeth developed the Iowa Inventiveness Inventory (III), which measured attitudes and perceptions of adult

inventors (males only) who held one or more patents. The III included items that tapped perceptions of the inventiveness process among adult inventors. These items (1–19) were included in the Invent Iowa Survey (IIS) and were used to elicit attitudes of young inventors regarding the inventiveness process. For each of the items (1–19) a student selected from one of five choices:

- (1) Strongly Disagree
- (2) Disagree
- (3) Neutral
- (4) Agree
- (5) Strongly Agree

A multivariate analysis of variance (MANOVA) was performed to look for significant global differences between males and females in their mean responses to

items 1–19. In other words, when one examines all of the items at the same time, is there a difference between the responses of males and females? A MANOVA procedure was significant at the $p < 0.05$ level ($F(19,251)=2.58$), indicating a difference between the answers of males and females on items 1–19. The eta-squared value is a measure of effect size, or ‘practical significance’. It indicates that, although the global test was significant, only a small proportion (16%) of the variance in all the dependent variables is accounted for by the differences between the two groups. Thus, although there was a difference between males’ and females’ mean responses, the practical significance of the difference may be questioned.

A univariate analysis of variance was performed as a follow-up to the significant MANOVA (Table 2). This was done to identify the individual items males and females were responding to differently. The analysis

Table 2. Univariate analysis of variance for items 1–19 on the 2001 Invent Iowa Survey.

Item	Males (Mean)	Females (Mean)	Type I Sum of Squares	df	Mean Square	<i>F</i>	Sig.	Eta-Squared
1. I like to hang around places where people are making or fixing things	3.76*	3.48	4.90	1	4.90	5.67	0.018*	0.0206
2. I can figure things out that others have trouble understanding	4.02	3.98	0.03	1	0.03	0.05	0.830	0.0002
3. I need to get a lot of ideas in order to get a really good idea	3.09*	3.39	5.59	1	5.59	4.19	0.042*	0.0153
4. When I start working on a project, I just won't quit	3.82	3.88	0.09	1	0.09	0.10	0.757	0.0004
5. I want to invent only things which can help people	3.40	3.40	0.19	1	0.19	0.14	0.708	0.0005
6. Inventiveness is something you can be taught. (Reversed)	3.55	3.65	0.48	1	0.48	0.38	0.539	0.0014
7. It seems like too much school could cause you to lose your creativity	2.39	2.25	1.11	1	1.11	0.78	0.378	0.0029
8. I like to be alone when I am thinking of new ideas	3.03	3.13	0.56	1	0.56	0.42	0.520	0.0015
9. I sometimes have a lot of projects going at once	3.61	3.80	1.83	1	1.83	1.33	0.249	0.0049
10. I like to have a place to make things	3.75	3.61	1.42	1	1.42	1.35	0.246	0.0050
11. When I think of a new thing or machine, I can 'see' the complete idea in my mind before I start working on it	4.05	3.76	4.00	1	4.00	3.77	0.053	0.0138
12. My best friend and I build things together	3.09	3.04	0.03	1	0.03	0.02	0.880	0.0001
13. Whenever I look at a machine, I can see how to change it	3.09	2.84	3.47	1	3.47	3.68	0.056	0.0135
14. I don't really consider myself a good student, but I do have the ability to solve problems	2.40	2.16	5.12	1	5.12	3.56	0.060	0.0130
15. When I decide to solve a problem, my mind is full of that problem	3.60	3.45	0.69	1	0.69	0.65	0.422	0.0024
16. You can't explain inventiveness	3.27	3.17	0.34	1	0.34	0.24	0.628	0.0009
17. You don't have to have good grades in school to be a good inventor	4.00	3.83	1.68	1	1.68	1.14	0.286	0.0042
18. I am a person who likes to take things apart	4.07*	3.21	45.00	1	45.00	29.89	0.0000001*	0.1000
19. I am more interested in how a toy or object works than in playing with it	3.25*	2.70	16.28	1	16.28	12.64	0.0004*	0.0449

* $p < 0.05$.

Table 3. Univariate analysis of variance for items 20–22 on the 2001 Invent Iowa Survey.

Dependent Variable	Males (Mean)	Females (Mean)	Type I Sum of Squares	df	Mean Square	F	Sig.	Eta-Squared
20. It is important to keep notes about my invention	3.61*	3.97	9.95	1	9.95	8.31	0.004*	0.028
21. I like to draw my invention before I start building it	3.70	3.70	0.02	1	0.02	0.02	0.903	0.0001
22. I like to make a smaller model of my invention before I start building it	2.52	2.61	0.61	1	0.61	0.47	0.493	0.002

* Significant difference between male and female responses $p < 0.05$.

indicates mean responses by males and females on items (1) 'I like to hang around places where people are making or fixing things', (3) 'I need to get a lot of ideas in order to get a really good idea', (18) 'I am a person who likes to take things apart', and (19) 'I am more interested in how a toy or object works than in playing with it' were significantly different. Males tended to indicate stronger agreement with items 1, 18, and 19 than females. Females tended to indicate stronger agreement with item 3. The measures of effect size (eta-squared) for the responses to items 1 (2%), 3 (1.5%), 18 (10%), and 19 (5%) were small, however.

From the research of Colangelo et al. (1992) and Colangelo, Assouline, Kerr, Huesman and Johnson (1993) the higher the mean on each item, the more the response is consistent with the responses of adult inventors with patents. Two items elicited a different response from young inventors versus adult inventors: item 7 'It seems like too much school could cause you to lose your creativity', and item No. 14 'I don't really consider myself a good student, but I do have the ability to solve problems'. Adult inventors were very negative about the role of school (see Colangelo et al., 1992, 1993) and did not see themselves as good academic students, compared to young inventors. Perhaps the school environment has been changing and is currently more conducive to creative and inventive endeavors.

On all items except four, boys and girls were similar. On item 3 girls were more like adult inventors than boys and on item 7, 18 and 19, boys were more like adult inventors than are girls. But the important finding here is that young inventors are similar in perceptions about the inventiveness process regardless of gender.

Item 20, 21, 22 also come from Colangelo et al. (1992) and focus on *initiating* the inventiveness process. Table 3 indicates that girls are more likely to keep notes (as do adult inventors), and both boys and girls are likely to want to draw their concepts before building. Unlike adult inventors, young inventors are not inclined to want to make a model before building.

A multivariate analysis (MANOVA) was performed to look for significant global differences between males and females in their mean responses to items 20–22.

Again, when one examines all of the items at the same time, there is a difference between the responses of males and females. A MANOVA procedure was significant at the $p < 0.05$ level ($F(3,283) = 3.24$), indicating a difference between the answers of males and females on items 20–22. The eta-squared value indicates that, although the global test was significant, only a small proportion (3%) of the variance in all the dependent variables is accounted for by the differences between the two groups.

A univariate analysis of variance was performed as a follow-up to the significant MANOVA. It can be seen from Table 3 that the global significant result can be attributed to item 20 'It is important to keep notes about my invention'. Females tended to indicate more agreement with this statement than males. Again, the proportion of variance (about 3%) accounted for by the difference in responses between males and females is small.

Attitudes About School

The fact of the matter is that young inventors are going to be in school and they will be in school for the vast majority of their young life. Thus, their feelings about school are important. Colangelo, Assouline, Kerr, Huesman and Johnson (1993) reported that adult inventors did not have positive memories and attitudes

Table 4. Young inventors' attitudes about school: by gender.

	Gender*			
	Males		Females	
How do you feel about school in general?	N	%	N	%
A. I love it	27	21.3	49	30.4
B. I like it	89	70.1	105	65.2
C. I don't like it	9	7.1	6	3.7
D. I don't like it at all	2	1.6	1	0.6
Total	127	100	161	100

B. I like it	13	48.1	42	63.6	57	66.3	48	73.8	18	64.3	16	100.0
C. I don't like it	2	7.4	5	7.6	3	3.5	2	3.1	3	10.7	0	0.0
D. I don't like it at all	1	3.7	0	0.0	0	0.0	0	0.0	2	7.1	0	0.0
Total	27	100	66	100	86	100	65	100	28	100	16	100

* Percentages may not add to 100 because of rounding.

about school. Most of their recollections were either neutral or negative about school and its importance to their inventiveness.

In responding to an item on the IIS regarding attitude about school, young inventors were overwhelmingly positive. Table 4 reports the general attitude about school by gender. While girls are a bit more positive, especially in 'loving school', the pattern is consistent for boys and girls. The general attitudes about school are also presented by grade (see Table 5) and indicate no unique patterns other than highly positive at each grade.

Attitudes About Types of Students

One of our interests was to understand how young inventors viewed the hierarchy of types of students in their school. Putting it in basic terms, we wanted to know who the young inventors thought were the 'cool' students in school.

The item represented in Table 6 asked young inventors to rank the types of students that seem to be most attractive to the kids in school. Athletes were ranked highest (most attractive) by both males and females, and Hard Working (surprisingly) was ranked 2nd. Class Comedian and Popular were next. Inventor was ranked low on the list. Interestingly, however, the girls ranked it higher. We also did an analysis by grade (see Table 7), but no strong patterns emerged. Looking at the category of Inventor, this was rated less attractive by the 7th and 8th graders and more attractive by elementary school students. There may be a trend regarding the attractiveness of being an inventor by age and grade. This trend would need to be further investigated since the numbers in this study were too small to warrant definitive statements.

So, what do young inventors invent? We thought it would be revealing to do a systematic analysis of the types of inventions that were displayed at the State Invention Convention in 2001. There were 288 inventions by 364 young inventors at State in 2001. (The reason there are more inventors than inventions is that

students can team up on an invention (maximum of 2 inventors on a team) and we had several teams.)

The 288 inventions were classified using the general categories developed by the United States Patent Office to categorize patents. The detailed definitions of each category can be found by going to the U.S. Patent Office Website at www.USPTO.gov. The descriptions are much too extensive to include in a chapter. However, we have provided a very brief description of each category (see Appendix B) to give a sense of what type of inventions would be included in each category. Each invention was analyzed by a team of three raters in order to determine which category it fit best. Table 8 provides the results of that analysis by gender and grade.

The most popular categories of inventions were Tools, Kitchen/Bath, and Organization, which accounted for 141 of 288 inventions (49%). The

Electronic	4	3.1	1	0.6	5	1.7
Disabled	1	0.8	2	1.3	3	1.0
Total	129	100	159	100	288	100

categories of Clothes/Accessories, Safety/Protection/Rescue, and Farm accounted for 70 inventions (24%). Categorized inventions by gender were fairly comparable except in the categories of Kitchen/Bath and Organization where the girls outnumbered boys in these categories by slightly less than 2:1. Proportionately, inventions in the category of Tools more often were submitted by boys.

Discussion/Summary

From our research there are some issues that emerge:

- (1) It is a stereotype that 'inventing' is a boy thing. Boys and girls are comparably inventive and interested in participating in invention contests;
- (2) Inventive boys are similar to inventive girls in their attitudes about school and inventiveness;

- (3) In contrast to well-established adult inventors, the young inventors in our study had a positive attitude about school and their academic abilities;
- (4) The inventions of young inventors run a gamut of the classifications of the U.S. Patent Office. There are some gender differences in the classifications of types of inventions generated by young inventors.

The inventiveness spirit is quite alive and well in children and adolescents. Programs like Invent Iowa give expression and outlet to this spirit. It is important to promote inventiveness programs because inventiveness is a talent not usually identified and nourished in the traditional curriculum of schools. Historically, we have envisioned ourselves as a nation of 'doers', of innovative and practical people. It seems the accuracy of this is reflected in our young inventors.

Appendix A: Invent Iowa Evaluation Rubric

		LEVELS OF MASTERY				POINTS
		<i>Expert</i> INVENTOR 5	<i>Skillful</i> INVENTOR 4	<i>Amateur</i> INVENTOR 3	<i>Beginner</i> INVENTOR 2	
Novelty	A. Does the invention involve a <i>novel</i> idea?	A significant level of difference between this invention and prior products 5	A substantial level of difference between this invention and prior products 4	Some simple differences between this invention and prior products 3	Very similar to prior Products 2	Novelty A _____ +
	B. Is the invention a <i>fresh</i> or <i>unexpected</i> idea?	Unique and exciting product idea 5	Very interesting product idea 4	Attractive but predictable idea 3	Traditional product idea 2	B _____ = <input type="text"/>
Usefulness	C. Is the invention <i>workable</i> ?	Clear and convincing evidence that this invention will work effectively 5	Sufficient evidence that this invention will work effectively 4	Minimal evidence that this invention will work effectively 3	Little evidence that this invention will work effectively 2	Useful C _____ +
	D. Is the invention <i>appropriate</i> for the stated need or idea?	A clear and convincing connection between the problem or idea and the invention 5	Sufficient evidence of a connection between the problem or ideas and the invention 4	Minimal evidence of a connection between the problem or idea and the invention 3	Little evidence of a connection between the problem or idea and the invention 2	D _____ = <input type="text"/>
Appeal	E. Does the invention have strong <i>interest</i> and <i>appeal</i> to intended audience?	Professional in appearance and well-suited to the intended audiences 5	Attractive and useful for the intended audiences 4	Useful to some people in the intended audience 3	Idea might have potential interest and appeal 2	Appeal E _____ +
	F. Is the invention <i>well-crafted</i> and <i>complete</i> ?	Clear and convincing evidence that materials and construction are the best for the invention 5	Sufficient evidence that materials and construction can be used for the invention 4	Minimal evidence that materials and construction can be used for the invention 3	Little evidence that materials and construction can be used for the invention 2	F _____ = <input type="text"/>

Comments:

Appendix B: Brief Definitions of U.S. Patent and Trade Office Patent Classifications

- (1) Tools:
Inventions categorized as *Tools* included hand tools and presses.
- (2) Kitchen and Bath:
Inventions categorized as *Kitchen and Bath* included devices or methods used in baths, closets, sinks, and spittoons, cutlery, refrigeration, food and beverage preparation, treating, and preservation, and power-driven conveyors.
- (3) Organization:
Inventions categorized as *Organization* included packages, flexible/portable closures, partitions, or panels, special receptacles or packages, and support racks.
- (4) Clothes and Accessories:
Inventions categorized as *Clothes and Accessories* included apparel, boots and shoes, buckles, and jewelry.
- (5) Safety, Protection, and Rescue:
Inventions categorized as *Safety, Protection, and Rescue* included equipment used for body restraint or protective covering, rescue, or as a fire extinguisher or casing.
- (6) Farm:
Inventions categorized as *Farm* included methods or devices used in animal husbandry, methods and structures used to raise and care for bees, and devices or methods for crop threshing or separating.
- (7) Amusement:
Inventions categorized as *Amusement* included sporting goods, toys, games, and devices or methods related to music.
- (8) Pets:
Inventions categorized as *Pets* included harnesses, fluid handling, farriery, and dispensing of solids.
- (9) Automotive:
Inventions categorized as *Automotive* included devices and methods used by or for motor vehicles.
- (10) Furniture:
Inventions categorized as *Furniture* included devices for supporting the weight of a person in a seated position.
- (11) Medical:
Inventions categorized as *Medical* included devices used in a variety of medical situations.
- (12) Cleaning:
Inventions categorized as *Cleaning* included devices or chemicals used for the removal of foreign material.
- (13) Electronic:
Inventions categorized as *Electronic* included devices for producing light or related to television functioning.
- (14) For the Disabled:
Inventions categorized as *For the Disabled* included devices or methods used to accommodate people with physical disability.

Exceptional Creativity Across the Life Span: The Emergence and Manifestation of Creative Genius

Dean Keith Simonton

Department of Psychology, University of California, Davis, USA

Abstract: Major innovations in the arts and sciences can be largely attributed to the output of creative geniuses. But how do such great innovators emerge? And how does their creativity manifest itself? The first question shall be addressed by examining the early experiences that contribute to the development of extraordinary creative potential. The factors include family background, education, and professional training. The response to the second question concentrates on the typical career trajectory of illustrious creators. Features of this trajectory include the ages at which geniuses tend to produce their first great work, their best work, and their last great work.

Keywords: Age; Creativity; Genius; Creative potential; Career trajectories; Life-span development.

Introduction

The terms ‘creativity’ and ‘innovation’ are sometimes used interchangeably, and other times are considered to represent quite distinct phenomena. However, creativity involves the capacity to produce some idea or product that is both original and functional. By the same token, innovation involves the act of introducing something new. Hence, creative individuals are necessarily innovators, and their ideas or products can be considered innovations. However, sometimes researchers prefer to distinguish between the origination of a new idea and the dissemination or adoption of that idea by others. This distinction is especially useful when discussing technological change. It is one thing for an inventor to devise and patent a ‘better mousetrap’, but quite another for that mousetrap to become widely adopted in households or businesses. A person who adopts the new mousetrap is then called an ‘innovator’ even when he or she had absolutely nothing to do with its creation. However, this distinction between creators and innovators becomes much less tenable when we examine other domains of achievement in the arts and sciences. For example, when Albert Einstein applied Max Planck’s new quantum theory to explain the photoelectric effect, Einstein was acting as an innova-

tor in the sense that he was adopting and disseminating a new theory. Yet Einstein’s innovation only has significance because it took the form of a creative product—a novel and successful treatment of a critical phenomenon. Indeed, so important was Einstein’s application that it earned him a Nobel Prize, just as Planck had received one for the original theory. Speaking more generally, innovation usually takes place when one creative product becomes the basis for another creative product. Hence, in this chapter I shall use creativity and innovation as essentially equivalent terms.

Creativity or innovation can be studied from several different perspectives. Some researchers investigate the phenomenon from the standpoint of the psychological processes that underlie the origination of a creative product or innovation (e.g. Kaufmann, 2003; Root-Bernstein & Root-Bernstein, 2003; Weisberg, 2003). Other investigators examine the characteristics of the products that emerge from these processes (e.g. Simonton, 1980c, 1986c; Sternberg, Pretz & Kaufman, 2003). Yet other researchers concentrate on the attributes of the person that enable him or her to engage those processes or generate those products. It is this

person-approach that I will adopt in the present chapter. In particular, I wish to scrutinize those individuals who seem to exhibit the highest levels of this creative capacity, namely, those who display genius-level creativity.

The Creative Genius

Ever since Galton's (1869) pioneering work, psychologists have become accustomed to look at the distribution of human capacities in terms of the normal 'bell-shaped' curve. Most people are of average ability, and persons with higher-than-average or lower-than-average abilities become more rare to the degree that they depart from the population mean. Although the capacity for creativity might be viewed in the same fashion (Nicholls, 1972), such a conception has no empirical or theoretical support (Simonton, 1997b, 1999c). If creative ability is gauged according to the production of major innovations—of outright creative products in a particular domain of achievement—then the distribution of that ability is far from normal (Dennis, 1954a, 1954c, 1955; H. Simon, 1955). On the contrary, the cross-sectional distribution of total output is highly skewed right, so that a small proportion of the creators is credited with a lion's share of the innovations produced. In concrete terms, the top 10% of the innovators in a particular domain are typically responsible for about half of everything produced, whereas the bottom 50% can usually only claim about 15% of the contributions. Indeed, the mode of the distribution is almost invariably a single innovation only. Most inventors have only one patent; most poets publish only one poem. Moreover, the most prolific contributors to a domain are at least a 100 times more productive than their least productive colleagues. As Cesare Lombroso (1891) once affirmed in his classic *The Man of Genius*, "the appearance of a single great genius is more than equivalent to the birth of a hundred mediocrities" (p. 120). Creative productivity clearly displays a highly elitist distribution.

In line with Lombroso's remark, we can refer to those individuals who make up the productive elite as the *creative geniuses* of their chosen achievement domain. A prototypical example is Thomas Edison, whose output of inventions was so prodigious that he still holds the record for patents at the United States Patent Office. Moreover, among his more than a thousand inventions are several that radically transformed modern civilization, such as the microphone, the phonograph, the motion picture, and the incandescent lamp. Edison's status as an inventive genius is unquestionable.

The goal of this chapter is to examine creative genius from the standpoint of lifespan developmental psychology. From this perspective, the life of outstanding creators consists of two major phases (Simonton, 1975b, 1997b). The first phase represents the period in which the individual acquires the necessary capacity

for creativity—what may be styled 'creative potential'. The second phase encompasses the period in which this acquired potential becomes actualized in the form of creative products, whether those products be discoveries, inventions, treatises, novels, plays, poems, paintings, or musical compositions. This chapter then concludes with a discussion of the factors involved in the final termination of this second phase—the creator's death and the works that close the creator's career.

The Development of Creative Potential

"Genius must be born, and never can be taught", claimed John Dryden (1693/1885, p. 60). When the English dramatist said this he was expressing an idea already centuries old. However, the first scientist to subject this belief to empirical test was Francis Galton in his 1869 *Hereditary Genius*. Galton accomplished this by examining the family pedigrees of eminent achievers in a diversity of domains, including outstanding creators in science, literature, music, and painting. According to the results of his systematic statistical analysis, creative geniuses are highly likely to come from family lines that contain other eminent individuals, very often in the same domain of accomplishment. Moreover, the likelihood of such a distinguished pedigree is far greater than would be expected according to any reasonable baseline. Although this finding has been replicated many times (e.g. Bramwell, 1948), the theoretical significance of these results has been often contested. In fact, the first major attack on Galton's conclusions came only a few years later, when Candolle (1873) published an empirical study of the environmental factors that contribute to the emergence of creative genius in the sciences. Candolle's investigation inspired Galton (1874) to conduct his own inquiry into the origins of scientific creativity. The resulting book was called *English Men of Science: Their Nature and Nurture*, the subtitle suggesting that Galton had backed off a little from his extreme genetic determinism. At the same time, Galton's 1874 study introduced the 'nature-nurture issue' into the behavioral sciences (cf. Teigen, 1984). Henceforth, investigators would need to determine the relative impact of genetic and environmental influences in the development of creative potential.

Below I review some of the key findings regarding this problem. I begin by discussing the role of the environment and then end by discussing the impact of genetic endowment.

Environmental Factors

Since the time of Galton (1874) and Candolle (1873), researchers have unearthed an impressive inventory of circumstances and conditions that appear to nurture the acquisition of creative potential (Simonton, 1987a, 1994). These diverse influences may be roughly

grouped into three categories: family, school, and society.

Family Background

Galton's (1874) pioneer investigation devoted a considerable amount of scrutiny to the home environments of his highly eminent subjects. This emphasis was well placed. The home dominates infancy and childhood, and continues to exert some influence all the way through adolescence. One of the most critical of these long-term factors appears to be the socioeconomic status of the parents. Specifically, creative individuals tend to come from professional or entrepreneurial homes in which the parents place a high value on learning and education (e.g. Chambers, 1964; Cox, 1926; Ellis, 1926; Galton, 1874; Roe, 1953). This value almost invariably takes the form of a home replete with opportunities for intellectual stimulation, such as a large and varied library, ample and diverse magazine subscriptions, and family outings to museums and galleries (see also Schaefer & Anastasi, 1968; Terman, 1925). Not surprisingly, the children raised in such homes exhibit deep and varied interests, with a particularly strong inclination toward omnivorous reading, which makes a powerful contribution to creative development (Goertzel, Goertzel & Goertzel, 1978; McCurdy, 1960; Simonton, 1986b).

At the same time, families of religious or ethnic minorities produce eminent creators out of proportion to their representation in the population (Galton, 1869; Hayes, 1989; Helson & Crutchfield, 1970). A case in point is the conspicuous representation of Jews among the eminent creators of European civilization (Arieti, 1976; Hayes, 1989). However, this asset only appears when minorities enjoy some of the same basic rights as the majority (Hayes, 1989; Simonton, 1998a).

Interestingly, some family background variables assume a major role in determining the domain in which creative potential develops. One example is birth order. Galton (1874) indicated that his eminent scientists were more likely to be firstborns, but subsequent work suggests that the relation between ordinal position and creativity is more complicated than that (Clark & Rice, 1982; Ellis, 1926; Sulloway, 1996). Firstborns appear to gravitate to those domains that are high in prestige, power, and respect for authority, whereas laterborns tend to go into those areas that encourage more independent, individualistic, high-risk, and iconoclastic forms of creative achievement (Simonton, 1999b; Sulloway, 1996). Hence, scientific creators are more likely to be firstborns (Eiduson, 1962; Galton, 1874; Roe, 1953; Terry, 1989), whereas artistic creators are more likely to be laterborns (Bliss, 1970; see also Eisenman, 1964). If a scientist is a laterborn, he or she is more likely to become a revolutionary rather than a defender of the received paradigms (Sulloway, 1996). Likewise, more conservative forms of artistic creativity, such as classical music, tend to attract firstborns

more than laterborns (Schubert, Wagner & Schubert, 1977).

Another interesting example concerns the impact of traumatic experiences. Surprisingly, exceptional creativity does not always emerge from the most favorable home environments (e.g. Eisenstadt, 1978; Goertzel, Goertzel & Goertzel, 1978; Walberg, Rasher & Parkerson, 1980). On the contrary, creative potential seems to require a certain amount of exposure to: (a) diversifying experiences that help weaken the constraints imposed by conventional socialization; and (b) challenging experiences that help strengthen a person's capacity to persevere in the face of obstacles (Simonton, 1994). Yet these developmental inputs seem especially important for artistic forms of creative behavior (Berry, 1981; Brown, 1968; Post, 1994; Raskin, 1936; Simonton, 1986b). Not only is artistic creativity more unrestrained than scientific creativity, but in addition the career paths for artists often require more struggle than the typical career path in science.

Education and Training

Research on talent development has pointed to the supreme importance of training (Howe, Davidson & Sloboda, 1998). That is, one does not acquire world-class competence in fields like sports, chess, or music performance without first devoting about a decade to extensive and deliberate practice (Ericsson, 1996). To a certain extent, the same '10-year rule' applies to creative genius (Gardner, 1993; Hayes, 1989; Simonton, 1991b). Creative individuals do not produce new ideas *de novo*, but rather those ideas must arise from a large set of well-developed skills and a rich body of domain-relevant knowledge (Csikszentmihaly, 1990). At the same time, research on creative development suggests that this process is far more complicated than first appears (cf. Weisberg, 2003). To begin with, creators vary greatly in the amount of preparation they need, the greater the creativity manifested in adulthood the less time was needed to attain mastery (Clemente, 1973; Simonton, 1991b, 1992b; Zuckerman, 1977). So the creative genius can somehow acquire the requisite knowledge and skill more quickly than the norm. Furthermore, it is not necessarily the case that the greater creators have attained higher levels of formal training or education in their chosen domain. On the contrary, frequently the creative genius has acquired somewhat less than normally expected (Goertzel, Goertzel & Goertzel, 1978; Simonton, 1976a, 1987a). In fact, there is evidence that overtraining or overspecialization can actually harm rather than enhance the growth of creative potential (Simonton, 1976a, 2000). Sometimes highly creative individuals will have received considerable training, but in another field that is marginal to the domain in which they later attain eminence (Hudson & Jacot, 1986; Simonton, 1984e).

Complicating this picture all the more is the fact that education and training operate somewhat differently

depending on whether the creative potential is directed toward the arts or the sciences (Simonton, 1999b). For the most part, formal instruction and practice play a bigger role in scientific creativity than in artistic creativity (Hudson, 1966; Schaefer & Anastasi, 1968; Simonton, 1984d). As a consequence, the scientific genius will tend to display higher levels of scholastic performance and training than will the artistic genius.

Sociocultural Context

To make the case against Galton's (1869) extreme biological determinism, Candolle (1873) presented data proving that creative genius was very much contingent on the economic, political, cultural, and social milieu. So persuasive is this dependence that some sociologists and anthropologists have argued that creativity is mostly if not entirely a sociocultural phenomenon (e.g. Kroeber, 1944). However, it is possible to accept the influence of these forces while still maintaining that creativity represents a psychological phenomenon (Simonton, 1984d). This possibility ensues from the fact that the sociocultural environment, to a very large extent, influences the course of creative development. To see how this can be so, let us turn to the following three sets of findings:

- (1) If Galton's (1869) genetic determinism were correct, the number of creative geniuses would not drastically alter from one generation to the next. Such rapid fluctuations cannot happen because the gene pool for any given human population cannot change rapidly. Yet as Kroeber (1944) pointed out, creative geniuses tend to cluster over the course of history, forming dramatic 'Golden Ages' separated by dismal 'Dark Ages' (see also Schneider, 1937; Sorokin & Merton, 1935). Furthermore, Kroeber suggested that these clusters or 'cultural configurations' likely reflect the operation of a social learning process—what he styled 'emulation'. Each generation provides role models and mentors for the next generation. Using generational time-series analysis, this conjecture has been confirmed for European, Chinese, and Japanese civilizations (Simonton, 1975b, 1988b, 1992a). That is, for any given domain of creative achievement, the number of eminent creators in generation g is a positive linear function of the number of eminent creators in generation $g-1$ (Simonton, 1984c). This inter-generational effect occurs because the productive period of those in a given generation overlaps the developmental period of those in the following generation (see also Simonton, 1977b, 1984a, 1996).
- (2) Certain political environments also operate during the developmental stages of an individual's life, either encouraging or discouraging the acquisition of creative potential. Thus, on the one hand, growing up in times of anarchy, when the political

world is plagued by assassinations, coups d'état, and military mutinies, tends to be antithetical to creative development (Simonton, 1975b, 1976c). On the other hand, growing up when a civilization is fragmented in a large number of peacefully coexisting independent states tends to be conducive to the development of creative potential (Simonton, 1975b). In fact, nationalistic revolts against the oppressive rule of empire states tend to have positive consequences for the amount of creativity in the following generations (Kroeber, 1944; Simonton, 1975b; Sorokin, 1947/1969). Many nations have experienced Golden Ages after winning independence from foreign domination, ancient Greece providing a classic example.

- (3) The rationale for the last-mentioned consequence seems to be that nationalistic rebellion encourages cultural heterogeneity rather than homogeneity (Simonton, 1994). Rather than everyone having to speak the same language, read the same books, follow the same laws, and so on, individuals are left with more options. This suggests that cultural diversity may facilitate creative development, and there is evidence that this is the case. Creative activity in a civilization tends to increase after it has opened itself to extensive alien influences, whether through immigration, travel abroad, or studying under foreign teachers (Simonton, 1997c). By enriching the cultural environment, the ground may be laid for new creative syntheses. This finding is consistent with what was noted earlier about the developmental asset of ethnic marginality. The result also falls in line with research indicating the creativity-augmenting effects of exposure to linguistic, ideological, and behavioral diversity (Campbell, 1960; Lambert, Tucker & d'Anglejan, 1973; Nemeth & Kwan, 1987).

The above sets of findings taken together show how the *Zeitgeist* will often affect genius during the critical phase in which an individual acquires creative potential.

Genetic Factors

The preceding section did not by any means exhaust the list of environmental conditions and events that affect creative development. Some psychologists have concluded from such inventories that creative genius is 100% nurture and 0% nature (e.g. Howe, 1999). In other words, Dryden's quote got everything backwards. Genius is not born, but made, and Galton's (1869) original thesis was way off the mark. Yet such an inference would be very much mistaken. Sufficient evidence has already accumulated to suggest that to a certain, even if limited, extent, the genes inherited at the moment of conception influence the individual's

capacity for creativity. Consider, for example, the following four items:

- (1) A distinctive set of personality and cognitive traits are associated with the magnitude of creativity displayed (Martindale, 1989; Simonton, 1999a). That is, certain traits distinguish creative from non-creative people, and creative geniuses from those who are less notably creative (Feist, 1998). Yet, significantly, almost all of the characteristics associated with creativity have nontrivial heritability coefficients (Bouchard, 1994; Eysenck, 1995). By nontrivial I mean traits in which 30–50% of the variance can be ascribed to genetic inheritance. Examples include intelligence, introversion, energy level, and psychoticism. If creativity is linked with a specific cluster of traits, and if many of those traits have significant genetic components, then it is logically impossible to infer that creative genius is entirely an environmental product.
- (2) It is becoming increasingly recognized that the genetic basis of creativity may not operate according to a simplistic additive model (Waller, Bouchard, Lykken, Tellegen & Blacker, 1993). Instead, the numerous genetic components of genius may function according to some kind of multiplicative function (Simonton, 1999c; cf. Burt, 1943; Sternberg & Lubart, 1995). This multiplicative inheritance has been called ‘emergence’ (Lykken, 1998), and it has several critical implications (Simonton, 1999c). These include: (a) a highly skewed cross-sectional distribution for innate creative ability (precisely like that observed for individual differences in productive output); (b) low probabilities of familial inheritance (contrary to Galton’s, 1869, belief); and (c) attenuated validity coefficients for predicting creativity using an additive model (the inevitable procedure).
- (3) Modern behavioral genetics has shown that the influence of inherited characteristics does not appear all at once, but rather often unfolds gradually during the course of personal development (e.g. Bouchard, 1995; Plomin, Fulker, Corley & DeFries, 1997). It is for this reason that identical (monozygotic) twins reared apart in separate homes actually become more similar as they age. This epigenetic development, when combined with the aforementioned emergent inheritance, produces additional complexities in the acquisition of creative potential (Simonton, 1999c). For instance, a combined emergent–epigenetic process supports the emergence of ‘late bloomers’ whose creative abilities might not have been apparent in childhood. The reverse can happen as well, once promising talents may fail to realize their creative potential because of unfavorable epigenetic trajectories.

- (4) Behavior geneticists have devised powerful statistical methods for partitioning the variance in any individual characteristic into three sources: the genetic, the shared environment, and the nonshared environment (Bouchard, 1994). The shared environment includes those things that all siblings have in common, such as the socioeconomic background and child-rearing practices of their parents, whereas the nonshared environment encompasses those things that are unique to each sibling, such as birth order or peer relationships (Harris, 1995; Sulloway, 1995). The fascinating finding is that for a majority of human traits, the nonshared environment accounts for much more variance than does the shared environment (Bouchard, 1994). This would seem to contradict some of the findings regarding the impact of family background on the development of creative potential. If shared environment plays such a small part, why is creative genius more likely to emerge in specific home conditions? The answer is that many of these so-called environmental factors are actually genetic factors operating incognito (Scarr & McCartney, 1983). For example, parents who value education and who have professional occupations are likely to have above-average intelligence, and the latter asset is passed down to their offspring. The fact that the parents fill their homes with intellectually stimulating materials may only be an outward sign of the intellectual superiority of their children rather than a cause of that superiority. Many other supposed effects of the family environment may similarly reflect underlying genotypic traits shared by both parent and child (Simonton, 1994).

The foregoing four sets of findings suggest that the nature–nurture debate has not ended with an outright victory for the proponents of nurture. Creative development involves some combination of genetic and environmental factors, albeit the latter probably play the larger role. Creative genius is both born and made.

The Realization of Creative Potential

Once nature and nurture combine to produce an individual with high creative potential, how is that potential creativity converted into actual creative productivity? From a lifespan perspective, this issue can be broken down to several subsidiary questions: When does creative output begin? When does the creative genius reach his or her career peak? When does the creative career effectively end? In other words, what is the trajectory of productivity across the course of a creator’s career? Remarkably, the oldest empirical study in the behavioral sciences was specifically devoted to this very issue. In 1835 Quételet published the classic *A Treatise on Man and the Development of His Faculties*. Here he pioneered the

use of statistics to study individual differences and longitudinal changes. Among the studies in the latter category was an inquiry into the relation between age and creative productivity, with a specific focus on the careers of English and French playwrights. Perhaps Quételet was ahead of his time, for this particular investigation inspired no follow-up investigations. For instance, when Beard (1874) turned to the same subject nearly 40 years later, he did so using qualitative methods that Quételet (1835/1968) had already rendered obsolete. About a century after Quételet, however, a quantitative approach was revived by Harvey C. Lehman, culminating in his 1953 book *Age and Achievement* (see also Lehman, 1962). Since that time, quantitative methods have been substantially improved so that a great deal is now known about the career trajectories for creative genius (Simonton, 1988a, 1997b). The key findings of this research literature can be grouped under two major headings, namely, those that concern endogenous factors and those that regard exogenous factors.

Endogenous Career Development

To investigate the age-productivity curve, Quételet's (1835/1968) tallied the number of plays produced in consecutive 5-year age periods. The resulting aggregate tabulation yielded a curvilinear function with a single peak—or what may be described as an inverted-backward J-curve (Simonton, 1980c, 1988a). Subsequent investigators, and especially Lehman (1953), have replicated this curve over and over, perhaps making it the best replicated finding in developmental psychology (see also Lehman, 1962). Across a great diversity of creative achievements, the same longitudinal pattern emerges. Creative productivity usually begins sometime in the middle 20s. The output rate per unit of time then increases rapidly until the peak productive age is reached sometime in the 30s or 40s. Thereafter creativity output slowly declines until, by the final decades of life, works are being produced at about half the rate witnessed at the career acme. Hence, there appears to be an optimal age for making a major contribution to human civilization.

Despite the robustness of these results, the findings were often attacked on methodological grounds (e.g. Cole, 1979; Dennis, 1954d, 1956; Zuckerman & Merton, 1972). These criticisms largely focused on the post-peak decrement, arguing that it was some kind of artifact. Of the various criticisms, the following three were the most important (Simonton, 1988a):

(1) The empirical age curves were obtained by aggregating output across large numbers of notable creators. Although this seems like a reasonable procedure, it opens the way for the introduction of spurious results. There is no guarantee that what holds at the aggregate level will in fact be descriptive of what holds at the level of all the

individuals composing the aggregate. That is, there may intrude some form of aggregation error. The most obvious instance are the consequences of the fact that not all creators live to the same ripe old age (Dennis, 1956). Because no creative genius can ever continue output after death, the number of works produced by those in their 80s will be necessarily less than those produced by those in their 40s simply because more people live to 50 than live to 90. Hence, the aggregate tabulations will display an exaggerated age decrement. Fortunately, there are several methods for removing this artifact (Simonton, 1988a, 1991a). For instance, Quételet (1835/1968) calculated creative output per age period after making adjustment for the number of creators still alive each age period. Dennis (1966), however, confined his samples to creators who had lived to become octogenarians. Whatever the procedure adopted, the outcome is clear: the age decrement is not the result of some aggregation error (Simonton, 1988a).

(2) For most creative domains, the number of creators making contributions to those domains has increased over historical time (Lehman, 1947; Simonton, 1975b, 1988b, 1992a). This increase is due to both the exponential growth of the human population in general (Taagepera & Colby, 1979) and the explosive growth of activity in certain domains, such as those in the sciences (Price, 1963). What this means is that as creators get older, they have to endure more competition from colleagues than they had to face at the beginning of their career (Dennis, 1954d). That increased competition may imply increased difficulties getting papers published, patent application approved, paintings exhibited, or films distributed, depending on the creative domain. One problem with this criticism, of course, is that it implicitly assumes that the vehicles or outlets for disseminating creative products have not increased in the same proportion as the number of active creators. In the sciences, for instance, the number of professional journals has also grown explosively. More important, however, is the fact that the age decrement in creative output cannot be dismissed as a spurious consequence of increased competition (Simonton, 1988a). The post-peak decline still appears even after introducing controls for the number of competitors active in each age period (e.g. Simonton, 1977a).

(3) Many of the early studies, such as those conducted by Lehman (1953), did not tabulate total output, but rather only included high-impact or highly acclaimed works in the tabulations. It has been argued that this practice exaggerates the observed age decrement (e.g. Dennis, 1955d). The hypothesized distortion arises from the supposition that the age curves for total output has a more or less flat

post-peak age trend (see, e.g. Dennis, 1966). However, ever since Quételet's (1835/1968) pioneering investigation, this assumption has been shown to be plain wrong (see also Simonton, 1977a, 1985, 1997b). When lifetime output is split into 'hits' and 'misses' and then tabulated into separate time series, the resulting age curves are virtually identical. Those age periods with the most hits are also those with the most misses. Hence, across the career course, quality of output is closely associated with total quantity. Even more astonishing, the quality ratio or hit rate—the number of hits per age period divided by the total number of attempts (hits plus misses)—does not systematically increase or decrease over time, nor does it exhibit some curvilinear form (Oromaner, 1977; Over, 1989; Simonton, 1977a, 1985, 1997b; Weisberg, 1994). Instead, the quality ratio fluctuates unpredictably over the course of the career, hovering around some average hit rate. This longitudinal constancy in the proportion of hits to total attempts has been called the *equal-odds rule* (Simonton, 1997b; cf. Simonton, 1988a).

In light of the foregoing, the conclusion is inevitable that an age decrement does indeed tend to appear in the latter part of the career. Even so, there do exist several factors that govern the specific shape and location of the age curve, including the magnitude of the post-peak decline. The more crucial of these moderating variables are discussed below.

Career Age Versus Chronological Age

The original research plotted output as a function of the creator's chronological age (Dennis, 1966; Lehman, 1953; Quételet, 1835/1968). However, this is not the only longitudinal function possible. A significant alternative is to consider creative output as a function of how long the creator has been producing original ideas in a given domain. This alternative has been called 'career' or 'professional' age (Bayer & Dutton, 1977; Lyons, 1968; Simonton, 1998a). For instance, the productivity of a scientist might be gauged from the age in which he or she received the Ph.D. in the chosen specialty (e.g. Lyons, 1968). Admittedly, in many instances the chronological age and career age will correlate very highly across large samples of individual creators (Bayer & Dutton, 1977). This correlation results from the fact that the age at career onset will often be very similar—usually sometime in the middle or late 20s (Raskin, 1936; Simonton, 1991a). Even so, the age at which the career begins is by no means fixed, permitting some appreciable discrepancies to take place (Simonton, 1998b). Given this possible variation, the question then arises: Which longitudinal function is most descriptive, one based on chronological age or one based on career age? Recent empirical research points to the second definition as the more appropriate

(Simonton, 1988a, 1991a, 1997b). The longitudinal changes in creative output are best described in terms of career age. If a creator launches the career earlier than normal, the peak will appear earlier in terms of chronological age but in the same place in terms of career age. Likewise, a late start in the career will shift the whole career trajectory over to the later years of life.

The dependence of creative output on career age has two valuable implications:

- (1) Nothing prevents a creative genius from attaining a career peak at a chronological age when the vast majority of creators are well into the age-decrement portion of the age curve (i.e. 'over the hill'). A concrete example of such an exceptional 'late bloomer' is the Austrian composer Anton Bruckner. Not discovering his mission as a symphonist until he was in his late 30s, his first undoubted masterpiece did not appear until he was 50, and his last great work was left incomplete when he died in his early 70s. His best works appeared over a 20-year interval, which is normal, but the whole career was atypically shifted over by more than 10 years. Another fascinating instance is the career of the French scientist Michel Eugène Chevreul. Having already had an extremely productive career as a chemist, in his 90s he began to notice the effects of aging. This observation inspired him to switch fields and thereby become a pioneer in gerontological research—and simultaneously resuscitate his creative potential. His last publication appeared when he was 102, just one year before his death at age 103.
- (2) If the longitudinal function involves career age rather than chronological age, then creative productivity across the life span must be the consequence of something intrinsic to the creative process itself. In fact, I have offered a mathematical model that explains this phenomenon in terms of a two-step cognitive process (Simonton, 1984b, 1991a, 1997b). In the first step, creative potential is gradually converted to various ideas that make up 'works-in-progress' (the ideation stage); in the second step, these ideas are transformed into finished products (the elaboration stage). However, attempts to explain the career trajectory according to extrinsic factors are doomed to fail. For instance, insofar as the aging process is contingent on chronological age, then the age decrement cannot be attributed to declines in cognitive or physical functioning (cf. Lehman, 1953; McCrae, Arenberg & Costa, 1987). Indeed, as the Bruckner case illustrates, nothing prevents someone from reaching a career peak at an age when the aging process should already have been well advanced. This is not tantamount to saying that these various extrinsic factors are totally irrelevant. For example,

it could very well be that a career peak that occurs in the 30s or 40s might display a higher quantity of output than a career peak that occurs in the 50s or 60s. Nevertheless, the shape of the age curve is decided by how long the creative genius has been active in the domain, not by how old he or she happens to be.

This last point will receive additional support in the next section.

Domain of Creative Achievement

The two-step cognitive model mentioned above predicts that the specific shape of the career trajectory will necessarily vary according to the rates of ideation (in step one) and elaboration (in step two). Moreover, the ideation and elaboration rates will depend on the nature of the ideas that make up a given domain of creativity (i.e. their abstractness, diversity, number, and complexity). Hence, as an immediate consequence, the model predicts that the expected trajectories should vary across distinct domains (Simonton, 1984b, 1991a). This prediction has been abundantly confirmed (Dennis, 1966; Lehman, 1953; Simonton, 1991a). For instance, lyric poets, in comparison to novelists, tend to reach their peaks earlier and to exhibit much steeper post-peak declines (Lehman, 1953). In fact, the characteristic career trajectories can be used to estimate the ideation and elaboration rates for various creative domains (Simonton, 1984b, 1989a). Needless to say, because the ideation and elaboration rates are intrinsic properties of the creative process, these results again confirm that longitudinal changes in creative output are determined more by career age than by chronological age (Simonton, 1989a, 1991a, 1997b). After all, the aging process is probably the same for all creators, whether they be poets or novelists, mathematicians or geologists, and thus it would be difficult to explain, except on a *post hoc* basis, the distinctive career peaks and age decrements.

The domain contrasts in career trajectories have important consequences regarding the longitudinal location of a creator's *career landmarks* (Simonton, 1991a, 1997b; cf. Raskin, 1936). These landmarks indicate three events: the age of the creator's first great work, the age of the creator's single best work, and the age of the creator's last great work. In other words, the landmarks pinpoint the onset, acme, and termination of that period of the career in which high-impact works are being produced. According to the equal-odds rule mentioned earlier, quality is a function of quantity, and therefore those periods that feature the greatest total output will tend to be those that contain the most influential work. Because the single best work will be found among the best works, the age for this career landmark must differ appreciably across creative domains, closely tracking the expected age for the

maximum output rate. That prediction has been amply confirmed for domains in both the arts and sciences (Simonton, 1988a, 1997a). For instance, lyric poets produce the best work at a younger age than do novelists, a difference that is transhistorically and cross-culturally invariant (Simonton, 1975a). An analogous set of arguments apply to the other two career landmarks. For example, those fields that display the most severe post-peak age decrements in total output will tend to be those in which the last influential work will appear earlier in the career (Simonton, 1991a). Conversely, those domains in which the decline is negligible will tend to see great contributions appear very late in life. This tends to be the case for such fields as history and philosophy (Dennis, 1966; Lehman, 1953; Simonton, 1989a).

Nonetheless, the next moderating factor is even more powerful in determining the longitudinal location of the first and last major work.

Individual Differences in Creative Potential

At this chapter's outset I noted how much creators can vary in terms of total lifetime output. The most outstanding creators in a given domain will often be hundreds of times more productive than are their least prolific colleagues (viz., those who made only one contribution each). According to the two-step cognitive model, these individual differences in lifetime output can be credited to an underlying latent variable called *creative potential* (Simonton, 1991a, 1997b). The higher the level of creative potential an individual enjoys, the more ideas can be generated in a given unit of time. In other words, high creative potential manifests itself as a higher mean output rate throughout the career course, which necessarily includes a higher than normal maximum output rate. However, someone with low creative potential will exhibit a low mean output rate and a low maximum output rate. Otherwise, the career trajectories will be unchanged. The following pair of implications result:

- (1) Those who are highly prolific in their 40s will have been highly prolific in their 20s and 30s and will continue to be so in their 50s, 60s, and subsequent decades, as their life spans permit. In contrast, those who are less prolific in their 40s will have been correspondingly less prolific in the decades either before or after. So creative output per unit of time must exhibit considerable longitudinal stability (Cole, 1979; Dennis, 1954b; Helmreich, Spence & Thorbecke, 1981). In particular, the correlations among the output levels for various pairs of decades will be uniformly high. Even more critically, the correlations will all be approximately the same size (Simonton, 1997b). Hence, the correlation between output in the 30s and output in the 50s will be about the same magnitude as the

correlation between output in the 30s and output in the 40s. This turns out to be an especially important consequence of there being a single latent variable, creative potential, underlying output in each period (Simonton, 1997b). It means that the intercorrelations follow what is known as a 'simplex structure', a pattern that completely contradicts alternative theories of longitudinal stability (cf. Simonton, 1991c). According to the theory of cumulative advantage (Allison, Long & Krauze, 1982; Allison & Stewart, 1974), for example, output in adjacent decades should be more highly correlated than those in nonadjacent decades, yielding a correlation typical of an autoregressive process (Simonton, 1997b). But that prediction is strictly disproven.

- (2) Individual differences in creative potential also have critical repercussions for the location of the three career landmarks (Simonton, 1991a, 1997b). To keep the argument simple, imagine two creators working within the same discipline and who started their careers at the same age, but who differ greatly in creative potential. Then the career trajectories for the two creators will look identical, except that the curve for the high-potential creator will have a higher amplitude. That is, high creative potential is associated with more productivity throughout the career course. In the case of the middle career landmark—the age at the best work—this difference in amplitude will make no difference whatsoever. Because the best work will be located around the age of maximum total output, both high- and low-potential creators will produce their most influential product at the same age. Nonetheless, something very different occurs for the first and last career landmarks. Because the creator with the highest potential is accumulating output at a faster rate in the first decade of the career, the chances increase that he or she will get their first hit sooner. Similarly, because the high-potential creator is producing at a higher rate in the final decade of the career, he or she will claim the last hit later in life. Hence, the higher the creative potential, the earlier appears the first landmark, the later appears the last career landmark, but the location of the middle career landmark remains unchanged (Simonton, 1991a, 1997b). Whether creative potential is gauged by total lifetime output, maximum output rate, mean output rate, or achieved eminence, these expectations have been amply confirmed in empirical research (Raskin, 1936; Simonton, 1991a, 1991b, 1992b, 1997b).

Significantly, cross-sectional variation in creative output is far greater than longitudinal variation (Levin & Stephan, 1989, 1991; Over, 1982a, 1982b; Simonton, 1997b). As a consequence, if one is trying to predict a creator's productivity in a particular age period, it is far

more crucial to know who the person is than how old that person is. Take the typical case of a domain with an age decrement of 50% between the peak in the 40s and the decade of the 70s. Someone with a low creative potential who produces a total of two products at their career acme would be expected to produce but one product in the 70s. In contrast, someone with a high creative potential might generate 100 products in the 40s, and thus anticipate an output of 50 products in the 70s. Hence, the highly creative septuagenarian would be 25 times more productive than the low-creative individual at his or her career peak!

Career Flexibility and Openness

Judging from what has been said thus far, creative potential may seem to operate like a retirement account. During the developmental period of a future creator's life, deposits are made into this account, so that creative potential slowly builds up to a sizable 'nest egg'. Then during the productive period of the active creator's career, withdrawals are made from this account to 'purchase' creative products to offer the world. Some creators may have big accounts that enable them to buy a large inventory, whereas others only have a meager account that barely maintains some semblance of productivity. But in either case, the account is gradually used up, only those with the most impressive savings at the outset having any hope of having the supply last until death renders the funds unnecessary anyway.

This conclusion is not entirely unjustified. The amount of time and energy that a person can devote to creative development is far greater in childhood and adolescence than in adulthood, when a myriad of responsibilities and distractions may interfere. For instance, future great scientists usually devoted about 50 hours per week in graduate school to attaining mastery of their chosen discipline (Chambers, 1964). It is very difficult for a fulltime professor to maintain this level of continuing education. Course preparation and grading, committee meetings, and other professorial tasks compete for on-the-job time, while ever growing family responsibilities and activities vie for what time remains. Even so, studies of eminent scientists suggest that they manage to adopt strategies that serve to resuscitate creative potential at least to some degree. The following three strategies seem especially valuable:

- (1) Omnivorous reading was previously indicated as playing a major role in creative development. Such reading habits continue to preserve creative potential throughout the careers of highly successful scientists (Blackburn, Behymer & Hall, 1978; Dennis & Girden, 1954). The latter not only read extensively in their own specialty, but also try to keep up on the latest advances in disciplines adjacent to their own (R. Simon, 1974).

- (2) High-impact scientists tend to have extensive contacts with other scientists (Crane, 1972; Simonton, 1992c). The notion of the ‘lone genius’ is thus pure myth. These contacts consist of colleagues, collaborators, and competitors who, in one way or another, help stimulate and thus maintain the capacity to generate new and fruitful ideas. Those scientists who have these exchanges to an exceptional degree accordingly tend to have longer and more productive careers (Simonton, 1992c).
- (3) Great scientists do not work on one idea until it is exhausted, and then switch to another idea to push to the hilt (Garvey & Tomita, 1972). Instead, they tend to have several works in progress going on simultaneously, each at various degrees of development, and each having variable odds of having a successful outcome (Dunbar, 1995; Hargens, 1978; Root-Bernstein, Bernstein & Garnier, 1993; R. Simon, 1974). Not only does this provide them with a backup project when another project encounters unforeseen obstacles, but also cross-talk will often occur among the various projects so that the solution to one problem may lead to the solution to another, even seemingly unrelated problem (Tweney, 1990; see, e.g. Poincaré, 1921). The latter possibility is reinforced by the fact that prolific scientists tend to engage in a ‘network of enterprise’, that is, a collection of diverse but nonetheless interrelated ideas (Gruber, 1989; see also Feist, 1993; Simonton, 1992b). The ideational interaction among these projects helps the scientist get more mileage out of his or her creative potential.

Although the above three points concern scientific creativity, it is likely that similar strategies facilitate the maintenance of creative potential in artistic creativity. Thus, great artists, in contrast to their lesser colleagues, also tend to participate in abundant interrelationships with fellow artists (Simonton, 1984a). Likewise, the greatest composers appear to sustain their creativity by switching back and forth between different genre (Simonton, 2000) and by engaging in various stylistic shifts (Martindale, 1990; Simonton, 1977b). Hence, it is probably a general phenomenon. If a creative genius wants to avoid ‘drying up’ or ‘running out of steam’, it behooves him or her to be flexible and open throughout the career course (see also Georgsdottir, Lubart & Getz, 2003).

Exogenous Career Influences

The creative genius does not generate ideas in isolation from the outside world. On the contrary, many external events impinge on creators during the course of their careers. These extraneous events can deflect the career trajectory from what would be anticipated on the basis of what has been discussed so far. Such external events are of two kinds, the impersonal and the personal.

Impersonal

Earlier in this chapter I listed some of the political events that contribute to creative development, such as civil disturbances. Some political events, however, have little or no effect on the acquisition of creative potential but instead have an impact on the realization of that potential. The best example is war. In general, war has a negative repercussion on creativity, both the quantity and quality of creative products declining when conceived under wartime conditions (Fernberger, 1946; Price, 1978; Simonton, 1976b, 1980a, 1986c). To be more precise, major wars between nation states are associated with an overall decline in creativity in the participating countries. In contrast, wars fought far away from the homeland, like European imperial or colonial wars in Africa, Asia, or the Americas, had no consequences whatsoever, whether positive or negative (Simonton, 1980a). Thus, the two World Wars were detrimental to creative output in European nations, but not the Boer War in South Africa, the Spanish Conquest of Mexico or Peru, or the Opium War in China. In short, the war had to be of the sort that would have a direct impact on the creator. It is also essential to note that the negative repercussion of military conflict tends to be short-lived or transient (Price, 1978; Simonton, 1975b). When peacetime conditions return, creativity recovers quickly, at least at the individual level. The latter stipulation is necessary because sometimes the impact of war is so devastating on a particular country that many of its most creative denizens end up seeking their fortunes in nations less harmed by the events. A case in point is the episode of the numerous and illustrious creators who enriched the United States by the end of the Second World War.

Incidentally, dramatic political events and circumstances like war affect creative output in yet another manner—the very nature of the piece. For instance, the thematic content or style of a creative product tends to betray its conception under wartime conditions (Cerulo, 1984; Martindale, 1975; Simonton, 1986a, 1986c). That is, to a certain extent the product reflects the external conditions in which it was created. This even holds for scientific creativity, including creative products in psychology (McCann & Stewin, 1984; Padgett & Jorgenson, 1982; Sales, 1972).

Personal

No matter what the magnitude of achievement, the creative genius remains a human being, with a personal life that can sometimes interfere with work. One obvious source of interference is any serious bout with physical illness (Lehman, 1953; Simonton, 1977a). Perhaps more subtle, but still a harmful intrusion is having a family life. Francis Bacon (1597/1942) put the problem this way:

He that hath wife and children hath given hostages to fortune; for they are impediments to great enter-

prises, either of virtue or mischief. Certainly the best works, and of greatest merit for the public, have proceeded from the unmarried or childless men, which, both in affection and means, have married and endowed the public. (p. 29)

In support of this observation, Havelock Ellis (1926) noted from his scrutiny of British geniuses that there was “a greater tendency to celibacy among persons of ability than among the ordinary population” (p. xiv). Not counting priests, the rate was nearly 1 out of 5. Another investigation into the lives of a more elite sample of historic figures found that 55% never married (McCurdy, 1960). Marriage often tends to abbreviate or depress the creative career (Kanazawa, 2000), an adverse consequence that may mostly result from the cares and responsibilities imposed by parenting children (Hargens, McCann & Reskin, 1978; Kyvik, 1990).

It goes without saying that these negative repercussions of marriage can be more severe for female creators than for their male colleagues. Thus, women who win an entry in *Who's Who* are four times more likely than similarly illustrious men to be unmarried (Hayes, 1989). In addition, those who do get married tend to do so at a later age than is the norm for their social class (Ellis, 1926), and these successful women who somehow fit marriage in their lives are three times more likely to be childless in comparison to comparably accomplished married men (Hayes, 1989). In fact, between 1948 and 1976 in the United States, the proportion of doctorates that were granted to women correlated -0.94 with the average cohort fertility, a very remarkable aggregate-level correlation (McDowell, 1982).

I mentioned that impersonal factors may shape a creative product's content or style. Personal factors can also have this consequence. For instance, research on the musical compositions making up the classical repertoire has shown that the originality of the melodic material is positively associated with the intensity of stress that the composer was experiencing at the time of a work's creation (Simonton, 1980b, 1987b). In a sense, the unpredictability of the musical themes reflects the unpredictability of the creator's life.

The Termination of a Creative Life and Career

This chapter began at the moment of conception—when creators-to-be inherit a distinctive collection of genes from their parents. From that initial impetus we traced the acquisition of creative potential, including family experiences and conditions, education and training, and even the epigenetic growth of the individual's inborn potential. We next switched gears to examine how that potential was realized during the course of a creative career. This examination included endogenous factors like age at career onset, domain of creativity, and magnitude of creative potential as well

as exogenous factors like war, family, and health. The end result of these diverse factors is a body of work on which all creators must stake their respective reputations (Galton, 1869; Simonton, 1991c). Even so, a somewhat pessimistic saying laments that ‘all good things must come to an end’. Even the most outstanding genius must eventually die, an event that must once and for all cut off transformation of potential creativity to actual creative products.

Curiously, although the creative life must be ended by death, the very timing of the moment of death is partly contingent on the nature of that creative life. In particular, life expectancies vary according to the specific domain in which a genius attains eminence (Cox, 1926; Simonton, 1997a). Not only do writers tend to die younger than creators in other fields do (Kaun, 1991), but among writers, poets tend to have shorter life spans than do the rest (Simonton, 1975a). Although scientists as a group tend to enjoy long lives (Cassandro, 1998; Cox, 1926), eminent mathematicians constitute a notable exception (Simonton, 1991a). According to these data, anyone who aspires to exceptional longevity should avoid becoming either a mathematician or a poet!

Exactly why these life-expectancy contrasts appear is more problematic. One explanation is predicated on the fact that life span is negatively correlated with creative precocity (Simonton, 1977b; Zhao & Jiang, 1986). That is, those who achieve their first career landmark at a younger age tend to die younger as well. Because the various domains of creativity differ in the age at which the first contribution tends to appear, it is conceivable that the life expectancies merely track the contrasts in precocity (Simonton, 1988a). Hence, poets and mathematicians may die younger because they are prone to create influential products at younger ages than creators in other artistic or scientific domains. Yet this answer somewhat begs the question. Why do precocious creators die younger in the first place? Conceivably this might merely represent a sampling artifact. Because eminence is impossible without producing at least one high-impact work, those who accomplish this achievement at younger ages can still die young and claim some place in the history of their discipline.

Although this explanation seems plausible, empirical studies show that it cannot completely account for the domain contrasts in life expectancy (Cassandro, 1998; McCann, 2001). Other factors must be operating as well. One such variable is psychopathology, for the rates of mental disorder vary across disciplines (Ludwig, 1995; Post, 1994). For instance, poets are more disposed towards psychopathology than are other creators (Ludwig, 1995). In addition, such psychological difficulties are indicative of a shortened lifespan. The latter effect may result from outright suicide (Lester, 1991) or from unhealthy behaviors, such as alcoholism (Davis, 1986; Lester, 1991; Post,

1996). Both suicide and alcoholism are in fact very common among poets as well. Nonetheless, this explanation raises yet another question: Why is psychopathology unevenly distributed among the alternative domains of creative achievement? Is it because young creative talents choose the domain that best fits their own personality disposition? Or is it because achievement domains differ greatly in the stresses and strains that creators must confront to achieve distinction? Apropos of the latter alternative, there is evidence that the stresses of creative achievement can increase psychopathological behaviors (Schaller, 1997) and that different achievement domains vary in the amount of stress they impose (Simonton, 1997a). Yet this explanation cannot completely solve the puzzle. For example, highly versatile scientific creators—those who make contributions to more than one domain—have shorter life spans than do colleagues who confine themselves to a single field, but the same does not hold for artistic creators (Cassandro, 1998). How can this be? In all likelihood the connection between life span and the creative domain is the joint function of a host of factors operating in complex interactions.

Whatever the explanation, creative geniuses are seldom blind to the approaching termination of their careers. Except in cases of lethal accidents or homicides, creators will often see the end coming. The decline in mental functioning and physical health will become ever more apparent, and the rate at which death takes away a colleague, friend, or family member will gradually accelerate. Under such circumstances, creators may experience some kind of ‘life review’ (Butler, 1963). Past goals, ambitions, plans, and hopes will undergo reminiscence and reassessment. This end-life process may then influence the creative ideas that emerge from their minds.

Now there are data showing that creative individuals can experience significant psychological transformations as death approaches near. For instance, they are more likely to display some decline in conceptual complexity (Suedfeld, 1985; Suedfeld & Piedrahita, 1984). It is significant that this tendency toward cognitive simplification is not seen in those who died unexpectedly, and that the declines are a function of proximity to death, not of age per se. More to the point, research has indicated that changes do indeed take place in the creative products that emerge toward the end of life. For example, artists frequently evolve a distinctive ‘old-age style’ (Lindauer, 1993; see also Munsterberg, 1983). A frequently cited case is that of Titian, the Italian painter whose late *Christ Crowned with Thorns*, a product of his 90s, departs dramatically from the style on which he based his fame. Naturally, some might be inclined to dismiss these late-life creations as sad illustrations of the deteriorating powers of a once-great genius. But such a judgment would be incorrect. In fact, the works that emerge during those closing years can surpass anything that the

creator has done for years. It is almost as if the creator is pouring into these final thoughts every remaining ounce of their creative potential. Accordingly, these products can constitute ‘last artistic testaments’ that provide fitting capstones to the creator’s entire career. This more favorable interpretation is supported by the *swan-song phenomenon* (Simonton, 1989b).

Music critics and historians have often suggested that classical composers can feature creative transformations in their final years (e.g. Einstein, 1956). Instances include the *Four Serious Songs* of the 63-year-old Johannes Brahms or the *Four Last Songs* of the 85-year-old Richard Strauss. Of course, these are both cases in which the composers were very old. Yet last-work effects have been attributed to works of much younger composers, such as Franz Schubert’s appropriately titled *Schwanengesang*, published posthumously after the composer died only 31 years old. Supporting these conjectures is a quantitative study of the works created by 172 classical composers, including those just noted (Simonton, 1989b). Each composition was scored on several variables, such as melodic originality, duration, aesthetic quality, and popularity in the repertoire. The analysis then determined how these variables changed as a function of the work’s proximity to the composer’s death year. To avoid confounding the closeness of death with the composer’s age, the latter was statistically partialled out (along with numerous other potential sources of artifact). The outcome was clear. Regardless of age, compositions created within or close to the year of death were highly distinctive. To be specific, they tended to be shorter and to contain less original melodies. At the same time, late-life works tended to score high in aesthetic significance and to secure a prominent place in the classical repertoire. These were not inferior creations by any means, but masterpieces that managed somehow to say more with less, to encapsulate a career in an elegant and forthright affirmation. Even if outstanding creators cannot usually decide *when* their creativity is going to end, they retain capacity to pronounce *how* their creativity is going to end.

Innovations by the Frail Elderly

Thomas E. Heinzen and Nancy Vail

Department of Psychology, William Paterson University of New Jersey, USA

Abstract: Discovering the principles that underlie innovation requires a variety of research strategies. One counter-intuitive strategy is to study populations whose extreme circumstances make innovation unlikely. The principles abstracted here are derived from case studies of frail elderly people living in nursing homes. Varied innovations are described and interpreted as a consequence of the interaction between external stressors and internal characteristics, despite significant environmental and personal limitations. The article examines the validity of the fit between these observations and Amabile's description of necessary and sufficient components for innovative behavior.

Keywords: Innovation; Frail elderly; Creativity; Aging; Circumstances; Counter-intuitive; Frustration; Motivation; Stressors.

Introduction

Understanding the principles that reliably predict innovation will require all of the customary tools in our collective research tool kit. Even then, it is likely that we will have to develop still more techniques because the nature of the phenomenon we are seeking to understand is not only pervasive but also inherently surprising and complex. Consequently, the present chapter begins by offering a brief rationale for the mildly unusual approach presented here: naturalistic/clinical observations of a population *unlikely* to practice innovation, specifically, the frail elderly living in nursing homes.

Interspersed throughout the chapter are three case study reports that progressively describe: (a) a problem requiring innovation; (b) failed or marginally successful solutions to that problem that force the innovating individuals to clarify the problem and search for alternative answers; and (c) eventual innovations. The chapter abstracts principles that emerge from the combination of relevant literature and these case observations.

The only modifications to these case studies are those details necessary to honor the customary constraints of confidentiality and informed consent.

The Complex Causes of Innovation

Like the proverbial swan gliding elegantly on the water but paddling furiously beneath the surface, the product

of innovation may appear to be a single, elegant act, but the process that produces that innovation is a multi-factored, emotionally complex process (Shaw, 1994). A variety of theoretical models with varying degrees of empirical support agree on this fundamental observation about the complex nature of innovation (Runco & Shaw, 1994). One such model, useful because it is directive (Albert & Runco, 1990) that also proposes creativity-enhancing interventions (Amabile, 1990), is Amabile's (1983) componential framework, used to understand the innovations described here. Those components include domain-relevant skills, creativity-relevant skills, and task motivation.

At the broadest definitional level, Amabile (1990, p. 66) recognizes that there is a fairly high consensus that both creativity and innovation are accurately defined as consisting of both novelty (or originality) and whatever works (effectiveness). At a more specific level, the components articulated by Amabile continue to bear a fairly high level of face validity as well as allowing for more discriminating predictions and applications. For example, her componential definition worked well in a study of a particular technological evaluation (Heinzen, 1990) revealing that one form of distance education (one-way video, two-way audio) met or exceeded participant expectations within each domain except for that related to creativity-relevant skills, particularly creative thinking. Participants were disappointed in the degree to which this technology did

not facilitate creative thinking. The twin elements of novelty and effectiveness were embedded in this more detailed analysis of a particular technology. The model also appears to offer some measure of construct validity, as suggested by the way it clarified the distinctive roles played by mid-level managers in state government documented as producing innovation in spite of the bureaucratic restraints (Heinzen, 1990, 1994). In this example, novelty and effectiveness represented distinctive roles played by particular managers that, when functioning as a team, led to innovation with state government. The model also more pragmatically articulated unplayed roles that tended to block innovation while contributing to a particular kind of organizational analysis.

Each of the components is complex. For example, the affective component of the innovation process appears to include a range of cognitively driven self-assessment activities at various points in the process (Shaw, 1994). Similarly, the pragmatic skills which support innovation within particular domains (such as medical research, non-fiction literature, cooking, or public administration) are themselves unique to the domain and even more specific to the particular tasks within those sub-domains (Heinzen, 1994b). For example, innovations within public administration involve fairly mundane skills such as being able to run a good meeting to a detailed knowledge of the causes of public transportation successes and failures in diverse communities, as well as the differential causes of those outcomes (Heinzen, 1994a). But the component most difficult to understand appears to be the affectively related component of task motivation.

The motivational component of innovation is the subject of intense, thoughtful theoretical and empirical debate. The debate focuses on both the measurement and validity of the distinction between intrinsic and extrinsic motivation and their varying consequences (Eisenberger & Cameron, 1996). This slow but important level of empirical debate is beneficial to our understanding of innovation as it forces us to clarify our terms and intended meanings. But for the time being, we can use this brief review of innovation literature to assert a fairly obvious but nevertheless important recognition: *the process that produces innovation is complex.*

Case Study 1: The Difficulties of a Smoking Habit in a Nursing Home

B. V. is an 84-year-old, long-term cigarette smoker who was compelled, by a stroke, financial circumstances, and limited family support, to move to a nursing home following a stroke. The stroke left B. V. confined to a wheelchair with limited use of her left side in both the upper and lower extremities. In addition to the stroke, B. V. was suffering from severe, long-term depression related to the shock and adjustment requirements of moving away from her

previously supportive but aging community support network to a nursing home much closer to her nearest relative. In these circumstances, B. V. declared that the chief satisfaction of her life was “to smoke cigarettes, and I don’t care at all if it kills me”. She especially wished to start her day with an early morning cigarette.

The nursing home was understandably not eager to support a smoking habit within a facility where many residents were immobile and maintaining respiratory function through oxygen support. In addition to concerns about B. V.’s health, the nursing home also worked hard to remove all fire hazards and was particularly sensitive to threats posed by long-term smokers. Consequently, B. V. reluctantly agreed to a ‘contract’ limiting her cigarette smoking to one cigarette in the morning and another in the evening, outside the facility, and only while supervised. However, B. V. also was free to smoke more if she could persuade others to help her achieve these safety requirements. Regardless of whatever ethical issues are engaged by this decision, the resulting situation was that B. V. was a highly motivated smoker. She was limited by severe mobility deficits (barely strong enough to wheel her own wheelchair), by living on the third floor of a nursing home, and by needing an elevator to take her to the ground floor where she might be able to go outside and smoke. It is within the context of her severe limitations as well as her highly motivated (i.e. addictive) desire to fulfill this goal of smoking as much as possible that we can view and come to understand her innovations.

Innovation and Unusual Methodologies

Although there is frequently significant reluctance to give credence to innovative scientific methods and their sometimes disturbing conclusions, the history of science suggests that our degree of openness to new ways of addressing scientific issues significantly contributes to the energy that drives scientific revolutions (Kuhn, 1962). Scientific discoveries in psychology certainly are no exception. For example, a significant amount of research on attraction depended on a simple experimental paradigm developed by Byrne (1971). As another example, research on self-recognition among both infants and infants depended upon ‘dreaming up’ the idea of placing colored dots on foreheads and observing their behavior before a mirror (Gallup, 1977, 1995). That idea was adapted by Cameron (1988) to observe infants ‘playing’ with their shadows. This methodological innovation clarified (and lowered) the age at which we can demonstrate infant self-recognition.

The slow progression of knowledge in psychology is the consequence of these innovative methodologies as surely as other sciences have depended upon improved capabilities to view previously unseen phenomena by

progressively more inventive microscopes. Moreover, as a subject of investigation, innovation is by definition both surprising (novel) and wide (pervasive), yet nonetheless deep (complex). The principles that predict and support innovation are diverse because innovation occurs across ‘disciplines’, drives evolution (Heinen, 1994b), yet produces adaptive responses that individuals report as personally transforming. So a second common-sense assertion about innovation, also drawn from the literature, is that *understanding innovation will require a wide range of methodological approaches*. The study of unlikely populations is one such methodological innovation capable of producing insights into innovation that may generalize to other populations.

Case Study 2: How to Repair a Velcro Strap

A. S. is a 94-year-old male who is in generally good health. However, he fatigues quickly and has difficulty using his fingers due to arthritis. Nevertheless, he retains a sense of humor and enthusiasm for problem-solving, reminiscing, and eating even though his taste sensitivity has been severely limited. A. S. lives in a nursing home, and his source of discretionary spending is limited to fifty dollars per month. He is obligated by the practice of this particular home to spend most of that money on a clothing allowance and toiletries in addition to those already supplied, and any gifts, cards, or ‘extras’ that he may desire.

His immediate problem was that he spilled broccoli soup on the strap of his sneakers. The straps use velcro to secure the shoes to his feet. The soup proved to be difficult to clean and the consequent scrubbing damaged the velcro so that the velcro strap no longer ‘grabbed’ efficiently; although the straps fastened initially, they came apart when A. S. walked. A. S. was reluctant to ask the aide for further assistance because he felt embarrassed at being needy in any form; he also enjoyed the challenge of trying to solve problems himself. This was a fairly urgent problem because A. S. could not walk confidently or very far unless his shoes were securely fastened to his feet.

Insights From Non-Representative Samples

Studying unlikely or inappropriate populations is among the counter-intuitive approaches and techniques that appear to have provided an unreasonable level of scientific advance. For example, the particular and very small proportion of the HIV-positive population who do not develop full-blown AIDS is now serving as one promising model for how to understand, treat, and maintain immune function and thus manage the disease (Kolata, 2001). In this case, the non-representative exception to the rule may prove to be instructive.

The effectiveness of a different kind of ‘error’ was demonstrated by Piaget. Piaget broke several fundamental rules of population sampling by his attentive (perhaps we should dare to say ‘loving’ or at least ‘fascinated’) observations of his own children. Although details of his theories have been modified, it was Piaget’s own inventiveness in documenting his observations that led to their subsequent refinement. Moreover, his core observation of cognitive development, as well as the methods he used to document those observations, has led to thousands of studies, theoretical variants, and distinctive interventions.

The example of the child development theories proposed by Piaget is particularly applicable to the present chapter because these case studies document unusual, innovative cognitive activity among a different yet distinctive age-population: the frail elderly. What would Piaget have made of these observations?

Subsequent research regarding Piaget’s many ideas, inspired mostly by Piaget’s methods, has led to several modifications. Specifically, Berk (1988) noted that Piaget probably underestimated the competencies of infants and children and that he inaccurately doubted that training could influence development. In addition, improved methods suggest that cognitive stages are more gradual than discrete and that they probably continue much longer into the lifespan. However, Piaget’s initial observations of his children, the methods he employed to validate those observations, and the observation of continuing cognitive growth have retained their validity. They have inspired ever more innovative research, and suggest that non-normative populations can lead to productive, creative thinking that holds up under more careful, empirical tests. It is not unusual to learn from extreme or unlikely populations; indeed, they may compel more creative thinking that our customary theories generally allow. The observations documented here represent one way to rethink our attitudes and expectations regarding the capabilities of the frail elderly, as well as the factors that facilitate or impede innovation.

Consequently, even though the abstraction of principles from such unlikely samples would not appear to generalize to larger populations, they appear to provide an opportunity for insight that might otherwise be lost or relatively inaccessible. So a third assertion of this chapter is that *non-normative populations can provide insights that may generalize to larger populations*.

Case Study 3: How to Accept the Unacceptable

L. N. is a 96-year-old female living in a nursing home. She is diagnosed with Parkinson’s Disease, mild dementia, arthritis, macular degeneration, and depression. L. N. is a lifelong religiously oriented individual who carried a personal ‘secret’ for approximately 80 years. Raised in a small, rural, conservative and very religious community outside

the United States, she became pregnant when she was 15 years old. L. N. was quietly moved by her family to a larger city in the United States, in order to avoid the social embarrassment of an unwanted pregnancy. The resulting infant was returned to the home community where it was raised by relatives of the father while L. N. herself continued her life by moving and working in the New York metropolitan area. L. N. eventually married, produced several children, grandchildren, and great-grandchildren.

During our first interview, L. N. agreed to further visits but only under the condition that “there are some things that I will never tell you”. A few months later, L. N. received a letter from her first child, now 81 years of age. This daughter’s daughter had ‘found’ her maternal grandmother through a variety of church records and genealogies published on the Internet. L. N. did not want to meet with this ‘new’ family because she wished to maintain her lifelong secret. However, the letter seeking information about her had become known throughout her family during the genealogical search, and L. N. was obliged to meet the daughter she had given up for adoption 81 years earlier. Against her will, L. N.’s secret had been revealed.

Learning About Innovation From the Frail Elderly

One population that appears to be unlikely to demonstrate significant innovation is the frail elderly. The factors that would seem to oppose innovation by individuals living in nursing homes are many. First, that population is pre-selected as physically needy, usually the result of a major health crisis such as a debilitating stroke, Alzheimer’s disease, vascular dementia, or functional limb loss such as a hip replacement due to a fall, often related to osteoporosis. Moreover, many psychological disorders are co-morbid with these physical difficulties. The proportion of the elderly who carry the risk factors associated with depression is estimated at 80% with significant co-morbidity accompanied by other innovation-suppressing factors such as “disabling illness, chronic illness, financial strain, lack of social support, prior history of depression, and family history of depression” (Tangalos et al., 2001). Innovation seems unlikely to flourish in such a setting.

However, this population of frail elderly does offer something that other more conventional populations do not. They are living under conditions of chronic stress. These exceptional levels of stress are highly motivating personal circumstances and support reactive creativity and consequent innovation (Heinzen, 1994). Verbal innovations seem particularly likely to flourish since this is the one remaining domain-relevant skill that is common to most, but not all, of this particular population (Heinzen, 1996). This suggests a fourth, more tentative assertion about innovation: *The impetus*

for innovation may be external, unpleasant, and unwelcome.

Case Study 1: The Real Problem is Keeping the Elevator Open

From the moment she awoke, B. V.’s primary purpose was to smoke cigarettes as much and as often as possible. However, there were several obstacles to her goal, each occurring at three distinct stages. First, she had to persuade staff to care for her before others so she could be in her wheelchair as soon as possible. Second, she had to make her way to the elevator, reach the call button, enter the elevator, direct it to the proper floor, and exit the elevator. Third, B. V. needed to find the individuals who had access to her cigarettes and matches and persuade someone downstairs to take her outside and sit with her while she smoked. Each of these steps presented very real physical and emotional difficulties that B. V. persistently sought to overcome throughout all her waking hours.

The first need for cooperation from nursing aides and nurses who administer medications was set within the context of many, complex personalities, limited resources, and a high level of demand from fellow residents. In addition, the personalities holding some measure of responsibility and consequent authority over a nursing home resident are many, an unavoidable feature of a 24-hour care facility that includes among fellow residents, nurses, nurses’ aides, physicians, and a variety of therapists (physical, occupational, speech, and psychological).

For example, each nurse’s aide is responsible for as many as seven to ten patients. In addition to the intrinsic variability of their personal needs, each patient is acutely aware of the importance of their own needs and understandably less aware of the severity of the needs of others they cannot see (but may hear). Furthermore, the aides do not work seven days per week and occasionally take vacations. Combined with an every-three-month employee rotation pattern across the floor, a particular individual has at least three aides to cover their 24-hour needs plus another three aides to accommodate various shift changes. Each three-month rotation of nurse’s aides (usually a contractual feature of the workplace) introduced a new set of ‘helping’ personalities to the frail, elderly residents. Consequently, B. V. was obliged to discover ways in which each aide and nurse might be more or less effectively persuaded to prioritize her morning care so that she could satisfy her strong desire for cigarettes.

Once she arrived downstairs, B. V. faced a similarly daunting set of inter-personal challenges to find a sympathetic, available helper so that she could achieve her goal of maximal cigarette smoking. Stages one and three of B. V.’s problem-solving

were difficult, constantly shifting, inter-personal problems. To a moderate degree, B. V. solved these problems through flattery, loud complaining, accusations, praise, and threats of poor behavior. In short, B. V. used the customary currency of human relations to cajole individuals to help her fulfill the demands of her cigarette addiction. However, the focus of the present observation is on B. V.'s far more tangible, intermediate goal of manipulating the elevator.

There were several obstructions confronting B. V. in her attempt to achieve what appears to be a simple goal. Although, the elevator was approximately 75 feet from the entrance to her room, the staff was keenly aware that B. V. represented a potential fire hazard with her willingness to break the facility rules for cigarette smoking. Consequently, they were not generally disposed to be helpful when B. V. sought assistance to get to the elevator, believing also that greater help could be offered to B. V. by helping her to stop cigarette smoking entirely. Second, B. V.'s stroke as well as the long-term effects of cigarette smoking made the act of wheeling herself to the elevator exhausting. Third, the buttons for working the elevator were hidden behind a spring-loaded cover that was placed at a height of about four feet. This height represented a significant reach upward for a slightly built individual with osteoporosis and confined to a wheel chair.

In addition to these constraints, B. V.'s stroke limited her to having only one arm available to position the wheelchair, manipulate the cover, reach the button, and then wheel herself into the elevator after the door opened. Finally, and perhaps most daunting to B. V., was that after achieving all of this, the door to the elevator remained open only for a limited period of time. If B. V. did not cross the electric eye with her wheelchair quickly enough, the door would close and B. V. would have to reposition her wheelchair and repeat the entire, laborious process once again.

Situation-Driven Versus Personality-Inspired Innovation

Taken together, these three accounts demonstrate a 'source of motivation continuum' that describes the range of motivations to innovate. At one end of the continuum is situation-driven innovation, as demonstrated in these case study accounts of innovation by the frail elderly and noted as an impetus to innovation in diverse other settings (Heinzen, 1994b). Individual circumstances sometimes require innovation in order for some goal to be realized. In our case studies, these included cigarette smoking, fastening damaged velcro, or discovering a way to emotionally accommodate oneself when a life-long secret has been revealed. This situation-driven innovation would not occur unless the situation provided no other alternative.

At the other end of the continuum is personality-driven innovation. This is creative and self-initiating innovation. We tend to attribute 'creativity' to those personalities that chronically explore, change, adjust, invent, and seem disposed to do so whether or not circumstances are pressuring them. Moreover, it seems likely that such creative personalities are likely to innovate more readily when faced with challenging circumstances. However, such 'creative types' seem to be relatively rare, in keeping with the low frequency of genius and the corresponding low probability of any individual being strongly equipped with all three of Amabile's necessary and sufficient components for creativity.

Consequently, we can offer this fifth assertion that complements the observations of our case study: *Innovation does not require a 'creative personality'; ordinary personalities in extraordinary circumstances will attempt to innovate.*

Case Study 2: An Unsatisfactory Solution to the Velcro Problem

A. S. was highly motivated to walk. The velcro that continually 'came apart' when he tried to walk represented a severe threat to his independence and to his sense of himself as a competent individual. His inability to afford new sneakers, his reluctance to ask for help, and his determination to continue walking motivated A. S. to search for new ways to solve his velcro problem. His first attempt was to wrap rubber bands around his sneakers. This was a relatively difficult task to achieve, given his level of arthritis, limited movement, and the necessity of applying the rubber bands while his sneakers were on his feet.

However, A. S. did achieve some limited success using his rubber band solution: the velcro stayed in place, but only if it was not very tight. In addition, the rubber bands tended to move as A. S. shuffled across the floor. The rubber bands proved to be only a temporary, relatively unsatisfactory solution.

Frustration and Innovation

These three case studies all have in common the experience of significant frustration, even suffering. This commonality begins to tie these observations to the literature describing the relationship between frustration and innovation. A. S. was frustrated in his attempt to fix the velcro on his sneakers. While a trivial inconvenience for most of the population, this frustration represented a significant loss of mobility, some social embarrassment, and a personal humiliation. Similarly, B. V. was deeply frustrated in her desire to smoke cigarettes. She applied a lifetime's worth of human relationship skills to persuade different individuals to assist her to smoke yet remained frustrated by her inability to manipulate the elevator doors. L. N. also experienced frustration but it was about a less tangible goal. She wished to preserve a personal secret

that she had successfully shielded from various family and friends for more than 80 years. A. S. and B. V. were frustrated in active pursuit of a goal; L. N. was frustrated when an outside force imposed frustration on the goal that she already had achieved. All three individuals, in their own particular way, were frustrated.

Frustration, we now recognize, leads to many consequences. The most well-known, frequently studied consequence of frustration is aggression (Dollard et al., 1939). But this does not exhaust the network of possible consequences of frustration. Other candidates for the consequences of frustration include the kind of depression known as learned helplessness, renewed perseverance, a variety of intra-psychic defense mechanisms, resetting one's goal, and innovation (Heinzen, 1994a). It is likely that each of the participants in these three case studies experienced each of these reactions, in varying degrees.

The psychological literature has addressed the relationship between frustration and innovation in a variety of ways. Psychodynamic authors identified 'sublimation' as a defense mechanism whose purpose was to transform privately psychic frustrations into socially acceptable works of creativity (Freud, 1933; May, 1975). Using a more straightforward, social perspective, Lewin (1935) expressed a similar relationship between frustration and creativity but in a far more pragmatic manner. Lewin articulated frustration as an obstruction to a goal that provoked a variety of responses, including circumvention and consequent innovation as a means of goal attainment. Heinzen (1994b) proposed a relatively coherent model of responses to frustration in his description of the frustration-response network. Consequently, a variety of literatures, both theoretical and empirical, affirm the experiences identified in these case studies: *Frustration inspires innovation*.

Case Study 3: Recognizing the Lack of Alternatives

L. N.'s initial reaction to being 'discovered' by the child she gave up for adoption 81 years earlier was extremely negative. She reported disappointment in her failure to maintain what she considered to be an embarrassing secret. She experienced both sadness and guilt that her grandchildren and great-grandchildren would be burdened with a sense of shame and social embarrassment. She expressed annoyance that she was still alive. She became 'mad at God' for allowing this to take place. She felt fear at having to meet and face the possible judgment of her 'new' daughter. She re-experienced the social disapproval of particular family members and a private sense of shame, not so much for bearing a child 'without benefit of clergy', but for singling herself out in such a public way.

L. N. also experienced increasing anxiety as the details of flights, family meetings, and related

arrangements systematically counted down towards the actual day of the meeting, aggravated by the general sense of excitement that family members conveyed to her. L. N. had successfully 'buried' her secret and experienced very real suffering as her secret was systematically revealed against her will. However, L. N. also recognized the inevitability of the event, was unwilling to consider taking her own life as a way to avoid the situation, and slowly started to reconcile herself to facing the situation she had spent 80 years avoiding.

Suffering Also Can Lead to Innovation

The term 'frustration' does not accurately convey the quality of experience that L. N. reported when she was first contacted by her 81-year-old daughter. A more appropriate term may be 'emotional suffering' and there is additional evidence that this deeper, longer lasting, more profound experience also is capable of producing innovation and creativity. In a book appropriately titled *Hope Never Dies*, holocaust survivor Sarah Wahrman (1999) describes the forced labor required in Nazi concentration camps, the depth of suffering imposed upon those victims, and the startling and inventive coping that this suffering inspired.

Specifically, Wahrman describes working the night shift at Guben, Germany, processing fine wire and metal spools in order to support the German war industry. Prompted by hunger pains and the need to barter for food, this survivor created wire flowers using the colors provided in the fine wire (green, bronze, and silver). She fashioned these onto heavier wires and created flowered pins, the shape of a rabbit, the appearance of a French poodle, and a reindeer with horns. She bartered these with the camp cook for extra food that was then divided among a larger group of 'in-mates'. This kind of invention in the face of shared disaster suggests that innovation is more than just a clever ornament that periodically improves daily existence—innovation is a fundamental survival tool, a product of human evolution focused first on survival rather than amusement, decoration, or improvement.

Similarly, during the more recent genocide in Rwanda, the terror experienced by children was represented artistically in an innovative attempt to help children recover from the severe trauma of that more recent holocaust. In only 100 days during the year 1994, more than 100,000 people were murdered in Rwanda as "an integral part of the Hutu government's plan to exterminate the Tutsi population . . . This holocaust claimed 800,000 lives and created 300,000 orphans". A portion of those children were cared for by relief agencies seeking to help them deal with their private traumas and it was within this context that Salem (2000) was able to document their innovation.

These children indicated the range of response anticipated by the frustration-response network. They reacted "with aggression and rage; others live in

constant fear. More than 60% of the children interviewed in the aftermath of the Rwandan genocide said they did not care if they grew up” (Clinton, 2000). Relief workers and trauma counselors, desperate to find some way to alleviate the stress experienced by some of these 300,000 children, noticed that the children “spontaneously created” drawings “some three to four years after the genocide ended” (Salem, 2000, p. 7). Their drawings and comments documented their private memories of that atrocity and appear to have contributed in some small measure to their personal adjustment. It is difficult to imagine the effect on a small child of witnessing not only the murder of one’s parents, but the systematic destruction of all the individuals in your home village.

These same authors report that one desperate mother placed her well-dressed child on the road and directly in the path of oncoming soldiers, hoping they would spare him. But when she observed other children being slaughtered, she created a disruption, drawing the soldiers off the road after herself and away from her child. Although the mother was killed, her child was rescued by field medics (p. 42), some of whom later reported the story. Suffering may not merely lead to innovation, it may require innovation and creativity as a coping mechanism in the cause of survival and adjustment to a more peaceful world.

We can tentatively assert from these descriptions that *suffering threatens survival, clarifies goals, and thereby facilitates innovation*. It is worth mentioning two related applications of these principles, one cautionary and the other challenging. First, since innovation is complex and requires many components, there is no guarantee that suffering will lead to innovation and no consequent need to perversely impose suffering in order to produce innovation. Second, it is nonetheless still helpful to recognize that not all suffering is inherently detrimental. Necessary surgical interventions are often painful. Similarly, most parents agree that shaping the attitudes and behavior of children in a positive way sometimes requires uncomfortable levels of constraint and discipline. Personal growth may involve, or even require, some level of suffering. Regardless of whatever particular psychological mechanism may be at work, our general conclusion is this: *Suffering can nurture innovation*.

Case Study 1: Adapting a Tool to Solve the Elevator Problem

B. V. was moderately successful at negotiating the complex personality issues related to persuading a wide variety of individuals to provide minimal assistance in order to help her smoke. They were willing to ‘get her up’ in time for an early cigarette. This is a remarkable success, partly because B. V.’s desire to smoke early in the morning was especially inconvenient. The morning is an especially demanding time of the day for the staff. From

7.00 a.m.–8.30 a.m., the staff was busy delivering meals, administering medications, and attending to a wide range of personal needs among the residents of the facility.

However, after arriving at the elevator doors, B. V. repeatedly found herself in an unproductive, repetitive pattern of behavior. With her one good arm, B. V. laboriously positioned herself near the button calling for the elevator. She then reached up to the metal door protecting the buttons, opened it, pressed the button, and then failed to move past the electric eye that would keep the door open long enough for her to enter the elevator. B. V.’s own frustration appeared to be increasing as staff refused to assist her. On the day that I was unobtrusively observing her, B. V. repeated this cycle six times, with rest pauses imposed as the elevator doors closed and the elevator traveled to other floors.

After the sixth failure to get to the elevator’s electric eye quickly enough to keep the doors open, B. V. stared at the closed elevator door for a lengthy period of time and then retreated to her room. Although I assumed that she was discouraged and had temporarily ‘given up’, B. V. reappeared in the hallway some minutes later. Wedged in her wheelchair was a two foot long ‘grab bar’, a device designed to assist individuals with limited mobility to reach further, fasten on light objects, and retrieve or place them as needed. It is customarily used for light clothing, sections of a newspaper, or other light-weight objects.

Although she was now extremely tired by her efforts, B. V. first attempted to use the grab bar to manipulate the door to the call buttons from a distance, but the grab bar was not equal to the dexterity required for this maneuver. However, after calling for the elevator in her customary way and positioning herself as close to the doors as possible, B. V. frantically waved the grab bar in front of the electric eye after the door opened. She succeeded in keeping the elevator door open until she could enter the elevator. She then used the grab bar to press the appropriate button and move her further along the path to her goal.

Levels of Frustration and Cognitive Clarity

Are we justified in referring to B. V.’s behavior as innovative? Clearly reminiscent of tool use by primates, B. V.’s slight modification of the use of the grab bar to manipulate the electric eye of the elevator was an innovation for her. Her action met the twin definitional requirement of being both original and effective and helped her achieve a goal that was important to her. It is interesting to note that B. V. appeared to come up with the idea after experiencing increasing levels of frustration and then calming herself sufficiently to focus on the details of the particular problem she was trying to solve. When we interviewed her later about

how she came up with the solution to this problem, her only clarification was, "I just thought of it, that's all". B. V.'s increasing frustration and her eventual self-calming response so that she could think up a solution suggests an idea indicated by other empirical literature (Heinzen, 1989): *Frustration will not lead to innovation unless it is sufficiently annoying to force new ways of thinking about a problem.*

Case Study 2: Using a Common Object in a New Way

A. S. continued to have difficulty with the velcro strap of his sneakers and remained frustrated by his relative inability to walk. The combination of limited discretionary money, his private insistence on not asking for help, and his painful arthritis made his temporary solution of applying rubber bands around his shoes inadequate. It also was difficult to maintain since the rubber bands frayed and broke quickly and were somewhat painful to his feet. They were also mildly unattractive and produced some negative comments from others. The rubber band solution seemed to broadcast his disability and A. S. found this public display of his disability and his limited means embarrassing. Consequently, A. S. remained highly motivated to discover a better solution.

The solution came while A. S. was sitting on a couch and observing a secretary stapling papers together. When the secretary left for a brief period, A. S. furtively borrowed her stapler, took it back to his couch, removed his sneakers, opened the stapler so that the bottom would not close the ends of the staple, and painfully pressed one staple through the velcro strap. He tested it, noted that it would grip, and applied about a half dozen staples to substitute for the damaged velcro. This innovation 'held' the strap together. Although it was somewhat more difficult to remove the strap, that inconvenience was preferable to several re-fastenings per day.

Why Innovation Survives, Even in a Nursing Home

The innovation that A. S. achieved also appears to fit the general definition of innovative behavior. A. S. certainly succeeded in adapting an existing device to solve a new problem. Moreover, A. S.'s efforts strike me as a more distinctive application of a stapler than B. V.'s adaptation of a grab bar to solve her particular problem. But both innovations were adaptations to the peculiarities of their private situation. When we interviewed A. S. about his innovative behavior, he proudly reported, "I'm pretty damn clever, aren't I? Well, you have to be in a place like this".

The additional observation that may generalize from this particular observation is that A. S. appeared to be aware of his own habits of innovation, attributed them somewhat to the constraints of living in a nursing home, and enjoyed thinking and behaving in an innovative fashion. This association between innova-

tive behavior and positive affect has been explored in a variety of ways. Isen et al. (1987), for example, demonstrated how small acts that made people feel good appear to 'prime' particular affectively sensitive cognitive structures and thereby increase positive affect and facilitate problem-solving. Isen et al. (1978) suggest that such priming facilitates access to cognitive structures, thus engaging greater complexity and consequent creativity. Given the affective complexity of innovation (Shaw, 1994), both suffering (as a clarifying impetus to solve problems) and positive affect (as an intrinsically satisfying activity) are acknowledged parts of the process that can lead to innovation. Not only does innovation solve a practical problem, but the process of moving from frustration or even suffering to problem-solving and innovation is self-rewarding, both pragmatically and emotionally. The underlying principle suggested here about innovation is that *innovative behavior is both externally and internally self-rewarding.*

Case Study 3: When Changing Yourself is the Only Alternative

L. N. was very clear within herself that she did not want her secret to be made public. For more than 80 years, she had maintained this lifelong secret of giving birth and then giving up a child when she was a 15-year-old mother. However, the manner in which she was 'discovered' made it impossible to shield this news from any of the individuals within her family that she had been trying to protect. Furthermore, L. N. recognized that there was no person appropriate to 'blame' for this revealing of her private secret. L. N. knew that it was her granddaughter, not her actual daughter, who had sought her out. Her motivation was a genealogical search rather than an anticipation that she still was alive. In short, the only acceptable solution to this state of affairs was for L. N. to change herself. The best solution was for L. N. to accept, at the age of 96, what had been unacceptable to her for more than 80 years. Over time, L. N. even succeeded at discovering a way to enjoy this surprising event, even though the process of arriving at that emotional state was uncomfortable.

We interviewed L. N. several times after the meeting took place between herself, her daughter, her granddaughter, and various members of her more immediate family. There were additional surprises for L. N. as a result of this meeting, not the least of which was that she discovered that she was a great-great-grandmother. It took several weeks for L. N. to experience and to clarify for herself how she felt about this meeting.

Over time L. N. reported that her greatest and most pleasant surprise was the lack of shame or embarrassment conveyed to her by her immediate family, especially the grandchildren. She was also

startled by the striking physical resemblance between herself and her newly discovered daughter. She reported, "It was like looking in a mirror". She indicated that, "it was a lot for an old woman to go through". L. N. reported that the general stress of learning this news, anticipating the meeting, experiencing the new relationships, and coping with family reactions as well as the emotional ups and downs after the meeting had left her feeling fatigued. She seemed to conclude her own perceptions of this event with the words, "I'm glad that it happened; after all, I don't really have any other choice than to be happy about it, do I?"

Changing Ourselves as the Innovation of Last Resort

The innovation suggested in this last of the three case studies does not have a tangible product or technique to which we can point. When L. N. adjusted herself to her new circumstances, it did not feature B. V.'s novel use of a grab bar to get in the elevator or A. S.'s adaptation of a stapler to hold together the velcro straps of his sneakers. However, we think L. N. qualifies as a clinical innovation because L. N. created something new within herself. Specifically, she created a novel and effective attitude for herself that allowed her to accept and even enjoy what had been, for more than 80 years, unacceptable. Consequently, we can suggest another principle of innovation that may rank somewhat higher on the evolutionary scale of human development: *Changing ourselves represents one form of innovation.*

The principles of innovation, proposed from these case studies and related literature, are summarized below.

- (1) The process that produces innovation is complex;
- (2) Understanding innovation will require a wide range of methodological approaches;
- (3) Non-normative populations can provide insights about innovation that may generalize to larger populations;
- (4) The impetus for innovation may be external, unpleasant, and unwelcome;
- (5) Innovation does not require a 'creative personality'; ordinary personalities in extraordinary circumstances will innovate;
- (6) Both frustration and suffering can inspire innovation;
- (7) Frustration will not lead to innovation unless it is sufficiently annoying to force new ways of thinking about a problem;
- (8) Innovative behavior is both externally and internally self-rewarding;
- (9) Changing ourselves represents one form of innovation.

These principles of innovation have emerged from people living in notoriously noxious circumstances: the coerced institutionalization of frail, elderly individuals

due to a variety of physical and mental disabilities. Consequently, these principles are biased in the direction of insights shaded by these distressing circumstances. Nevertheless, as we asserted in our opening three principles, there is reason to believe that they may prove to be enduring principles that will help us in the daunting task we have assigned ourselves: understanding innovation.

Comparing the Case Studies to the Componential Model of Creativity

Amabile (1983) proposed that novel (i.e. innovative) behavior required three necessary and sufficient components: domain-relevant skills, creativity-relevant skills, and task motivation. She subsequently developed the principle of intrinsic motivation, which in turn generated considerable debate (Eisenberger & Cameron, 1996). The case studies presented here may not clarify that debate, but they do suggest that sufficient external frustration, even suffering, can lead to innovation. Whether that experience qualifies as intrinsic or extrinsic motivation is probably best resolved by acknowledging the complex, fluctuating nature of affect in the creative process (Shaw, 1994).

These case studies also suggest that Amabile is right to focus on the motivational component of innovation, in spite of its inherent definitional difficulties. These individuals enjoyed minimal domain-relevant and creativity-relevant capabilities. Nevertheless, the motivational pressure to innovate spurred them to maximize what capabilities they still possessed to solve everyday problems in remarkable ways.

The Measurement of Innovativeness

Ronald E. Goldsmith¹ and Gordon R. Foxall²

¹ College of Business, Florida State University, USA

² Cardiff Business School, Cardiff University, Wales, U.K.

Abstract: Diffusion of innovations is a theory that describes the spread of new things through social systems as they are adopted or rejected by individuals. Innovativeness refers to interindividual differences in how people react to these new things and accounts for much of their success or failure. Innovators may welcome them; the majority may gradually adopt them; laggards either slowly or never adopt them. Thus, the measurement of innovativeness is an important activity for both theory testing and practical purposes. This chapter presents many of the current theoretical perspectives on innovativeness and describes the measures that reflect them.

Keywords: Innovativeness; Measurement of innovativeness; Interindividual differences; Diffusion of innovations.

Introduction

The way in which innovativeness is measured depends upon the intentions of the researcher and the conception of innovativeness that is driving his or her work. Only when these matters have been resolved can the measurement of innovativeness itself be considered. This chapter discusses each of these in turn. First, the reasons researchers would have for measuring innovativeness are addressed. These range from intellectual curiosity—the desire simply to find out—to practitioner concerns—the expectation that behavior can be modified by the application of knowledge. Second, the researcher's understanding of the nature of 'newness', 'change', and 'innovation' is addressed. The role of discontinuity in the definition of innovativeness is discussed, and the points are illustrated with material from research on innovativeness in industry, marketing, and consumer choice. The conceptualization of innovativeness as a trait or latent process as opposed to a behavior-based understanding of innovativeness is also raised. Third, the intellectually driven approach will be illustrated by the role of psychometrics in assessing innovativeness. Discussion follows on the relationship of innovativeness to: (a) personality; and (b) situations, and the measurement issues arising from each are examined. Global vs. situation-specific measures of innovativeness are compared. Both qualitative and quantitative approaches to measurement are con-

sidered, though issues of quantification are treated in greater detail.

Diffusion of Innovations

Diffusion theory describes how new things (such as new products) spread through a social system (Rogers, 1995). The diffusion of innovations has been and remains an important topic in marketing management and consumer behavior owing to the importance of new products to the health of many companies. As consumers make their individual *adoption* decisions, these aggregate to produce the timing and pattern of *diffusion*. Thus, adoption is an individual or micro decision process, while diffusion is a social or macro process. In diffusion theory, when the time of adoption of a new thing since its introduction is plotted as a frequency distribution, the result is a normal or bell-shaped curve. A cumulative plot of adoptions yields an S-shaped curve describing the spread of the new thing through the social system as increasing numbers (followed by decreasing numbers) of individuals adopt. Most discussions of adoption and diffusion are based on these basic principles.

The importance of diffusion theory was recognized by some of the first academics to describe consumer behavior as a topic of systematic study (e.g. Zaltman, 1965), and diffusion was prominently featured in some of the first consumer behavior texts (Engel, Kollat &

Blackwell, 1968; Howard & Sheth, 1969; Wasson & McConaughy, 1968). Diffusion continues to be an important topic requiring space in recent texts in both marketing management (e.g. Kotler, 2000) and consumer behavior (e.g. Hawkins, Best & Coney, 1998). A key element in diffusion theory is the concept of 'innovativeness'. While there are several definitions, they all incorporate the notion that people differ in their reaction to the novel, ranging from quick acceptance to outright rejection. These concepts form the subject of this chapter.

What is an Innovation?

The term 'innovation' has many meanings. It can refer to the inventive process by which new things, ideas, and practices are created; it can mean the new thing, idea, or practice itself; or it can describe the "process whereby an existing innovation becomes a part of an adopter's cognitive state and behavioral repertoire" (Zaltman, Duncan & Holbek, 1973, pp. 7–8). The first meaning is the domain of the New Product Development (NPD) process, an important aspect of marketing management (Thomas, 1993, 1995). Our concern is with the second and third of these meanings. We understand innovations to be things, ideas, or practices that are perceived to be new to the audience to which they are introduced (Rogers, 1995). How consumers react to them, whether they are adopted or not, and how rapidly they spread if adopted are the results of a decision-making process by individual adopters who are subject to a variety of influences both internal and external. The measurement of 'innovativeness' is important to this process.

Definitions of 'innovation' abound. This is because the concept of innovation appears in many different fields of study and social theories. In the area of high technology, for instance, we are told that "Innovation is the use of new knowledge to offer a new product or service that customers want. It is invention + commercialization" (Afuah, 1998, p. 13; see also Foxall, 1984). In the context of educational research (Evans, 1967, pp. 15–16) an innovation is described as having two subcomponents: "First, there is the idea or item which is novel to a particular individual or group and, second, there is the change which results from the adoption of the object or idea". Evans adds an important qualification. "We would also include among innovations those items or ideas which represent a recombination of previously accepted ideas". In high-technology businesses innovations can be totally new devices or ways of using devices, or they can be modifications of existing machines or processes (Foxall, 1988; von Hippel, 1988). Examples of medical innovations are a new drug, apparatus, or treatment (Coleman, 1966). Agricultural innovations are new seeds, fertilizers, equipment, or farm practices (Lionberger, 1960).

In the marketing context, new products are very important to the long-run success of a business. We can observe several different types of new products:

- Modifications—these are the venerable 'new and improved' versions of brands. They may be relatively minor changes, and they replace the existing version, which vanishes;
- Line extensions—These are different varieties of the product. They are new sizes, flavors, formulations, and packages that supplement the product line and sit side by side with the existing versions;
- Brand extensions—Companies execute brand extension strategies by putting a brand name onto products in a different category than the first;
- New Brands—In this instance, the product may be common, but the brand name is new;
- Innovations—We want to reserve the term 'innovation' to refer to a new-to-the-world product. It may replace an old version or sit beside it, but the product itself is unlike anything that has existed before.

In the marketing context, any of the first four types of new products may involve the fifth concept, but they do not have to in order to qualify as new products. That is, all innovations can be new products, but not all new products are innovations.

Thomas S. Robertson (1971, p. 7) proposed that new products could be arrayed along a continuum of "newness in terms of consumption effects" describing how continuous or discontinuous their effects were on established consumption patterns. This scheme described three categories:

- (1) A *continuous* innovation has the least disrupting influence on established consumption patterns. Alteration of a product is usually involved, rather than the creation of a new product. An example would be a new microwaveable snack food.
- (2) A *dynamically continuous* innovation has more disrupting effects than a continuous innovation. Although it still generally does not involve new consumption patterns, it involves the creation of a new product or the alternation of an existing one. An electric car is arguably 'dynamically continuous' owing to the relatively minor changes owners would make in fueling and driving patterns.
- (3) A *discontinuous* innovation involves the establishment of new consumption patterns and the creation of previously unknown products. The fax machine was discontinuous, as was downloading music as MP3 files.

Thus, the concept of 'innovation' is broad enough to cover new things in many domains and in many forms. But what does 'new' mean? By explication of this concept we can get a better idea of what innovations are all about.

One way of viewing this issue is to argue that newness implies at least three different qualities. The first is *recency*. Things are new when they are encountered or acquired recently (Richins & Bloch, 1986). Thus, consumers speak of the 'new car' just as if they describe the 'new baby'. A second aspect of newness is *originality*. Things are judged as new when they are unfamiliar because they are so original. 'That's new to me', we might say, upon viewing unfamiliar art or an unfamiliar product. Finally, newness is a function of *similarity* (Barnett, 1953). How similar or different a thing is from existing things of the same type lead to perceptions of newness. Fashionable clothing, for example, might be considered innovative in so far as it has only recently appeared in the marketplace, it is creative and original, and it is stylistically different from existing clothing.

Since newness is often in the eye of the beholder, it should be possible to measure perceived newness of innovations by measuring perceived recency of acquaintance, perceived originality, or perceived similarity to existing things. That is, the perceived recency, originality, or similarity of a stimulus may be assessed in much the same way, via semantic differential scales for instance, as researchers assess the perceived qualities of any other stimulus. It may be as important to measure 'perceived newness' as it is to measure innovativeness since these two constructs may interact as the adoption decision process proceeds.

Why Measure Innovativeness?

The measure of innovativeness depends in part on the motives of those doing the measurement and on the contexts of their measurement. In other words, investigators may want to measure innovativeness for different purposes. Thus, researchers may want an interval level measure of innovativeness as an individual difference variable, much like any other personality or intelligence measure; or they may want simply to categorize people into an 'adopter category'. This latter notion comes from Rogers (1995, p. 262) who used the bell-shaped distribution of adoption partitioned into its standard deviations from average time of adoption to form five categories of adopters:

- (1) innovators (the first 2.5% to adopt);
- (2) early adopters (the next 13.5% of adopters);
- (3) the early majority (34%);
- (4) the late majority (34%);
- (5) laggards (the last 16% to adopt).

Some researchers study diffusion theory, seeking to understand this social phenomenon in greater detail. They may, for instance, be trying to identify the influence that innovativeness has on other market-related phenomena, such as search for and processing of information, decision-making, or brand loyalty (Klink & Smith, 2001). Innovativeness may be incor-

porated into models as an independent variable, a moderator or covariate, or as a dependent variable. Multiple-item interval level measures facilitate the incorporation of innovativeness into structural equation models. Theory-oriented research emphasizes innovativeness measures that correspond closely to the way innovativeness is conceptualized for a specific theoretical context (Foxall, 1988). They will most likely want an interval level measure that possesses high levels of content and construct validity, and emphasize reliability, generalizability, or uniqueness. Ease of use and convenience may be sacrificed to attain these psychometric characteristics.

Other researchers have applied commercial reasons for studying innovativeness. They are trying to solve specific problems involving the spread of new things, especially new products. If members of the different adopter categories can be identified, even crudely as a tripartite classification of 'early adopters', 'majority consumers', and 'laggards', this information may help those responsible for developing strategies to promote or to retard innovation spread. While desiring the psychometric rigor of theory-oriented measures, they will likely put more emphasis on speed, simplicity, and ease of use. McDonald & Alpert (1999) describe six practical reasons for identifying innovators:

- (1) *To enlist the cooperation of innovators in refining and improving new products.* The idea of enlisting innovative lead users for new product ideas and evaluations is well established in industrial marketing (von Hippel, 1988) and in the marketing of consumer goods (e.g. McCarthy, 1998). We can suggest that a related reason for identifying innovators is that they may be able to identify new products that are destined to fail with cutting-edge buyers.
- (2) *To enhance the speed of new product diffusion in order to generate cash flow.* Thus, the innovators can be targeted for concentrated marketing effort designed to persuade them to adopt quickly. Marketing spending for a relatively small number of early buyers should be more productive than for the larger mass markets further along the diffusion curve. And because innovative consumers are relatively price-insensitive (Goldsmith & Newell, 1997) sales should yield greater gross margins.
- (3) *Early adopters promote new products to other buyers.* The diffusion process is driven largely by social communication or word-of-mouth (Gatignon & Robertson, 1991). Innovators play a key role in initiating this process as they provide positive role models and recommendations to later adopters. Finding them and cultivating their good will and good opinions will enhance the acceptance of the new product in the rest of the market.
- (4) *Early adopters are often heavy users of the product category.* While making up a minority of buyers,

heavy users account for a disproportionate share of sales and profits in most product fields (Hallberg, 1995), and the overlap between innovativeness and heavy usage is well documented (Goldsmith, 2000a; Taylor, 1977). Innovators are experienced consumers who have a level of product knowledge and expertise in consumption plus a degree of wealth that allows them to make earlier adoption decisions and to act on them. Their capacity to make adoption decisions relatively earlier and relatively quickly stems in large part from their being heavy users of the product category (Foxall, 1993).

- (5) *Early adopters help create a 'market leader' image.* Firms may want to be seen as market or product leaders, the source of breakthrough products that are the choice of the innovative consumer in their product field: "Product leaders have to prepare markets and educate potential customers to accept product that never before existed" (Treacy & Wiersema, 1995, p. 87). Identifying and understanding lead users (innovators) may be a key to success in this strategy.
- (6) *Some may want to stop the diffusion of an undesirable innovation.* "Not all innovations are good, and some are socially undesirable or destructive" (McDonald & Alpert, 1999). Agencies that want to inhibit the spread of undesirable innovations might start with identifying those innovative souls who would be the first to adopt them and target them with counter-adoptive strategies.

Companies or agencies wishing to measure innovativeness for one or more of these reasons are chiefly interested in identifying innovators (and membership in the other adopter categories). They wish to categorize consumers and may likely be willing to sacrifice content and construct validity for criterion-related (predictive) validity and easy of use and flexibility (adaptable to a variety of data-collection contexts, such as personal and telephone interviews). They may be able to classify innovators based on records of prior behavior and not need to conduct primary data gathering activities. Of course, innovativeness measures developed and used by one group of researchers might also be used by others; the distinction is not mutually exclusive.

Three Concepts of Innovativeness

The concept of innovativeness refers to interindividual differences that characterize people's responses to new things. There are at least three approaches to the conceptualization of innovativeness, each of which carries its own implications for the measurement of the construct: behavioral, global trait, and domain-specific activity. Each makes its own contribution to the purposes of the investigator and requires its own interpretation of the results it produces.

Behavioral

The behavioral perspective on innovativeness identifies the concept with the act of adoption. Consumers are thus designated as innovators or not depending on whether they adopt a new product or not. Moreover, the degree of innovativeness they possess depends on how quickly they adopt after encountering the innovation. This simple, time-based approach to the conceptualization of innovations has given rise to a more sophisticated behavioral approach to the diffusion of innovations, which emphasizes the external rewards available to consumers at each successive stage of the product-market life cycle (Foxall, 1993, 1994b). Conceived within a broader behavioral perspective approach to consumer behavior (Foxall, 1990), this depicts the behavior of the earliest adopters of new products (*consumer initiators*) as determined by the high levels of both utilitarian (functional, technical, economic) and symbolic (social, psychological) rewards available to the consumer at this initial phase of the life cycle. Only consumers with the appropriate learning history of innovative behavior are likely to purchase at this stage. Subsequently, *earlier* and *later imitators* are induced to adopt by patterns of reward that emphasize first the utilitarian and then the symbolic benefits of purchasing at that time. Finally, the *last adopters* venture into the market place when the benefits of adopting the 'new' item are obvious to all, and the alternative products these consumers have hung on to for so long have themselves disappeared from the market (Foxall, 1996).

Global Personality Trait

The global trait view argues that innovativeness is a type of personality trait. Personality traits are thought to be relatively enduring patterns of behavior or cognition that differentiate people. Innovativeness describes reactions to the new and different. These reactions range from a very positive attitude toward change to a very negative attitude. Across the population, these attitudes are hypothesized to follow a bell-shaped normal distribution (Rogers, 1995). In Jackson's (1976) personality theory, innovation exists along side other personality traits such as conformity, risk taking, or tolerance as one of a battery of traits that describe "a variety of interpersonal, cognitive, and value orientations likely to have important implications for a person's functioning" (Jackson, 1976, p. 9). Another example can be found in the Five Factor Model of Personality, which contains a trait called 'openness to experience' that has been described as "how willing people are to make adjustments in notions and activities in accordance with new ideas or situations" (Popkins, 1998). Costa & McCrae (1992) characterize openness as curiosity and a motivation toward learning. Hurt, Joseph & Cook (1977) describe innovativeness as a willingness to try new things

- (1) Global Innovativeness: A personality trait 'willingness to try new things'.
Related to other personality traits: risk taking, openness to experience. Of the demographic variables, only youth may be related. Only weakly related to any specific overt behaviors.
- (2) Consumer Innovativeness: Describes consumers who want to be the first to buy new products.
Related to other consumer characteristics: marketplace knowledge, opinion leadership, price insensitivity. Higher levels of income and gregariousness (cosmopolitanism) may characterize consumer innovators.
- (3) Domain Specific Innovativeness: Describes consumers in specific product fields who wish to be cutting edge, the owners of the newest products in the field.
Related to consumer characteristics: product-category knowledge, domain-specific opinion leadership, involvement in the product category, a heavy user of the product. May be characterized by specific demographic characteristics, such as age and gender, and these will vary by product category.

Figure 1. Conceptual levels of innovativeness.

(Goldsmith, 1991). This global trait can be compared to other traits at a similar level of specificity (e.g. Goldsmith, 1987).

Domain-Specific Personality Trait

An alternative to the global view of innovativeness suggests that while it is true that people can be differentiated in this way, for the purposes of prediction and explanation in marketing, it is useful to think also of innovativeness as a domain-specific characteristic. That is, consumers are thought of as being more or less innovative within specific product categories, such as a fashion enthusiast, a wine connoisseur, or a movie buff. Innovativeness does not overlap across product categories unless these are closely related (Goldsmith & Goldsmith, 1996). For example, the wine connoisseur may have no interest in new movies but may be enthusiastic about new restaurants; the movie buff may keep up with the latest in popular music but have no interest in new wines.

In this view, innovativeness may manifest itself at different levels of generality/specificity or abstraction/breadth (see Clark & Watson, 1995). A consumer may be characterized by an overall level of global innovativeness, and also by different levels of domain-specific innovativeness. Global innovativeness may be linked to domain-specific innovativeness (Goldsmith, Freiden & Eastman, 1995), but not necessarily (Foxall & Szmigin, 1999). Possessing higher levels of global innovativeness predisposes individuals to seek the new and different across many facets of life, and this influence may extend to consumption. The desire for the new and different may manifest itself in specific product domains where the individual is innovative, seeking the new and different products as they appear, but perhaps shunning newness in other product categories. Conceivably, a given product innovator may be generally conservative when it comes to new things in general.

Figure 1 summarizes the three concepts of global, consumer, and domain-specific innovativeness. Each is related to the lower level construct, but relationships

with overt behaviors grow stronger as one proceeds down the scale of specificity.

Three Ways to Measure Innovativeness

Behavioral

The behavioral perspective of innovativeness identifies the concept with: (1) adoption or non-adoption of an innovation; and (2) the time of adoption. Consumers are classified as innovators or non-innovators depending on their purchase (consumption) of a new product. They may alternatively be graded on their innovativeness by marking their time of adoption as measured from the instant the new product appears in the marketplace. This latter approach, termed the "temporal conception" of innovativeness (Midgley & Dowling, 1978), was for many years the most commonly used way to measure innovativeness. Unfortunately, trying to measure innovativeness by the time-of-adoption method has many flaws.

Theoretically, it confuses the behavioral phenomenon to be explained and predicted with one of the chief concepts employed to explain and predict it. That is, what social scientists often want to explain and predict is time of adoption, and one of the most theoretically relevant and powerful concepts used to explain and predict time of adoption is 'innovativeness'. Innovativeness is a hypothetical or latent construct. It refers to interindividual differences in personality. The relative recency with which a new product is adopted is a behavior that is partially explained by innovativeness: higher levels of innovativeness, *ceteris paribus*, lead to faster adoption. One would not use 'years married' as a measure of spousal affection, although the latter may explain and predict the former.

Methodologically, time of adoption is most appropriate as an indicator of precisely what it refers to: how much time passed since the new product was introduced before it was adopted. Even as an indicator of behavior, however, time of adoption is a fallible measure. The exact time when a new product is introduced into a specific market may be unknown.

There may be no record of purchase to show exact time of adoption. Moreover, consumers may not be able to accurately recall when they did adopt, and memory shortcomings are a well-documented flaw in many measures used in marketing research. There may be a difference between when the new product is introduced to the market and when the consumer learns about it. Although innovators are earlier to adopt than later consumers, there will be differences in the time between the appearance of a new product and when it is perceived. Finally, innovators may reject new products; non-innovative consumers may buy them. Not buying a new product because it is of poor quality, inappropriate for one's needs, or because one cannot afford it does not make an innovative consumer less innovative. A non-innovative consumer, for instance, may buy a new product as a gift for an innovator.

An alternative measurement technique proposed to overcome the shortcomings of time-of-adoption is termed the 'cross-sectional' method (Midgley & Dowling, 1978). This approach provides a list of new products, and level of innovativeness is indicated by how many of these the consumer has purchased. Not only does this measurement approach have many of the problems of the time-of-adoption method, but also it would seem to be indicative of the more global concept of innovativeness than of innovativeness in any specific product category, unless one limited the list of new products to a single category. (But what if there were few new products in the category, or they were widely spaced in time?) Determining which products are new and whether consumers were exposed to all of them (not all new products may be available in a specific market area) contribute to the methodological difficulties of measuring innovativeness by the cross-sectional method.

It can be argued that these behavioral measures are best thought of as measures of what they are simply said to be: behavior. Time of adoption is a measure of when a consumer purchased a new product after its appearance in the market. This may be an important dependent variable in a larger study of new product adoption but is not suitable as a measure of innovativeness as a latent construct. The cross-sectional method denotes ownership of a variety of new products, again, possibly a key dependent variable in a study of ownership of new products (e.g. *America's Taster-makers*, 1959). Both measures, it should be kept in mind, are subject to measurement errors.

Global Trait

Innovativeness as a global trait is best measured by means of a standardized self-report. Such scales are normally the products of rigorous validation procedures, so that they can be used with some confidence that they meet conventional standards of reliability and validity. Their psychometric shortcomings should be well described by their scale developers (in contrast to

the unknown and likely unknowable errors in the behavioral measures).

Four scales have been described in literature that seem to do a reasonable job measuring global innovativeness: Jackson, Kirton, NEO, Hurt et al. (1977).

The Jackson Personality Inventory (Revised) contains 300 True/False items comprising 15 scales that are organized in terms of five higher-order dimensions. One of these 20-item scales is termed 'innovation' and measures the global personality dimension as described above.

M. J. Kirton (1989) developed a pencil-and-paper self-report, the Kirton Adaption-Innovation Inventory or KAI, to measure individual differences in decision-making and problem-solving. Innovators seek to change the context in which problems are imbedded, while adaptors try to disturb these frameworks as little as possible to solve the problem. Adaptors try to do things better, while innovators seek to do things differently. The KAI consists of 32 items organized into three subscales. High scores identify innovators and low scores adaptors, but no especial value is accorded to either tendency, as both cognitive styles are important. The bipolar nature of this scale has important implications for the measurement and conceptualization of innovativeness. Expecting consumer innovators to show the characteristics of Kirton's *innovators*, Foxall (1994c) undertook a series of studies of early adopters of new food products and brands, which identified the heaviest purchasers of these items as *adaptors*. Further investigation revealed that adaptors who were highly involved with the product category bought most new products or brands, followed by innovators (whether high- or low-involved) and finally less-involved adaptors (Foxall, 1995; Foxall et al., 1998). These results are of considerable practical relevance since they explain: (a) why marketing research has consistently found only weak relationships between innovator personality characteristics and early adoption; and (b) why so many new consumer products, aimed promotionally at innovators (in Kirton's sense), fail at the point of consumer acceptance. Clearly, marketing campaigns need to take adaptors into greater consideration. Similar results have been found for consumers' adoption of new financial products, use of credit cards, use innovativeness with respect to computer software, and organizational computer utilization (Foxall, 1999).

The NEO Personality Inventory (Costa & McCrae, 1992) contains the Openness to Experience subscale. The sense of this scale is that synonyms are "original, imaginative, broad interests, and daring" (McCrae & Costa, 1987, p. 87).

Hurt et al. (1977) describe a 20-item scale to measure innovativeness as a global personality trait characterized by a "willingness-to-change" or a "willingness-to-try new things". Their original scale actually contained items measuring this concept as well

as items identifying a “creative and original person”. The scale has been evaluated for its psychometric characteristics, and there is good evidence that the Innovation Subscale is a valid measure of the global trait (Goldsmith, 1991; Pallister & Foxall, 1998).

Consumer Innovativeness

While global personality traits are important concepts in the explanation of behavior, they have proved to be only weakly associated with specific consumer behaviors (see Foxall & Goldsmith, 1988). For this reason, efforts have been made to conceptualize ‘consumer innovativeness’ as the tendency to buy new products soon after they appear in the marketplace (Foxall, Goldsmith & Brown, 1998, pp. 40–45). Thus, consumer innovativeness is a more restricted or less general concept than global innovativeness.

The consumer innovator has long been of interest to marketers and to advertisers (How Consumers Take to Newness, 1955; Who are the Marketing Leaders?, 1958). Most of the earliest studies in marketing of consumer innovativeness used time of adoption as a means of identifying innovators. Some thought, however, was given to developing other ways of measuring innovativeness. An early study of American consumers (*America’s Tastemakers*, 1959) identified a leading-edge group of consumers termed the ‘high mobiles’ who disproportionately adopted many of the current innovations. Membership in this group was derived from their geographical, social, and economic mobility.

In the 1960s advertising researchers originated the concept of lifestyle. To measure lifestyle (psychographics) they developed large batteries containing items designed to tap a variety of lifestyle dimensions. In one of the Activities, Interests, and Opinions (AIO) batteries developed in advertising to measure lifestyles can be found in sets of items labeled in ways that suggest a measure of innovativeness. Wells & Tigert (1971) present three items in a large AIO scale to designate the ‘New Brand Tryer’. These items would form a Likert scale, self-report measure of consumer innovativeness. Leavitt & Walton (1975) attempted to develop a self-report measure of general consumer innovativeness. Their Open Processing scale showed some promise as a measure of consumer innovativeness, but little effort was made toward a thorough psychometric evaluation. One study did show that four of these innovativeness scales (Jackson, KAI & Hurt et al., Open Processing) generally exhibited convergent validity indicating that they are measuring either the same or highly related constructs (Goldsmith, 1986).

Within the framework of measuring consumer innovativeness, some scholars have expanded and enriched this concept by conceptualizing and measuring varieties or dimensions of consumer innovativeness. Venkatraman & Price (1990) distinguish ‘cognitive’ from ‘sensory’ innovativeness. The

former refers to individuals who prefer to engage in activities that stimulate the mind, while the latter seek sensory stimulation. Their 16-item Likert scale contains two eight-item subscales to measure the two types of innovativeness. Similarly, Manning, Bearden & Madden (1995) distinguish two aspects of consumer innovativeness: consumer independent judgement-making and consumer novelty-seeking. The former is defined as the degree to which an individual makes innovation decisions independently of the communicated experience of others (Midgley & Dowling, 1978) while the latter is defined as the desire to seek out new product information (Hirschman, 1980). Finally, Price & Ridgway (1983) formulated the concept of ‘use innovativeness’. They defined this concept as the use of previously adopted products in novel ways (Hirschman, 1980) and developed a scale to tap the five dimensions of the concept: creativity/curiosity, risk preference, voluntary simplicity, creative reuse, and multiple use potential.

Domain-Specific Innovativeness

Although conceptualizing innovativeness at this level of generality/specificity may be an improvement over the global personality approach for marketing purposes, it still leaves something to be desired for researchers interested in the new buyers for a specific product. Because consumer innovativeness is largely domain-specific, measures of general consumer innovativeness will identify the effects of that construct on behavior, but will not be good measures of consumer innovativeness within a specific product category; consumer innovativeness tends to manifest itself within specific categories with little overlap to other categories (Goldsmith & Goldsmith, 1996).

Consequently, researchers who wish to study consumer innovativeness will likely focus on a single product category to discover how this individual difference variable functions within a network of other variables where it can operate as an independent variable, a dependent variable, a mediating variable, or a moderating variable. Applied researchers would like to be able to identify innovators within the product category of their firm so that they can target innovators with unique marketing strategies, seek the input of innovators in the NPD process, or test how different consumers react to various marketing and advertising strategies. With these concerns in mind, Goldsmith & Hofacker (1991) developed the Domain Specific Innovativeness Scale (DSI). This is a balanced Likert scale with three positively and three negatively worded items (Bearden & Netemeyer, 1999, pp. 86–87).

The DSI has been evaluated for its psychometric characteristics (e.g. Goldsmith & Flynn, 1995). It has been shown to be internally consistent and free from both social desirability and acquiescent response bias. There is evidence for its convergent, discriminant, and nomological validity as well as its predictive and

known-group validity (Goldsmith, 2000b, 2000c; Goldsmith, d'Hauteville & Flynn, 1998). Using the DSI yields a distribution of scores with a theoretical range of 6–30 with a mean of 18. The items can be used to assign a single score to each consumer studied, or the items can be used as multiple measures of the construct in a structural equations model.

Conclusion

This chapter has discussed the measurement of innovativeness in the context of research into innovation and has, therefore, taken concepts of innovativeness and the purposes of the investigator into central consideration. It has shown how researchers' expectations of a simple relationship between the behavior of the earliest adopters of new products and their personality traits and types gave way to a more sophisticated treatment of both the concept of 'newness' and the measures that could be brought to bear on the empirical identification of innovativeness and its impact on behavior. In this conclusion, we draw attention once again to the interconnectedness of concepts of innovativeness and the ways in which this construct is measured.

We employed the idea that innovation lies, ultimately, in the 'eye of the beholder'. This remains a convenient but unanalyzed term: as behavioral scientists we seek the underlying psychological characteristics that may make such terminology empirically intelligible. Foxall (1994a) draws attention to the confusion inherent in much usage of 'innovation', 'innovator', and 'innovativeness'. Such confusion arises in part from the same term being used to describe distinct conceptual levels from the hypothetical and abstract notions of 'innate' and 'inherent' innovativeness, to the concrete and observable 'actualized' innovativeness. To use the same term in each case, while claiming that the former provides an explanatory basis for the latter, is to prejudice the issue of whether innovative behavior is attributable to an underlying personality system. Between these extreme concepts there are a plethora of terms that refer to measurable intervening variables: sensory innovativeness, cognitive innovativeness, hedonic innovativeness, adaption innovation, and so on. Finally, at the level of consumption rather than purchasing, the term 'use innovativeness' has been proposed to refer to the deployment of a product in a novel application (Hirschman, 1980).

One means of addressing this problem is to adopt terms that distinguish the earliest adopters of new products (currently called 'innovators') from the underlying trait that is hypothesized to account for their behavior ('innovativeness'). Foxall (1994a) proposed 'consumer initiators' for the earliest adopters, a term that emphasizes the role of these purchasers in the initiation of markets. A synonym is 'initial adopters', which similarly depicts an observable level of analysis

which may be related on the basis of further empirical and conceptual work to an underlying trait or to the environmental consequences (the pattern of utilitarian and symbolic rewards) that induce adoption at each stage of the diffusion process, or to both. This approach leaves open the question of what causes innovative behavior and, in addition, encourages the investigation of a diversity of underlying traits (e.g. adaption as well as innovation, to use Kirton's terms) which may form the basis of empirical research. This approach also readily embraces Robertson's continuum of innovations (from the most continuous to the most discontinuous) and the idea of use innovativeness (perhaps 'use initiation' would be a more consistent term).

This is one source of solution, of course, but one that has been incorporated in both the consumer behavior and marketing research literatures as a means of both encouraging the resolution of terminological confusion and emphasizing that the measurement of innovativeness cannot be divorced from the meanings we attach to the term.

Developing High Potentials for Innovation in Young People Through the Schoolwide Enrichment Model

Sally M. Reis and Joseph S. Renzulli

The National Research Center on the Gifted and Talented, The University of Connecticut, USA

Abstract: The Schoolwide Enrichment Model (SEM): (1) focuses on a pedagogy that brings innovative productive persons to our attention; and (2) organizes programs around a continuum of services model that accommodates a wide variety of potentials across academic domains as well as other areas of human endeavor. The SEM also applies the knowledge gained about how we can help students become more innovative to the process of school change and improvement. Based on the belief that ‘a rising tide lifts all ships’, the SEM includes specific vehicles for providing *all* students with opportunities for ‘high end’ learning, creativity, and innovative thinking.

Keywords: School-based enrichment; Programming; Opportunities; Innovation; Creative productivity; Gifted students; SEM.

Introduction

How can we develop the creative potential of young people and inspire in them a spirit of innovation, inquiry, entrepreneurship, and a sense of power to change things? How can educators and parents help children learn to think creatively, and to value opportunities for creative work of their choice? The Schoolwide Enrichment Model (SEM), developed during 20 years of research in programs for talented and gifted students enables each faculty the flexibility to develop unique programs for talent development and creative productivity based on local resources, student demographics, and school dynamics as well as faculty strengths and creativity. The major goal of SEM is to promote both challenging and enjoyable high-end learning across a wide range of school types, levels and demographic differences. The idea is to create a repertoire of enrichment opportunities and services that challenge all students. Any individual student does better in a school when all students appreciate creativity and innovation; and therefore the underlying theme of schoolwide enrichment is ‘a rising tide lifts all ships’. This approach allows schools to develop a collaborative school culture that takes advantage of resources and appropriate decision-making opportuni-

ties to create meaningful, high-level and potentially creative opportunities for students to develop their talents. In this chapter, innovation is used to describe these creative opportunities and their innovative outcomes.

The SEM suggests that educators examine ways to make schools more inviting, friendly, and enjoyable places that encourage talent development instead of regarding students as repositories for information that will be assessed with the next round of standardized tests. Not only has this model been successful in addressing the problem of high potential in all students who have been under-challenged, but it also provides additional learning paths for gifted, talented, and creative students who find success in more traditional learning environments.

At the heart of the SEM is the Enrichment Triad Model (Renzulli, 1977) developed in the mid-1970s and initially implemented by school districts primarily in Connecticut in the United States. The model, which was originally field-tested in several districts, proved to be quite popular, and requests were received from all over the United States for visitations to schools using the model and for information about how to implement the model increased. A book about the Enrichment

Triad Model (Renzulli, 1977) was published, and more and more districts began asking for help in implementing this approach. It was at this point that a clear need was established for research about the effectiveness of the model and for practical procedures that could provide technical assistance for interested educators to help develop programs in their schools. We became fascinated by the wide range of Triad programs developed by different types of teachers in different school districts, some urban, rural and suburban. In some programs, for example, teachers consistently elicited high levels of creative productivity in students while others had *few* students who engaged in this type of work. In some districts, many enrichment opportunities were regularly offered to students not formally identified for the program, while in other districts only identified gifted students had access to enrichment experiences.

In the more than two decades since the Enrichment Triad Model has been used as the basis for many educational programs for gifted, talented, and creative students, an unusually large number of examples of creative productivity have occurred on the parts of young people whose educational experiences have been guided by this programming approach. Perhaps, like others involved in the development of theories and generalizations, we did not fully understand at the onset of our work the full implications of the model for encouraging and developing creative and innovative productivity in young people. These implications relate most directly to teacher training, resource procurement and management, product evaluation, and other theoretical concerns (e.g. motivation, task commitment, self-efficacy) that probably would have gone unexamined, undeveloped, and unrefined without the favorable results that were reported to us by early implementers of the model. We became increasingly interested in how and why the model was working and how we could further expand the theoretical rationale underlying our work, and the population to which services could be provided. Thus, several years of conceptual analysis, practical experience, and an examination of the work of other theorists brought us to the point of tying together the material in this chapter, which represents approximately 23 years of field-testing, research, evolution and dissemination.

In another chapter in this handbook, Renzulli (2003) has provided a description of the conception of giftedness upon which this model is based. This chapter presents a description of the Enrichment Triad Model and a chronology of how the model has expanded and changed. Space does not permit a review of the numerous research studies that have been carried out on the model over the years, but interested readers are invited to visit the Research and Evaluation section of the folder on The Schoolwide Enrichment Model at our website (www.gifted.uconn.edu).

An Overview of the Enrichment Triad Model

The Enrichment Triad Model was designed to encourage creative productivity on the part of young people by exposing them to various topics, areas of interest, and fields of study, and to further train them to *apply* advanced content, process-training skills, and methodology training to self-selected areas of interest (see Root-Bernstein, this volume). Accordingly, three types of enrichment are included in the Triad Model (see Fig. 1).

Type I enrichment is designed to expose students to a wide variety of disciplines, topics, occupations, hobbies, persons, places, and events that would not ordinarily be covered in the regular curriculum. In schools that use this model, an enrichment team consisting of parents, teachers, and students often organizes and plans Type I experiences by contacting speakers, arranging minicourses, demonstrations, or performances, or by ordering and distributing films, slides, videotapes, or other print or non-print media.

Type II enrichment consists of materials and methods designed to promote the development of thinking and feeling processes (see Root-Bernstein & Root-Bernstein, this volume). Some Type II training is general, and is usually carried out both in classrooms and in enrichment programs. Training activities include the development of: (1) creative thinking and problem-solving, critical thinking, and affective processes; (2) a wide variety of specific learning how-to-learn skills; (3) skills in the appropriate use of advanced-level reference materials; and (4) written, oral, and visual communication skills. Other Type II enrichment is specific, as it cannot be planned in advance and usually involves advanced methodological instruction in an interest area selected by the student. For example, students who become interested in botany after a Type I experience might pursue additional training in this area by doing advanced reading in botany; compiling, planning and carrying out plant experiments; and seeking more advanced methods training if they want to go further.

Type III enrichment involves students who become interested in pursuing a self-selected area of personal interest or that they consider a problem (see Root-Bernstein, problem generation, this volume) and are willing to commit the time necessary for advanced content acquisition and process training in which they assume the role of a first-hand inquirer. The goals of Type III enrichment include:

- providing opportunities for applying interests, knowledge, creative ideas and task commitment to a self-selected problem or area of study;
- acquiring advanced level understanding of the knowledge (content) and methodology (process) that are used within particular disciplines, artistic areas of expression and interdisciplinary studies;

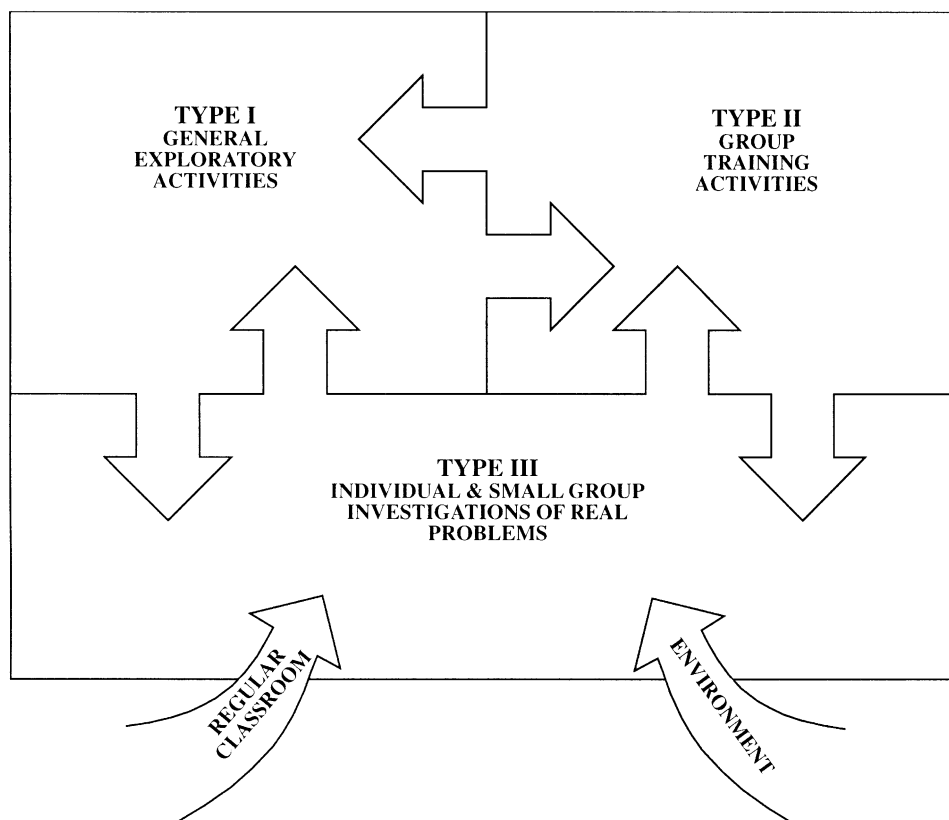

Figure 1. Enrichment triad model.

- developing authentic products that are primarily directed toward bringing about a desired impact upon a specified audience;
- developing self-directed learning skills in the areas of planning, organization, resource utilization, time management, decision-making and self-evaluation;
- developing task commitment, self-confidence, and feelings of creative accomplishment.

The Revolving Door Identification Model

As our experience with Triad Programs grew, our concern about the students who were being identified to participate and those who were not being included in these programs also grew. We became increasingly concerned about students who were not able to participate in enrichment programs because they did not score in the top 1–3% of the population in achievement or intelligence tests.

Research conducted by Torrance (1962, 1974) had demonstrated that students who were rated highly on creativity measures do well in school and on achievement tests but are often not selected for gifted programs because their scores are often below the

cutoff for admission. Some of our own research (Reis & Renzulli, 1982) indicated that when a broader population of students (15–20% of the general population called the ‘talent pool’) were able to participate in Types I and II enrichment experiences, they produced equally good Type III products as the traditional ‘gifted’ students (the top 3–5%). This research produced the rationale for the Revolving Door Identification Model (RDIM) (Renzulli, Reis & Smith, 1981) in which a talent pool of students receives regular enrichment experiences and the opportunity to ‘revolve into’ Type III creative productive or innovative experiences. In RDIM, we recommend that students be selected for participation in the talent pool on the basis of multiple criteria that include indices of creativity, because we believe that one of the major purposes of gifted education is to develop creative thinking and creative productivity in students. Once identified and placed in the talent pool through the use of test scores, teacher, parent, or self-nomination, and examples of creative potential or productivity, students are observed in classrooms and enrichment experiences for signs of advanced interests, creativity, or task commitment. We have called this part of the process ‘action information’

and have found it to be an instrumental part of the identification process in assessing students' interest and motivation to become involved in Type III creative or innovative productivity. Further support for expanding identification procedures through the use of these approaches has recently been offered by Kirschenbaum (1983) and Kirschenbaum & Siegle (1993) who demonstrated that students who are rated or test high on measures of creativity tend to do well in school and on measures of achievement. The development of the RDIM led to the need for a guide dealing with how all of the components of the previous Triad and the new RDIM could be implemented, and the resulting work was entitled *The Schoolwide Enrichment Model (SEM)* (Renzulli & Reis, 1985, 1997).

The Schoolwide Enrichment Model (SEM)

In the SEM, a talent pool of 10–15% of above-average-ability/high-potential students is identified through a variety of measures including: achievement tests, teacher nominations, assessment of potential for creativity and task commitment, as well as alternative pathways of entrance (self-nomination, parent nomination, etc.). High achievement test and IQ test scores automatically include a student in the talent pool, enabling those students who are underachieving in their academic schoolwork to be included.

Once students are identified for the talent pool, they are eligible for several kinds of services; first, interest and learning styles assessments are used with talent pool students. Informal and formal methods are used to create or identify students' interests and to encourage students to further develop and pursue these interests in various ways. Learning-style preferences which are assessed include: projects, independent study, teaching games, simulations, peer teaching, programmed instruction, lecture, drill and recitation, and discussion. Second, curriculum compacting is provided to all eligible students for whom the regular curriculum is modified by eliminating portions of previously mastered content. This elimination or streamlining of curriculum, enables above-average students to avoid repetition of previously mastered work and guarantees mastery while simultaneously finding time for more appropriately challenging activities (Reis, Burns & Renzulli, 1992; Renzulli, Smith & Reis, 1982). A form, entitled *The Compactor* (Renzulli & Smith, 1978), is used to document which content areas have been compacted and what alternative work has been substituted. Third, the Enrichment Triad Model offers three types of enrichment experiences. Type I, II, and III Enrichment are offered to all students; however, Type III enrichment is usually more appropriate for students with higher levels of ability, interest, and task commitment.

Separate studies on the SEM demonstrated its effectiveness in schools with widely differing socio-economic levels and program organization patterns

(Olenchak, 1988; Olenchak & Renzulli, 1989). The SEM has been implemented in thousands of school districts across the country (Burns, 1998), and interest in this approach continues to grow.

Newest Directions for the Schoolwide Enrichment Model

The present reform initiatives in general education have created a more receptive atmosphere for more flexible and innovative approaches to challenge all students, and accordingly, the SEM has been expanded to address three major goals that we believe will accommodate the needs of gifted students and, at the same time, provide challenging learning experiences for all students. These goals are:

- To maintain and expand a continuum of special services that will challenge students with demonstrated superior performance or the potential for superior performance in any and all aspects of the school and extracurricular program;
- To infuse into the general education program a broad range of activities for high-end learning that will: (a) challenge all students to perform at advanced levels; and (b) allow teachers to determine which students should be given extended opportunities, resources, and encouragement in particular areas where superior interest and performance are demonstrated;
- To preserve and protect the positions of gifted education specialists and any other specialized personnel necessary for carrying out the first two goals.

School Structures

The Regular Curriculum

The regular curriculum consists of everything that is a part of the predetermined goals, schedules, learning outcomes, and delivery systems of the school. The regular curriculum might be traditional, innovative, or in the process of transition, but its predominant feature is that authoritative forces (i.e. policy-makers, school councils, textbook adoption committees, state regulators) have determined that the regular curriculum should be the 'centerpiece' of student learning. Application of the SEM influences the regular curriculum in three ways. First, the challenge level of required material is differentiated through processes such as curriculum compacting and textbook content modification procedures. Second, systematic content intensification procedures should be used to replace eliminated content with selected, in-depth learning experiences. Third, the types of enrichment recommended in the Enrichment Triad Model (Renzulli, 1977) are integrated selectively into regular curriculum activities. Although our goal in the SEM is to influence rather than replace the regular curriculum, application of certain SEM components and related staff develop-

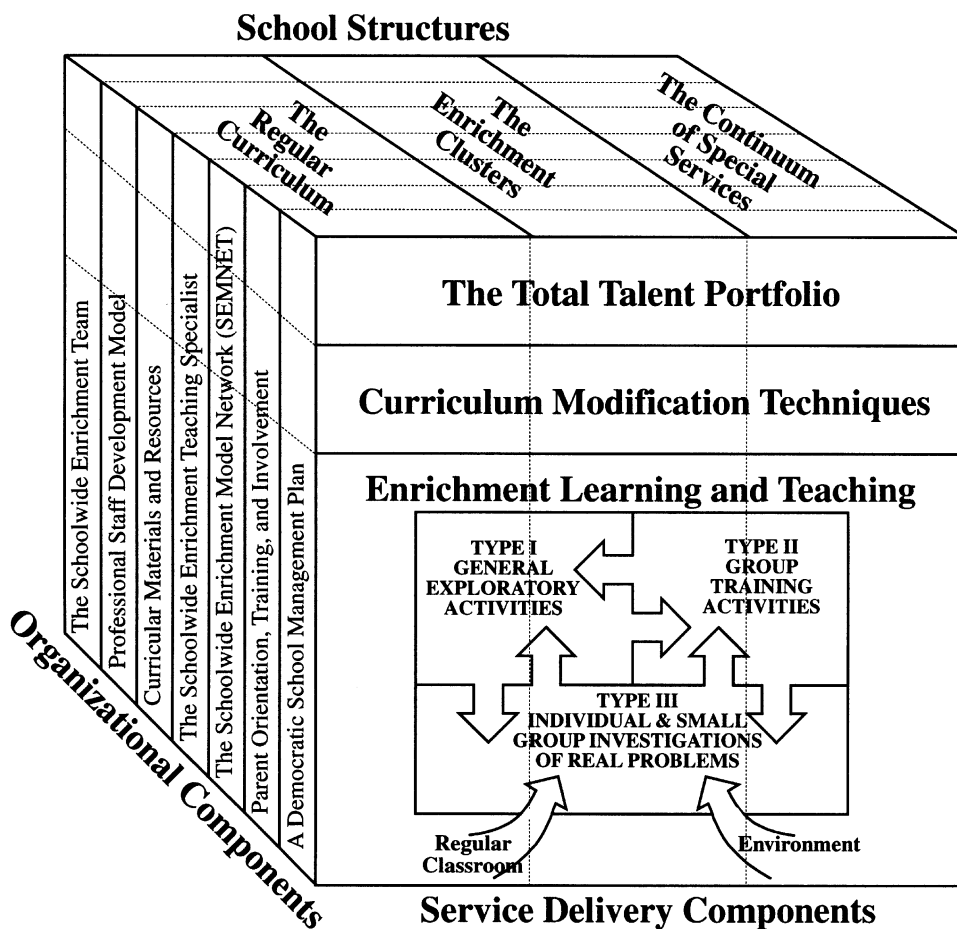

Figure 2. Schoolwide enrichment model.

ment activities has resulted in substantial changes in both the content and instructional processes of the entire regular curriculum.

The Enrichment Clusters

The enrichment clusters, a second component of the Schoolwide Enrichment Model, are designed to celebrate creativity and innovation. They are non-graded groups of students who share common interests, and who come together during specially designated time blocks during school to work with an adult who shares their interests and who has some degree of advanced knowledge and expertise in the area. The enrichment clusters usually meet for a block of time weekly during a semester. All students complete an interest inventory developed to assess their interests, and an enrichment team of parents and teachers tally all of the major families of interests. Adults from the faculty, staff, parents, and community are recruited to facilitate enrichment clusters based on these interests, such as

creative writing, drawing, sculpting, archeology and other areas. Training is provided to the facilitators who agree to offer the clusters, and a brochure is developed and sent to all parents and students highlighting the role of student interests and select choices of enrichment clusters. A title and description that appeared in a brochure of clusters in a school using the SEM follows:

Invention Convention

Are you an inventive thinker? Would you like to be? Brainstorm a problem, try to identify many solutions, and design an invention to solve the problem, as an inventor might give birth to a real invention. Create your invention individually or with a partner under the guidance of Bob Erikson and his students, who work at the Connecticut Science Fair. You may decide to share your final product at the Young Inventors' Fair on March 25th, a statewide daylong celebration of creativity and innovative.

Students select their top three choices for the clusters, and scheduling is completed to place all children into their first or, in some cases, second choice. Like extracurricular activities and programs such as 4-H and Junior Achievement, the main rationale for participation in one or more clusters is that *students and teachers want to be there*. All teachers (including music, art, physical education, etc.) are involved in teaching the clusters; and their involvement in any particular cluster is based on the same type of interest assessment that is used for students in selecting clusters of choice.

The model for learning used with enrichment clusters is based on an inductive approach to solving real-world problems through the development of authentic innovative products and services. Unlike traditional, didactic modes of teaching, this approach, known as enrichment learning and teaching (described fully in a later section), uses the Enrichment Triad Model to create a learning situation that involves the use of methodology, develops higher-order thinking skills, and authentically applies these skills in creative and situations. Enrichment clusters promote cooperativeness within the context of real-world problem solving, and they also provide superlative opportunities for promoting self-concept. "A major assumption underlying the use of enrichment clusters is that *every child is special if we create conditions in which that child can be a specialist within a specialty group*" (Renzulli, 1994, p. 70).

Enrichment clusters are organized around various characteristics of differentiated programming for gifted students on which the Enrichment Triad Model (Renzulli, 1977) was originally based, including the use of major disciplines, interdisciplinary themes, or cross-disciplinary topics (e.g. a theatrical/television production group that includes actors, writers, technical specialists, costume designers). The clusters are modeled after the ways in which knowledge utilization, thinking skills, and interpersonal relations take place in the real world. Thus, all work is directed toward the production of a product or service. A detailed set of lesson plans or unit plans is not prepared in advance by the cluster facilitator; rather, direction is provided by three key questions addressed in the cluster by the facilitator and the students:

- (1) What do people with an interest in this area (e.g. film making) do?
- (2) What knowledge, materials, and other resources do they need to do it in an excellent and authentic way?
- (3) In what ways can the product or service be used to have an impact on an intended audience?

Enrichment clusters incorporate the use of advanced content, providing students with information about particular fields of knowledge, such as the structure of a field as well as the basic principles and the functional

concepts in a field (Ward, 1960). Ward defined functional concepts as the intellectual instruments or tools with which a subject specialist works, such as the vocabulary of a field and the vehicles by which persons within the field communicate with one another. The methodology used within a field is also considered advanced content by Renzulli (1988a), involving the use of knowledge of the structures and tools of fields, as well as knowledge about the methodology of particular fields. This knowledge about the methodologies of fields exists both for the sake of increased knowledge acquisition and for the utility of that know-how as applied to the development of products, even when such products are considered advanced in a relative sense (i.e. age, grade, and background considerations).

The enrichment clusters are not intended to be the total program for talent development in a school, or to replace existing programs for talented and creative youth. Rather, they are one vehicle for stimulating interests and developing talent potentials across the entire school population. They are also vehicles for staff development in that they provide teachers an opportunity to participate in enrichment teaching, and subsequently to analyze and compare this type of teaching with traditional methods of instruction. In this regard the model promotes a spill-over effect by encouraging teachers to become better talent scouts and talent developers, and to apply enrichment techniques to regular classroom situations.

The Continuum of Special Services

A broad range of special services is the third school structure targeted by the model; a diagram representing these services is presented in Fig. 3. Although the enrichment clusters and the SEM-based modifications of the regular curriculum provide a broad range of services to meet individual needs, a program for total talent development still requires supplementary services that challenge our most academically talented young people who are capable of working at the highest levels of their special interest and ability areas. These services, which cannot ordinarily be provided in enrichment clusters or the regular curriculum, typically include: individual or small group counseling, various types of acceleration, direct assistance in facilitating advanced-level work, arranging for mentorship with faculty members or community persons, and making other types of connections between students, their families, and out-of-school persons, resources, and agencies.

Direct assistance also involves setting up and promoting student, faculty and parental involvement in special programs such as Future Problem Solving, Odyssey of the Mind, the Model United Nations program, and state and national essay competitions, mathematics, art, and history contests. Another type of direct assistance consists of arranging out-of-school

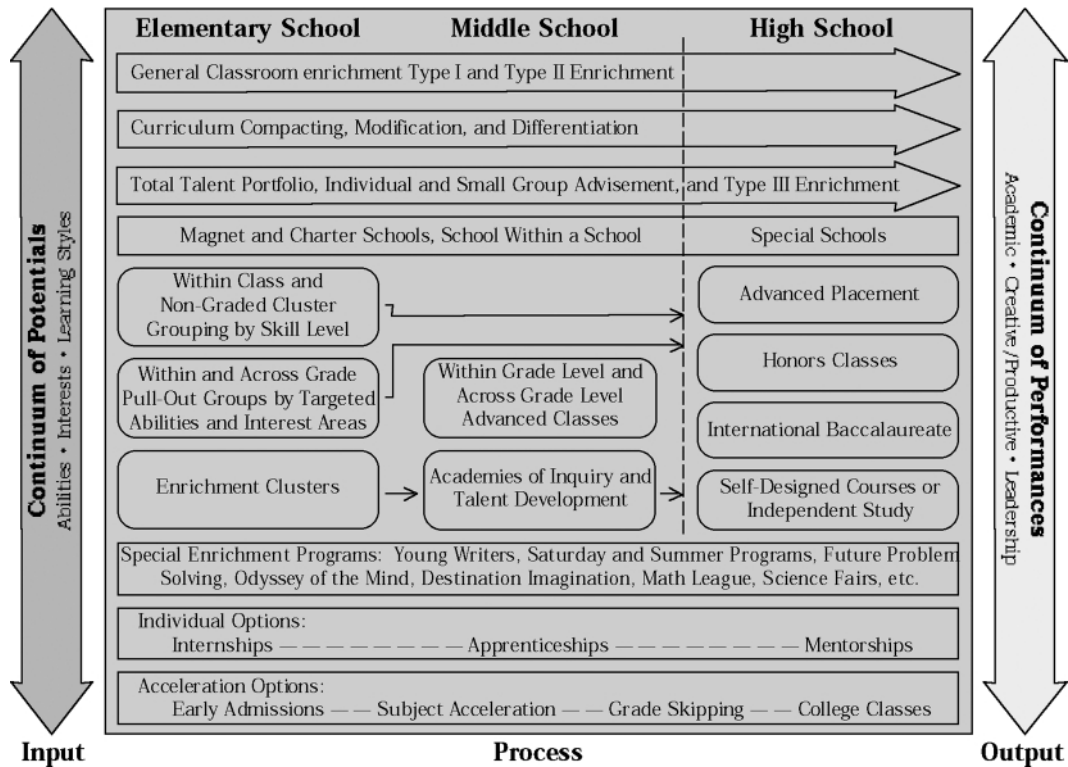

Figure 3. The integrated continuum of special services.

involvement for individual students in summer programs, on-campus courses, special schools, theatrical groups, scientific expeditions, and apprenticeships at places where advanced-level learning opportunities are available. Provision of these services is one of the responsibilities of the schoolwide enrichment teaching specialist or an enrichment team of teachers and parents who work together to provide options for advanced learning. Most schoolwide enrichment teaching specialists spend two days a week in a resource capacity to the faculty and three days providing direct services to students.

Service Delivery Components

The Total Talent Portfolio

The Schoolwide Enrichment Model targets specific learning characteristics that can serve as a basis for talent development. Our approach to targeting learning characteristics uses both traditional and performance-based assessment to compile information about three dimensions of the learner—abilities, interests, and learning styles. This information, which focuses on strengths rather than deficits, is compiled in a management form called the ‘Total Talent Portfolio’ (see

Fig. 4) which is used to make decisions about talent development opportunities in regular classes, enrichment clusters, and in the continuum of special services. The major purposes of the Total Talent Portfolio are to collect several different types of information that portray a student’s strength areas and to regularly update this information. This information is periodically reviewed and analyzed to make purposeful decisions about providing opportunities for enrichment experiences in the regular classroom, the enrichment clusters, and the continuum of special services. Various acceleration and enrichment learning options and opportunities are then provided for students through participation in a shared decision-making process with their teachers and parents. This information is used for educational, personal, and career counseling about talent development opportunities and their child’s involvement in them.

This expanded approach to identifying talent potentials is essential if we are to make genuine efforts to include more under-represented students in a plan for total talent development and the development of innovation. This approach is also consistent with the more flexible conception of developing gifts and talents

that has been a cornerstone of our work and our concerns for promoting more equity in special programs.

Curriculum Modification and Differentiation Techniques

The second service delivery component of the SEM is a series of curriculum modification techniques designed to: (1) adjust levels of required learning so that all students are challenged; (2) increase the number of in-depth learning experiences; and (3) introduce various types of enrichment into regular curricular experiences. The procedures used to carry out curriculum modification are curriculum compacting, textbook analysis and removal of repetitious material from textbooks, and a planned approach for introducing greater depth into regular curricular material. Due to space restrictions, curriculum compacting is described in depth here, and other modification techniques are described in detail in other publications (see, for example, Reis et al., 1993; Renzulli, 1994).

How to Use the Compacting Process

Defining goals and outcomes. The first of three phases of the compacting process consists of defining the goals and outcomes of a given unit or segment of instruction. A major goal of this phase of the compacting process is to help teachers make individual programming decisions; a larger professional development goal is to help teachers be better analysts of the material they are teaching and better consumers of textbooks and prescribed curricular material.

Identifying students for compacting. The second phase of curriculum compacting is identifying students who have already mastered the objectives or outcomes of a unit or segment of instruction that is about to be taught. The first step of this phase involves estimating which students have the potential to master new material at a faster than normal pace; knowing one's students is, of course, the best way to begin the assessment process. Scores on previous tests, completed assignments, standardized achievement tests, and classroom participation are the best ways of identifying highly likely candidates for compacting.

Being a candidate for compacting does not necessarily mean that a student knows the material under consideration. Therefore, the second step of identifying candidates involves finding or developing appropriate tests or other assessment techniques that can be used to evaluate specific learning outcomes. Unit pretests, or end-of-unit tests that can be administered as pretests are appropriate for this task, especially when it comes to the assessment of basic skills. An analysis of pretest results enables the teacher to document proficiency in specific skills, and to select instructional activities or practice material necessary to bring the student up to a high level on any skill that may need some additional reinforcement.

The process is slightly modified for compacting content areas that are not as easily assessed as basic skills, and for students who have not mastered the material, but are judged to be candidates for more rapid coverage. First, students should have a thorough understanding of the goals and procedures of compacting, including the nature of the replacement process. The amount of time for completion of the unit should be specified, and procedures such as periodic progress reports or log entries for teacher review should be agreed upon. Of course, an examination of potential acceleration and/or enrichment replacement activities should be a part of this discussion.

Another alternative is to assess or pretest all students in a class when a new unit or topic is introduced; although this may seem like more work for the teacher, it provides the opportunity for all students to demonstrate their strengths or previous mastery in a given area. Using a matrix of learning objectives, teachers can fill in test results and establish small, flexible, and temporary groups for skill instruction and replacement activities.

Providing acceleration and enrichment options. The final phase of the compacting process can be one of the most exciting aspects of teaching because it is based on cooperative decision-making, innovation, and creativity on the parts of both teachers and students. Efforts can be made to gather enrichment materials from classroom teachers, librarians, media specialists, and content area or gifted education specialists. These materials may include self-directed learning activities, instructional materials that focus on particular thinking skills, and a variety of individual and group project oriented activities that are designed to promote hands-on research and investigative skills. The time made available through compacting provides opportunities for exciting learning experiences such as small-group, special-topic seminars that might be directed by students or community resource persons, community-based apprenticeships or opportunities to work with a mentor, peer tutoring situations, involvement in community-service activities, and opportunities to rotate through a series of self-selected mini-courses. The time

saved through curriculum compacting can be used by the teacher to provide a variety of enrichment or innovative opportunities for the student.

Enrichment strategies might include a variety of Type I, II, or III or a number of options included on the continuum of services. Acceleration might include the use of material from the next unit or chapter, the use of the next chronological grade level textbook or the completion of even more advanced work. Alternative activities should reflect an appropriate level of challenge and rigor that is commensurate with the student's abilities and interests.

Decisions about which replacement activities to use are always guided by factors such as time, space, and the availability of resource persons and materials. Although practical concerns must be considered, the ultimate criteria for replacement activities should be the degree to which they increase academic challenge and the extent to which they meet individual needs. Great care should be taken to select activities and experiences that represent individual strengths and interests rather than the assignment of more-of-the-same worksheets or randomly selected kits, games, and puzzles! This aspect of the compacting process should also be viewed as a creative opportunity for an entire faculty to work cooperatively to organize and institute a broad array of enrichment experiences. A favorite mini-course that a faculty member has always wanted to teach or serving as a mentor to one or two students who are extremely invested in a teacher's beloved topic are just some of the ways that replacement activities can add excitement to the teachers' part in this process as well as the obvious benefits for students. We have also observed another interesting occurrence that has resulted from the availability of curriculum compacting. When some previously bright but underachieving students realized that they could both economize on regularly assigned material and 'earn time' to pursue self-selected interests, their motivation to complete regular assignments increased; as one student put it, 'Everyone understands a good deal!'

The best way to get an overview of the curriculum compacting process is to examine an actual example of how the management form that guides this process is used. This form, 'The Compactor', presented in Fig. 5, serves as both an organizational and record-keeping tool. Teachers should fill out one form per student, or one form for a group of students with similar curricular strengths. The Compactor is divided into three sections:

- (1) The first column should include information on learning objectives and student strengths in those areas. Teachers should list the objectives for a particular unit of study, followed by data on students' proficiency in those objectives, including test scores, behavioral profiles and past academic records;

Figure 5. The compactor.

- (2) In the second column, teachers should detail the pretest vehicles they select, along with test results. The pretest instruments can be formal measures, such as pencil and paper tests, or informal measures, such as performance assessments based on observations of class participation and written assignments;
- (3) The third column is used to record information about acceleration or enrichment options; in determining these options, teachers must be fully aware of students' individual interests and learning styles. We should never replace compacted regular curriculum work with harder, more advanced material that is solely determined by the teacher; instead, students' interests should be taken into account. If, for example, a student loves working on science fair projects, that option may be used to replace material that has been compacted from the regular curriculum. We should also be careful to help monitor the challenge level of the material that is being substituted. We want students to understand the nature of effort and challenge, and we should ensure that students are not simply replacing the compacted material with basic reading or work that is not advanced.

Rosa: A Case Study in Curriculum Compacting

Rosa is a fifth grader in a self-contained heterogeneous classroom; her school is located in a lower socioeconomic urban school district. While Rosa's reading and language scores range between four or five years above grade level, most of her 29 classmates are reading one to two years below grade level. This presented Rosa's teacher with a common problem: What was the best way to instruct Rosa? He agreed to compact her curriculum. Taking the easiest approach possible, he administered all of the appropriate unit tests for the grade level in the Basal Language Arts program and excused Rosa from completing the activities and worksheets in the units where she showed proficiency (80% and above). When Rosa missed one or two questions, the teacher checked for trends in those items and provided instruction and practice materials to ensure concept mastery.

Rosa usually took part in language arts lessons one or two days a week; she spent the balance of the time with alternative projects, some of which she selected. This strategy spared Rosa up to six or eight hours a week with language arts skills that were simply beneath her level. She joined the class instruction only when her pretests indicated she had not fully acquired the skills or to take part in a discussion that her teacher thought she would enjoy. In the time saved through compacting, Rosa engaged in a number of enrichment activities. First, she spent as many as five hours a week in a resource room for high-ability students. This time was usually scheduled during her language arts class,

benefiting both Rosa and her teacher, since he did not have to search for all of the enrichment options himself. The best part of the process for Rosa was that she did not have to make up regular classroom assignments because she was not missing essential work.

Rosa also visited a regional science center with other students who had expressed a high interest and aptitude for science. Science was a second strength area for Rosa, and based on the results of her *Interest-A-Lyzer*, a decision was made for Rosa to proceed with a science fair project on growing plants under various conditions. Rosa's Compactor, which covered an entire semester, was updated in January. Her teacher remarked that compacting her curriculum had actually saved him time—time he would have spent correcting papers needlessly assigned! The value of compacting for Rosa convinced him that he should continue the process. The Compactor was also used as a vehicle for explaining to Rosa's parents how specific modifications were being made to accommodate her advanced language arts achievement level and her interest in science. A copy of The Compactor was also passed on to Rosa's sixth-grade teacher, and a conference between the fifth and sixth grade teachers and the resource teacher helped to ensure continuity in dealing with Rosa's special needs.

The many changes that are taking place in our schools require all educators to examine a broad range of techniques for providing equitably for *all* students. Curriculum compacting is one such process that has demonstrated that many positive benefits can result from this process for both students and teachers.

Enrichment Learning and Teaching

The third service delivery component of the SEM, which is based on the Enrichment Triad Model, is enrichment learning and teaching that has roots in the ideas of a small but influential number of philosophers, theorists, and researchers such as Jean Piaget (1975), Jerome Bruner (1960, 1966), and John Dewey (1913, 1916). The work of these theorists coupled with our own research and program development activities, has given rise to the concept we call enrichment learning and teaching. The best way to define this concept is in terms of the following four principles:

- (1) Each learner is unique, and therefore, all learning experiences must be examined in ways that take into account the abilities, interests, and learning styles of the individual;
- (2) Learning is more effective when students enjoy what they are doing, and therefore, learning experiences should be constructed and assessed with as much concern for enjoyment as for other goals;
- (3) Learning is more meaningful and enjoyable when content (i.e. knowledge) and process (i.e. thinking

skills, methods of inquiry) are learned within the context of a real and present problem; and therefore, attention should be given to opportunities to personalize student choice in problem selection, the relevance of the problem for individual students at the time the problem is being addressed, and authentic strategies for addressing the problem;

- (4) Some formal instruction may be used in enrichment learning and teaching, but a major goal of this approach to learning is to enhance knowledge and thinking skill acquisition that is gained through formal instruction with applications of knowledge and skills that result from students' own construction of meaning (Renzulli, 1994, p. 204).

The ultimate goal of learning that is guided by these principles is to replace dependent and passive learning with innovative, engaged learning. Although all but the most conservative educators will agree with these principles, much controversy exists about how these (or similar) principles might be applied in everyday school situations. Numerous research studies and field tests in schools with widely varying demographics have been carried out (Renzulli & Reis, 1994). These studies and field tests provided opportunities for the development of large amounts of practical know-how that are readily available for schools that would like to implement the SEM. They also have shown that the SEM can be implemented in a wide variety of settings and used with various populations of students including high-ability students with learning disabilities and high-ability students who underachieve in school.

Concluding Thoughts

The many changes taking place in general education have resulted in some unusual reactions to the SEM that might best be described as the good news/bad news phenomenon. The good news is that many schools are expanding their conception of giftedness, and they are more willing than ever to extend a broader continuum of services to larger proportions of the school population. The bad news is that with increasing attention paid to raising test scores, it is even more challenging to continue arguing for opportunities for creativity and innovation in our schools. We are pleased to conclude this chapter with some non-negotiables about the SEM. Before continuing, however, it is important to say that the material that follows is based on the assumption that the reader is familiar with the model and has reviewed the work in this chapter that summarizes our most recent book on this approach, entitled *The Schoolwide Enrichment Model: A Comprehensive Plan for Educational Excellence* (Renzulli & Reis, 1997).

First, although we have advocated a larger talent pool than traditionally has been the practice in gifted education, and a talent pool that includes students who

gain entrance on *both* test and non-test criteria (Renzulli, 1978, 1982, 1986, 1988b, 2002), we firmly maintain that the concentration of services necessary for the development of high level potentials cannot take place without targeting and documenting individual student talents and abilities. Targeting and documenting does not mean that we will simply play the same old game of classifying students as 'gifted' or 'not gifted', and let it go at that. Rather, targeting and documenting are part of an ongoing process that produces a comprehensive and always evolving 'Total Talent Portfolio' about student abilities, interests, and learning styles. The most important thing to keep in mind about this approach is that *all information should be used to make individual programming decisions about present and future activities, and about ways in which we can enhance and build upon documented strengths*. Documented information: (1) will enable us to recommend enrollment in advanced courses or special programs (e.g. summer programs, college courses, etc.); and (2) will provide direction in taking extraordinary steps to develop specific interests and resulting projects within topics or subject matter areas of advanced learning potential.

Enrichment specialists must devote a *majority* of their time to working directly with talent-pool students, and this time should mainly be devoted to facilitating individual and small group investigations (i.e. Type IIIs). Some of their time with talent-pool students can be devoted to stimulating interest in potential Type IIIs through *advanced* Type I experiences and *advanced* Type II training that focuses on learning research skills necessary to carry out investigations in various disciplines. To do this, we must encourage more classroom teachers to become involved in talent development through both enrichment opportunities and curriculum modification and differentiation within their classrooms.

A second non-negotiable is that SEM programs must have specialized personnel to work directly with talent-pool students, to teach advanced courses and to coordinate enrichment services in cooperation with a schoolwide enrichment team. The old cliché, 'Something that is the responsibility of everyone ends up being the responsibility of no one', has never been more applicable than when it comes to enrichment specialists. The demands made upon regular classroom teachers, especially during these times of mainstreaming and heterogeneous grouping, leave precious little time to challenge our most able learners and to accommodate interests that clearly are above and beyond the regular curriculum. In a study recently completed at The National Research Center on the Gifted and Talented (Westberg, 1991), researchers found that in 84% of regular classroom activities, *no differentiation was provided for identified high-ability students*. Accordingly, time spent in enrichment programs with specialized teachers who understand how

to encourage student creativity and innovation is even more important for high-potential students. Related to this non-negotiable are the issues of teacher selection and training, and the scheduling of special program teachers. Providing unusually high levels of creative challenge requires advanced training in the discipline(s) that one is teaching, in the application of process skills, and in the management and facilitation of individual and small group investigations. It is these characteristics of enrichment specialists rather than the mere grouping of students that have resulted in achievement gains and high levels of creative productivity on the parts of special program students.

Summary

The SEM creates a repertoire of services that can be integrated in such a way to create ‘a rising tide lifts all ships’ approach. The model includes a continuum of services, enrichment opportunities and three distinct services: curriculum modification and differentiation, enrichment opportunities of various types, and opportunities for the development of individual portfolio including interests, learning styles, product styles and other information about student strengths. Not only has this model been successful in addressing the problem of high-potential students who have been under-challenged but it also provides additional important learning paths for creative students who achieve academic success in more traditional learning environments but long for opportunities for innovation in school.

The absence of opportunities to develop creativity in all young people, and especially in talented students, is troubling. In the SEM, students are encouraged to become responsible partners in their own education and to develop a passion and joy for learning. As students pursue creative enrichment opportunities, they learn to acquire communication skills and to enjoy creative challenges. The SEM provides the opportunity for students to develop their gifts and talents and to begin the process of lifelong learning, culminating, we hope, in higher levels of creative and innovative work of their own selection as adults.

Towards a Logic of Innovation

Gerald F. Smith

*Department of Management, College of Business Administration, University of Northern Iowa,
USA*

Abstract: This chapter identifies the most promising avenues for promoting and improving idea generation, and assesses the possibilities and limitations of such an endeavor. The chapter will discuss research streams and programs, identifying specific heuristics and strategies that can be employed to generate innovative ideas. It will also consider fundamental questions regarding the extent to which idea generation can be 'rationalized' and the ways in which a useful logic of innovation might be developed. Traces of such a logic can be found in the many idea-generation methods that have been proposed, but rarely tested, in the creativity literature.

Keywords: Innovation; Creativity; Idea generation, Scientific discovery; TRIZ; Inventive problem-solving.

Thomas Edison's famous analysis of genius—that it is '1% inspiration and 99% perspiration'—pertains to innovation and other endeavors that depend on the generation of creative ideas. His epigram juxtaposes two contrasting views of the mental activities involved in innovation. Per the inspiration account, innovative ideas result from dazzling mental leaps and 'Aha' experiences. This view, part of the popular image of creative genius, has attracted the attention of scientists intent on explicating the creative process (Smith, Ward & Finke, 1995). By contrast, the perspiration account sees innovative breakthroughs as resulting from more effortful and mundane activities (Weisberg, 1993, 2003). Innovators often employ a brute force, trial-and-error strategy in which many possibilities are successively tried until an acceptable solution is found. Less appealing to empirical investigators, this view was favored by Edison.

Their value notwithstanding, each account has inadequacies. Inspiration is unreliable, incapable of being enacted at will, so would-be innovators derive few benefits from this perspective. The perspiration account, however, fails to explain how people generate insightful, non-obvious possibilities that result in major innovative breakthroughs. Thus, the poetic qualities that make Edison's epigram memorable also make it misleading. Recognizing the most divergent aspects of innovative thought, it overlooks elements that are more central, notably the importance of domain knowledge and intelligent deliberation. Reliance on knowledge

and reflective thought were the hallmarks of Edison's own approach to invention; witness his conscious use of analogies (Weisberg, 1993) and employment of expert scientists (Friedel, 1992).

These resources also predominate in more pedestrian idea-generation efforts, as when a writer devises the opening paragraphs of a chapter like this. Rather than waiting for inspiration or relying on simple-minded trial and error, most writers (the present author included) are tacitly aware, from their reading and writing experiences, of strategies for latching onto a reader's attention: ask a provocative question; narrate an interesting vignette; make an outrageous claim; or explore the implications of an epigram. These strategies suggest possibilities that can be shaped, by reflection, to fit the situation at hand.

In this chapter I consider whether innovation exhibits or can be equipped with a 'logic', that term being construed broadly to encompass any consciously controlled mental activities that enhance one's prospects for generating valuable ideas. Such a logic would lie in the considerable space between inspiration and perspiration, providing mental tools that innovators can deploy in their search for solutions. My interest in this issue reflects a belief that idea generation is a critical part of the innovation process and that much can be done to improve it.

The chapter's next section frames the issue. This is followed by a discussion of the search for a logic of scientific discovery, a parallel endeavor of direct

relevance to the chapter’s topic. The chapter’s longest section reports and analyzes various research programs devised to support the generation of innovative ideas. The most promising extract lessons from past incidents of creative thought. The contents of these sections inform the chapter’s concluding discussion of the revealed nature of the logic of innovation.

Can Idea Generation Be Empowered?

What is innovation? Most simply, it is the introduction of or change to something new. When innovating, one makes progressive changes that result in novel states of affairs. So understood, innovations can be characterized in several respects. They have an object or target, that which is being changed. This can be a product, a process, or such things as an individual’s lifestyle, an organization’s strategy, and a society’s culture. Innovations vary in extent or magnitude, the degree to which one deviates from the past. Though there is ‘nothing new under the sun’, some innovations diverge more substantially than others from known precedents. A final characteristic is the impact of the change, the significance or range of its effects. Boden’s (1991) distinction between psychological and historical creativity—having ideas that are novel for oneself vs. novel for humankind—is apposite. Some innovations

change the trajectory of history; others change the way a CD collection is organized.

Organizing the Conceptual Landscape

The innovation process begins with a felt need for change and culminates in its successful implementation. Key process stages include the generation of ideas, development of the most promising, and their acceptance by relevant parties. A process perspective highlights several concepts related to innovation, most being concerned with the generation of innovative ideas, this chapter’s focus. These concepts and their relationships are depicted in Fig. 1.

Innovation is closely related to *problem-solving*, as suggested by similarities between models of the two processes (Schroeder, Van de Ven, Scudder & Polley, 2000). A problem is a difficult or challenging situation that bears improvement; problem-solving is the thinking done to improve things (Smith, 1998b). Problem-solving is not always innovative—one can adopt tried-and-true solutions—but innovation invariably includes problem-solving since the generation and implementation of ideas for change never transpire without difficulty.

The early stages of the innovation process, concerned with the generation and development of novel ideas, are called *invention*. This term is especially

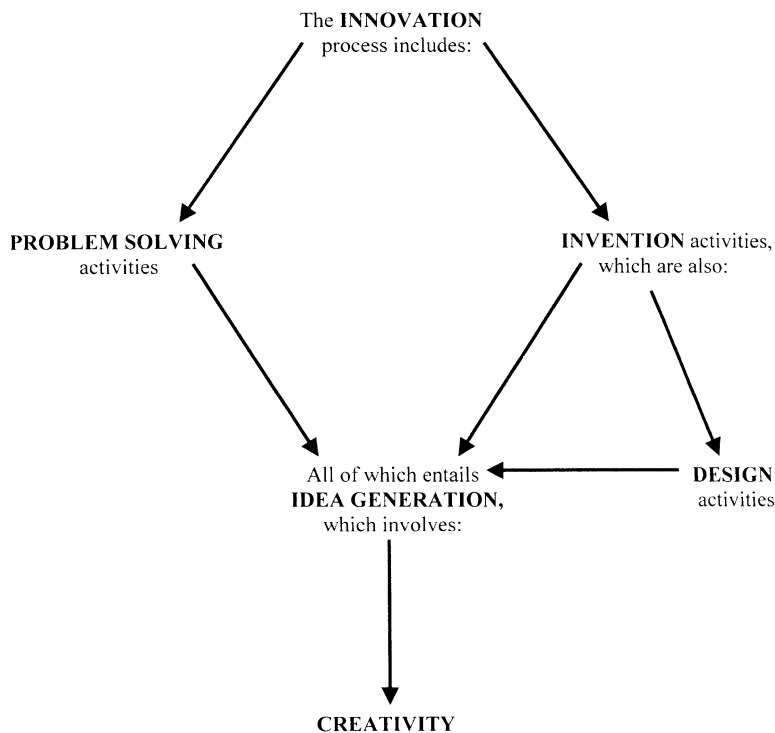

Figure 1. Innovation, idea generation, and related concepts.

applicable if the ideas could be patented. Because it is a challenging mental task, invention involves problem-solving activity. Much of this thinking/problem-solving is *design* work. Design is the development or devising of complex things. Not all design is invention, the latter having a higher standard for originality (Dasgupta, 1996). Architects design but do not invent buildings. However, an architect might invent by devising a novel solution to a design problem.

Idea generation, the mental production of possibilities or alternatives, must be performed at various points in most problem-solving episodes. Lying at the heart of both invention and design, it is widely acknowledged to be a key part of the innovation process (Van de Ven, Angle & Poole, 2000; Weber & Perkins, 1992). One's idea-generation ability and performance are usually attributed to the person's *creativity*. Creativity can be regarded as a fixed trait or as an acquired repertoire of mental skills, habits, and attitudes.

Innovation Research

Progressive change, the core meaning of innovation, is a matter of much importance and widespread applicability. This is reflected in innovation research: there is a huge amount of it spread across many fields (cf., Downs & Mohr, 1976; Rogers, 1983; Van de Ven, Angle & Poole, 1989). No academic disciplines exist exclusively for the study of innovation, and few journals are dedicated to the topic. Technological innovation has attracted the most attention because of its role in the rise of Western civilization (Mowery & Rosenberg, 1998). There are substantial streams of research that study innovation in different fields (e.g. education, healthcare); it has also been investigated from various disciplinary perspectives, notably economics and sociology (cf., Mansfield, 1968; Steil, Victor & Nelson, 2002).

Since the topic's practical importance is responsible for the great volume of innovation research, it follows that this research should be relevant to practice: it should contribute to increases in the amount and effectiveness of innovative activities. Most scientists would accept this need for practical relevance. At the same time, however, they would address it indirectly, following Lewin's dictum that "nothing is as practical as a good theory" (1945, p. 129). Scientists develop a deep theoretical understanding of empirical phenomena, holding that such understanding will enable prediction and control of practical outcomes. This theory-based strategy has been enormously successful in the physical and biological sciences, where scientific theories underlie technological development of practical artifacts and interventions. However, the strategy has rarely been effective in the human sciences. This may be because few human phenomena are susceptible to being deeply explained by scientific theories (Dupre, 1993; Rosenberg, 1994).

Innovation is, of course, a quintessentially human phenomenon. Within this vast area of research, two large streams would seem to have considerable potential for practical application. One is psychological research on creativity, which could presumably help people generate innovative ideas. The other, research on the management of innovation, tries to promote effective innovation practices in organizations. Have these two bodies of research delivered the practical goods? Reasonable people could disagree in their assessments, but in this author's judgment, neither of these substantial research streams has had a significant impact on innovation practice. Granting this claim, if only for the sake of argument, why might it be true? What has kept scientific research from having a larger effect on innovation practice?

With regard to research on the management of innovation, it is likely that the phenomenon in question—innovation activity in organizations—is too diverse, complex, and contingent to be explained by a scientific theory. Recent descriptive studies have concluded that prior academic assumptions about organizational innovation were simplistic, and that the process may be the result of a "nonlinear dynamic system" (Van de Ven, Polley, Garud & Venkataraman, 1999, p. 5). This characterization offers no added leverage for process improvement. Proposed theories of organizational innovation processes (e.g. Poole & Van de Ven, 2000) do not provide the explanatory insights required for prescriptive support. Indeed, the most useful research in this area is indifferent to theory, focusing instead on the identification and validation of 'best practices', what innovative companies do that makes their change efforts successful (Kanter, Kao & Wiersema, 1997; Zairi, 1999). Even here, there are prescriptive limitations: innovation begins with and depends on the generation of ideas, an individual-level mental activity that organizations can enable but not cause.

This limitation does not apply to psychological research on creativity, which is expressly concerned with idea generation. Moreover, psychology is among the most highly developed of the human sciences, having produced knowledge of considerable value in many practical applications—child development, education, and marketing, among others. Why has psychological research not been as useful with regard to innovation? Several reasons come to mind:

- First and foremost, creativity is difficult to understand. Psychology has been hard-pressed to develop adequate theories of higher-order thinking processes like judgment and reasoning, and creativity is assuredly the most elusive of these:
- Second, much research treats creativity as a trait that is fixed for each person (Torrance, 1988). This approach offers no support for individual idea generation performance;

- Third, a substantial portion of creativity research studies the influence of factors—personality and culture, for instance—that are not susceptible to control (Csikszentmihalyi, 1988);
- Fourth, the cognitive research strategy that is most promising, from a prescriptive standpoint, is relatively new and undeveloped (Smith, Ward & Finke, 1995). But even cognitive accounts run into impasses, capacities and processes like intuition and insight that are resistant to conscious direction and improvement.

Surprisingly, elements of the idea generation process that are subject to individual control—for instance, the selection and use of creativity techniques—have not attracted much research attention (Smith, 1998a). Indeed, setting aside a few noteworthy exceptions (e.g. Perkins, 1981), it might seem that creativity researchers are not especially concerned with practical applications of their work

Is Prescription Possible?

Perhaps creativity research has had so little effect on practice because there is little effect it could have. The generation of innovative ideas may be an activity that simply cannot be improved by outside interventions. Such a view follows from Campbell's (1960) claim that creativity is a blind variation and selective retention process. It is suggested by trait theories of creativity, which regard idea-generation performance as determined primarily by an individual's innate endowment of creative capacity (Torrance, 1988). And it follows from cognitive theories that emphasize uncontrollable mental processes like intuition (Bowers, Farvolden & Mermigis, 1995). These concerns raise doubts about the prospects for improving idea generation. Are there grounds for believing the opposite, for claiming that people can be helped to generate innovative ideas?

There has been a widespread tendency—among researchers and lay people—to regard idea generation as unfettered, free-wheeling thought (Adams, 1979; Buzan, 1983). Artistic imagination is taken as its model, creativity being seen as the unconstrained exploration of possibilities that satisfy few real world demands. Indeed, the wilder the idea, the better. This conception overlooks a critical distinction: whereas many artists regard art's role as one of disturbing mainstream beliefs, this is not the case for other forms of innovation. Outside the realm of art, innovation pursues the goal of progressive change, making things better, more adequate to human needs. For this to happen, innovative ideas must present possibilities that are feasible, capable of being implemented within relevant contexts. An idea's craziness per se is not a virtue; the wildly improbable must still be doable. Because implementation contexts are dense, posing many constraints and demands, the generation of innovative ideas is a knowledge-intensive process.

Losing some of its similarity to artistic imagination, idea generation takes on qualities associated with practical problem-solving (Sternberg et al., 2000).

Thinking that is more constrained, as by feasibility considerations, is more knowledge-intensive. Knowledge of relevant constraints and demands must be taken into account for such thinking to reach acceptable conclusions. Thinking that is more knowledge-intensive is more susceptible to individual monitoring and control. Inspiration gives way to perspiration; instead of relying on free-flowing imagination, it becomes more productive to mentally work one's way through to a solution (Weisberg, 2003). Such thinking is also susceptible to assistance and support from techniques, heuristics, and other interventions (Root-Bernstein, 2003). These tools can embody relevant knowledge or bring it to mind. Idea generation becomes more reasoned, reflective, analytical, and logical as one tries to deal with pertinent constraints and demands, avoiding the dead ends they impose and exploiting the possibilities they present. Thinking also becomes more experience-based, past instances providing examples of what works and what does not. This enables support by interventions that bring experiential knowledge to bear on idea generation tasks.

The role of analytical and knowledge-based thought in idea generation is evidenced by many creativity techniques (Smith, 1998a). A method like morphological analysis (Allen, 1962), which decomposes a problem into parameters and components, searching for combinations that have promising solution implications, demonstrates how logical analytical thought can lead to innovative ideas. The checklists used by product developers to generate new product ideas (Higgins, 1994)—“Vary the size, shape, or color of an existing product”—summarize knowledge compiled from successful past innovations.

Thus, the knowledge-intensive nature of innovation tasks creates the potential for idea generation to be intelligently disciplined and directed. Though divergent imaginative thought has a role, convergent reasoning and analysis are also productive. Experiential knowledge is important, and there may be general principles of innovation to identify and exploit. In short, there are good reasons for believing that a logic of innovation exists or can be developed.

The Logic of Scientific Discovery

The attempt to develop a logic of innovation can profit from an investigation of scientific discovery. Discovery and innovation are closely related activities and achievements. Commonly conceived as relying on creative thought processes that are immune to conscious control, each is often viewed as being unamenable to prescription. We can create propitious environments for scientific discovery and innovation, and we can insure that motivated, creative people are employed to perform such tasks. But thereafter, it is

argued, little can be done: scientists, inventors, and the rest of society can only hope that insights, inspirations, and breakthroughs occur.

Research on scientific discovery has challenged this portrayal. Studies from various disciplinary perspectives have identified the considerable role of reflective thought in the discovery process (Dasgupta, 2003; Giere, 1992; Kantorovich, 1993; Nickles, 1980b). There is strong evidence of a logic of scientific discovery, noting again that ‘logic’ is to be taken, not as deductive, algorithmic procedures, but as thinking that is susceptible to conscious control and improvement. These findings lend encouragement to the search for a logic of innovation. They offer insights as to what a logic of innovation might consist of and provide content that can be directly incorporated into that logic.

Task Analysis

Discovery is often contrasted with invention, both being ways of coming up with something new: one can either find it or make it. Though everyday uses of the terms are more elaborate, these root meanings provide a valuable contrast. Innovation, as noted earlier, is a broad notion that includes acts of invention. It also takes in some acts of discovery. For instance, Fleming’s discovery of penicillin led to innovations in the treatment of bacterial infections.

However, scientific discovery is more diverse and complex, encompassing achievements that are not really discoveries in the simple sense of finding something new. Indeed, the most significant scientific discoveries are more like inventions than findings. Newton formulated his laws of motion and conceived that objects were attracted by gravity, rather than finding these ‘things’ fully realized during his studies. Darwin devised an evolutionary account of life on earth, and Einstein developed his theories of relativity. Even Lavoisier’s discovery of oxygen has an element of invention, the construction of a plausible account of reality. The reason scientific discovery has this inventive character is that scientists rarely look for things that can simply be seen. Rather, they search for evidence of theoretical entities, things like atoms and genes that are invisible to human eyes. Most of their searches are not for things at all, but are instead for scientific explanations, deep theoretical accounts of empirical phenomena. Explanations are created, not found, constructed through extended mental efforts rather than being directly perceived. Simon’s development of the cognitive approach to individual and organizational decision-making exemplifies this kind of effortful achievement (Dasgupta, 2003).

The dual nature of scientific discovery is reflected in a distinction by Kantorovich (1993). In ‘discovery by exposure’, the scientist becomes aware of something that is already there—for instance, Galileo’s discovery of the moons of Jupiter. This process is usually

perception-driven. With ‘discovery by generation’, however, “the object of discovery . . . is in a sense a product of the discovery process” (Kantorovich, 1993, pp. 32–33). The scientist invents a theory of certain phenomena, creating an explanation that did not previously exist. Even something as eternally real as gravity was, in a significant sense, created through its discovery: though it had always been there, gravity became ‘real’ for people as a result of Newton’s theory.

Several influential accounts of science (Laudan, 1977; Nickles, 1980b; Simon, 1977) view it as a form of problem-solving. Each type of scientific discovery cited by Kantorovich matches up with a major conceptual component of the problem-solving process. Discovery by exposure results from search activity. Search, the systematic exploration of a set of possibilities, is, per Newell & Simon (1972), the fundamental problem-solving process. Search is guided by knowledge that directs the problem-solver’s attention in directions most likely to yield solutions. Being susceptible to prescriptive support, knowledge-driven heuristic search provides grounds for believing that discovery by exposure is similarly susceptible.

The other kind of discovery, by generation, is a form of design, another important problem-solving activity. As noted earlier, design is the development of complex things, the creation of artifacts serving certain purposes. A scientific theory is such an artifact. An artifact’s design is subject to constraints, this being the case with theories (Nickles, 1980a). Design includes search activity—for instance, an architect’s search for possible building entryways. This is replicated in the design of theories, when scientists search for variables and relationships that provide explanatory power (Bechtel & Richardson, 1993). Being shaped by past experience and prevailing practices, design is knowledge-intensive. Viewed as design, scientific discovery offers opportunities for the deployment of strategies, methods, heuristics, and other forms of procedural knowledge.

Thus, a task analysis of scientific discovery suggests substantial room for development of a supporting logic. It clarifies the close relationship between scientific discovery, innovation, and other concepts featured in Fig. 1. This provides grounds for believing that studies of the logic of scientific discovery will have implications for innovation.

Elements of Logic

Interest in the logic of scientific discovery originated with Reichenbach’s (1938) distinction between the discovery and justification of scientific claims. Philosophers of science concluded that while justification had a logic that scientists employ and philosophers could improve, such was not the case for discovery. In his book *The Logic of Scientific Discovery*, Popper denied that there was any such thing, saying that “the act of

conceiving or inventing a theory, seems to me neither to call for logical analysis nor to be susceptible of it" (1959, p. 31). Discovery occurs through inspiration or intuition, making it a matter for psychological investigation, rather than rational reconstruction by philosophers. Note, however, that these philosophers employed a narrow, deduction-centered, notion of logic and that they wrote at a time when psychologists had virtually no understanding of higher-order mental processes.

The first significant argument on behalf of a logic of discovery was made by Hanson (1965), who contended that scientific discovery evidences the use of abductive reasoning, inference to the best explanation. Observing certain surprising phenomena, a scientist infers the hypothesis that most plausibly explains them, this hypothesis becoming the object of further investigation. This account has serious inadequacies—for instance, it says why a hypothesis is selected, but not how it came to be identified in the first place. Hanson's work stirred up interest in scientific discovery, leading to a program of research by philosophers informally known as the 'friends of discovery'. Following the example of Kuhn (1962), scholars analyzed historical cases of discovery, searching for elements of method and logic (cf. Nickles, 1978).

Since the 1970s, this program has received support from the newly prominent field of cognitive science. Cognitivism revived the psychological study of thinking, developing scientifically rigorous ways of studying unobservable mental activity. As their interests expanded, cognitive researchers became interested in the thinking of scientists. Viewing discovery as problem-solving, Simon and others developed computational models that generate theoretical concepts and deduce scientific laws (Langley, Simon, Bradshaw & Zytkow, 1987; Simon, Langley & Bradshaw, 1981; Thagard, 1988, 1992). For instance, Langley's BACON program used heuristic processes to derive Kepler's laws from its analyses of relevant data sets (Langley et al., 1987). Though critics allege that these 'discoveries' were assisted by structuring devices unavailable to working scientists, computational studies demonstrate the role and utility of heuristic strategies in scientific discovery. Thus, by the end of the twentieth century, a broad-based research effort had identified many aspects and elements of a logic of scientific discovery.

Scientific thinking, including discovery, is influenced in the most general way by fundamental presuppositions, methodological rules and principles, and core concepts, all of which Holton (1973, 1978, 2003) subsumed under the notion of 'theme'. These would include a belief in causality and forms of conservation, and commitments to norms of deductive and inductive reasoning. The principle of parsimony is a theme, as is the assumption that the universe is governed by laws that can be represented mathemat-

ically. Scientists can benefit from an awareness of this intellectual milieu. For instance, when trying to explain certain phenomena, it is helpful to be aware of the kinds of explanation used in one's field—for instance, functionalist accounts, stage theories, and mathematical models. Since scientific discovery is given direction and made more intelligible by thematic resources and constraints, they are part of its logic.

At the other extreme in terms of specificity, and much closer to traditional notions of logic, are relatively formal techniques used for discovery purposes. Most of these are statistical methods used to identify patterns in data. Factor analysis, curve-fitting methods, and exploratory data analysis are among the most popular. These clearly belong to the logic of discovery, being analytical tools devised for the performance of discovery-related tasks.

Certain general mental skills and practices are widely employed as part of discovery. These include normal mental capacities—mental imagery, for instance—that scientists use to generate theories and hypotheses. There is ample evidence that scientists conduct thought experiments as a way of pre-testing hypotheses (Gooding, 1992). They manipulate mental images to achieve insights into phenomena (Nersessian, 1992). They also reason analogically, their thinking being affected by the technical analogues—clockworks or computers, for instance—favored at the time (Bechtel & Richardson, 1993). Some of these mental practices can be improved through prescriptive support (Root-Bernstein & Root-Bernstein, 2003). For instance, there are rules of analogical rigor—maintain structural consistency, avoid mixed analogies, among others—that scientists can learn (Gentner & Jeziorski, 1989). The informed deployment of these mental capacities is a source of rationality in the discovery process. It is likely to be a source of logic in innovation as well.

The most numerous instances of discovery logic are the many strategies and heuristics used by scientists. They have been identified in various ways. Dunbar (1995) studied working scientists in molecular biology labs, noting how they used negative evidence, explored analogies, followed up on surprising results, and were influenced by their social context. In contrast, Tweney (1989) examined historical documents from the work of Michael Faraday, the 19th century English physicist, finding that Faraday employed confirmatory–disconfirmatory heuristics proposed by researchers: scientists should seek confirming evidence early in the life of a hypothesis, but shift toward seeking disconfirming evidence as things progress. Gigerenzer (1994) looked at various research programs in proposing his tools-to-theories heuristic: the tools scientists use to justify their theories provide concepts and metaphors that inspire new theories.

Adopting a perspectivist approach to research, McGuire (1989) proposed heuristics for use during the

formative stages of a research project: explore the meaning of key variables through conceptual analysis; conjecture the limits of hypothesized relationships; and hypothesize the contrary relationship, trying to explain it. An extensive set of heuristic advice was reported by Root-Bernstein (1989). He collected ideas from an array of sources, mostly famous scientists, compiling them into a 'Manual of Strategies for Discovery'. The following are among the most interesting: Delbruck's principle: "Be sloppy enough that something unexpected happens but not so sloppy that you can't tell what happened" (p. 412); Macfarlane's law: "When a number of conflicting theories coexist, any point on which they all agree is the one most likely to be wrong" (p. 413); George's strategy: "Vary the conditions over the widest possible range" (p. 416); and Burnet's advice: "Do as large a proportion as possible of your experiments with your own hands" (p. 418). Many of these suggestions apply to innovation tasks.

Some methods and heuristics are domain-specific; others only apply to certain discovery tasks, though these could appear in many disciplines. Bechtel & Richardson (1993) discussed the task of developing a mechanistic explanation, explaining a complex system's behavior in terms of the functions performed by its parts and relationships among these parts. Such explanations often appear in biology, psychology, and the social sciences. Per these authors, scientists who develop mechanistic explanations rely on two heuristics: decomposition, breaking the system down into components; and localization, identifying system activities with the behavior of specific components. Various strategies—analysis of system breakdowns, inhibitory or deficit studies, and excitatory studies—can generate information and insights regarding system functioning. These methods may pertain to innovation, prompting analyses of existing or analogous systems that suggest ideas for improvement.

A final form of prescriptive support derives from research on the 'illogic' of scientific discovery, thinking mistakes that scientists, like the rest of us, are prone to commit. It has long been recognized that scientists are not immune from such mistakes as over-valuing results from small samples, being biased by vivid information, and maintaining beliefs that have been discredited by new evidence (Kahneman, Slovic & Tversky, 1982; Nisbett & Ross, 1980). Making scientists more aware of common mental mistakes enhances their capacity for metacognitive self-monitoring. Thus, it is another aspect of the logic of scientific discovery.

Implications for Innovation

The foregoing constitutes a substantial array of mental tools that scientists consciously deploy for discovery purposes. The value of these resources notwithstanding, they do not exhaust the discovery process; assuredly, many important activities transpire beyond their reach. Relevant knowledge may or may not come

to mind; key patterns may or may not be seen; insights and intuitions may or may not occur. Scientific discovery involves mental activities that are not susceptible to prescriptive support. Nonetheless, it is heartening to find so many opportunities for aiding and improving the process.

Notably absent from this account is anything like a formal logic or algorithmic procedure. The statistical techniques employed for discovery purposes only suggest promising areas for investigation; computational models fall far short of automating discovery in real world contexts. Studies of discovery consistently demonstrate that, because of its context sensitivity and knowledge dependence, this ill-structured generative process cannot be fully proceduralized. Rather than a few powerful procedures, scientific discovery involves the use of many informal methods, strategies, and heuristics. These have varying degrees of generality and, following the well-known generality-power trade-off, the more general tend to be less effective. One would expect this to be true for innovation as well: effective idea generation practice is likely to involve a multitude of informal heuristic methods.

Generating Innovative Ideas

Where would one look to find a logic of innovation, consciously deployable means of generating innovative ideas? Some sources mirror those prominent in the logic of scientific discovery. Others are unique to innovation, reflecting its differences from discovery. This section discusses four sources of innovation logic. The first, process studies, investigates mental activities of innovators, seeking effective practices that can be employed by others. Another source derives lessons from analyses of inventions and other innovation products. The work of Genrich Altshuller (1984, 1996) typifies and motivates most of these efforts. A third source addresses process and other non-product targets of innovative activity. Finally, there is overtly prescriptive material—creativity techniques—that directly addresses the idea-generation task. Each of these sources will be discussed with the intent of identifying elements of innovation logic.

Process Studies

Several streams of research contribute to our understanding of the process by which innovative ideas are generated. Studies of inventors have identified mental capacities and activities that drive their achievements (Weber & Perkins, 1992). Studies of designers offer insights into their creative performances (Lawson, 1980; Rowe, 1987). Cognitive research uses experimental settings to explore facets of creativity (Smith, Ward & Finke, 1995). Research in these areas tries to demystify the creative process, solving Perkins' (1988) *ex nihilo* problem by explaining how people can create something that is genuinely new. Process studies have identified four kinds of resources that can be brought to

bear for this purpose: the innovation task or problem; mental capacities; informal heuristics, methods, and strategies; and prior knowledge and experience.

Innovation Tasks/Problems

Innovative thought should be adapted to or constrained by the problem one is trying to solve (Isaak & Just, 1995). Effective innovators exploit problem characteristics, shaping their mental activities to the task. For instance, since there are many acceptable solutions to innovation problems, a search usually proceeds forward in light of one's objectives, rather than working backwards from a predefined goal. Since innovation is often aimed at developing a physical artifact, visual imagery, graphic representations, and physical models are powerful tools for generating, evaluating, and developing solution alternatives.

Innovation problems start out as general objectives—say, a cure for cancer. Poorly specified at the outset, goals are elaborated as candidate solutions emerge and develop. Goals are a kind of constraint, the broader set of requirements an innovation must satisfy (Smith & Browne, 1993). Some constraints originate externally—building codes, for instance. Internal constraints emerge when solution alternatives are developed; the design of one part of a product limits the way other parts can be constructed. Constraints can be soft or hard, more or less amenable to violations. Innovators surface and assess self-imposed constraints, their preconceptions about the problem's solution (Lawson, 1980). They challenge boundaries implicit in prevailing artifactual forms. The proliferation of internal constraints leads innovators to employ a 'least commitments' design strategy (Goel & Pirolli, 1989): Solutions to sub-problems should be minimally constraining on subsequent design work. Solutions to some problems are organized as 'homing spaces' (Perkins, 1992), allowing one to know if progress is being made towards the goal. The Wright Brothers demonstrated another way of exploiting problem structure: unlike their competitors who searched design space for a machine that would fly, they decomposed the problem of flight into functional components—lift and lateral control, for instance. Searches of these function spaces yielded solutions that were combined in the first airplane (Bradshaw, 1992).

Mental Capacities

Like scientific discovery, innovative thinking employs mental capacities that are susceptible to improvement. The most fundamental is our ability to form and manipulate mental representations. Gorman (1997) included mental models—dynamic representations that can be operated in the imagination—in his cognitive framework for understanding innovation. Research on creative cognition focuses on 'pre-inventive structures', mental representations of promising ideas that might be developed into creative products (Ward, Smith &

Finke, 1999). Design theorists note the importance of a 'primary generator', an appealing idea that narrows the search space while being elaborated into a detailed solution (Lawson, 1980).

Studies of creative cognition have identified processes people use to generate and evaluate mental structures (Ward, Smith & Finke, 1999). These processes rely on existing knowledge, as when established concepts are stretched to suggest new possibilities. Our capacity for mental imagery figures prominently in innovative thought. Finke's laboratory studies demonstrated how visual forms suggest new functions (1990); Crouch claimed that the Wright Brothers were set apart by their "genius for visualizing the abstract" (1992, p. 84). Mental images can be made explicit in pictures, diagrams, and other graphic representations, which appear prominently in historical studies of invention (cf. Carlson & Gorman, 1990; Gorman & Carlson, 1990) and in the work of designers (Smith & Browne, 1993).

Innovative thinking involves the use of analogy as a vehicle for carrying ideas from one domain to another. Engineers recognize the value of natural analogies, how nature solves a problem, looking, for instance, to clam shells for hinge ideas. Architects use iconic analogies, designing buildings that resemble an appropriate object—praying hands for Wright's Unitarian church and sails for Utzon's Sydney Opera House (Rowe, 1987).

These capacities are employed in a process that is fundamentally conjectural: promising ideas are generated and developed as possible solutions, conjectures that will be discarded if insurmountable barriers or more appealing possibilities arise. The generation of innovative ideas can be aided by interventions that facilitate their visual depiction, or which highlight stimulating concepts, relationships, and analogies (Root-Bernstein & Root-Bernstein, 2003). The evaluation and development of innovative ideas involve reflective thought that is highly susceptible to knowledge-based support.

Heuristics, Methods, and Strategies

Consciously employed mental practices that innovators can acquire through experience or training, heuristics, methods, and strategies are by nature part of the logic of innovation. Recent interest in heuristics can be traced to Polya (1957), who offered suggestions for solving mathematical problems. Some of these—look for related problems, draw a figure, separate the parts of the condition—are applicable to innovation. Almost as venerable are 'weak methods'—means-ends analysis, working backwards, and hill-climbing, among others—identified by cognitive research on problem-solving (Lesgold, 1988). The drag hunt device favored by Edison (Gorman & Carlson, 1990) is a generate-and-test method that systematically tries many alternatives.

Though many heuristics are equally applicable to scientific discovery, others only apply to innovation. Thus, the development of the electron microscope was motivated by a realization that optical microscopes had reached their upper performance limit, and the heuristic of exploring different solution principles when that is the case (Weber & Perkins, 1992). Informal strategies and pieces of advice often seem like common sense—deliberately move away from old paths; try to integrate the desirable properties of many things; if something works, use it again (Perkins & Weber, 1992)—but they can have a huge impact on thinking.

Decomposition—breaking large problems down into many simple ones—is the most important strategy for invention. Its power was demonstrated by the Wright Brothers, who combined solutions to lift, control, and power sub-problems into a successful airplane. Decomposition is the prototypical means of addressing design problems (Simon, 1973). Design affords decomposition “because systems can be understood as hierarchies of components at different levels” (Smith & Browne, 1993, p. 1215), levels being defined around the system’s structural parts or intended functions. Design problems are recursive, decomposing into smaller design problems that can be solved or further broken down. While an innovation might begin as a vague idea, its development entails extensive decompositional elaboration, a process that tests the idea’s feasibility.

Prior Knowledge and Experience

Though innovation, by definition, involves a change to something new, process studies demonstrate that changes inevitably use and partially preserve the old and established (Weisberg, 1993, 2003). Innovations embody elements of the past; nothing is totally new or unprecedented. The generation of innovative ideas relies on knowledge of existing artifacts and practices (Ward, Smith & Finke, 1999). The use of analogies is typical of a process in which ideas, rather than being generated *ex nihilo*, are borrowed from various sources and shaped to fit the situation at hand. Studies have identified precedents supporting development of the telephone (Gorman & Carlson, 1990), moving pictures (Carlson & Gorman, 1990), ultrasonic imaging (Wild, 1992), and other inventions. Carlson and Gorman use the term ‘mechanical representations’ to refer to “the specific, working components an inventor uses to construct physical models of his invention” (1990, p. 392). Mechanical representations include the “levers, screws, wedges, wheels” and other artifacts that are “basic building blocks of invention” (p. 393). Some inventors have favorite devices that reappear in their creations; Edison was partial to the cylinder and stylus, double-action pawl, and polar relay (Jenkins, 1984). But all innovators draw on a culture’s stock of artifacts, its repertoire of tried-and-true means of achieving certain ends. Studies of design note the same phenomenon, using the term ‘design types’ or ‘prototypes’ to

refer to standard solutions to design problems—for instance, ways of constructing watertight roofs (Smith & Browne, 1993).

The importance of standard solutions explains the salience of historical material in design education. Rather than learning powerful idea generation methods, architectural students learn how their forbearers solved certain problems, so those solutions will be mentally available when practical situations require. Similarly for engineers and other inventors: education is largely a matter of becoming aware of means that inventors past have made available for the solution of current problems. This part of an innovator’s education and idea generation practice can be assisted by technology, for instance, case-based reasoning systems that provide designers with past cases pertaining to their current problem-solving needs (Kolodner, 1993).

In addition to these resources for the generation of innovative ideas, process studies have identified common mental mistakes made by innovators. Lawson (1980) warns against the ‘category trap’—categorizing a problem in solution terms—and other mental pitfalls. This is another element for our emerging logic of innovation. Thus far, that logic closely resembles the logic of scientific discovery. However, we now consider an approach to innovation that has no parallel in science.

Product Analysis

The attempt to develop ‘logical’ creativity methods is as old as the study of creativity itself. During the past several decades, this endeavor has been fueled by a powerful new strategy that has delivered impressive results. The strategy is product-analytic: the results of innovative activities are analyzed in the hopes of identifying patterns that can be used to direct idea generation. This strategy is based on a structuralist assumption that the infinite variety of things making up our world is shaped by a smaller set of principles. Once discovered, these can be represented in rules, methods, and heuristics for the generation of innovative ideas.

The first, most highly developed, and most influential program of product analysis was undertaken by Genrich Altshuller. Altshuller is a Russian inventor and patent inspector who began, in 1946, to develop an “algorithm for the solution of inventive problems”. The approach he used was to study patents issued in the Soviet Union for technical inventions. Since then, he has analyzed over 40,000 patents, doing much of this work during six years spent in a Siberian prison camp—his criticisms of Soviet innovation policy rubbed Stalin the wrong way. Altshuller identified useful regularities of various kinds. These were organized and developed into a ‘Theory of Inventive Problem Solving’, commonly known by its Russian acronym, TRIZ. During the 1960s, TRIZ achieved prominence in the Soviet Union, even being taught to high school students. Altshuller’s work (1984, 1996)

began to appear, in translation, to Western audiences in the 1980s. During the 1990s, Altshuller achieved the ultimate apotheosis: his work was picked up by American consulting firms which market related products and services as breakthrough boosts to creative thinking.

Like many others, Altshuller conceives the idea-generation problem as one of reducing the size of the search space. He is skeptical of psychological studies of the creative process, which do not address the 'primary and objective side of creativity' (1984, p. 8). He is also unimpressed by brainstorming and traditional creativity methods, which rarely solve difficult problems. The 'objective side of creativity' has to do with overcoming contradictions that are at the core of most problems. Technical contradictions exist insofar as improvements in part of a system create troubles in other parts. These derive from underlying physical contradictions.

By analyzing thousands of patents, Altshuller developed knowledge of different kinds of contradictions and means of overcoming them. Most of this knowledge existed initially as particularized insights and pieces of advice, mostly having to do with physical effects and phenomena that could be exploited for problem-solving purposes. Thus, an electrical effect called the 'Corona Discharge' can be used to measure the gas pressure inside a light bulb (Altshuller, 1996). More abstract insights were also identified and confirmed through repetition in multiple cases—for instance, the strategy of separating contradictory properties in space or time, or the principle of preparatory action (do it in advance). Much of TRIZ reflects Altshuller's attempt to encompass myriads of insights in a 'theory', a compelling conceptual framework that integrates these parts into a meaningful whole. His theoretical endeavors tend to be 'scientific', using language—S-field analysis, contradiction, algorithm, law—which implies a level of rigor that may not be achievable with such subject matters.

More modestly conceived, Altshuller's project can be viewed as producing three important outputs. First, and at the lowest conceptual level, TRIZ includes a substantial set of physical effects and devices that inventors can use to achieve particular purposes. Thus, phase transitions can be used to stabilize temperatures; movement can be controlled through the Toms, Bernoulli, or Weissenberg effects; and dimensions of objects can be measured by applying and reading magnetic and electrical markers. These means are summarized in a table (Altshuller, 1984), a compendium of stock solutions or raw materials for innovations involving physical phenomena.

Second, at a middle level of abstraction, Altshuller identified a wealth of heuristics that innovators can learn and apply. Some of these—change the state of the physical property; introduce a second substance, for instance—are tied to the kinds of physical inventions

Altshuller studied. Others are more general. Do it inversely; do a little less; fragmentation/consolidation; Ideal Final Result; and Model with Miniature Dwarfs (Altshuller, 1996, p. 168): all can be applied with socio-technical systems and other problems that are not solved at the chemistry-and-physics level. Some of these heuristics have been identified in other fields. Forcing an object to serve multiple functions (Altshuller, 1996, p. 159) is a standard design strategy; as will be seen, Weber (1992) independently recognized the value of incorporating multiple objects into one system (Altshuller, 1996, p. 29). This aspect of TRIZ, which resembles Polya's (1957) work on mathematical discovery, is a significant contribution to the logic of innovation.

The most abstract and intendedly general element of Altshuller's program is his 'algorithm for solving inventive problems', initially called ASIP, later ARIZ. This procedure includes typical problem-solving steps—selection of the problem, constructing a model of the problem, and so forth—fleshed out with pertinent sub-tasks and heuristics. ARIZ includes S-field analysis, a method Altshuller devised for representing problematic systems in ways that suggest solutions. These structured procedural elements of TRIZ may be useful, but they are unlikely to be as powerful as their maker suggests. Indeed, their effectiveness is likely to derive from the lower-level heuristics they include. Arguably, Altshuller's basic conceptual scheme, focused on overcoming contradictions, lacks the depth needed to drive a problem-solving method that is both powerful and general.

In summary, Altshuller's work is significant, even though his theories, algorithms, and laws do not satisfy criteria normally associated with those terms. If he has not developed an idea-generation method of unprecedented power, his work has yielded a wealth of heuristic knowledge and advice from which innovators in many fields can profit. Of special importance for current purposes is Altshuller's methodology—the analysis of innovative products—a research strategy he has developed further than anyone else.

Recognizing the importance of Altshuller's work, others have tried to extend and capitalize on it. One line of development involves software implementations; the 'Invention Machine Lab' of Invention Machine Corp. and 'Innovation Tools' by Ideation International Inc. are representative products. Another approach uses Altshuller's ideas to create new methods for solving innovation problems. Mohrle & Pannenbacker (1997) combined Altshuller's content with Five-Field-Analysis—a problem-solving scheme that looks at the current state, resources, goals, the intended state, and transformations—creating a technique they call 'Problem-Driven Inventing'. Helfman (1992) presented 'Analytic Inventive Thinking' as a practical model for the support of innovation. His model has nine stages

that organize Altshullerian devices—a focus on contradictions, the use of ‘tools’ and ‘elves’, consideration of ideal states—in a functional analysis of problematic systems. As was the case with Altshuller’s own work, while these techniques may be useful, their power is likely to derive from lower-level heuristics, not from the procedural frameworks constructed around those elements.

A more significant offspring of Altshuller’s program is the work of Goldenberg, Mazursky & Solomon (1999a, 1999b, 1999c). Rather than replacing Altshuller’s content, these scholars borrowed his product-analytic methodology, using it to study things other than patent applications. Their analyses of new products identified ‘templates’, common patterns in a product’s development. For instance, Attribute Dependency occurs when two previously independent product variables are related, as when Domino’s Pizza connected price and delivery by offering a discount for late deliveries (Goldenberg & Mazursky, 2000). Subsequent experimental research has shown that the use of a template-driven approach improves idea-generation performance over traditional creativity techniques (Goldenberg et al., 1999c). Employing the same methodology, these researchers studied product advertisements, identifying six ‘creativity templates’—for instance, pictorial analogy and extreme situations—commonly employed in high-quality ads (Goldenberg et al., 1999b). Again, empirical research indicates that utilization of the templates enhances idea-generation performance. Goldenberg and his associates have demonstrated that Altshuller’s product analytic methodology can be applied to different kinds of innovation tasks.

A final program of research, undertaken by Robert Weber (1992), resembles Altshuller’s work, though it was conducted independently. Weber analyzed inventions, mostly everyday artifacts like hand tools, to discover principles underlying their success. He concluded that heuristics are “the engine that drives inventive variation” (1992, p. 83), identifying a substantial set of these. For instance, many inventions incorporate an inverse function, a means of undoing their primary action: pencils come with erasers; hammers include nail-pulling claws. The Swiss Army Knife exemplifies the complement heuristic—combining tools used in the same context—and the shared-property heuristic—join common parts of tools to eliminate redundancies. Weber’s work is more modest in its claims than Altshuller’s—he does not propose laws, theories, or formal methods for generating innovative ideas—but his findings are a comparably significant contribution to the logic of innovation.

Summing up, product-analytic research has generated a wealth of heuristics and other insights that support idea generation. These can be incorporated into formal techniques, although this structuring adds little

value, over and beyond that carried by the heuristics themselves. The product-analytic approach is effective because it taps into regularities that underlie and are embodied in observed artifacts. These regularities may not be laws, as claimed by Altshuller, but they express principles that can inform idea-generation practice. And, as the work of Goldenberg and his associates demonstrates, the product-analytic approach can be applied in almost any field where innovative product ideas must be generated.

Process Analysis

Innovation efforts have always been directed primarily at the development of products, especially new inventions and consumer products. During the 1980s, however, organizational processes became a prominent target of innovation activity (Davenport, 1993). This prominence has not diminished; many companies maintain teams and departments with ongoing responsibility for improving organizational processes. Our interest is in whether these process-innovation efforts exhibit a logic, intelligible reliable practices that can be used to generate new process ideas.

Before the 1980s, organizational processes were an almost invisible aspect of corporate life, like a building’s electrical system, part of the infrastructure that attracts attention only when something goes wrong. Industrial engineers rationalized production activities—say, the movements of product assemblers—but no one paid attention to business processes—the handling of vendor shipments and customer orders, the processing of insurance claims. The quality movement changed this. Quality was the dominant business buzzword of the 1980s, and the pursuit of product quality led to a recognition that related processes—of product design, production, and customer service, among others—had to be improved. When Total Quality Management (TQM) made quality improvement an organization-wide imperative, managers realized that all organizational products and processes, internal and external, needed attention (Juran, 1992). This put process innovation on the agenda of every manager.

Though valuable, TQM’s approach to process improvement was conservative. Existing organizational processes were analyzed with an eye towards reducing errors and creating economies, usually by eliminating unnecessary activities. Rather than being totally replaced, processes were revamped, sometimes to great effect. This approach was challenged, during the early 1990s, by reengineering, a more aggressive program of process innovation (Davenport, 1993; Hammer & Champy, 1993). TQM’s successor in management buzzword history, reengineering called for the wholesale abandonment of existing organizational processes and their replacement by radically new ones, designed from the ground up (Hammer, 1990). Reengineering’s start-from-scratch, clean-slate approach to process

innovation was motivated by and relied heavily on developments in information technology (IT). Advances in computing and communications had created resources that existing organizational processes were not using and that new processes could be designed to exploit. In a sense, IT was reengineering's equivalent of Altshuller's (1984) table of physical effects and phenomena: an important resource that innovators had not been adequately aware of. Michael Hammer's 1990 article in the *Harvard Business Review*, which initiated the reengineering revolution, showed what could be done. Hammer described how the Ford Motor Company used IT in a redesigned accounts-payable process to reduce the headcount of its 500 person operation by 75%.

If IT is a process-innovation resource, there remains the question of how innovative ideas for improvement are generated. Much of the reengineering literature begs this question, offering homilies about critical and creative thinking. Thus, Davenport admits that "there is less to say about the design phase of process innovation", describing design activity as "largely a matter of having a group of intelligent, creative people review the information collected . . . and synthesize it into a new process" (1993, p. 153). Hammer's work is more useful. His 1990 article identified principles of reengineering—for instance, link parallel activities instead of integrating their results. Hammer & Champy (1993) identified themes commonly encountered in reengineered processes (e.g. workers make decisions), traditional rules that can be broken by modern IT (e.g. field personnel can send and receive information wherever they are), and symptoms of reengineering opportunities (e.g. complexity, exceptions, and special cases reflect accretion onto a simple base process). These insights can be incorporated into a process-innovation logic. Beyond the use of these heuristics, however, it is likely that reengineering experts get their ideas the old-fashioned way: by adapting known solutions to process design problems to meet current situational demands. Like every other form of innovation, reengineering draws heavily on the past.

Benchmarking, another process-improvement methodology, is clear about the origins of its ideas: they come from other organizations, especially world-class performers in an area one is trying to improve. Thus, in the study that made benchmarking famous, when Xerox was trying to improve the order-handling performance of its distribution units, it examined the order-fulfillment process at L. L. Bean, identifying cost-saving methods that could be implemented in Xerox facilities (Camp, 1989). As this case demonstrates, benchmarking reaches beyond industry boundaries, searching for 'best practices' wherever they can be found. Nonetheless, its copy-cat strategy has been derided by reengineering proponents who claim that "benchmarking is just a tool for catching up, not for jumping way ahead" (Hammer & Champy,

1993, p. 132). This criticism is unjustified since there is no innovation method or approach, reengineering included, that consistently advances the state-of-the-art. As with creative performances (Boden, 1991), most innovations are locally, rather than globally, new. This is especially true for organizational processes, things that are not patented or publicized. Whether one is borrowing from other organizations or from the past, it is still innovation if progressive changes are made.

Indeed, benchmarking's borrowing strategy is at the heart of a broader 'best practices' approach that constitutes an important new perspective on management. Rather than looking to academic theories or the proclamations of gurus for advice, managers are advised to study practices used in world-class organizations. Osborne & Gaebler's (1992) book, *Reinventing Government*, demonstrated what public organizations could learn from their peers. Since then, a wealth of literature (e.g. Hiebeler, Kelly & Kettelman, 1998) has identified business processes, structures, strategies, and other characteristics of high-performing entities that can be adapted to serve the needs of other organizations. This is a major source of ideas for innovation, a source based on a simple but powerful precept: borrow intelligently from others.

During the mid-1990s, I engaged in a project aimed at quality and process improvement. The project employed a case-analytic strategy similar to that used by Altshuller, though at the time I was unaware of Altshuller's work. The quality boom had created a large literature of case histories of problem-solving efforts, written by people in organizations who wanted to share their success stories. I collected over 700 cases of this kind from books and journals, analyzing each in search of lessons having a useful degree of generality. My methodological approach is described in Smith (1994); the project's results are reported in *Quality Problem Solving* (Smith, 1998b).

Case analyses yielded many insights. Some were included in chapters that discussed key problem-solving tasks, like problem definition and diagnosis (Smith, 1998b). Most appeared in chapters devoted to particular types of quality problems—efficiency and process design, among others (Smith, 1998b). Thus, I identified 15 kinds of unnecessary activities that could be eliminated to improve process efficiency. For instance: discontinue activities that create unused outputs; eliminate unnecessary controls by empowering employees and using periodic audits; discontinue tests and inspections that rarely find exceptions; develop templates for activities with reusable outputs; discontinue activities initiated in response to one-time needs; unless the consequences of an occurrence are severe, discontinue activities that protect against rare events; and add storage capacity to reduce the frequency of materials handling (Smith, 1998b, p. 222). Other case-derived prescriptions addressed such process design issues as process flow and layout, input

screening and control, exception handling, setup, coordination and consolidation of activities, and process triggers.

This project applied Altshuller's case-analytic strategy to organizational problem-solving episodes. It yielded lessons applicable to problem situations, mostly process-related, that often appear in organizations. The lessons serve as heuristic advice for making improvements or innovations in organizational processes. Process innovations are rarely new in a universalistic sense. But they are new for that organization or that process, and their performance effects can be substantial. Since they offer useful guidance to would-be innovators, these case-based heuristics, business best practices, and reengineering principles comprise a process-innovation logic.

Idea-Generation Methods

Creativity or idea-generation methods might be regarded as existence proofs of the logic of innovation. They are, after all, mental tools that people use to generate innovative ideas. Barring widespread irrationality, their popularity indicates that there are consciously deployable means of improving idea-generation performance. The huge variety of creativity methods invites consideration as to the nature of their functioning. How do idea-generation methods work, and do the devices they employ comprise part of the logic of innovation?

This line of reasoning would fail if creativity methods do not really drive the generation of ideas, but only evoke or channel mental activities, largely uncontrolled, that do the actual work. On this view, a method only initiates a creative process that proceeds without conscious control, so the method's value-added is marginal. Indeed, there are idea-generation methods for which this may be the case. Free association techniques or methods like Idea Tracking (Van Gundy, 1981), which sets the problem aside so unconscious mental processes can take over, are examples. Thus, some idea-generation methods depend on means that are not part of innovation logic, on account of being non-operational, insusceptible to conscious control.

At the other extreme lies a contrasting possibility. Perhaps the generation of innovative ideas can be proceduralized, reduced to an algorithm, a strong method that reliably produces creative outputs. If this were true, the logic of innovation would become a logic in the narrower, traditional sense of deduction. All the informal strategies and heuristics that we have uncovered would be trumped, marked as inferior, second-rate tools that must necessarily give way to more powerful procedures. Over the years, more or less extreme versions of this claim have been proposed (Crovitz, 1970; Zwicky, 1969). A number of people have suggested that creativity can be captured in an algorithm. The argument runs as follows: all possible solutions to an innovation problem possess certain

attributes, each of which can take on various values. An algorithmic creativity method will generate all relevant attributes, all possible values for each, and all possible attribute-value combinations. From this exhaustive set of alternatives, the most promising solutions can be identified. Zwicky's (1969) 'morphological box' pursued this approach. The basic combinatorial strategy can be seen in Crovitz's (1970) method of 'relational algorithms', which uses a set of relational words to generate combinations. Tauber's (1972) 'heuristic ideation' technique is a relatively pure implementation of the strategy, intended for use in the generation of new product ideas.

The fact that these methods have not driven their less proceduralized cousins into extinction indicates that something is awry. It is possible that such techniques are done in by combinatorics, that they generate more possibilities than an army of evaluators could sift through. More likely, the approach is mistaken in its assumption that one can identify all the attributes, and values of attributes, around which creative alternatives can be defined. Arguably, the most innovative solutions to problems are marked by attributes and values that had not previously been recognized as problem-relevant. So, for the time being at least, our emerging informal logic of innovation does not seem to be threatened by a more powerful, formalized competitor.

Several years ago I conducted research on idea-generation methods, the results of which were published in the *Journal of Creative Behavior* (Smith, 1998a). The project was motivated by a belief that the many creativity methods in use drew on a limited set of 'active ingredients', devices that plausibly promote idea generation. The research tried to specify those active ingredients. To this end, I identified 172 idea-generation methods and used an iterative analytical procedure to determine how they worked, how the method might promote idea generation. This analysis resulted in the identification of 50 idea-generation devices. This set is reasonably complete: 46 of these 50 devices were initially identified in the first 90 (out of 172) idea-generation methods that were analyzed, and no new devices were discovered in the last 32 methods that I analyzed.

Three kinds of idea-generation devices were differentiated. Strategies are active means for generating ideas. The most numerous and significant type, most strategies refer to identifiable mental activities. The following are typical: Fantasy, conceiving of states in which reality constraints have been dropped; Relationship Search, looking for relationships among two or more things; Boundary Stretching, exploring extreme values of variables in the situation; and Combination, combining elements, attributes, and other aspects of the problem. Tactics, the least common type of device, are stimulatory tools that support strategies. Among the tactics are: Elaboration, enriching the problem situation to provide idea-generation material; Changing

Environment, mentally or physically leaving one's normal thinking environment; and Concrete Stimuli, using physical things or pictures as stimuli during idea-generation sessions. Finally, enablers are passive means of promoting idea generation. Enablers create conditions under which ideas are more likely to occur. Goal Setting, establishing quotas or time deadlines for idea generation, is an enabler, as is Non-Disclosure, not stating the problem at the outset of sessions, and Anonymity, insuring that ideas cannot be traced to their originators. The research identified 31 idea-generation strategies, seven tactics, and 12 enablers.

Many devices are familiar from work discussed in this chapter. Thus, the strategies of Analogy, Decomposition, Abstraction, and Mental Simulation are widely employed by innovators. So too with Enhancement, the strategy of modifying ideas to make them more feasible and effective. Perkins and Weber noted that sometimes invention involves "searching for a purpose to fit a thing" (1992, p. 320), an approach reflected in the Circumstance strategy: think of circumstances in which an idea might be effective. The Checklists strategy, using an established set of ideation prompts to generate alternatives, suggests the templates identified by Goldenberg et al. (1999a, 1999b, 1999c) and other outputs of the product-analytic approach.

However, many idea-generation devices do not have clear precedents. This is true of interpersonal strategies like Group Interaction—verbalizing thoughts in a group so one person's ideas prompt others—and the Nominal Group strategy—generate and share ideas silently within a group. Rearrangement, changing the structure of a situation by rearranging its parts, might be used informally by inventors and designers. More outlandish idea-generation strategies—for instance, Identification, imaginatively becoming a non-human part of the problem, and Negation, adopting counter-assumptions for problem-relevant beliefs—are less likely to be useful in innovation tasks where most reality constraints must be honored.

Some devices apply beyond idea generation, to other mental tasks. Challenge Assumptions, questioning beliefs associated with the problem, pertains to most high-level cognitive activities (Root-Bernstein, 2003), as does Change of Perspective, thinking about the problem from the viewpoints of different agents. Dialectic, conducting a debate between opposing sides on an issue, applies more to evaluation than idea generation, and Structure, organizing information to reveal relationships, is used by many diagram-based problem-definition methods. Two enablers—Block Removal, removing mental barriers that inhibit idea generation, and Incubation, setting the problem aside to escape mental ruts—are widely applicable means of clearing one's mind.

Their prominence in creativity techniques notwithstanding, some devices seem weak, unlikely to be effective. Thus, Association, a strategy of mentally

following associative links among ideas in memory, lacks the direction found in more powerful tools. Change of Attitude, adopting different attitudes toward the situation, is not promising. Remote Stimuli, providing stimuli unrelated to the task, is a widely used tactic that has no compelling rationale (Perkins, 1983), the same being true of Force Fit, an enabler in which ideas are forced together to create breakthroughs. De Bono (1992) endorsed Provocation, drawing attention to the problem or task, but this enabler is unlikely to provide much mental leverage.

Many of these tools are valuable additions to the logic of innovation. This is true of strategies like Bootstrapping, analyzing known alternatives to generate new families of possibilities, and Integration, combining alternatives to make better solutions, and of many devices already discussed. Even enablers can be productive: both Competition, arranging idea generation contests between groups or individuals, and Deferred Evaluation, withholding evaluation of ideas so as not to inhibit generation, can have positive effects on idea-generation performance.

Not surprisingly, then, creativity techniques embody effective idea-generation devices, and their prescribed mental behaviors are ones that successful innovators often employ on their own. Some devices fall short on the operationality requirement for innovation logic: their performance is not sufficiently subject to conscious control. None exhibits the degree of procedural structure and power associated with algorithms. But this study of the 'active ingredients' employed in idea-generation methods did yield noteworthy additions to the logic of innovation.

In Conclusion

This chapter has demonstrated that the process of generating innovative ideas can be directed intelligently. Though unbridled imagination has a role, the idea-generation process can benefit significantly from deliberative, reflective thought that uses knowledge to achieve its goals. As support for this conclusion, the chapter identified elements of the logic of innovation, pieces of declarative and procedural knowledge that promote idea generation. This logic is heuristic, not formal. No strong idea-generation procedures have been uncovered. Rather, innovation logic encompasses a variety of informal methods, strategies, and pieces of advice.

Though innovation logic can be viewed as consisting of concepts, principles, methods, heuristics, and other such components, another kind of characterization may be illuminating. Some of the logic consists of recommendations that innovators use certain innate mental capacities. Thus, they are told to fantasize and free associate; to construct mental models and images; to conduct thought experiments and conceive bold conjectures and hypotheses. Little guidance is provided concerning how to do these things; it is assumed that

the capacities exist and can readily be employed. Advice of this kind is warranted by evidence that successful innovators think in these ways. Another kind of element warns innovators against mental errors or shortcomings. In addition to the design traps discussed by Lawson (1980), there are more general errors, for instance, judgmental biases (Kahneman et al., 1982). Other shortcomings are addressed by the block removal devices used in creativity techniques (Adams, 1979), and the incubation enabler that helps people get out of mental ruts (Smith, 1998a). This advice responds to predictable inadequacies in innovative thought, warning against avoidable mistakes as a form of prevention, and offering assistance for overcoming common weaknesses.

Both kinds of elements are purely psychological. They suggest that idea generation will be improved if innovators think in some ways and not others, these ways being definable in process terms, without reference to the content one thinks about. This psychological approach to improving innovation is exemplified by research on creative cognition (Ward, Smith & Finke, 1999), work that tries to lay bare the mental activities leading to creative outcomes.

There are psychological elements in the logic of innovation that have a different character. Innovators are encouraged to challenge assumptions and to look at things from different perspectives. Advice of this kind prompts one to question dominant ways of thinking in a field, to think about its content. The recommendation to think more abstractly about the innovation task aims at inducing a deeper understanding of the problem, one that grasps its fundamental nature. This advice also fosters engagement with content. The use of analogies, a common motif in the chapter, reflects an assumption that similarity is a useful basis for inference. It is, in this respect, content-driven: the thinking practice only makes sense if reality has the character assumed. These examples suggest that the logic of innovation is as much about the world and innovation tasks as it is about cognitive processes.

The content or declarative knowledge side of innovation logic is clearly represented in Altshuller's (1984) table of physical effects and the knowledge of information technology possessed by reengineering experts. This knowledge of how the world works and of the means available to achieve certain ends is an essential ingredient in the idea-generation process. Innovation can be promoted by making such knowledge more readily available.

Even more important for innovation purposes is knowledge derived from past experience. Such knowledge appears repeatedly in the chapter, in various forms: as mechanical representations cited by Carlson & Gorman (1990) and prototypes used by designers; as templates that Goldenberg, Mazursky, & Solomon (1999a, 1999b, 1999c) identified through case analysis; as lessons learned from benchmarking studies and

research on quality problem-solving. The relevant principle is expressed in Polya's (1957) advice to look for related problems. Experiential knowledge is important because innovation tasks always have precedents; there are solutions to problems in other times and organizations that are usefully pertinent to the current situation. So knowledge of precedents is a valuable source of ideas, and a key part of innovation logic.

The most substantial part of this logic consists of activities, mostly mental, that are infused with or devised in light of knowledge about innovation tasks and the world. Innovators are advised to think about certain things in certain ways because these ways of thinking are consonant with reality; they reflect and exploit its underlying structure. Decomposition is an effective strategy because many things can be decomposed into nearly independent parts, and our mental limitations make it easier for us to solve many small problems than one large one. Some innovation problems exist in homing spaces (Perkins, 1992), so a hill-climbing strategy may be viable and effective. Problem difficulties often result from tradeoffs—strength vs. weight of materials, or speed vs. accuracy of a performance, for instance—so Altshuller's focus on contradictions and the means of overcoming them offers insights. Tools should be designed with an inverse function because one may need to undo a previous action. Indeed, experiential knowledge is valuable for the same reason: previously solved problems are structurally similar to the one currently being addressed, so what worked then might work now.

Rather than being an abstract formal or purely psychological procedure, the logic of innovation is infused with content. Recommended thinking practices embody knowledge of innovation tasks and the nature of reality. In this respect, innovation logic conforms to the psychological dictum that behavior is an adaptation to reality and, like the meanderings of Simon's (1981) ant, can only be understood in light of the task environment. Borrowing from Gibson (1979), innovation logic exploits environmental 'affordances'; it uses opportunities provided by the idea-generation task. Many opportunities derive from the underlying structure of reality, its regularities, expressed in principles of widespread applicability. Innovation logic is evidence for the structuralist claim that a more fundamental reality underlies the phenomenal world of experience. Effective thinking about innovation tasks taps into this reality, relevant principles being expressed in innovation logic.

This suggests the possibility that higher-order thinking in general is infused with content. Effective thinking practices of whatever kind—inferential, judgmental, and so forth—are effective by virtue of being adapted to the realities they address, as a result of being informed by knowledge of those realities. Accordingly, learning how to think is largely a matter of acquiring

insights into reality and thinking tasks that humankind has accumulated during its history. One's ability to identify causes is improved as a result of learning the distinction between causes and conditions, realizing that causes can be proximate or remote, and knowing the types of causes recognized by Aristotle. The 'hows' of thinking tasks are filled in, not with refined cognitive operations, but with declarative knowledge content and content-informed mental activities.

The content dependence of thought might lead some to conclude that thinking is domain-dependent, that effective thinking behaviors vary substantially across academic disciplines and fields of practice. Baer (1998), for instance, argued that creativity is domain-specific. There are, to be sure, domain-specific elements of thought, as can be seen with the logic of innovation. The templates for product innovations and effective advertisements identified by Goldenberg and his associates are specific to those artifacts and the marketing domain to which they belong. However, content dependence of thought does not imply domain dependence when content itself is general. Thinking that is driven by content will be common across domains to the extent that the driving content is common. Causal thinking has considerable generality for this reason. Decomposition and most other heuristics in the logic of innovation also possess a substantial degree of generality. Thinking that is adapted to underlying structures shares the generality of those structures.

Thus, the logic of innovation applies to innovation tasks in most, if not all, fields of practice. There is a need to develop both the general and domain-specific elements of this logic. General elements can be included in thinking skills instruction made available to all students and adults. Domain-specific elements can be included in courses and training programs intended for particular professions (e.g. chemical engineers), with more focused versions being developed for professionals working in specific organizations or on particular innovation tasks. But the bottom-line message of this chapter should be clear: there is a way between the horns of Edison's inspiration—perspiration dilemma. The way—logic of innovation—uses consciously controlled mental activities informed by content knowledge to generate promising ideas and alternatives.

The Development of Innovative Ideas Through Creativity Training

Maria M. Clapham

Drake University, USA

Abstract: Creativity training became popular in the 1950s with programs such as Osborn's brainstorming approach to problem-solving. Half a century later, in an effort to enhance innovative thinking, creativity training programs of various types have proliferated in educational institutions and business environments. These programs vary in methods and scope. With such popularity and diversity of programs, it is appropriate to examine their effectiveness in enhancing innovation. This chapter will provide an overview of various types of creativity training programs and will examine recent research findings regarding their effectiveness for stimulating the development of innovative ideas.

Keywords: Innovation; Creativity; Innovative ideas; Creativity training; Innovative thinking; Creative problem-solving.

The word 'innovate' comes from the Latin word 'innovare', which means 'to renew, to make new'. Innovation is a form of problem-solving that begins, according to Smith (2003), with the feeling that change is needed and ends with the successful implementation of an idea. A critical component of innovation is idea generation, or ideation. One must first develop a new idea before it can be introduced. Divergent thinking, a cognitive process that focuses on developing multiple possibilities rather than finding a single solution, results in greater ideation. Ideation is important during several phases of innovative problem-solving, including the development of ideas about problems to solve and the development of solutions to those problems (Doolittle, 1995). The term 'creativity' has been associated with innovation in various ways. Sometimes it has been used to refer exclusively to the process of ideation and at other times it has been used synonymously with innovation to refer to both the development and implementation of new ideas (Unsworth, Brown & McGuire, 2000). In either case it is clear that creativity is closely linked to the process of innovation. This chapter will focus on the ideational component of the innovation process.

In the world of business, innovation is a key to success. Rapid changes and advances characterize today's business environment, and in order to remain competitive in the global marketplace, companies must

develop and implement new ideas. Business organizations, more than ever before, recognize that they need employees who think creatively in order to maintain their competitive edge. Many in the past decade have turned to creativity training as a means of enhancing innovative thinking in their employees. The belief underlying this movement is that most employees are capable of making creative contributions in their work (Farr, 1990; Weisberg, 1986). If they are not doing so, it is because they do not have the skills or motivation to think creatively (Steinmetz, 1968). Popular magazines have touted the benefits of creativity training (Campbell, 1993; Higgins, 1994; Wise, 1991; Zelinski, 1989), and many anecdotal reports exist of its effectiveness (Gundry, Kickul & Prather, 1994). Does creativity training really work? Can it improve organizational innovation? If so, what forms of creativity training are most effective? These are important questions to address.

In the past, creativity tended to be viewed as a fixed inborn trait. Currently, while exceptions exist, experts generally conceptualize creativity as a multifaceted construct that is affected by both nature and nurturing processes. A widely held view of creativity is that we are born with a range of creative potential, and environmental factors will influence the extent to which our creativity develops to its maximum capacity (Plucker & Runco, 1999). According to the popular

model proposed by Amabile (1990), creative performance in any domain requires domain-relevant skills, creativity-relevant skills, and task motivation. Ripple (1999) similarly states that creativity consists of a combination of abilities, skills, motivation, and attitudes. Skills, motivation and attitudes are modifiable characteristics. If these indeed form part of the creative process, then some aspects of creativity are malleable. But are these malleable aspects of creativity subject to individual control? A widely held belief is that creativity is too intuitive a process to be regulated by an individual, that one cannot control how and when 'insight' will come (Smith, 2003). Skills, however, are learned proficiencies, so it seems logical to conclude that creativity could be enhanced through deliberate training and education. Furthermore, it is possible that training and education could affect the motivational element of creative performance. Many educators support the view that creativity can be developed through educational techniques (Baer, 1987; Christensen, 1988; Doolittle, 1995; Fasko, 2000; Ghosh, 1993; Sternberg & Williams, 1996; Torrance, 1972) and believe that promoting innovative thinking should begin in childhood (Carter, 1984; McCormack, 1984). According to Smith (1998), we are handicapped in our practical application of these techniques by the fact that limited research effort has been devoted to examining creative processes that are subject to individual control.

Creativity Training Techniques and Programs

What are some of the techniques proposed to increase innovation? A number of recent reviews of methods used to stimulate creativity exist, including those of Parnes, Plucker and Runco, Ripple, and Runco in *The Encyclopedia of Creativity* (1999). This section provides a summary of general approaches to enhancing ideation, as well as a brief description of the most frequently used and researched instructional programs.

The development of innovative ideas occurs, according to Parnes (1999), when new associations are made between already existing pieces of information. He uses an analogy to describe the necessary ingredients for this process to take place: creativity requires fuel to make it run and the removal of brakes to allow it to run. The fuel consists of sensory impressions from any source including books, environment and experience. The brakes consist of any constraints, internal or external, that limit our mental exploration. Using this model, we can loosely categorize techniques used in creativity training programs as being designed to either 'add something' or 'subtract something'. Training may teach individuals tactics for scanning the environment to come up with new associations. Such tactics include checklist, forced relationship, attribute listing, analogies, scanning the environment, and imagery. Training may also focus on tactics or strategies for removing

blocks. These may include deferring judgment, engaging in relaxation, enhancing self-confidence or self-efficacy, increasing appreciation for creativity, allowing oneself time and space to let ideas flow, or providing the necessary resources to facilitate the flow of ideas. Most creativity training programs use a combination of both 'adding' and 'subtracting' techniques.

Many creativity training programs exist. They may focus on one or several stages of the innovation process, and can be taught by themselves or in combination with other cognitive processes. Thus, creativity training programs may simply try to teach individuals ways of coming up with ideas, or they may teach people how to work through the various stages involved in solving problems, from the problem-finding stage to the solution implementation stage. They may also teach people how to manage their cognitive processes to effectively alternate between the generation of ideas and the evaluation of ideas. Furthermore, training programs may vary depending upon the target population. Some programs are designed for children, while others are focused on adults in educational or business settings. Some techniques focus on enhancing individual ideation while others teach people to work as groups, such as the popular techniques of ideawriting, delphi, and nominal groups (Moore, 1987). A brief description of instructional programs follows:

Brainstorming

Introduced by Alex Osborn, this approach to enhancing ideation is based on the premise that quantity of ideas breeds quality that production of many different ideas increases the likelihood of coming up with a high-quality idea. In this approach, idea generation is separated from idea evaluation. Proponents believe that early evaluation of ideas restricts the process of idea generation, so participants are taught to defer judgment until the idea-generation stage has concluded. In addition, participants practice various idea-generating tactics. Research has found that initial ideas are frequently not chosen as the most preferred (Basadur & Thompson, 1986), supporting the contention that effort extended toward developing more ideas is beneficial. Brainstorming is a technique for idea generation that has been incorporated into many more extensive creativity training programs.

Creative Problem-Solving (CPS)

The Osborn-Parnes CPS process structures problems into five stages: fact-finding, problem-finding, idea-finding, solution-finding, and acceptance-finding. Working through these stages requires the appropriate application of idea generation and idea evaluation. Participants learn a variety of techniques for managing these cognitive processes at each stage of creative problem-solving through practice. Principles of

brainstorming are central to idea generation in this approach. According to Parnes (1987, 1999), while the basic elements of CPS remain the same, procedures used in training have evolved over time. Currently, participants are using more imaginative exercises in problem-finding and developing plans for action, the beginning and end stages of the creative problem-solving process. In addition, participants are focusing more on visions than on goals, a process that Parnes calls 'visionizing'.

Synectics

Developed by Gordon & Prince, *synectics* means the joining together of seemingly unrelated elements. The program is similar to CPS in that it addresses all stages of the creative problem-solving process, and emphasizes differentiation between idea generation and idea evaluation. The strategies used in training, however, vary. *Synectics* relies heavily on metaphors to 'make the strange familiar and the familiar strange'. Proponents of the use of metaphors in creativity training argue that, by examining the similarity between apparently dissimilar objects, people will be able to look at objects differently. *Synectics* teaches the use of three metaphoric forms: the personal analogy emphasizes empathic involvement by having subjects try to identify with the object of the analogy; the direct analogy focuses on making connections between the object of the analogy and external facts/knowledge; the symbolic analogy is a two-word description of the object of the analogy in which the words appear to contradict each other (Griffith, 1987). *Synectics* distinguishes between three roles: the facilitator is in charge of managing the process, but does not direct content; the client is the problem owner; the participants are others that contribute their ideas about the problem at hand. Because participants do not own the problem, it is believed that they can provide the unique perspectives necessary for finding an innovative solution. Kostoff (2003) also emphasizes the importance of obtaining fresh perspectives through cross-disciplinary access and experience.

Lateral and Vertical Thinking

Edward de Bono contends that there are two forms of thinking: vertical thinking involves the implementation and utilization of already existent ideas ("digging the same hole deeper") whereas lateral thinking involves developing new ideas ("digging a whole somewhere else") (cited in Parnes, 1999). His program focuses on cognitive strategies to increase the development of new ideas. According to de Bono, two processes necessary to stimulate lateral thinking are 'escape' and 'provocation'. Escape consists of rejecting assumptions and pre-formed concepts by shifting perspectives, and provocation consists primarily of suspending judgment (Murray, 1992). De Bono stresses the importance of

positive emotions for lateral thinking, and thus uses strategies like humor, fantasy and play extensively (Sikka, 1991).

Hemisphericity

Hemispheric approaches to creativity training, influenced by Ned Herrmann, are based on the notion that the two hemispheres of our brain are specialized for handling different types of tasks. According to this view, the left hemisphere is more effective at performing tasks requiring sequential processing of information. The right hemisphere, however, is more effective at performing tasks involving simultaneous processing of information and is therefore better able to make associations between remote elements. Hemispheric training approaches encourage the use of the right hemisphere through the practice of information-processing tasks that are thought to be dominated by the right hemisphere or that require more balanced usage of both hemispheres. They rely heavily on imagery techniques, relaxation, art and music. They also use physical and sensory exercises such as heterolateral walking, a form of walking in which the opposite arm and leg are forward, and upside down drawing (Carter, 1983).

Khatena Training Method

Khatena's method consists of five main strategies for enhancing ideation. Breaking away from the obvious and commonplace involves viewing the environment in a different way. Transposing ideas means transferring an idea into a different mode of expression. Exploring analogies forces participants to examine unexpected similarities between elements. Restructuring involves reorganizing the various components of a structure. Synthesizing ideas consists of incorporating new ideas into the existing structure (Sikka, 1991). In applying these five strategies, Khatena relies heavily on guided imagery and relaxation (Vaught, 1983).

Packaged Educational Programs

A number of programs intended for educational settings have been packaged into a format of several lessons. The Purdue Creative Thinking Program consists of numerous lessons in which divergent thinking is emphasized. Stories about famous creative people are presented to stimulate interest in creativity, techniques to enhance creativity are suggested, and then practice exercises are conducted. The Productive Thinking Program is aimed at developing creative problem-solving skills, and improving attitude and self-confidence toward such problem-solving. Program materials include mysteries or detective problems that require use of both convergent and divergent thinking to be solved (Sikka, 1991). The Torrance Ideabooks are workbooks for practicing perceptual and cognitive skills that are the basis for divergent thinking.

Psychogenics and Psychosynthesis

These methods take a 'let it happen' approach to developing creativity. Wenger's psychogenics is based on Wallas's notion of incubation, and emphasizes the use of meditation and imagery. Assagioli's psychosynthesis is based on the view that the unconscious plays a vital role in creativity, and emphasizes reliance on one's intuition (Du Pont de Bie, 1985). Markley (1988) supports the use of intuition for strategic innovation.

Technology-Based Programs

A number of programs rely heavily on the use of computers. Such programs may consist of interactive computer games (Doolittle, 1995), software that guides individuals through brainstorming or the stages of creative problem-solving (Markas & Elam, 1997; Rickards, 1987; Small, 1992), or programs that generate unusual word associations (Brown, 1997).

Reviews of Effectiveness of Creativity Training

Several important reviews of creativity training research have been conducted. Torrance (1972) reviewed 142 studies involving evidence about the effectiveness of teaching children to think more creatively. He classified the methods used to teach creativity in these studies into nine categories: Osborn-Parnes CPS techniques; packaged programs such as the Productive Thinking Program or the Purdue Creativity Program; other disciplined approaches such as semantics or creativity research; creative arts; media and reading programs; curricular and administrative arrangements; teacher-classroom variables such as fostering a creative classroom environment; direct motivational techniques such as rewards; and testing conditions. This review was conceptualized very broadly as it includes teaching approaches that directly focus on developing skills for self-regulating creativity as well as approaches that involve the manipulation of environmental factors that influence creativity. The most frequent criteria for effectiveness in these studies were scores on divergent thinking tests. In the great majority of the studies included in the review (103 out of 142), the criteria consisted of scores on the *Torrance Tests of Creative Thinking* (TTCT). This is a set of divergent thinking tests that provides scores in fluency (the number of ideas produced), flexibility (the number of different types of ideas produced) and originality (the uniqueness of the ideas) in both verbal and figural form. Other criteria consisted of Guilford-based divergent thinking measures, creative writing, research projects, problem-solving, art projects, question-asking, and more. Torrance found that the most frequently examined approaches to teaching creativity were Osborn-Parnes programs, complex packages, and teacher-classroom variables, while the most successful approaches, as indicated by the extent to which the approach achieved its specified criteria for success, were Osborn-Parnes CPS programs and other dis-

ciplined approaches. Other fairly successful approaches included complex packages, creative arts, and media and reading programs. Torrance concluded that creativity training is effective for enhancing ideation and that the most successful programs emphasize both cognitive and emotional components.

According to Mansfield, Busse & Krepelka (1978), Torrance's conclusions are optimistic. These authors conducted a review of studies involving only multiple-session training programs. The primary programs reviewed were the Productive Thinking Program, the Purdue Creative Thinking Program, the Osborn-Parnes CPS Program, the Myers-Torrance Workbooks, and the Khatena training method. The authors found mixed support for the effectiveness of these programs; studies of sound design that showed the highest rate of success were those using criteria similar to the tasks used during training. Of the programs evaluated, the CPS program showed the highest rate of success for improving idea generation. Overall, the authors concluded that creativity training can improve idea generation, but that results may not transfer easily to 'real-life' innovation. Because of the combination of elements required for creativity at the professional level, the authors suggest that creativity training may not be very useful for improving organizational innovation. Furthermore, they stated that it is unclear why the programs are effective for increasing idea generation. Are gains in scores the result of an improvement in skills, enhanced motivation, a clearer understanding of the desired responses, or experimental demands placed on the subjects? If either the skills do not transfer to other tasks, or the motivation to perform is limited to the treatment situation, then transfer of training will be limited. Feldhusen & Clinkenbeard (1986) concurred with Mansfield et al. (1978) in expressing reservations about creativity training's effectiveness. They argued that, because of conceptual and methodological problems in research studies, conclusions about the effectiveness of such training are premature.

In an effort to better quantify the effectiveness of creativity training, meta-analytic techniques have been applied. Rose & Lin (1984) used several criteria to select studies for their meta-analysis. First, similarly to Mansfield et al. (1978), only studies that examined the effect of several lessons/training treatments were included. Second, to facilitate comparability of studies, only studies that used the TTCT as criteria were included. Third, studies needed to provide sufficient data to be included in the meta-analysis. A total of 46 studies met the criteria. Of these, 22 were doctoral dissertations, 13 were articles in periodicals, and 11 were unpublished studies. Training programs used in these studies were classified into six categories: Osborn-Parnes-type programs, the Productive Thinking Program, Purdue Creative Thinking Program, other programs combining several elements of creativity,

classroom arrangements, and special techniques such as dramatics or meditation. The authors found that creativity training accounted for 36% of the variance in verbal creativity and 14% of the variance in figural creativity. This difference in effectiveness for verbal and figural creativity is not surprising; the majority of training programs rely on verbal activities that may transfer more easily to performance on verbal tests. When comparing scores on originality, fluency and flexibility, the greatest impact of training in both verbal and figural creativity was found on originality scores. Training accounted for 25% of the variance in verbal and figural originality scores. The authors concluded that, while further research is needed to understand its processes, creativity training can have a positive impact on ideation. Cohen (1984) conducted another meta-analysis of creativity training research. In her examination of 106 dissertations and article publications, she found greater effectiveness in studies that used creativity tests as criteria and when tasks employed during training were similar to the tasks used as the performance criteria. Both of these meta-analyses indicate that creativity training can improve scores on creativity tests.

Past qualitative and quantitative reviews of creativity training studies have resulted in similar conclusions. They find that creativity training can be effective for enhancing idea generation as indicated by performance on divergent thinking tests. They also indicate that training is most likely to show positive effects when post-training tasks are similar to training experiences. Most of the research on creativity training incorporated in these reviews was conducted in educational settings with children, teenagers or college students. These issues lead to concerns about transfer of training to other types of tasks and environments and lend support to the view that creativity is domain-specific (Baer, 1994). Arguing that studies of creativity may lack generalizability to real world situations, Roweton (1989) stated that “we drifted away from recognizable forms of creativity” (p. 250) in our efforts to gain experimental control. Can creativity training really improve organizational innovation? If so, which forms of training are most effective? Perhaps recent research can address these questions.

Recent Research on Effectiveness of Creativity Training

What have we learned about creativity training since the reviews conducted in the 1970s and 1980s? To address this question, a search was conducted in primary databases of psychology (PsychInfo), education (ERIC), and business (Business Source Primer) for studies published from 1982 to 2002 that examine creativity training. The 1982 date was selected to ensure coverage of studies that may not have been included in the 1984 meta-analyses due to publication lag time. A decision was made to only report studies

that used experimental or quasi-experimental designs because of questions about causal effects in other studies. Of the studies found published within this period, the great majority met the design criteria. The search resulted in 11 dissertations, and 29 publications in periodicals. This review, while not inclusive of all studies of creativity training, is representative of the body of research in the field. A summary description of the characteristics of these studies, organized by target population, follows:

Creativity Training for Children and Teenagers

The majority of recent studies examining creativity training have focused on training children or teenagers in educational settings. Creativity training for children is based on two assumptions: it is inherently beneficial for children, and it can increase the pool of innovative individuals entering the work force in the future. Of the studies reviewed here, seven involved training children, eleven trained adolescents/teenagers, and two studied both children and adolescents/teenagers. Using an approach that also has the ultimate goal of improving student creativity, three studies examined how training teachers affected teacher attitudes and behaviors in the classroom.

Studies conducted with children generally used the TTCT as criteria. Markewitz (1982) found that 12 divergent thinking sessions had a significant effect on kindergartener's TTCT flexibility scores. Jaben (1983, 1986) found that a 12-week Purdue Creativity Training Program had a significant positive effect on TTCT verbal fluency, flexibility and originality scores of behaviorally disordered and learning disabled children. Meador (1994) found that training in synectics twice a week for 12 weeks had a significantly positive effect on TTCT figural scores and verbal skills of both gifted and regular kindergarten students. In Glover (1982), 5th grade teachers underwent two days of training in applied behavior analysis emphasizing the reinforcement of fluency, flexibility, and originality. Their students obtained higher scores than a comparison group on both figural and verbal TTCT 12 weeks after the training. Furze, Tyler & McReynolds (1984) showed significant effects of a 14-week training program involving artist-educators in the classroom on a different criterion, a test that the authors argue measures originality called the *Obscure Figures Test*. Taken together, these studies indicate that extended programs emphasizing ideation can have a significant positive impact on children's divergent thinking.

One study involving children used expert evaluations of creative performance as criteria rather than divergent-thinking scores. Baer (1994) found that 2nd graders who experienced 16 one-hour sessions of divergent-thinking training that emphasized brainstorming showed significant improvements in the creativity of various verbal tasks such as writing stories, telling stories and writing poems, but not in

collage-making. These results, according to Baer, support the contention that creativity training effects do not generalize well to tasks that differ from those practiced in training.

Studies conducted with adolescents and teenagers from both gifted and non-gifted programs show mixed results. The studies involving brainstorming or the CPS model generally showed positive results. Baer (1988) used the Osborn–Parnes CPS approach in combination with other techniques such as Synectics in a three-day training program, and found significant positive effects 6 months later on creative problem-solving scores. Westberg (1996) found that teaching the process of invention had positive effects on verbal divergent-thinking scores and number of invention ideas produced. While the study did not show positive effects on the quality of ideas produced, the author expressed concerns about the psychometric characteristics of the measure used to assess quality revealed in her study. Kovac (1998), using brainstorming and directed imagination training over 10 months, found significantly higher flexibility scores in the training group than the control group. Russell & Meikamp (1994) showed that training in brainstorming had a significantly positive effect on the metacognitive strategy of concept mapping in gifted, regular education, and learning-disabled students.

Other creativity training techniques have been less successful in enhancing teenagers' verbal or figural divergent thinking. In studies of imagery training across 10 sessions (Vaught, 1983), imagery training and the Khatena technique in four 45-minute sessions (Sikka, 1991), the Scamper ideation technique (Mijares-Colmenares, Masten & Underwood, 1988; Mijares-Colmenares et al., 1993), and a hemispheric approach with short duration (Carter, 1983; Masten, 1988; Masten, Khatena & Draper, 1988), the training groups did not show significantly higher scores in divergent thinking than the comparison groups.

Two studies have examined the effects of training gifted students in several grade levels over an extended period. LeRose (1987) conducted a 12-year longitudinal study on students starting in kindergarten. Students in the experimental groups learned various divergent thinking strategies, and showed higher TTCT flexibility scores in 1st and 9th grade than a comparison group of gifted students. Heiberger (1983) examined the effects of workbook activity sheets several hours a week during most of an academic year in 2nd–7th grade, and found that such activity increased scores on the figural TTCT.

Studies examining the effects of providing teachers with creativity training have also found positive training effects. McConnell & LeCapitaine (1988) found that student ratings of teacher acceptance and openness to new ideas improved in teachers who participated in 40 hours of Synectics training. Participation in a combination Osborn–Parnes CPS/hemi-

sphericity program (Murray, 1992), and an Osborn–Parnes CPS program (Mammuraci, 1989) resulted in more positive teacher attitudes toward creativity and higher external ratings of the creativity of teachers' lessons.

The recent studies with children and teenagers confirm the findings of previous reviews: creativity training can improve divergent-thinking performance and, of the training approaches tested to date, the most effective tend to focus on ideational strategies such as brainstorming or Osborn–Parnes-type techniques. These studies also suggest that such training can be effective for various types of students, including gifted, regular and disabled students. They do little, however, to verify that training effects generalize to applied problems, or to explain the mechanisms through which creativity training works.

Creativity Training Applied to College Students

The ten studies of college students reviewed in this chapter generally used scores on divergent-thinking tests as criteria. Clapham & Schuster (1992) tested the effects of a two-hour training session designed to improve divergent thinking with undergraduate engineering students. Students who participated in this training showed increased scores one week later on the *Structure of the Intellect Learning Abilities* test and the *Owens Creativity Test* compared to students who participated in interview training. The significant effects of general ideational training on the *Owens*, a mechanical ideation test, shows that training effects can generalize to content applications not covered in the training. Harkins & Macrosson (1990) examined the effects of a 10-week program that primarily emphasizes right-hemisphere utilization through drawing exercises on the verbal and figural TTCT of undergraduate business students. The comparison group received only study time. Results showed higher scores of the training group on figural fluency and flexibility, but not on any verbal scores, supporting the contention that creativity is domain-specific. Griffith (1987) examined how 15 sessions of Synectics and lateral thinking training affected the performance of undergraduate management students on the figural and verbal TTCT, and the *Remote Associates Test* (RAT). He found that the training group performed significantly higher than a control group on overall scores of the verbal and figural TTCT as well as subscores of verbal originality and figural fluency and originality. No significant effects were found for the RAT. While these studies show positive effects of creativity training on divergent thinking scores, the results are mixed regarding the generalizability of scores to content different from that encountered in training.

In another study, Kabanoff & Bottger (1991) examined the effects of a program modeled after the Osborn–Parnes CPS program, taught over 10 weeks with two 80-minute sessions per week, on the verbal

TTCT scores of MBA students. The comparison group consisted of MBA students who received no training but were given incentives to show improvement in creativity. Both the training and the comparison groups were told that the number and originality of ideas affected scores. Both groups improved in fluency, while only the training group improved in originality, suggesting that motivational, practice or demand characteristics may have affected fluency and flexibility whereas the training itself affected originality. Rose and Lin in their meta-analysis also found that creativity training had the greatest impact on originality. In their examination of personality factors affecting self-selection into the course, the authors found that individuals with a high preference for achievement and dominance and low deference were less likely to take the creativity course. These results contribute to our understanding of the self-selection process into these courses.

Several comparative studies examined what components or types of creativity training are most effective. Clapham (1997) compared the effects of a 30-minute training seminar, incorporating both motivational and skills components, to a training session of 10 minutes involving exclusively ideational tactics. She found that both types of training were effective in increasing scores on the figural TTCT compared to a control group who received word-processing training. Blissett & McGrath (1996) compared the effects of two 5-hour training programs, the Khatena Training Method and interpersonal problem-solving training, on verbal TTCT scores and interpersonal problem-solving ability of undergraduate students. Results showed that the creativity training had a significant effect on ideation but not on interpersonal problem-solving, suggesting that these are independent processes. Furthermore, neither training had a significant effect on self-perceptions of innovative style, as measured by the *Kirton Adaption-Innovation Inventory*. This is in accordance with two other studies: Murdock, Isaksen & Lauer (1993) found that undergraduates in a college creativity course based on the Osborn-Parnes CPS program showed no overall change in scores on the *Kirton Adaption-Innovation Inventory* compared to a control group of marketing students. In another study, Daniels, Heath & Enns (1985) found that two creativity training sessions designed to enhance ideation did not improve the self-perceptions of creativity in undergraduate women as measured by the *Something About Myself (SAM) Creative Perception Inventory*. Thus, while the training appears to improve divergent thinking, it does not positively affect self-ratings of creative style.

Two studies reported real-world creative performance indicators. Parrott (1986) compared the effects of imagery utilization training to divergent thinking training using Parne's Creative Behavior Workbook in first-year mechanical engineering students. Both types

of training took place across eight weeks, one hour per week. Results showed that both types of training resulted in a higher self-reported vividness of visual imagery. Furthermore, while not tested directly, some evidence of transfer was found in that self-ratings of use of imagery in a design project were positively associated with performance in engineering examinations. Kellstrom (1985) examined how a 50-minute training program involving a combination of imagery and relaxation affected the creativity of projects developed by undergraduate instructional design students. The projects were instructional design materials rated on creativity and effectiveness by trained experts who were blind to the treatment conditions of participants. Results showed that the imagery training groups had higher ratings on both creativity and effectiveness of their materials than an alternate training group. Both of these studies suggest that creativity training may transfer to real-life projects.

The studies of college students do more than confirm the ideational effects found with children and teenagers. Some of the studies, in comparing effectiveness of different types of programs or program components, address the question of what makes this training work. Other studies, in examining the effects of training on project performance, address the issue of transfer of training. While these studies are not yet conclusive, they are leading us toward a better understanding of creativity training, and suggest that training may enhance project innovation.

Creativity Training in Business Settings

The research on creativity training in business setting is quite limited. A total of seven studies were found. Min Basadur and his colleagues have been at the forefront of this work. Arguing that most of the research on creativity training has focused on the ideational stage, they have conducted a number of studies examining the stages of creative problem-solving. In Basadur, Graen & Green (1982), engineers, engineering managers and technicians underwent a total of three days of training and assessment divided. The experimental group underwent an Osborn-Parnes-type training program in creative problems solving by working through the ideation and evaluation components in each of the stages of problem-finding, problem-solving and solution implementation in an experiential way. A placebo group received alternate training, and a matched control group received no training. Results showed that the creativity training resulted in higher preference of ideation in problem-solving, practice of ideation in problem-finding, and problem-finding performance immediately after the training. Furthermore, the results showed some transfer of training in that the experimental group showed higher scores in practice of ideation in problem-solving two weeks after the training as reported by self and by coworkers. Basadur, Graen & Scandura (1986) reported that a three-day

CPS training program had a positive impact on the attitudes toward ideation in problem-solving of manufacturing engineers as measured by self-report and reports of superiors both immediately after the training and five weeks later.

Other studies have focused on specific components of the CPS model. Fontenot (1993) examined the creative problem-finding components of the model in an eight-hour training program with business people. Results showed that the training was effective in enhancing group performance on fluency in data-finding and problem-finding, flexibility in problem-finding, but not the complexity of final problem statements presented when examining business cases immediately after training. Basadur & Finkbeiner (1985) distinguished between two components of ideation: active divergence consists of aggressively generating many ideas and premature convergence consists of judging ideas in their early stages. They found that a combination of training in high active divergence and low premature convergence resulted in greater fluency and higher-quality ideas. Basadur, Wakabayashi & Takai (1992) found that training in creative problem-solving had a positive impact on the attitudes toward active divergence and premature convergence in Japanese managers.

Yet other studies have examined how individual preferences and style mediate the effectiveness of creativity training. Basadur, Wakabayashi & Graen (1990) found that the CPS program significantly reduced attitudes toward premature convergence in managers and nonmanagers, and increased attitudes toward active divergence in managers. The effects varied, however, depending upon the style of the trainee. Four styles were identified: optimizers prefer thinking and evaluation, generators prefer experience and ideation, conceptualizers prefer thinking and ideation, and implementors prefer experience and evaluation. In the overall sample, the training had the greatest impact on attitudes toward active divergence in optimizers. In contrast, the training had a positive impact on attitudes toward premature convergence in all four styles. In another study, Bush (1998) examined the relative effectiveness of two types of training for enhancing the creativity of engineers' concept designs. Engineers in this study were involved in a one-day program in which they were pretested for creativity, personality and style preferences, and then trained for two and one half hours in either creative attitude blocks or de Bono's Provocation and Movement process. Participants were then given a company problem to solve independently for three hours. Their proposed solutions were then rated for creative value by three judges. Results showed that engineers who tended to have a preference for small incremental changes and detailed work produced more creative concepts with the Provocation and Movement training, whereas those who preferred larger-scale changes and high-level

organizing work performed better with the attitude-oriented training. These studies provide initial evidence that individual differences interact with training effectiveness.

The studies of creativity training in business environments, while limited in number, have greatly expanded our understanding of creativity training effectiveness. Their results indicate that creativity training, and in particular the Osborn-Parnes CPS model for training, can have a positive impact on the creative problem-solving capacity of professionals by improving performance at several stages of creative problem-solving. Furthermore, this research suggests that training effects interact with personal variables.

Conclusions

Creativity training can improve ideational innovation. We see this in studies that examine creativity training in children, college students and professionals. Furthermore, creativity training has positive effects on both divergent thinking test scores and project performance. However, many questions remain about creativity training.

We do not yet know how creativity training works. Are effects due to an increase in skills, a change in attitude, or something else? Is the process different for children than for adults? Perhaps, as Runco (1999) suggests, understanding the mechanisms by which it works is not as important as knowing that it does work. I would argue that a greater understanding of the mechanisms through which it works has practical as well as theoretical benefits. It can aid us in the development of more effective and efficient training programs, and contribute to our understanding of the construct of creativity.

We do not have a thorough understanding of conditions that facilitate the transfer of training to real-world creativity. As indicated at the beginning of this chapter, because of the importance ascribed to organizational innovation, creativity training has become very popular in business settings, yet surprisingly little research has been published on the effectiveness of creativity training in business organizations. While exceptions exist, the majority of studies continue to use divergent thinking test scores as criteria. Furthermore, most studies in business settings apply the CPS training model. Is this the most effective approach for businesses? Little research exists comparing its effects to other approaches for enhancing organizational innovation. We also do not fully understand how domain specificity affects transfer of training. The extent to which domain specificity limits generalizability of training effects will have implications for how creativity training is conducted.

The organizational climate will also impact transfer of training. Because organizational innovation depends upon several factors beyond ideational skills, it is likely that transfer of training is limited in practice. Many

researchers argue that creativity is a process that occurs in a social context (Amabile, 1990, 1996) and if this is the case, then the organizational context must be taken into consideration to maximize transfer of training to professional behavior. It is unfortunate if we do not maximize the use of creative skills in organizations by providing a climate that promotes ideation. A combination of creativity training and creative climate would be optimal for organizational innovation.

Other questions about creativity training need further examination. What is the association between learning styles and effectiveness of training? What are the long-term effects of creativity training? What training approaches are most appropriate for different types of jobs? Basadur (1995) has initiated work in this area. What other benefits might be obtained from creativity training? Researchers suggest that benefits may include improved mental health and increased learning (Conti, Amabile, & Pollack, 1995; Cropley, 1990; Hickson & Housley, 1997). While questions about creativity training remain, it is clear that research is providing more information about the benefits of such training for innovation.

Intuitive Tools for Innovative Thinking

Robert Root-Bernstein¹ and Michele Root-Bernstein²

¹ *Department of Physiology, Michigan State University, USA*

² *Independent Scholar, East Lansing, MI, USA*

Abstract: In this chapter we examine the fundamental role of intuitive thinking skills in creative endeavor across the arts and sciences. The imagination manifests itself in a set of 13 non-verbal, non-mathematical, non-logical thinking tools that innovative individuals in all disciplines say they use: observing, imaging, abstracting, recognizing and forming patterns, analogizing, body thinking, empathizing, dimensional thinking, modeling, playing, transforming and synthesizing. Private, unarticulated insights generated by means of these tools are then translated in an explicitly secondary step into verbal, mathematical and other modes of public communication. Any educational effort to promote creative thinking must therefore recognize and exercise intuitional thinking skills and directly address the process of translating idiosyncratic subjective thought into objectified public forms of discourse.

Keywords: Innovation; Intuition; Imagination; Insight; Synesthesia; Observation; Visualization; Pattern; Thinking tool.

Creative Process and ‘Tools for Thinking’

Creative thinking is inseparable from intuition and aesthetic experience. While asserting such a basis for artistic activity may not seem odd, it may be surprising to find that even in the sciences and technology, ideas emerge as insights that cannot at first be communicated to other people because they exist as emotional and imaginative formulations that have no formal language. Indeed, practitioners of disciplines across the arts and sciences, including physics and mathematics, have commented that all creative thinking begins in private, sensual feelings that reveal unexpected problems (see Root-Bernstein, ‘Problem Generation and Innovation’, this volume) and unforeseen opportunities. Once a person feels the existence of a problem or a possibility, he or she must then work with attendant emotions and sensations to translate them, in an explicitly secondary step, into forms that can be communicated. Thus it is necessary, in any description of the creative process, to distinguish between intuitive ‘tools for thinking’ (Root-Bernstein & Root-Bernstein, 1999) that yield those personal insights and the translation skills necessary to turn insights into verbal, logical-mathematical, visual, kinesthetic and other public modes of communication (what Howard Gardner has called ‘intelligences’). It is also necessary to reassert

the fundamental role of the private and sensual in creative thinking, so often overlooked. Indeed, understanding the non-verbal, non-logical basis for imaginative thought is essential for stimulating creativity and innovation. Exercising the ‘tools for thinking’ that comprise this pre-linguistic form of intuitional cognition is as necessary to education as formal training in the languages and logic of public communication.

Thinking With Feeling

It is very difficult to find any major figure in any art or science who has said that creative work is done using words, mathematics, logic, or any of the other higher order forms of thinking that are supposed to characterize intelligence. Even the most verbal poets and mathematical scientists maintain that their creative work emerges from feelings, emotions, and sensual images. Consider the case of T. S. Eliot, who has been characterized by Howard Gardner in his book *Creating Minds* (1993) as a prototypical ‘verbal thinker’. Eliot himself wrote that ‘the germ of a poem’ emerges from a musical “feeling for syllable and rhythm . . . (that) bring to birth the idea and the image” (Eliot, 1975, pp. 113–114). The object of poetry is to “find words for the inarticulate . . . to capture those feelings which

people hardly even feel, because they have no words for them” (Lu, 1966, p. 134). All this occurs, Eliot wrote in *The Music of Poetry*, “before it (the poem) reaches expression in words” (Eliot, 1975, p. 114). The words of a poem, Eliot wrote, are only a translation: “With a poem you can say, ‘I got my feeling into words for myself. I now have the equivalent in words for that much of what I have felt’” (Eliot, 1963, p. 97). What makes poets and novelists writers is not that they think in words, but that they express themselves preferentially in words.

Eliot’s description of his creative thinking and the difficulty of translating pre-verbal thoughts into words is typical of other writers, as we have demonstrated in our book *Sparks of Genius* (1999). Most find that they can write only after they feel, see, and hear their material in their imagination. For Robert Frost, “a poem . . . begins as a lump in the throat, a sense of wrong, a homesickness, a love sickness. It is never a thought to begin with” (Plimpton, 1989, p. 68). Similarly, E. E. Cummings said that, ‘The artist is not a man who describes but a man who FEELS’ (*). Thus we find that for poet Gary Snyder, writing comes from a process of visualizing situations that give rise to feelings:

I’ll replay the whole experience again in my mind.
I’ll forget all about what’s on the page and get in contact with the preverbal level behind it, and then by an effort of reexperiencing, recall, visualization, revisualization, I’ll live through the whole thing again and try to see it more clearly.

As the emotional images become clearer to Snyder, they give rise to the same sort of musical rhythms experienced by Eliot:

The first step is the rhythmic measure, the second step is a set of preverbal visual images which move to the rhythmic measure, and the third step is embodying it in words.

The notion that writing is a translation process occurs in autobiographical accounts of many other writers, too. Stephen Spender insisted that the challenge of writing is to find words for emotional images that have no words:

Can I think out the logic of images? How easy it is to explain here the poem that I would have liked to write! How difficult it would be to write it. For writing it would imply living my way through the imaged experience of all those ideas, which here are mere abstractions.

Novelist Dorothy Canfield Fisher also found that words would come only after “intense visualizations of scenes . . .”. Novelist Isabel Allende, however, relies upon gut feelings to bring forth words:

Books don’t happen in my mind, they happen somewhere in my belly . . . I don’t know what I’m going to write about because it has not yet made the trip from the belly to the mind . . . It is something that I’ve been feeling but which has no shape, no name, no tone, no voice.

Novelist and composer William Goyen characterizes the process of writing as “the business of taking it from the flesh state into the spiritual, the letter, the Word”.

The same distinction between creative thinking and modes of expression can be used to characterize scientists. Consider Albert Einstein, the man Howard Gardner characterizes in *Creating Minds* (1993) as his prototypical “logical-mathematical thinker”. Just as Eliot said he did not think in words, Einstein said that “No scientist thinks in formulae”. The “essential feature in productive thought”, he wrote, is an associative play of images and feelings:

The words of the language, as they are written or spoken, do not seem to play any role in my mechanism of thought. The psychical entities which seem to serve as elements in thought are certain signs and more or less clear images which can be ‘voluntarily’ reproduced and combined . . . The above mentioned elements are, in my case, of visual and some of muscular type.

Einstein went on to describe thinking as the ability to associate images and muscular feelings in a repeatable way with problems upon which he was working, adding that “. . . Conventional words or other signs have to be sought for laboriously only in a secondary stage, when the associative play already referred to is sufficiently established and can be reproduced at will”.

Again, Einstein’s non-verbal, non-mathematical thought is typical of scientists. Fellow Nobel laureate Richard Feynman described his problem-solving as kinesthetic, acoustic, and visual:

It’s all inspired picturing . . . In certain problems that I have done, it was necessary to continue the development of the picture as the method, before the mathematics could really be done.

Harvard astrophysicist Margaret Geller recounts a similar approach:

I have to have a visual model or a geometric model or else I can’t do it (physics). Problems that don’t lend themselves to that I don’t do.

Barbara McClintock, yet another Nobelist, also described a non-verbal approach:

When you suddenly see the problem, something happens that you have the answer—before you are able to put it into words. It is all done subconsciously . . . You work with so-called scientific methods to put it into their frame after you know.

Logic and mathematics, in other words, are the translations that scientists use to communicate their insights, just as writers use words.

Let there be no mistake: the thought processes that these scientists describe are a form of intuition. Einstein made the point explicitly:

Only intuition, resting on sympathetic understanding, can lead to it (insight); . . . the daily effort comes from no deliberate intention or program, but straight from the heart.

His colleague Henri Poincaré, perhaps the greatest mathematician of the early twentieth century, agreed: “It is by logic that we prove, but by intuition that we discover”. Mathematicians Edward Kasner and James Newman write similarly that, “Mathematical induction is . . . an inherent, intuitive, and almost instinctive property of mind” (Kasner & Newman, 1940, p. 35). That which is important must be deeply felt, as mathematical physicist Wolfgang Pauli made clear. During the initial phases of problem solving, “the place of clear concepts is taken by images of powerful emotional content”. Indeed, according to botanist Agnes Arber, without this emotional content, creative scientific thought is stymied:

New hypotheses come into the mind most freely when discursive reasoning (including its visual component) has been raised by intense effort to a level at which it finds itself united indissolubly with feeling and emotion. When reason and intuition attain this collaboration, the unity into which they merge appears to possess a creative power which is denied to either singly.

Thinking and feeling are, in short, just as inseparable to a scientist as to a writer or artist.

We want to emphasize the point that, despite the very real differences between the products created by artists, writers, and scientists, people in all fields use a similar set of pre-verbal, pre-logical forms of creative thinking. Pauli says that scientists must FEEL just as deeply as poet E. E. Cummings. Feynman’s development of the picture as a method could just as easily be Spender’s ‘logic of the images’. The physical concepts emerging from Einstein’s muscles could just as well be novels regurgitated from Allende’s belly. The important point is that each of these creative individuals knew something sensually and somatically before they were able to describe it formally to anyone else. Until we are able to access, practice and use such pre-linguistic, somatic thinking explicitly, we are cut off from our most innovative sources of thought.

Tools for Thinking

The emotional, intuitional, pre-verbal nature of creative thinking does not place it beyond comprehension. Just as logic and language build upon skills that can be learned and practiced, so does intuition. Hundreds of

autobiographical and archival sources, interviews, and formal psychological studies reveal that every creative person uses some subset of a common imaginative ‘tool kit’. This tool kit consists of a baker’s dozen of pre-logical, pre-verbal skills:

- (1) *observing*;
- (2) *imaging*;
- (3) *abstracting*;
- (4) *pattern recognizing*;
- (5) *pattern forming*;
- (6) *analogizing*;
- (7) *bodily kinesthetic thinking*;
- (8) *empathizing*;
- (9) *dimensional thinking*;
- (10) *modeling*;
- (11) *playing*;
- (12) *transforming*; and
- (13) *synthesizing*.

We emphasize that this tool kit consists of the imaginative skills common to all creative people, and the labels are those terms they use to describe their own thinking. Artist Brent Collins, who transforms mathematical equations into stunning wood sculptures, provides an apt example. In one brief passage describing his artistic process, he refers to the relationships between logic and image, aesthetics and intuition, and to his use of physical and mental tools:

I made (two-dimensional) templates exactly to scale The entire mathematical logic of the sculpture is inherently readable from the template. There are, however, many aesthetic choices The template serves as a guide for a spatial logic I somehow intuitively know how to follow. Using common woodworking tools and proceeding kinesthetically, I am able to gradually feel and envision its visual implications The linear patterns issue as abstractions (Collins, np).

While few innovators are as succinct in their description of the tools for thinking that underlie their creative work, reference to *Sparks of Genius* will show that many are just as explicit. It is therefore worth considering what mental operations each tool for thinking represents and the many ways in which each can be used.

Observing is perhaps the first and most basic of thinking tools. As human beings we are all equipped to sense the world, but observing is a skill that requires additional patience, concentration and curiosity. The American painter Georgia O’Keeffe looked carefully at things, and forces us to do so, too, in her very large paintings of flowers. “Still—in a way—” she said, “nobody sees a flower—really—it is so small—we haven’t the time—and to see takes time, like to have a friend takes time”. Observing is paying close attention to what is seen, but also what is heard, touched,

smelled, tasted and felt within the body. In dense jungles, biologists such as Jared Diamond observe and identify birds by sound; in the absence of sight, the blind biologist Geermet Vermeij observes seashells with his hands, by touch; bacteriologists and doctors observe bacteria by smell; chemists and doctors have—historically at least—observed sugar in the urine by taste. Inventors and engineers, and the mechanics they rely on, similarly observe kinesthetically by cultivating hands-on experience with tools and machines—they know how tightly the nut is screwed onto the bolt by the feel of it.

Imaging, also a primary thinking tool, depends upon our ability to recall or imagine the sensations and feelings we observe in the absence of external stimulation. We can image visually and also aurally, and with smells, tastes, tactile and muscular feelings as well. If you can close your eyes and see a thing, or imagine the taste, touch, smell, or sound of it when it is not present, then you are imaging. For example, those of us who are already good at visualizing can close our eyes and see a triangle—and if we're practiced, we can make it change color and dimension, rotate it, etc. And if we're really good at visualizing, we can imagine an object with a triangular profile from all sides—or the much more complex object Charles Steinmetz, inventor of electrical generators, was asked to envision. A group of colleagues at General Electric once approached him with a problem they could not solve: "If you take a rod two inches in diameter and cut it (in half) by drilling a two-inch hole through it, what is the cubic content of the metal that's removed?" Steinmetz was able to answer the question quickly, first by visualizing the removed core, then by applying equations that calculated its volume. Such visualizing, Eugene Ferguson argues in *Engineering and the Mind's Eye*, plays a central role in engineering and invention. Without it, the engineer cannot foresee the invention he wishes to make. By the same token, the chef cannot foretaste the delicacy she wishes to create in the absence of imaging; the musician cannot forehear the symphony she wishes to write down.

Abstracting is yet another important thinking tool. Because sense experience and sense imagery are so rich and complex, creative people in all disciplines use abstracting to concentrate their attention. Abstracting means focusing on a single property of a thing or process in order to simplify it and grasp its essence. Scientists and engineers work with abstractions all the time, for instance stripping a physical situation of all extraneous characteristics such as shape, size, color, texture, etc. and zeroing in on point mass, spring and distance. "I'll tell you what you need to be a great scientist . . ." says physicist Mitchell Wilson. "You have to be able to see what looks like the most complicated thing in the world and . . . find the underlying simplicity". Similarly, in the arts, abstracting means choosing which simplicity captures the

essence of some concrete reality. Pablo Picasso tells us how:

To arrive at abstraction, it is always necessary to begin with a concrete reality You must always start with something. Afterward you can remove all traces of reality

And he does just that in a series of etchings called 'The Bull'. Searching for the essence of bull, its minimal suggestion, he finally finds it in the simple linear description of its tellingly distorted shape, the tiny head surmounted by enormous horns, the massive body balanced by a short, hanging tail.

Abstracting often works in tandem with *patterning*, a tool with two parts. We organize what we see, hear, or feel by grouping things all the time. Sometimes we do so visually, as in a quilt or a graph, but of course, we can group things with all our senses. *Recognizing patterns* means perceiving a (repetitive) form or plan in apparently random sets of things and processes, whether in the natural world or in our man-made world. While the ability to recognize faces, and patterns that look like faces, seems to be ingrained in every normal human being, recognizing patterns is often influenced by culture. Westerners are inclined to hunt for a linear, back and forth, or up and down arrangement of information and our tables, graphs, books, and even architecture mirrors this predilection. Thus, although spirals are a common natural form (snails, sea shells, tornadoes, pinecones, whorls of hair on head), Westerners seldom use this pattern to design buildings, graphs or tables. Culture therefore plays a major role in what patterns we recognize and expect to perceive.

Recognizing patterns is also the first step toward creating new ones. Novel *pattern forming* always begins by combining two or more elements or operations in some consistent way that produces a (repetitive) form. For instance, the pattern found in 'watered' silk is created by folding the fabric at a slight bias and then pressing it under high heat and steam with great force. This process imprints the rectilinear pattern of the warp and woof of each fold of the fabric onto the opposing material at a slight offset. The result is what is known as a Moire pattern. Such Moire patterns can be produced by overlapping almost any regular grid over another, as when we look through two window screens or two sections of link fencing. The creation of novel Moire patterns is limited only by the imagination of the individual choosing what regular patterns to overlay.

Pattern forming is also at work when engineers design complex machines. There are only a very small number of basic machines—levers, wheels, screws, cogs and so forth—from which every mechanical device is constructed. Technological invention is the process of forming new patterns with simpler components by combining elements and operations in novel

patterns. The same can be said of pattern forming in language and the language arts, since a finite number of words, grammars and narrative structures can be potentially combined and recombined to myriad, innovative effect (J. Gardner, 1983, pp. 52–53).

Recognizing and forming patterns leads directly to *analogizing*, that is, recognizing a functional likeness between two or more otherwise unlike things. We use analogies all the time to broaden our understanding of things. For instance, biologists often describe different bird beaks as if they work like human tools. A nutcracker and a particular bird beak may not look the same, but they function similarly and therefore are analogous. Analogy also has an important place in engineering and invention. Velcro, as no doubt everyone knows, was developed by analogy to the grasping properties of the common bur. Biomimicry, the use of nature as source of ideas, has in fact, become a well-recognized method of innovation. One of the more striking, recent examples of bio-analogy in architecture and engineering is the Gateshead Millennium Bridge. Chris Wilkinson Architects in Great Britain took the human eyelid for its analogical model and designed a drawbridge that works like the eyelid. When the ‘lid’ is closed, the bridge is down and people can move across. When a ship approaches, the lid is raised and ships can pass under the resulting arch.

While reading the above description of the Gateshead Bridge, you may have paid unusual attention to the way your eyelid functions and feels. This is an example of *body* or *kinesthetic thinking*. Body thinking means just that: thinking with the body. It is based upon sensations of muscle, sinew and skin—sensations of body movement, body tensions, body balance, or, to use the scientific term, proprioception. For instance, if you can imagine how it feels in your hand to set various gears in motion, if you can imagine in your muscles how they feel in motion, you are thinking with your body. Charles ‘Boss’ Kettering, director of research at General Motors for many decades, is said to have chided his engineers when they became overly analytical and mathematical. Always remember, he told them, “what it feels like to be a piston in an engine”. Cyril Stanley Smith, the chief metallurgist for the Manhattan Project, clearly understood his creative debt to body thinking:

In the long gone days when I was developing alloys, I certainly came to have a very strong feeling of natural understanding, a feeling of how I would behave if I were a certain alloy, a sense of hardness and softness and conductivity and fusibility and deformability and brittleness—all in a curiously internal and quite literally sensual way.

The same kinesthetic and tactile imagination is at work, too, in what is often considered the abstract reasoning of mathematics. The mathematician Stanis-

law Ulam said he calculated “not by numbers and symbols, but by almost tactile feelings . . .”. While at work on the atomic bomb at Los Alamos he imagined the movements of atomic particles visually and proprioceptively, feeling their relationships with his whole body well before he was able to express the quantum equations in numbers. This same muscular sense for the body in motion may also provide insight into engineering and architecture. At Princeton University one architecture student recently combined a dance production called ‘The Body and the Machine’ with a senior thesis, explaining that “exploring conceptual issues (in architecture) kinetically helps me understand them” (Moseley, 18).

Empathizing, our next tool, is related to body thinking, for this imaginative skill involves putting yourself in another’s place, getting under their skin, standing in their shoes, integrating ‘I’ and ‘it’, feeling the objective world subjectively. Empathizing with other people, with animals, with characters on stage or in a book is standard fare for novelists, actors, and even physicians. But artists and scientists also empathize with nonhuman, even non-animal things and processes. Isamu Noguchi reified this sort of empathy in his sculpture, ‘Core’, a piece in basalt with carved holes. “Go ahead”, he told visitors to his studio. “Put your head into it. Then you will know what the inside of a stone feels like”. By putting her head ‘in there’, focusing her attention at the level of the corn chromosomes she studied, Nobel laureate Barbara McClintock was able to develop a ‘feeling for the organism’ so complete that she described herself as being down inside her preparations, and their genes became her ‘friends’. And astrophysicist Jacob Shaham talked of ‘reading’ his equations like scripts for a play in which the ‘actors’—energy, mass, light and so on—have intents and motives that he could physically act out.

Yet another tool that we most often learn unconsciously is *dimensional thinking*, rooted in our experience of space and time. Creative individuals think dimensionally when they alter the scale of things, as artists Claes Oldenburg and Coosje van Bruggen did in their *Batcolumn* in Chicago. Their ten-story-high rendition of a baseball bat strikes us very differently than the three-foot version. As any architect knows, size and mass can be altered to convey anything from flowery delicacy to dominating power. Moreover, the engineering of scale changes can be complex: different structural designs and different materials are almost certainly required as artist-engineers work dimensionally with properties such as strength and durability. Inventive individuals also think dimensionally when they map things that exist in three dimensions onto two dimensions, for instance in maps or blueprints. Indeed, this kind of dimensional thinking is at the heart of drawing in perspective. Artists, scientists and engineers also think dimensionally when they try to reconstruct

three-dimensional phenomena from information recorded in two dimensions. Construction engineers interpret and build three-dimensional structures from two-dimensional instructions. In fact, how we orient ourselves in space has implications for the patterns we form in two and three dimensions. Cartesian coordinates assume a world of right angles; polar coordinates map a spherical universe. Buckminster Fuller rejected both in favor of a tetrahedral coordinate system and, based upon that system, invented his geodesic dome. Each coordinate system permits us to recognize and solve a different set of problems.

The tools for thinking briefly sketched up to this point are what might be called primary tools. They can be learned and practiced somewhat independently, though they are always interacting. Body thinking is a kind of imaging; observing feeds into abstracting and patterning; patterning in turn merges with analogizing and so forth. The last four tools for thinking, however, are clearly tools that rely upon the acquisition of primary tools and integrate them into composite tools.

The first of these composite tools is *modeling*, that is, plastically representing a thing or a process in abstract, analogical and/or dimensionally altered terms. The point of modeling is to depict something real or imagined in actual or hypothetical terms in order to study its structure or function. Artists make and use models all the time by preparing maquettes, smaller conceptualizations of pieces in planning. Scientists and engineers also create simplified models of objects and processes. In the case of flight simulators, engineers model the hands-on experience of flying planes for educational purposes by imitating the reality of that experience in space and time. Molecules that can never actually be seen or touched are built millions of times their actual size out of plastic or wood. Stars, which are beyond our ability to comprehend in any realistic sense, become a series of equations describing their actions over time frames beyond the entire experience of humanity. Modeling, as many practitioners have said, is like playing god, toying with reality in order to discover its unexpected properties.

Playing, of course, is itself another integrative tool that builds upon the other primary skills. We play when we do something for the fun of it, when we break or bend the rules of serious activity and elaborate new ones. Play is the exercise of our minds, bodies, knowledge, and skills for the pure emotional joy of using them. Unlike work, play has no set, serious goal; yet by encouraging fun, play is useful, for when creative individuals play with techniques and ideas they very often open up new areas of understanding through serendipitous discovery.

Among the greatest of players was the sculptor Alexander Calder, whose early training was in engineering. One manifestation of his play was a lifelong habit of designing toys for children (and for himself, too) out of wire and wood. In fact, Calder's first true

success in the art world was as a result of having built himself a working model of a circus, complete with animals, props, entertainers with movable parts, a trapeze with a net and a tent. He actually played circus, too, inviting friends and acquaintances in the Parisian intelligentsia to watch him enact sights, sounds and stories under the big top. He was just having fun, yet his toys have been called a 'laboratory' for his subsequent, ground-breaking work. From movable toy figures he graduated to kinetic sculptures—hand-driven, then motor-driven—and finally to free-floating mobiles. In keeping with his playful spirit, however, he always refused to call his sculpture 'art', deeming the word too serious for his intentions.

Even the most serious innovations often have their origins in play. Alexander Fleming's discovery of penicillin has been traced to his hobby of collecting colored microbes for the 'palette' with which he created microbial 'paintings' on nutrient agar. Charles 'Fay' Taylor, the MIT engineer who made major strides in automotive engine design, explored mechanical objects by playing with kinetic sculptures. And Nobel laureate Richard Feynman said that his Nobel-winning work in quantum mechanics began when he started playing with the rotation of plates thrown in the air.

Play teaches us that how one learns something has no bearing on the importance of the lesson learned. What counts is the practice gained in extending the abilities and experience of one's mind and body. What counts is the practice gained in the use of more than one thinking tool at a time. Playing thus feeds into yet another imaginative tool, *transforming*, the serial or simultaneous use of multiple imaginative tools in such a way that one tool or set of tools acts upon another. To play is to transform, for one takes an object, observes it, abstracts essential characteristics from it, dimensionally alters the scale, and then, using body skills, creates a physical or mental representation of the object with which one can play. Take a look at any creative endeavor and you'll find such combinations of thinking tools being used to transform ideas and insights into one or more expressive languages.

In order to invent strobe photography, for example, engineer Harold Edgerton of MIT first transformed his mental image for a strobe light for ultrafast flash photography into a visual diagram, and then transformed the diagram into a working model. He played around with different versions of the strobe until he achieved one that matched his mental picture. Then, using his prototype, he played with setup conditions, different kinds of subjects and motions until, finally, he transformed all these components—film, camera, strobe, subject—into the results he wanted: a photograph that was both a scientific experiment and a work of art. In retrospect we can see that Edgerton made use of several imaginative tools: visualizing, modeling, playing, and something more, too, for without the ability to translate his ideas into words, diagrams,

strobe and photograph his imaginative invention of ultrafast flash photography would have come to naught. Indeed, such transformations are typical even of data, as Edward Tufte has beautifully demonstrated in his books on visual information. Every table or graph or illustrated set of instructions for assembling something is a transformation of one kind of knowledge into another.

The necessary consequence of transformational thinking is our final mental tool: *synthesizing*, the combining of many ways of thinking into a synthetic knowing. When one truly understands something, emotions, feelings, sensations, knowledge and experience all combine in a multimodal, unified sense of comprehension. One feels that one knows and knows what one feels. Einstein, for example, claimed that when he sailed he felt the equations of physics playing out through the interactions of the boat, the wind, and the water. He became a little piece of nature. Similarly, artists and writers describe the creative process as a melding of sight, sound, taste, touch, smell, and emotion in which all become interwoven in an experience so powerful that they lose their sense of self. Feeling and thinking become one in a process that is often described as ‘synesthetic’.

Synesthesia is a neurological term that refers to the experience that some people have of seeing colors when they hear certain sounds, or perceiving tactile feelings when tasting various foods. Artists and musicians, many of whom have some form of neurological synesthesia, often describe the ultimate aesthetic experience as being one in which a performer or observer of an art experiences all possible sensations simultaneously. A picture or a symphony may, for example, generate visual, acoustic, and tactile sensations along with definite emotions and even tastes, smells, and movements in the observer. One way to judge art is the degree to which it provokes such a multi-modal experience.

If we refer back to the descriptions of scientific thinking given by Einstein, Feynman, McClintock, Arber and other scientists in the opening of this chapter, then it is clear that scientists, too, experience a form of synesthesia. Ideas are inseparable from the emotions, the visual and tactile images and other sensations that accompany their genesis. Since the result of such sensory and somatic integration is not just an aesthetic experience, but also an intellectual one, we have suggested that it be called ‘synosia’, from a combination of ‘syn’, meaning together, and ‘osia’ from ‘gnosis’, the Greek word for knowledge. Synosia, in short, is the combination of knowledge and emotion, objective and subjective understanding into a synthetic whole.

The fact is that true understanding (by which we mean the ability to act upon the world), as opposed to knowledge (which is the merely passive acquisition of facts, often without the skills to use them), is always

synthetic. Immanuel Kant wrote many years ago that “The intellect can intuit nothing, the senses can think nothing. Only through their union can knowledge arise”. He understood that we recognize that which is important by its emotional impact on us and use our senses to explore how to respond. Thus, we can now understand why Einstein, Poincaré, and so many other innovators have claimed that intuition rather than reason is the basis of creative thought. To feel is to think, just as to think is to feel. Only when the two are integrated is innovation possible.

Training Intuition

Since intuition develops from the kinds of non-verbal, non-mathematical tools for thinking that we have just outlined, it can be exercised. The use of mental tools is no different than the use of physical tools: both require training and practice. Fortunately, many of the innovative people who have discussed how they have used observing, imaging, patterning, analogizing, and all the rest of the tools, have also described how they acquired skill in using these tools. The one thing they all say is that intuition results from doing things, not passively learning about them. One builds up a sense of how things should work by having experienced how they actually do (or do not) work. Thus, more than one innovator has stated that an expert is an individual who has made all the mistakes in the field.

Observing and imaging, for example, are often learned together through the practice of fine and applied arts and hobbies of all sorts. Collecting anything from stamps or coins to butterflies or buttons teaches an individual visual discrimination and memory. These talents are raised to a higher level by the practice of applied and fine arts. The artist-writer Leo Lionni’s first drawing teacher was his architect uncle who gave him lessons as a small boy. Similarly, the writer Vladimir Nabokov also learned as a child to make detailed drawings both from life and from memory of objects that he examined over and over again. By his own admission, he used his observing and imaging skills equally in his research on butterflies at the Harvard Museum of Comparative Zoology and in his literary undertakings. Many Nobel laureates in the sciences have echoed Santiago Ramon y Cajal’s statement that “that which has not been drawn has not been seen”. And the same lessons have applied to observing well in sound, smell, taste, and touch and recalling the images derived from these senses. Pioneering composer Charles Ives was taught by his musician-father to hear the ‘music’ in a thunderstorm or the tone of a pane of glass when it is tapped—things that most of us overlook, or more accurately overhear. Chemical ecologist Thomas Eisner was taught by his father, a perfumer, how to use his nose to identify the composition of substances. Eisner now uses that faculty to study the ways in which insects use odors to communicate with one another.

Abstracting can also be learned and practiced by observing how other people have performed the process and by copying them. Even the expert artists have to learn the abstracting process of eliminating all the unnecessary clutter to reveal some basic property of an object. This process is beautifully illustrated in Randy Rosen's extraordinary book, *Prints* (1978). He shows how Pablo Picasso and Roy Lichtenstein both eliminated various features of a bull, step by step over many months, to yield very different and yet very evocative abstractions of 'bullness'. Guides to good writing, such as *The Elements of Style* by Strunk and White, recommend that writers revise by cutting out words, sentences, paragraphs that are unnecessary—in other words, they advise writers to abstract, to jettison all but what is essential to the work. No better example of written abstracting exists than the one-line plot descriptions given in the TV Guide. Trying to duplicate such one-line descriptions is excellent training in discovering the essence of things.

Patterning can be learned by similar experience. Richard Feynman recounted that his first formal introduction to patterns was as a very young child. His father gave him a set of small ceramic tiles, some blue and some white, and then had him create simple patterns: all blue; all white; alternating blue and white; two blue and one white; one blue and two white; etc. Simply learning that patterns have permutations was the beginning of one of Feynman's greatest ideas, which is that nature always employs every possible path to achieve any given end. There is a lesson here for creative thinking, too. The greater the number of patterns one knows, the greater one's understanding of possibilities. Many forms of pattern recognition require formal training in music, poetry, and symmetry, and books about these subjects abound. Far better, however, is active participation in composing music, poetry, and artwork, since doing always teaches more than reading. For the same reasons, much can be learned about patterns by playing word games, building puzzles, learning to dance, becoming a chess master, or doing recreational mathematics. When one can recombine what one knows to invent new chess puzzles, choreograph a new dance, or invent new mathematical problems or poetic forms, then one has graduated to pattern forming, which brings creative joys unmatched by any passive hobby.

Artist-inventor-psychologist Todd Siler has written extensively on how to generate patterns connecting like and unlike using a process he calls 'metaphorming'. To metaphorm, one uses any and all forms of connection-making—including visual analogy, metaphoric figures of speech, narrative cause and effect and rational hypothesis—to explore the meaning inherent in the comparison of two or more things. Take any given object, he advises, and ask yourself what else is this like, what does it remind me of? And why? Articulate the connection as metaphor, as hypothesis, a symbol, as

pun. To metaphorm the mind with garden means to assert that the mind is a garden, that there are gardens of the mind. Thoughts germinate like flowers. The imagination is the soil in which they grow. The mind, layered like an onion, requires cultivation and nourishment. Ideas root themselves and become difficult to dislodge. Dangerous ideas create 'mind fields'. Taken literally, of course, there are 'mind fields', which can be studied by means of functional magnetic resonance imaging and other neurological techniques. Are we on the verge, as mind-gardeners, of intervening physically to enhance or otherwise influence the growth of a mind-plant? Metaphorming ideas in as many ways as possible is good practice in making the structural connections and functional analogies that animate art, science and technology. Similar pattern forming techniques have been adapted for elementary and secondary classroom use, for instance in *The Private Eye, Looking/Thinking by Analogy* guide for learning in art, writing, science, math and social studies (Ruef, 1992). Analogizing, that particular search for similarity of function, especially involves looking at things and processes in order to discover not simply how they work, but how they might work outside their given context. Young people exposed to such training acquire the active habits of mind necessary to the intuitive generation of novel ideas.

Body thinking is another tool best developed through active participation with the world. This may seem self-evident, but in an age when people spend increasing amounts of time in front of computers, simple body skills among students are declining dramatically. Children—and adults, too—spend less and less time handwriting, drawing, running, jumping and playing physical games and sports of all kinds. But the truth is, they cannot learn to ride a bike simply by reading about it. Nor can they really understand structural forms such as buildings or bridges without experience of thinking about the muscular supports of their own body; they cannot really understand physical processes such as the molecular behavior of solids, liquids and gases, without incorporating notions of speed and vector within themselves. All kinds of physical activity, including organized arts and athletics, work to develop body-thinking skills. Sports and dancing build gross body-thinking; finer body thinking skills result from making music, art, and building things. For added bonus, body thinking can be reviewed and practiced mentally. For instance, the pianist can see and feel herself playing a piece of music, remembering every detail without so much as moving a finger. The downhill skier can imagine each moment on a race course without leaving his room. Studies of people in every discipline from sports to music, engineering to design, show that imaging how it will feel to perform a particular set of actions can actually improve subsequent performance.

Dimensional thinking must also be learned by doing. One must learn how to translate a three-dimensional object into two dimensions by drawing or photographing it. One must learn how to transform the information given on a two-dimensional blueprint or assembly diagram into the three-dimensional object. Such skills can be acquired through formal classes in drafting and modeling, or through informal experience building furniture, knitting, sewing, or doing any other craft. Perhaps most challenging is learning how to transform a linear set of mathematical symbols into a graph or physical model of the equation—an exercise that was once common in geometry and algebra classes and which should be re-instituted universally.

Playing, and the modeling that it so often entails, is especially important to the exercise and training of intuition. Most innovators build models of sorts, play with a wide variety of games and tools, and generally have extensive experience with making things of all sorts. Carl G. Jung, the famous psychologist, recalled untold hours building models of castles as a teenager. He then took up painting, through which he discovered the function of mandalas (world images) as models for the psychological lives of his patients. Einstein, of course, spent his most creative years in a patent office, daily analyzing and playing with models of inventions. Many artists and writers, including Claes Oldenbourg and H. G. Wells, created entire imaginary civilizations with which they played as children and teenagers and from which they subsequently drew novel ideas for their arts as adults. Alexander Calder, as mentioned above, modeled a circus and derived from his experience not only contacts with the art world, but specific ideas about how to design moving sculptures. Such experiences are common among imaginative people. Indeed, one of the few good correlations that exists to predict which individuals will be creative reveals that they have, often from childhood, *made* things with hands and mind.

Just as all roads lead to Rome, all the experiences gained from the exercise of imaginative thinking tools lead towards synthesizing, that ability to pull together all one imagines with all one knows, that drive to meld sensual knowledge with received wisdom into a unified knowing that we have called *synosia*. We are often most aware of the ‘rational’ or sense-making character of synthetic breakthroughs in human thought—for instance, the explanatory power of Alberti’s drawings in perspective or Einstein’s theory of relativity, but non-rational feelings and perceptions play an equally important role in the generation of synthesis. There is that deeply troubling sick feeling in the pit of one’s stomach when one looks at a situation and knows that something is wrong; or the unmatched ‘high’ that accompanies the ‘Aha!’ of an unexpected insight. For mathematician-philosophers Bertrand Russell and Norbert Wiener, creative work almost always began with feelings of physical discomfort evoked by certain

unsolved problems in mathematics (Hutchinson, 1959, p. 19; Wiener, 1956, pp. 85–86; Wiener, 1953, pp. 213–214). Equally physical, orgasmic feelings of relief and achievement attended the solution of those problems. Nobel laureate Sabramanyam Chandrasekhar has called this “shuddering before beauty” (Curtin, 1982, p. 7).

Ultimately, all thinking tools, but especially modeling, playing, transforming, and synthesizing, give birth to the inarticulate sense-making called intuition. Intuition involves non-explicit expectations of what should happen when something is tweaked, of how a system will behave when it is twisted, of what kind of response a person will give in a particular situation. We build vague models of how things work and people behave based on our experiences. These models often owe a great deal to playing with tools, games, people, and systems to find out how they respond to various stimuli. We develop a ‘feel’ for what should happen. But because we have not analyzed our experience in any formal way, we cannot explain the resulting ‘intuitions’. They remain what philosopher and physicist Michael Polanyi has described as ‘personal knowledge’—pre-verbal understanding that yields insight before it yields the means to explain insight. Though personal knowledge is just that, personal and unspeakable, it is nonetheless valid and useful. In fact, Neils Bohr used to chide his students with the comment, “You’re not thinking; you’re just being logical!” (Frisch, 1979, p. 95). His colleague Enrico Fermi was known to dismiss mathematical ‘proofs’ of concepts with the comment that his ‘intuition’ told him they were wrong. Because Fermi had so much experience actually doing physics, building, making and inventing things, most of his colleagues trusted his intuitions, which were often right (Wilson, 1972). Learning to pay attention to that which moves us—to an accumulation of unarticulated but felt experience that forms our intuition—is key to creative work (Root-Bernstein, 2002).

Intuition and the Future of Innovative Education

Having placed intuition on a comprehensible footing, and outlined its role in the comprehensive, creative knowing that is *synosia*, we can now think about the educational implications such recognition must imply. Education in every discipline rightly emphasizes analytical, logical, technical, objective, descriptive aspects of each field. These inform the nature of public discourse between practitioners and their formal communication of disciplinary knowledge. But, as must by now be evident, the subjective, emotional, intuitive, synthetic, sensual aspects that make up the private human face of all creative inquiry deserve equal educational recognition. It is this human face, after all, that fuels desire to discover, to invent, to know. Without it, creative work has no motivation, no driving force. This is not to argue that practice of imaginative

thinking and the exercise of intuition is of greater import than mastery of the logical, analytical, technical aspects of any discipline. Far from it. Innovation is possible only when individuals emotionally engage in a subject and intuit novel ideas *and also* evaluate ideas and results logically and translate them into forms appropriate for communication and analysis by other people. Synosia cannot do one without the other, nor can an education that truly seeks to prepare students for innovation and invention.

Unfortunately, not only does our education system generally ignore the emotional and subjective aspects of creativity, so do the cognitive sciences. This is too bad, for theories in cognitive psychology do not mirror so much as they inform educational practice. And as mathematician Seymour Papert of MIT makes clear, the enormous impact cognitive theories often have on educational practice can be to the detriment of innovation. He writes:

Popular views of mathematics, including the one that informs mathematical education in our schools, exaggerate its logical face and devalue all connections with everything else in human experience. By doing so, they fail to recognize the resonances between mathematics and the total human being which are responsible for mathematical pleasure and beauty . . . (Papert, 1978, p. 104).

Papert finds grounds in this oversight to question the validity of cognitive theories as they inform education:

Implicit in the confrontation of these views of mathematics is a broader question about the legitimacy of theories of psychology, often called cognitive, which seek to understand thinking in isolation from considerations of affect and aesthetics (Papert, 1978, p. 104).

Papert has a point. The separation of cognition from somatic sensation and aesthetic feeling is both inaccurate and inappropriate: inaccurate, for if, as Einstein and McClintock both said, one must become a piece of nature in order to discover the hidden mysteries of nature, then the oversight of imaginative and intuitive thinking undermines our understanding of creative endeavor; inappropriate, because the same dualistic divorce of mind and body, emotion and reason, has had a deleterious effect on education. Psychologist Jeanne Bamberger has documented just how harmful. She studied a group of Boston teachers and some of their students who were considered bright but who performed poorly in school. Teachers and students were brought to Bamberger's Laboratory for Making Things in Cambridge, Massachusetts where they were asked to build mobiles. Most of the children had no difficulty building mobiles, but when asked how they did it and what physical principle they used, they were unable to answer. As one young man said, he "just knew . . . I

had a feeling of it, like on a teeter totter" (Bamberger, 1991, p. 38). The teachers, however, had learned the principle underlying mobile construction, which is the same as balancing two weights on a lever: 'weight times distance must be equal on both sides of the fulcrum'. They, however, were mostly unable to implement this principle in practice, and few built a functional mobile (Bamberger, 1991, p. 44). There is something obviously wrong with an educational system that can produce students unable to explain how they do what they do and teachers unable to do what they can explain.

The crux of the matter with education lies in the dissociation of mind from body and thus sciences from arts. For most of the twentieth century, psychology was dominated by an over-simplified use of Lewis Terman's theory of intelligence, which relied solely upon verbal and mathematical measures of problem-solving ability (Seagoe, 1975). Practitioners overlooked the fact that Terman himself had actually found that for very creative people, but not for average people, verbal and mathematical scores were sufficient to predict high achievement on visual, analogical, mechanical, physical and other tests. Initially, at least, communication skills with words and numbers were understood as predictors/indicators for some of our most important imaginative thinking skills: visualizing or imaging, analogizing, modeling and body thinking. As Terman's work affected the field, however, the communication skills that predicted creative intelligence took precedence over the imaginative substance of that intelligence—as evidenced by the heavy testing of verbal and mathematical skills at all levels of schooling.

Unfortunately recent multiple intelligences theories such as Howard Gardner's (1983) threaten to exacerbate the problem by focusing much-needed attention on a broader set of communications skills such as kinesthetic, musical, verbal, visual, and inter-personal abilities without simultaneously distinguishing them from creative thinking skills. The fact that people can be highly verbal, extraordinarily artistic, or wonderfully musical and at the same time have little or no creative ability seems generally to have been overlooked or ignored. Most creative people are, in fact, polymathic and utilize their skills in multiple domains (see Root-Bernstein, 'The Art of Innovation', this volume).

Bamberger, Papert and others point the way towards a more balanced view of innovative thinking by forcing us to look at mind as part of the body. Neurologists such as Antonio Damasio (1994) remind us that people who, for reasons of disease or accident, lose emotional affect also lose their ability to act reasonably. Rational decision-making, he argues, cannot be divorced from emotional affect. The anecdotal reports of so many of the world's most creative people are finally finding an analytical basis.

The implications of these findings for cognitive sciences and education cannot be underestimated. What they tell us is that any theory of mind that claims to account for creative thinking must describe the sensual, emotional, and somatic manifestations of thought as well as their analytical, objective, and communicable formulations. Moreover, the transformational process by which ideas are translated from their personal, bodily forms into formal languages for communication must be made explicit. Educationally, each of these points has equivalent importance. Words and numbers are not sufficient to produce innovative people, nor are the tools for thinking that we have outlined here. Tools for thinking are necessary to develop the sensual, emotional, bodily forms of thinking from which new ideas emerge, but tools for thinking are not sufficient for communicating these ideas to other people. In order to provide a complete education, tools for thinking need to be taught in an integrated fashion with a variety of expressive skills—verbal and mathematical, to be sure, but also bodily-kinesthetic, visual-spatial and others that pertain to Gardner's multiple domains. Translating and transforming skills that link imaginative tools to expressive modes and expressive modes one to another are equally necessary. Only when mind and body, synthesis and analysis, personal thought and public communication skills are all part and parcel of cognitive studies and educational practice will an enhanced capacity for innovation become available to everyone.

Stimulating Innovation

Ronald N. Kostoff

Office of Naval Research, USA

Abstract: Innovation is critical for maintaining competitive advantage in a high-tech global economy, especially for organizations or nations that do not possess low-cost labor forces. Many studies on innovation attempt to identify endogenous and exogenous variables that impact innovation (Kostoff, 1997a) in order to better understand the environment that promotes innovation. The author's recent efforts have focused on developing processes for enhancing innovation that exploit the transference of information and insights among seemingly disparate disciplines.

Keywords: Innovation; Discovery; Cross-discipline knowledge transfer; Literature-based discovery; Text mining.

The objective of this chapter is to describe how innovation can be promoted through the enhancement of discovery by cross-discipline knowledge transfer. The approach developed entails two complementary components—one literature-based, the other workshop-based. The literature-based component identifies the science and technology disciplines related to the central theme of interest, the experts in these disciplines, and promising candidate concepts for innovative solutions. These outputs define the agenda and participants for the workshop-based component. An example of this combined approach is presented for the theme of Autonomous Flying Systems. The hybrid approach appears to be an excellent vehicle for generating discovery and enabling innovation. However, it requires substantial time and effort in both phases.

Introduction

Innovation reflects the metamorphosis from present practice to some new, hopefully 'better' practice. It can be based on existing non-implemented knowledge, discovery of previously unknown information, discovery and synthesis of publicly available knowledge whose independent segments have never been combined, and/or invention. In turn, the invention could derive from logical exploitation of a knowledge base, and/or from spontaneous creativity (e.g. Edisonian discoveries from trial and error).

The process of innovation is of immense social interest and impact. Classical studies by Mansfield

(1980, 1991), Griliches (1958, 1979, 1994), and Terleckyj (1977, 1985) focused on the relationship between innovation and micro- or macro-economics. Studies by Wenger (1999) on combined visualization/brainstorming techniques, Patton (2002) and Taggar (2001) on the impact of group stimulation to creativity, Chen (1998) and Siau (1996) on contributions of electronic technology to creativity, and books by Boden (1991) and DeBono (1992) on mental processes in creativity, focused on the process of creativity and its contributions to innovation. Large-scale studies by the Department of Defense (DoD, 1969), Illinois Institute of Technology Research Institute (IITRI, 1968), Battelle (Battelle, 1973), and the Institute for Defense Analysis (IDA, 1990, 1991a, 1991b) focused on identifying the environmental and management conditions most conducive to innovation. Recent symposia have focused on the relation of innovation to: technology policy (Conceicao, 1998, 2001); technology forecasting (Arciszewski, 2000; Grupp & Linstone, 1999), competitive advantage (Hitt et al., 2000); and economic growth and impact (Archibugi & Michie, 1995; Spender & Grant, 1996; Van de Klundert et al., 1998). Yet both the process and impacts of innovation remain poorly understood.

One of the least studied components of innovation is the discovery and synthesis of publicly available knowledge whose independent segments have never been combined; i.e. the transfer of information and understanding developed in one or more disciplines to other, perhaps very disparate, disciplines. With the

explosion in availability of information, the number of opportunities to synthesize knowledge and enhance discovery from disparate disciplines increases non-linearly. Conversely, with accelerating production of information, scientists and technologists find it increasingly difficult to remain aware of advances within their own discipline(s), much less advances in other seemingly unrelated ones. Paradoxically, the growth in science has led to the balkanization of science!

As science and technology become more specialized, the incentives for interdisciplinary research and development are reduced, and this cross-discipline transfer of information becomes more difficult. The author's observation, from examination of many science and technology sponsoring agencies and performing organizations, supplemented by a wide body of literature (Bauer, 1990; Bruhn, 1995; Butler, 1998; Metzger, 1999; Naiman, 1999), is that strong cross-disciplinary disincentives exist at all phases of program/project evolution, including selection, management and execution, review, and publication. To overcome cross-discipline transmission barriers, and thereby enhance innovation, systematic methods are required to heighten awareness of experts in one discipline to advances in other disciplines. Most desirable are methods that *incorporate/require cross-disciplinary access as an organic component*.

This chapter presents two different, yet complementary, approaches to increase cross-discipline knowledge transfer and provide the framework for enhancing innovation. One is literature-based, and the other is workshop-based. Each approach individually represents a major advance in enabling discovery and subsequent innovation, and the hybrid of the two approaches provides a synergy that multiplies their combined benefits.

The literature-based approach is summarized first, followed by the workshop-based approach. The advantages of combining the two approaches are then presented. The details of each approach are presented in the appendices.

Accessing Linked Literatures for Enhancing Innovation-Summary

The first approach searches for relationships between linked, overlapping literatures, and discovers relationships or promising opportunities not obtainable from reading each literature separately. The general theory behind this approach, applied to two separate literatures, is based upon the following considerations (Swanson, 1986).

Assume that two literatures with disjoint components can be generated, the first literature AB having a central theme 'a' and sub-themes 'b', and the second literature BC having a central theme(s) 'b' and sub-themes 'c'. From these combinations, linkages can be generated through the 'b' themes that connect both literatures (e.g. AB → BC). Those linkages that connect

the disjoint components of the two literatures (e.g. the components of AB and BC whose intersection is zero) are candidates for discovery, since the disjoint themes 'c' identified in literature BC could not have been obtained from reading literature AB alone.

Some initial applications of the first approach have been published in the medical literature (Swanson, 1986). One interesting discovery was that dietary eicosapentaenoic acid (theme 'a' from literature AB) can decrease blood viscosity (theme 'b' from both literatures AB and literatures BC) and alleviate symptoms of Raynaud's disease (theme 'c' from literature BC). There was no mention of eicosapentaenoic acid in the Raynaud's disease literature, but the acid was linked to the disease through the blood viscosity themes in both literatures. Subsequent medical experiments confirmed the validity of this literature-based discovery (Gordon & Lindsay, 1996). (A website (Swanson & Smalheiser, 1998b) overviews the process used to generate this discovery, and contains software that allows the user to experiment with the technique. Finn (1998) outlines perceptions of different knowledgeable individuals on Swanson and Smalheiser's general technique.)

This literature-based discovery approach is in its infancy. Public and private financial support for this technology are minimal. *It is a research area of unlimited potential that seems to have fallen through the cracks*. There is essentially one group that is publishing results of literature-based innovation and discovery in the credible peer-reviewed literature (Smalheiser, 1994, 1998a, 1998b; Swanson, 1986, 1997, 1999), two groups that have published concept papers (Hearst, 1999; Kostoff, 1999a), and a few other groups that have replicated Swanson's initial results (Gordon & Lindsay, 1996; Weeber et al., 2001). Presently, the approach is not automatic. It requires much thought, expertise, and effort. The author's group is examining different approaches to make the process more systematic, while reducing the manual labor intensity. Given the potential benefits of the literature-based approach for stimulating innovation, it is truly a technology whose time has come. Appendix 1 generalizes and expands upon the literature-based approach, using the Database Tomography techniques and experience developed by the author since 1991 (Kostoff, 1993, 1994, 1998, 1999b, 2000a, 2000b). It outlines the theory of the expanded approach, the implementation details, and overviews the range of applications possible with this technique.

Interdisciplinary Workshops for Enhancing Innovation-Summary

The second approach consists of convening workshop(s) of experts from different disciplines focused on specific central themes. The purpose of such a workshop is to achieve multi-discipline synergies and cross-discipline transfers to generate promising

research directions for these central themes. The theory behind this approach is described in Appendix 2. To test this theory, a workshop on Autonomous Flying Systems was convened in December 1997. Its implementation mechanics and results are described in detail in Appendix 2.

The total workshop process consisted of three phases:

- (1) A two-month pre-meeting e-mail phase in which each participant provided descriptions of advanced capabilities and promising research opportunities from his/her discipline to all other participants;
- (2) A two-day meeting at the Office of Naval Research during which the promising opportunities identified beforehand were discussed, crystallized, and enhanced; and
- (3) A post-meeting e-mail phase in which each participant provided additional or embellished opportunities.

A number of important lessons were extracted from the conduct of this workshop, and they can be summarized as follows:

- (a) The workshop approach broke new ground toward stimulating innovative thought. It was not easy, simple, or effortless, and required substantial planning and work in order to be effective. One should not throw people from 15 different disciplines together in a room for two days and hope to get new ideas synthesized. There needs to be a common generic thread woven through the different disciplines represented to spark the innovative thought process.

Interdisciplinary workshops, when performed correctly, are the wave of the future in defining new research (and technology) areas and approaches. Because of the intensity and effort involved throughout the process, they are most appropriate for large-scale 'grand challenges' in full-blown workshop form, but appropriate as well for smaller scale issues.

- (b) Representatives from diverse technical disciplines, organizations, and development categories attended the workshop. There was substantial value in having a balance of discipline, category, and organization diversity at the same meeting. The different perspectives presented benefited all participants.

The use of modern information technology can expand the degree of diversity dramatically. Some of the concepts and group software proposed for network-centric peer review (Kostoff, 2001) can be easily adapted for use in innovation workshops. This would allow many more people, disciplines, and organizations to be represented, further enhancing the potential for cross-discipline infor-

mation transfer and resultant innovation and discovery.

- (c) Problem selection is crucial. The problem should be sufficiently general that many diverse disciplines can link to it. Given the choice of equally relevant problems, there is more potential for impact in selecting problem areas for which a large interdisciplinary community is not yet obvious.
- (d) It is important to select participants by the most objective processes available. A combination of expert recommendation and strategic topical maps based on computational linguistics, publications, and citations was used for the selection process, and this approach produced highly knowledgeable individuals. Incorporation of the full literature-based approach to innovation in the discipline or participant selection process could further enhance confidence that the most appropriate mix of disciplines and experts has been chosen.
- (e) It is extremely important that individuals selected for participation be world-class experts in their particular areas. There are relatively very few individuals producing the seminal works in any field (Kostoff, 1998, 1999b), and it is these people who should be central to any truly innovative workshops. However, in addition to these established experts, highly competent individuals new to the field should also be selected. One benefit of transcending selection of known experts is that fresh faces new to established communities appear. They can sometimes challenge established paradigms and offer concepts typically not advanced through panels based solely upon well-known, over-used panelists.
- (f) The e-mail component of the workshop is crucial. The gestation period between the input of promising ideas and their actual discussion at the workshop allows consideration of many different approaches and syntheses. It also saves substantial time at the workshop by clarifying confusing issues beforehand. However, in the first experience reported here, the stimulation of dialogue in the e-mail phase among most of the participants did not occur. The only participant to raise questions was the author, and this occurred only a few times. Nonetheless, in these instances, the dialogue was extremely valuable in clarifying issues and surfacing points of contention. In future workshops, it is strongly recommended that a few individuals representing different disciplines be asked to assume a role of facilitator, with the task of stimulating dialogue and raising questions during the workshop build-up phase.
- (g) All the attendees at the workshop were required to participate; there were no pure observers. This meant that they had to submit accomplishments and opportunities statements by e-mail. They also had to be prepared to lead discussions at the

workshop. This participation requirement was valuable in that each attendee obtained a sense of ownership in the workshop and its outcome. His/her contribution tended to be more substantive and creative than is typically the case at standard workshops. Those who contributed more in the e-mail phase tended to contribute more in the workshop phase. In addition, there was a sense of equality among participants when all were required to contribute, as opposed to an audience/performer environment with passive onlookers. The requirement that each attendee be an active participant translates directly into a limitation on audience size. However, it was concluded that the participation of a limited number of motivated and active individuals contributed more to the innovation process than the standard workshop of few active participants and many observers.

- (h) In general, there needs to be some incentive to motivate participation of world-class experts in these workshops. Unless they are able to envision some type of substantive impact resulting from their participation, either on larger science and technology issues or in their individual disciplines, they could be reluctant to invest the substantial amount of time required for serious participation. This, however, did not turn out to be a problem for the Autonomous Flying Systems workshop, apparently because of the limited size of the field and the interest of the participants in the type of workshop conducted.

In addition, during the workshop, participants did not appear to have reluctance in sharing new concepts. This is in stark contrast to some workshops the author has attended where novel ideas were held very closely. In the Autonomous Flying Systems workshop, there was a spirit of camaraderie and cooperation that pervaded the proceedings, and helped overcome the barriers to sharing. This spirit was fostered in the pre-meeting e-mail dialogue phase, and further nurtured during the meeting by having all attendees participate in the proceedings as equal partners.

Finally, interdisciplinary workshops are a powerful potential source of radically innovative ideas if conducted properly. There are three central requirements for success:

- (1) A problem of significant interest to the sponsoring organization must be selected;
- (2) An optimal mix of world-class experts appropriate to the problem must be chosen;
- (3) Conditions must be created which will motivate the participants to share their novel concepts.

The Autonomous Flying Systems workshop addressed these three requirements to a significant degree. A preliminary concept proposal emerged, and a copy of this proposal is available from the author.

Need for Literature/Workshop Synergy

Most organizations use some variant of a workshop/group dynamics approach for brainstorming or other proxies for stimulating innovation. The most current information is available, and real-time information exchange is unmatched. The attendees and participants in these groups tend to be focused subject experts representing a small fraction of the relevant technical community; there is rarely any complementary sophisticated literature analysis performed, and there are rarely experts present from strongly divergent disciplines. The outputs and discussion are highly subjective. The workshop techniques tend not to make full use of many of the information-technology advances of recent years. Probably most importantly, there are strong disincentives for the participants to reveal the latest innovations. What many workshops produce in practice are forums for 'selling' completed or near-completed research efforts.

A few performers, individuals or small groups of individuals, pursue the literature-based computer-assisted approach. This literature approach tends to be more sophisticated and technologically advanced than the workshop approach, and is more objective. It is more comprehensive, since it encompasses science and technology beyond the scope of any individual, or group of individuals, and can access data from many technical disciplines and many global sources. The source data are not as current as the workshop approach, due to the documentation time lag. However, with the advent of extensive on-line documentation, this time lag has been reduced considerably. One intrinsic limitation is that only a relatively modest amount of science and technology performed globally is documented and readily accessible to the wider user community (Kostoff, 2000c); obviously, any science and technology not documented cannot be accessed. The literature-based approach has not received widespread attention and may fall short of the interpretive and analytical strengths of the workshop approach. As a result, the literature approach is not widely used (e.g. Finn, 1998).

While either the workshop approach or the literature approach can be done independently to help stimulate discovery, they should be done in tandem to maximize the benefit provided by each. There is nothing on record to indicate that this joint approach to innovation has been implemented, or even considered. The Autonomous Flying Systems workshop described in this chapter has some elements of the combined approach. Some of the Database Tomography proximity analysis tools were used to identify the scope of related literatures, and the prolific individuals in these literatures. These individuals were then invited to the workshop. However, time constraints precluded using the full capabilities that the literature-based approach can offer.

In a joint workshop–literature effort, the literature approach would be included in the background pre-meeting phase of the workshop approach (as developed in Appendix 2). Accordingly, the literature study would provide:

- (1) Background reading for the workshop participants in related yet disparate science and technology areas;
- (2) Strategic maps of the broader science and technology literature as outlined in the DT papers referenced above;
- (3) Promising opportunities for innovation and discovery; and
- (4) The disparate science and technology disciplines from which the experts for the workshop could be drawn.

The hybrid literature–workshop approach would eliminate the limitations of each approach done separately. The right people from the right combination of disciplines could be identified by the literature-based approach and invited to the workshop. The literature-based analysis could structure the technical relationships, and provide an objective starting point for discussion. Network-centric peer review would allow linking, and fusing information from, large numbers of reviewers to incorporate more representative opinion sampling from the larger technical community. The only limitation not overcome is the disincentive for the participants, or document authors, to reveal their latest science and technology advancements.

There is extra time and cost involved with two approaches, and if responses were required with severe time limitations, then only one approach might prove feasible. For organizations that are serious about stimulating discovery and subsequent innovation, the additional time should not be a factor, given the potential high marginal benefits. Government could probably draw upon a more eclectic group than industry. Because of the competitive aspects, industry would probably rely more upon internal participants and contracted consultants, whereas government would draw upon individuals from many organizations.

Conclusions

The advent of large databases, and the parallel advances in computer hardware and software, provide the opportunity to augment and amplify traditional approaches of human creativity in generating discovery and subsequent innovation. This chapter has shown that multi-discipline structured workshops can enhance the science and technology discovery and subsequent innovation processes, and has shown that multi-discipline literature-based analyses can enhance the science and technology discovery process. The document has shown conceptually that the combination of

computer-enhanced literature-based analyses and multi-discipline structured workshops has the synergistic potential to dramatically improve the discovery and subsequent innovation process relative to the already strong capabilities available from each process separately. This literature–workshop synergy represents a potential major breakthrough for systematically identifying: (1) the most promising disciplines to be used in the workshop; (2) specific experts from these different disciplines; (3) candidate promising concepts that form the basis for discussion.

Appendix 1—Literature Approach

Overview

The theoretical basis of the literature approach mirrors the scientific process in many ways. Information from diverse literatures, with relevant interfaces, is examined. All information is first analyzed and then synthesized to produce discovery and innovation. Initial work (Gordon, 1996; Swanson, 1986) examined three variable classes or themes (c, b, a) in two literature categories (C and B) using two different approaches (start with ‘c’, determine ‘b’, then determine ‘a’; start with ‘c’ and ‘a’, then determine ‘b’).

The principal thematic variables determine a thematic literature. From the previous example, if Raynaud’s disease is the thematic variable specified initially, then the corresponding thematic literature might be all the papers in a given database that contain the phrase Raynaud’s disease. The remaining thematic variables and literatures are determined by applying different algorithms to the initial thematic literature and subsequent derived literatures. Again, from the previous example, an algorithm would be applied to the Raynaud’s disease thematic literature to determine the thematic variable blood viscosity, and a derived literature could then be determined as all the papers in a given database that contain the phrase ‘blood viscosity’.

The first approach in the initial reported work (Gordon, 1996; Swanson, 1986) could be viewed as addressing the question: What variables ‘a’ could influence variable ‘c’ through mechanisms ‘b’, or, in the example described above, What treatment factors ‘a’ could influence Raynaud’s disease ‘c’ through the different mechanisms ‘b’? This approach started with thematic variable ‘c’ (e.g. Raynaud’s disease), and used this variable to develop thematic literature C. Algorithms were applied to this thematic literature database to identify thematic variable ‘b’ values (b1, b2, etc., representing characteristics such as blood viscosity, blood flow, blood platelets, poor circulation, and others) closely linked to thematic variable ‘c’. Each value or theme of variable ‘b’ (b1, b2, etc.) was used to develop a thematic literature B1, B2, etc. Algorithms were applied to each of the thematic B literatures to identify thematic variable ‘a’ values (a1, a2, etc. representing characteristics such as fish oil, eicosapentaenoic acid, and others) closely linked to the specific thematic variable ‘b’ of each thematic B literature. Values of the thematic ‘a’ variables in each of the thematic B literatures not found in thematic literature C defined a subset of the thematic B

literatures that was disjoint from thematic literature C (e.g. the term ‘fish oil’ was not found in the Raynaud’s disease literature). These disjoint thematic ‘a’ variables and their associated thematic B literature subsets became candidates for discovery and innovation.

The other approach reported could be viewed as addressing the question: What are the mechanisms ‘b’ through which variable ‘a’ could impact variable ‘c’? This approach started with variables ‘c’ and ‘a’, and their associated literatures C and A, and identified variables ‘b’ that were linked to both variables ‘c’ and ‘a’. The same types of algorithms as in the first approach were used to identify closely linked variables, and the requirement for disjointness between literatures C and A was used as a basis for discovery.

From the experience of these two approaches, it becomes clear that the independent and dependent variables chosen, and the algorithmic approach selected, depend on the question being asked. Further examination shows that other approaches beyond these two are possible to answer other questions. The present chapter examines seven approaches to generate innovation and discovery that are structured to answer seven different questions, and shows how the algorithms and techniques developed in Database Tomography are used in these approaches.

Specific Approaches

The following discussion will be limited to scenarios of three variables ‘a’, ‘b’, ‘c’, and two literatures. In future studies, more complex cases could be candidates for analysis and experimentation.

For the simple two literature/three variable case, seven separate generic cases are possible, where the variables specified can be viewed as ‘independent’ and the variables determined can be viewed as ‘dependent’:

- (1) specify ‘a’, determine ‘b’ and ‘c’;
- (2) specify ‘c’, determine ‘a’ and ‘b’;
- (3) specify ‘b’, determine ‘a’ and ‘c’;
- (4) specify ‘a’ and ‘c’, determine ‘b’;
- (5) specify ‘a’ and ‘b’, determine ‘c’;
- (6) specify ‘b’ and ‘c’, determine ‘a’;
- (7) specify ‘a’ and ‘b’ and ‘c’, validate linkage existence.

Cases (1), (2), and (3) are the most open-ended and least constrained. In each case, one variable is specified, and the other two are determined using the DT algorithms, the condition of disjointness and, most importantly, expert judgement. Cases (4), (5), and (6) are more constrained, since two variables are specified, and the third is determined using similar processes to the above. Case (7) is fully constrained, and its purpose is to ascertain literature support for validation of a hypothetical relation between specified values of the three variables. Cases (4) and (5) are subsets of case (1); cases (4) and (6) are subsets of case (2); cases (5)

and (6) are subsets of case (3); case (7) is a subset of cases (1) through (6). The solution mechanics for each of these seven cases will now be outlined.

Opportunity Driven

This first case addresses the question: What are the potential variable 'c' impacts that could result from variable 'a', and what are the variable 'b' mechanisms through which these impacts occur? One specific variant of this question is of particular interest and importance to the science and technology community: What are the potential impacts on research, development, systems, and operations that could result from research on a given topic?

If the generic question of this first case is applied to the above example for the case where variable 'a' is 'fish oil' only, it could be phrased as: What are the potential impacts or benefits (positive or negative) resulting from fish oil that would not be obvious from examining the fish oil literature alone? This is an open-ended question, and places no restrictions on the mechanisms 'b' or the types of impact 'c'. The first case is represented schematically as:

$$a \rightarrow b \rightarrow c.$$

Here, 'a' is the independent variable, and 'b' and 'c' are the dependent variables that result from the solution process. The operational sequence is to start with the variable 'a' and generate a literature A. Again following the above example and using the abbreviations FO (fish oil), BV (blood viscosity), and RD (Raynaud's disease), this means that the process would start by identifying the FO literature (call this A1). Many approaches could be used to define this literature; the approach recommended here is the one used in recent Database Tomography studies (Kostoff, 2000a, 2000b) for defining literatures. As an example of one literature definition approach, the iterative Simulated Nucleation method (Kostoff, 1997b) would be used to identify all the papers in the Science Citation Index which contained FO (and other related terms in the query) in the title, keywords, and abstract fields. This collection of papers would constitute the FO literature.

The next step in the process is to identify the variables 'b' (b1, b2, ...) linked closely to variable 'a1', and then identify the literatures B associated with variable 'b' (B1, B2, ... the BV literatures). For this step, the proximity analysis method used in the recent Database Tomography studies (or other co-occurrence techniques) would be employed. For a journal-based database, this method conceptually identifies phrases in paper titles or abstracts or main texts physically located near the term of interest. As an example, if the term of interest in a given database is Raynaud's disease, then the proximity analysis method would provide a list of all phrases in close physical proximity to the term Raynaud's disease for all occurrences of this term in the text. The proximity analysis approach of Database

Tomography is based on the experimental findings that phrases within a semantic boundary (same sentence, paragraph, etc.) located physically close to the term of interest are contextually and conceptually close to the term of interest. Continuing the above example, this step uses the proximity analysis of Database Tomography to identify phrases in the FO literature physically close to the term FO, such as 'b1', 'b2', etc.

For each of these identified phrases 'b1', 'b2', etc., a literature (B1, B2, ...) is established by querying the SCI. The next step is, for each of these B literatures, to identify the linked variables 'c' (c1, c2, ...) The process used to identify the variables 'b1', 'b2', etc. linked to variable 'a1' is repeated to obtain the variables 'c1', 'c2', etc. linked to each value of variable 'b'. The subsets of the B literatures which are disjoint from literature A1 (e.g. the B literatures which do not contain the term FO) must then be identified, and the variables 'c' (and their associated linking mechanisms 'b' to variable 'a1') within these disjoint B literature subsets then become the candidates for discovery and innovation.

It is obvious that the process can easily mushroom out of control unless stringent limiting constraints are placed on the number of B literatures and 'c' variables selected. For example, suppose that three 'b' variables 'b1', 'b2', 'b3' (and their associated three B literatures (B1, B2, B3) are identified as closely linked to FO. Suppose also that each of these three 'b' variables is closely linked to five 'c' variables. Then four literature searches are required (A1, B1, B2, B3), and 15 abc linked pathways must be examined for disjointness and discovery, according to the following:

$$\begin{aligned} a1 \rightarrow b1 \rightarrow c11; a1 \rightarrow b1 \rightarrow c12; a1 \rightarrow b1 \rightarrow c13; \\ a1 \rightarrow b1 \rightarrow c14; a1 \rightarrow b1 \rightarrow c15; \\ a1 \rightarrow b2 \rightarrow c21; a1 \rightarrow b2 \rightarrow c22; a1 \rightarrow b2 \rightarrow c23; \\ a1 \rightarrow b2 \rightarrow c24; a1 \rightarrow b2 \rightarrow c25; \\ a1 \rightarrow b3 \rightarrow c31; a1 \rightarrow b3 \rightarrow c32; a1 \rightarrow b3 \rightarrow c33; \\ a1 \rightarrow b3 \rightarrow c34; a1 \rightarrow b3 \rightarrow c35 \end{aligned}$$

In reality, there will be hundreds, if not thousands, of candidate 'b' and 'c' variables. However, there are different ways by which the 'b' and 'c' variables can be sharply limited in number. First, the analysts performing the study would eliminate all non-technical content phrases that passed through the trivial word filter in the Database Tomography algorithm. Second, the numerical indices for each phrase generated by the Database Tomography proximity algorithm would be used as one figure of merit for pre-selection of key phrases. Third, those 'c' variables that reappear in different abc pathways would have a higher priority for selection. Fourth, analyst judgement would be applied to weight the potential value of the different abc pathways in computing figures of merit.

The literature searches and proximity analyses are fairly straightforward, and have been refined in the Database Tomography process. The main intellectual

efforts must be focused on prioritizing and reducing the number of linked variables or literatures to be examined, and interpreting the relationships among the final disjoint literatures to generate potential discovery relationships.

Requirements Driven

This second case addresses the question: What are the variables 'a' that could impact variable 'c', and what are the variable 'b' mechanisms by which these impacts are produced? Applied to the above example for the case where 'c' is Raynaud's disease only, it could be phrased as: What are the factors and their associated mechanisms that could impact the course of Raynaud's disease that would not be obvious from examining the Raynaud's disease literature alone? This second case is represented schematically as:

$$a \leftarrow b \leftarrow c$$

Here, 'c' is the independent variable, and 'b' and 'a' become the dependent variables. The operational sequence is to start with variable 'c', and generate a literature C. Again following the above example, this means that the process would start by identifying the RD literature (call this C1). The same literature definition process as in the first case would be used. The next step would be to identify the linked variables 'b' (b1, b2, etc.) to variable 'c1', and then their associated literatures B (B1, B2, the BV literatures). For this step, the proximity analysis method used in the recent DT studies would be employed again as in the first case. Continuing the above example, this step uses the proximity analysis of DT to identify phrases in the RD literature physically close to the term RD, such as 'b1', 'b2', etc.

For each of these identified phrases b1, b2, etc. a literature (B1, B2, etc.) is established by querying the SCI. The next step is, for each of these B literatures, to identify the variables 'a' (a1, a2, etc.) linked to variable 'b'. The process used to identify the variables 'b1', 'b2', etc. linked to variable 'c1' is repeated to obtain the variables 'a1', 'a2', etc. linked to each value of variable 'b'. The subsets of the B literatures that are disjoint from literature C1 (e.g. the B literatures which do not contain the term RD) must then be identified, and the variables 'a' within these disjoint B literature subsets (and their associated linking mechanisms 'b' to variable 'c1') then become candidates for discovery and subsequent innovation. The same stringent limits on variables and literatures used in the first case are applicable here.

Mechanism Driven

The third case addresses the question: For a given mechanism 'b', what are the variables 'a' that could impact the variables 'c'? Applied to the above example

for the case where 'b' is blood viscosity, it could be phrased as: What combinations of variables that could effect a change in the blood viscosity mechanism and could be impacted by a change in the blood viscosity mechanism are candidates for discovery that were not obvious from examining only the blood viscosity literature? The third case is represented schematically as:

$$a \leftarrow b \rightarrow c$$

Here, 'b' is the independent variable, and 'a' and 'c' are dependent variables. The operational sequence starts with variable 'b' and generates a literature B. Again following the above example, this means that the process would start by identifying and generating the BV literature (call this B1). The same literature definition and generation process as in the first case would be used. The next step would be to identify the variables 'a' (a1, a2, etc.) and 'c' (c1, c2, etc.) linked to variable 'b1', and then their associated literatures A (A1, A2, the FO literatures) and C (C1, C2, the RD literatures). For this step, the proximity analysis method used in the first two cases would be employed for the BV literature (B1). Continuing the above example, this step uses the proximity analysis of DT to identify phrases in the BV literature physically close to the term BV, such as 'a1', 'a2', etc. (FO literature) and 'c1', 'c2', etc. (RD literature). However, an arbitrary step is required at this point, since the proximity analysis only provides the aggregate of the linked variables 'a' and 'c'. The analyst is required to divide the aggregate linked variables obtained from the proximity analysis into two groups: 'a' variables and 'c' variables. In the above example, the proximity analysis would generate the linked variables such as fish oil and Raynaud's disease. The analyst would be required to specify two categorizations for these variables, such as 'dietary factors' for the 'a' variables and 'diseases' for the 'c' variables. This step will depend heavily on the analyst's expertise in the technical area and ability to create taxonomies.

The next step is to identify/generate A and C literatures using the approach described above. The final step is to identify the subsets of A literatures and C literatures that are disjoint. Each group of articles from the A literature and the C literature that contains a 'b1' variable is considered to be a linked group. The subsets of these literatures that are linked through the common 'b1' variable and that are disjoint (i.e. the C literature does not contain the 'a' variable and the A literature does not contain the 'c' variable) must then be identified. The variables 'a' and 'c' within these disjoint A and C literature subsets linked through the 'b1' variable then become the candidates for discovery and subsequent innovation. The same stringent limits on variables and literatures used in the first approach are applicable here.

Opportunity-Requirements Driven

This fourth case addresses the question: What are the mechanisms 'b' through which variable 'a' could impact variable 'c'? Applied to the above example for the case where 'c' is Raynaud's disease only, and 'a' is fish oil only, it could be phrased as: What are the mechanisms through which fish oil could impact Raynaud's disease that would not be obvious from examining only the Raynaud's disease literature or the fish oil literature? The fourth case is represented schematically as:

$$a \rightarrow b \leftarrow c$$

Here, variables 'a' and 'c' are independent, and variable 'b' is the dependent variable. The operational sequence is to start with the variable 'c', and generate a literature C, and with variable 'a', and generate a literature A. Again following the above example, this means that the process would start by generating the RD literature (call this C1) and the FO literature (call this A1). The same literature definition and generation process as in the first case would be used. The next step would be to identify the linked variables 'b', and then their associated literatures B for both the A1 literature and the C1 literature. For this step, the proximity analysis method used in the first two approaches would be employed, for the FO literature (A1) and the RD literature (C1). Continuing the above example, this step uses the proximity analysis of DT to identify phrases in the RD literature physically close to the term RD, such as 'b1', 'b2', etc. and to identify phrases in the FO literature physically close to the term FO, such as b51, b52, etc. The next step is to identify the subsets of the A1 literature and C1 literature that are linked. Each group of articles from the A1 literature and the C1 literature that contains a 'b' variable is considered to be a linked group. The subsets of these literatures linked through the common 'b' variables that are disjoint (i.e. the C1 sub-literature that does not contain the 'a1' variable and the A1 sub-literature that does not contain the 'c1' variable) must then be identified, and the variables 'b' within these disjoint A1 and C1 literature subsets then become the candidates for discovery and subsequent innovation. The same stringent limits on variables and literatures used in the first case are applicable here.

Opportunity-Mechanism Driven

The fifth case addresses the question: What are the variables 'c' which could be impacted by variable 'a' through mechanism(s) 'b'? While the schematic shown for this case is identical to that of case 1, the two schematics should be interpreted differently. In case 1, the intermediate mechanism(s) 'b' are not specified beforehand, but are a result of the solution process. In the present case, these 'b' mechanism(s) are specified beforehand. Applied to the above example for the case where 'b' is blood viscosity only, and 'a' is fish oil

only, the question in this case could be phrased as: What abnormalities could be influenced from the impact of fish oil on blood viscosity that would not be obvious from examining only the abnormality's literature or the fish oil literature? The fifth case is represented schematically as:

$$a \rightarrow b \rightarrow c$$

Here, 'a' and 'b' are the independent variables, and 'c' is the dependent variable. The operational sequence is to start with the variable 'a', and generate a literature A, and with variable 'b', generate a literature B. Again following the above example, this means that the process would start by generating the FO literature (A1) and the BV literature (B1). The same literature definition and generation process as in the first case would be used. The next step would be to identify the linked variables 'c', and then their associated literatures C (the collection of RD literatures) for the B1 literature. For this step, the proximity analysis method used in the previous cases would be employed for the B1 literature only. Continuing as before, this step uses the proximity analysis of DT to identify phrases in the BV literature physically close to the term BV, such as 'c1', 'c2', etc. The resulting C literatures are automatically linked to the A1 literature through the linking variable 'b1'. The 'c' variables which are disjoint to the A1 literature (i.e. the C sub-literature that does not contain the 'a1' variable and the A1 literature does not contain the 'c' variables) must be identified, and become the candidates for discovery and subsequent innovation. The same stringent limits on variables and literatures used in the first case are applicable here.

Requirements-Mechanism Driven

The sixth case addresses the question: What are the variables 'a' that could impact variable 'c' through mechanism 'b'? Applied to the above example for the case where 'b' is blood viscosity only, and 'a' is fish oil only, it could be phrased as: What factors could impact Raynaud's disease by impacting blood viscosity that would not be obvious from examining only the factors' literature or the Raynaud's disease literature? The sixth approach is represented schematically as:

$$a \leftarrow b \leftarrow c$$

Here, 'b' and 'c' are the independent variables, and 'a' is the dependent variable. The operational sequence is to start with the variable 'c', and generate a literature C, and with variable 'b', and generate a literature B. Again, this means that the process would start by identifying and generating the RD literature (C1) and the BV literature (B1). The same literature definition and generation process as in the first case would be used. The next step would be to identify the linked row of variables 'a' (a1, a2, etc.), and then their associated literatures A (the FO literatures) for the B1 literature. For this step, the proximity analysis method used in the

previous cases would be employed, for the B1 literature only. Continuing as before, this step uses the proximity analysis of DT to identify phrases in the BV literature physically close to the term BV, such as 'a1', 'a2', etc. The resulting A literatures are automatically linked to the C1 literature through the linking variable 'b1'. The 'a' variables which are disjoint to the C1 literature (i.e. the A sub-literature does not contain the 'c1' variable and the C1 literature does not contain the 'a' variables) must be identified, and become the candidates for discovery and subsequent innovation. The same stringent limits on variables and literatures used in the first case are applicable here.

Opportunity-Mechanism-Requirements Validation

The seventh case addresses the question: Does the literature support the possibility that variable 'a' could impact variable 'c' through mechanism 'b'? Applied to the above example for the case where 'a' is fish oil only, 'b' is blood viscosity only, and 'c' is Raynaud's disease only, it could be phrased as: Does the literature support the possibility that fish oil could impact Raynaud's Disease by altering blood viscosity in a way that would not be obvious from examining only the fish oil literature or the Raynaud's disease literature? The seventh approach is represented schematically as:

$$a \leftrightarrow b \leftrightarrow c$$

Here, 'a' and 'b' and 'c' are independent variables. The operational sequence could start with either 'a' or 'b' or 'c'. For the present discussion, the operational sequence starts with the variable 'b', and generates literature B. Again following the above example, this means that the process would start by identifying and generating the BV literature (B1). The same literature generation process as in the first approach would be used. The next step would be to extract the B1 sub-literatures which contain the variables 'a1' (literature A1) and 'c1' (literature C1).

The final step is to validate the existence of disjoint A1 and C1 sub-literatures (i.e. A1 sub-literature that does not contain the 'c1' variable and a C1 literature that does not contain the 'a1' variable). The 'a1'-'b1'-'c1' sequence then becomes a candidate for discovery and subsequent innovation. The same stringent limits on variables and literatures used in the first approach are applicable here.

Appendix 2: Crossing the Bridge: Interdisciplinary Workshops for Innovation

Background

The Office of Naval Research established a series of workshops in 1997 aimed at promoting innovation while also enhancing organization, category, and discipline diversity components. The focus of the first novel workshop founded on this plan was 'Autonomous Flying Systems', an area of perceived long-term

interest not only to the Navy and Department of Defense, but also to the National Aeronautics and Space Administration and other governmental and industrial organizations. The process employed was designed, starting with a clean slate, and was intended for application to very significant technical challenges. The present appendix further describes the process that was used to identify the technical theme of the workshop, select the participants, and conduct all three phases of the total workshop.

Workshop Theme Identification

It was decided that the initial workshop theme should: (1) focus on problems related to the main science and technology emphasis area of the author's home organization, Strike Technology; and (2) help establish the most supportive environment for innovation. The problem selected should be focused and understandable, and it should have a generic technical base amenable to soliciting people from many different disciplines. The topic finally selected was autonomous control of unmanned air vehicles, including takeoff and landing from limited areas on smaller Navy ships. It was apparent that the underlying science and technology permeated many different disciplines, including aerodynamics, controls, structures, communications, guidance, navigation, propulsion, sensing, and systems integration. Also, the naval applications for some aspects of this problem were sufficiently unique that probably not a great deal of work had been done in this area. Subsequent literature analyses validated this assumption.

Present naval air systems are either manned (most aircraft) or tele-operated, semi-autonomous (weapons and some aircraft). The weapons are a mix ranging from 'dumb' bombs and shells to 'smart' missiles. The future trend is toward 'smart' autonomous or semi-autonomous aircraft and weapons. Since a major role of the Office of Naval Research is to proactively address the technology that will influence future naval forces, it seemed natural to examine science and technology roadblocks on the path to unmanned autonomous 'smart' flight systems. Consequently, the focus of the initial workshop was defined as identification of the fundamental operational principles of autonomous flying systems over a fairly wide range of flight environments. In particular, the workshop was aimed at examining what had been learned about autonomous or semiautonomous operation from the animal (mainly flying) kingdom and from other unmanned autonomous/semiautonomous tele-operated systems such as autonomous underwater vehicles and locomoted robots. Animals are now being studied as integrated systems by scientists on the forefront of biological research. The issues of aerodynamics, flight mechanics, dynamic reconfiguration, materials, control, neuro-sciences, and locomotion are not being studied as separate disciplines by these scientists, but

rather are being studied in parallel in the same animal system and in their relation to the function and mission of the animal system. While this integrative biological research is in its infancy, and results are only starting to emerge, the time seemed appropriate for assembling these diverse groups and exploiting their synergy. Not only could there be benefit to the Navy from such cross-discipline interaction, but benefit could be possible for each of the contributing disciplines as well.

A major thrust of the workshop was projected to be identification of the autonomous operational principles for each unique system and the relation of these principles to mission and function, then extraction of the generic operational principles that underlay all the systems, both biological and man-made. It was hoped that the cross-fertilization of disciplines would be able to further elucidate and clarify the more important generic concepts, and then provide insight that could be utilized to enhance the autonomous operation of naval flying systems.

Participant Selection

Once the theme of the workshop was established, a sub-theme taxonomy was developed to focus the agenda and to identify workshop participants. A dual approach was followed to generate the taxonomy.

Discussions were held with agency experts on the generic theme concerning the taxonomy structure. In parallel, the Science Citation Index was queried for papers related to the generic theme. Both bibliometric and computational linguistics analyses of these papers were performed to provide strategic maps of the topical area, identifying key performers, journals, institutions, and their relations to the technical themes and sub-themes of the workshop. A taxonomy was constructed based on these strategic maps. (For a description of how the bibliometric and computational analyses are combined to generate strategic maps, see Kostoff (1998, 1999)).

Both of these taxonomy sources, in-house experts and the Science Citation Index, then provided initial candidates for participation in the workshop. These candidates were contacted, and asked to suggest additional candidates. This procedure continued until a large pool of potential candidates was established. Three main selection criteria for workshop participants were established:

- (1) Multiple recommendations;
- (2) Significant publications in the field; and
- (3) Literature citations.

These three criteria were tempered with judgment to insure that bright young individuals, who had not yet established a track record, were not excluded from the pool, and that the panel as a whole had the correct level of discipline, category, and organization balance. In addition, a guideline was established that all workshop attendees would be active participants, so the number

of attendees was limited to facilitate discussion and interactions.

All these constraints, guidelines, and selection criteria were used to arrive at the final panel size and structure. The result was a panel of slightly more than 20 people representing a mix of disciplines that included biologists (experts in bird, bat, frog, fish, or insect studies), robotics, artificial intelligence, controls, autonomous aircraft, fluid dynamics, sensors, neuroscience, cognitive science, autonomous underwater vehicles, aerodynamics, propulsion, and avionics.

Overview of Workshop Process Steps

Workshop Buildup

The buildup period for the workshop in question started about two months before the meeting. Specific guidance for the conduct of the workshop was sent to the participants by e-mail, including a statement of the naval technical problems to be addressed. The technical component of the buildup phase was then conducted by e-mail.

The main purpose of this buildup phase technical component was to have each participant generate new ideas from his/her discipline for all other participants to consider. The other participants could then dialogue by e-mail to clarify/modify/embellish these ideas. At a minimum, even if no dialogue resulted, there would be a gestation period of about two months for each participant to absorb these concepts from other disciplines. Specifically, each participant was requested to:

- Submit half a dozen leading-edge capabilities or accomplishments in his/her discipline(s) that could potentially impact the naval technical problems;
- Identify several leading-edge capabilities or accomplishments projected in his/her discipline(s) over the next decade that could potentially influence the naval technical problems; and
- Submit a few leading-edge capabilities or accomplishments in his/her discipline(s) whose impact on the naval technical problems was not obvious to him/her, but might be obvious to someone else.

The participants were free to comment on potential relations among any of the capabilities, accomplishments, or combinations of capabilities and accomplishments, and any of the naval technical problems, or combinations of problems. All of the comments received were then sent to all the participants. This exercise helped stimulate the thinking of the participants, and provided a documented record of the process. One of the functions of the participants from the author's organization was to facilitate and stimulate dialogue by raising questions and issues on the submitted information.

If any of the participants saw a capability or accomplishment from another participant that could

impact a problem in his/her discipline, but not impact a naval technical problem, then the two participants were free to dialogue together without informing all the participants. However, these two participants engaged in independent dialogue were requested to keep a record of their exchange for possible inclusion in the final workshop report as potential discovery. This would cover the real possibility of discovery occurring in topics other than the one targeted.

Workshop Meeting

As a result of the ideas presented during the buildup phase, it appeared that the seeds existed for a new science and technology program on Autonomous Flying Systems. Therefore, an agenda was sent to the participants with further guidance to address promising science and technology opportunities at the workshop, that would serve as the foundation of such a program. Specifically, the participants were asked to address the following issues at the workshop:

- What are the present leading-edge capabilities in your discipline?
- What are the desired future capabilities in your discipline?
- What are the leading research opportunities in your discipline and what additional capabilities could they provide if successful?
- What is the level of risk of these opportunities successfully achieving their targets?
- How would these potentially enhanced capabilities contribute to, or translate into, improved understanding and/or operation of autonomous flying systems?

The meeting occurred on 10–11 December 1997 at ONR. Since some of the leading-edge capabilities and potential accomplishments appeared to have applicability to naval technical problems (identified during the

e-mail buildup period), the proponent for the capability or accomplishment item took the lead in fleshing out his/her ideas and leading the discussion at the meeting. As a result, the workshop meeting tended to evolve into full panel discussions on each of these potential capabilities.

There were two rounds of discussion at the workshop. The first round consisted of presentations and discussions by each proponent. The second round of the workshop involved each participant identifying his/her leading promising research opportunities.

Workshop Cleanup

The participants were requested to provide any additional narrative information that added to or modified their ideas as a result of the workshop experience. The outcomes of the workshop included both the tangible and intangible.

Three immediate tangible outcomes were projected:

- (1) A concept proposal for a science and technology program focused on Autonomous Flying Systems would be generated;
- (2) Technical papers may be submitted to leading science journals based on innovations identified; and
- (3) One or more papers on the complete workshop experience might be submitted to leading science journals.

In addition to developing specific topics, it was anticipated that new, un-exploited ideas in interdisciplinary research and development might surface during contact between panelists. These novel subjects might form the basis of additional workshops. In addition, extensive lessons were learned as a result of the workshop process. These lessons were summarized in Section 1b.

Developing Innovative Ideas Through High Intellectual and Creative Educational Multimedia Technologies

Larisa V. Shavinina¹ and Evgueni A. Ponomarev²

¹ *Département des Sciences Administratives, Université du Québec en Outaouais, Canada*

² *Department of Physics, University of Ottawa, Canada*

Abstract: This chapter presents high intellectual and creative educational multimedia technologies (HICEMTs) as one of the possible methods to facilitate the development of innovative ideas in people. HICEMTs will constitute one of the innovative breakthroughs in science and technology of the 21st century and will lead to a new wave of innovations in psychology, education, and organizational learning. HICEMTs appear at the intersection of many subdisciplines of psychology, including general, cognitive, developmental, educational, personality, media, cyber, and applied psychology, education, and multimedia. The general and specific nature of HICEMTs is considered. The importance of HICEMTs is discussed from a technological, economic, societal, educational, and psychological perspective.

Keywords: Innovation; Educational multimedia; Technology; HICEMTs; Innovative ideas.

Introduction

Innovation begins with new ideas. Creative ideas are the foundation on which innovation is built (Amabile, 1988, 1996). Reis & Renzulli (this volume), Clapham (this volume), Kostoff (this volume), R. Root-Bernstein & M. Root-Bernstein (this volume), Smith (this volume) discuss a wide range of methods for enhancing an individual's ability to generate new ideas. Our chapter explores the role of contemporary educational multimedia technologies, especially high intellectual and creative educational multimedia technologies (HICEMTs), in the development of human abilities to produce new ideas.

Psychoeducational multimedia technologies (PMTs) and HICEMTs were first introduced in 1997 (Shavinina, 1997a). PMTs are multimedia technologies that base their five-part educational essence (discussed later in this chapter) on fundamental psychological processes and phenomena (Shavinina, 1998a). HICEMTs

constitute a special type of PMT whose general content is elaborated in accordance with underlying psychological mechanisms and states and whose special content is developed, structured, presented, and delivered according to the key principles of an individual's intellectual functioning and creative performance (Shavinina, 2000). The term *high* in HICEMTs refers to a significant saturation of the special content of these technologies through educational materials directed toward the actualization and development of human intellectual potential and creative abilities.

HICEMTs emerge at the crossroads of many subfields of psychology (e.g. general, cognitive, developmental, educational, personality, media, cyber, and applied), education, and multimedia technology. In describing HICEMTs, this article proceeds as follows. First, it seems expedient to discuss briefly the impact of information technology on human beings that sets in motion the emergence of HICEMTs. Second, today's

educational multimedia applications¹ available on the global educational multimedia market are analyzed from a psychological viewpoint to demonstrate how they contribute to the appearance of HICEMTs. Third, the importance of HICEMTs for contemporary people is described. Finally, the general and specific nature of HICEMTs is considered.

Psychological View of an Information-Based Society

Extraordinarily rapid information development is a key feature of the contemporary era. Extremely fast growth of information technology has an enormous impact on people, resulting in significant changes in everyday life and determining its qualitatively new level. In the professional, educational, public, and home settings, we are faced with the strong presence of new information and communication technologies. No one is surprised by individuals' daily use of the Internet or compact discs (CDs). Cyberspace is becoming an integral part of individuals' inner, psychological world.

¹ Educational multimedia applications refer to on-line (e.g. Internet) and off-line (e.g. CD-ROMs) multimedia products and services devoted to learning, teaching, and training. In turn, 'multimedia' refers to a new generation of communication tools that can draw on a full range of audio-visual resources, ranging from text and data to sound and pictures, and that store and process all of these diverse data in a single integrated delivery system. A general multimedia application thus delivers an integrated presentation that combines at least three of the following: (a) text (including notes, captions, subtitles, and resources such as tables of contents, indexes, dictionaries, and help facilities); (b) data (such as tables, charts, graphs, spreadsheets, statistics, and raw data of various kinds); (c) audio (including speech, music, atmospheric background noise, and sound effects); (d) graphics (often ranging from traditional media such as drawings, prints, maps and posters to images processed or created entirely within a computer); (e) photographic images from negatives, slides, prints, or even digital cameras (which record photographic images directly as computer graphics); (f) animation (whether recorded on film or video or created with a computer); and (g) moving pictures (specifically, digital video either converted from analogue film and video or created entirely within a computer).

Educational multimedia applications are almost completely unexplored from a psychological point of view, because multimedia tools in their modern forms (i.e. CD-ROMs and Internet-based programs) have appeared only during the last 5–6 years. It should be emphasized that this chapter deals only with multimedia, not computer-assisted instruction (CAI) or computer-based training (CBT). Much has been written concerning CAI and CBT over the past few years, provoked by the active entry of computers into educational and professional settings. Today, it is multimedia technology that is attracting attention, and it holds great promise in education in general and in organizational learning in particular. Of course, CAI–CBT and contemporary educational multimedia have some common properties (Honour & Evans, 1997).

Society's saturation by an unparalleled quantity of hardware, software, and applications has reached its threshold level, leading people to realize that we are actually living in an information society. Today's society means cybersociety. Everyday news about tremendous discoveries and amazing inventions in the area of information and communication technologies leaves no doubt concerning a novel reality of our life: We are living in an information era (Shavinina, 1998a).

The present state of information technology and its even more promising future (Lan & Gemmill, 2000) lead to an understanding of the unique challenges it presents. For example, global economic competition is increasingly harsh, and companies must rapidly bring innovative products and services to the global market. To survive and prosper, companies desperately need intellectual and creative employees whose novel ideas are, to a certain extent, a guarantee of companies' existence and success. Consequently, modern society desperately requires highly able citizens who can bring innovative solutions to its current challenges and at the same time produce new ideas for its ongoing advancement. The distinguishing characteristic of the new millennium is, consequently, a need for creative and intellectual people for further social progress (Shavinina, 1997a, 1997b).

Of course, there are courses on creative thinking and intelligence training, and creativity consultants actively travel around the world, teaching strategies for increasing people's abilities to overcome the everyday problems they face in their work and daily life. However, creativity and intelligence training are still available only to a small percentage of people,² and current textbooks and instruction manuals do not change this situation. This is especially problematic for

² Creativity and intelligence training are currently available only to a small percentage of people, mainly for economic reasons. The services of creativity consultants conducting such training are expensive, and, for the most part, only affluent companies can use these consultants. The available textbooks do not change this situation at all, mainly for psychological reasons. They do not provide a sufficient level of intrinsic motivation to follow their content. This is particularly important for children, who often need a teacher or parent to guide and stimulate their learning through textbooks. Only multimedia technology allows people to develop their intellectual and creative abilities while being guided and motivated by means of educational multimedia technology itself. This is possible because of the accessibility of any website practically from any place on Earth and at any time. Distinguishing features of multimedia technology, presenting a combination of text, sound, graphics, and animation, provide a higher level of stimulation than traditional textbooks. Conventional textbooks and learning manuals are low in cost, and this is their advantage. However, as more and more of today's schools, universities, and companies are connecting to the Web, many Internet-based programs are becoming free for students and employees.

children, who often need someone (i.e. parents, teachers, or other caregivers) to monitor and encourage them as they proceed through learning manuals. The appearance of multimedia technology gives people an exceptional opportunity to develop their intellectual and creative potential through being guided and stimulated by the means of educational multimedia technology itself (i.e. through specific multimedia effects and educational contents). A significant problem is how to elaborate the most successful educational multimedia technologies that could productively develop human abilities. This chapter represents one such attempt.

Certainly, the idea of developing an individual's abilities through computer technology is not a new one, having been discussed in the psychological literature (Bowen, Shore & Cartwright, 1993; Olson, 1986; Salomon, Perkins & Globerson, 1991). The novelty resides in the suggestion of developing an individual's intellectual and creative resources through multimedia technology. However, in adopting from educational content alone, multimedia technology, with its multiple effects and advantages, provides almost nothing for the development of human creative and intellectual potential. What is particularly needed is a well-developed variety of educational contents that, together with multimedia, form 'educational multimedia technology' (Shavinina, 1998a).

Furthermore, if today intelligence and creativity guarantee personal and economic success, at least to some extent, then the contemporary educational system across all of its levels should provide productive teaching and learning to increase people's creative and intellectual resources in direct accordance with the requirements of an information society. This is particularly important for children, whose adulthood will take place in a cyber environment entirely different from that of the present. Children must be prepared for this environment of the future. This means that, even today, they should be taught through radically new educational programs that will correspond to the needs of the 21st century information era (Olson, 1986; Salomon et al., 1991).

It is interesting to note that national governments realize this need for more productive teaching and learning models (Shavinina, 1997b). This expresses itself, for instance, in the rising attention of national governments to the development of citizens' intellectual and creative potential. For example, the following demonstrate the concern of the European Union about the future life of Europeans, which is predetermined by the human ability to innovate: (a) a white paper published on teaching and learning in a cognitive society ('Teaching and Learning', 1995); (b) the 'Education in the Information Society' initiative (1996); and (c) a resolution on educational multimedia prepared by the Council of the Ministers of Education of the European countries ('Educational Multimedia', 1996). The common view across these documents was

expressed by Olli-Pekka Heinonen, Finland's minister of education: "We want creative citizens, who can take responsibilities and who are able to solve problems that do not yet exist today" (Heinonen, 1996). The next step of the European Union in the face of growing challenges of cybersociety was establishment of its Educational Multimedia Task Force. The aim of the task force is to encourage and stimulate the development of high-quality learning, teaching, and training multimedia resources and to raise awareness of the educational potential of multimedia applications in teaching and learning through financing the most promising projects. Canada, in attempting to increase its citizens' ability to innovate, has established such foundations and initiatives as the Canadian Innovation Foundation (federal initiative) and the Innovators Alliance (Ontario provincial government initiative).

Indeed, it seems that today's educational multimedia technology holds the most promise for the development of human intellectual and creative resources. But multimedia opportunities that will considerably increase people's abilities are not yet well understood. More than 16 years ago, David Olson (1986) underlined that "the potential impact of computers . . . lies, in fact, on coupling the resources of the mind with the resources of the computer" (p. 355). This is generally true, but the idea is far from fully realized. Today multimedia applications—through the simultaneous use of audio, text, multicolor images, graphics, movies, and so on—provide an excellent opportunity for the development of educational technologies going far beyond computer-assisted instruction or computer-based training, existing educational software, and traditional curricula. For example, productive training of creative thinking cannot be formulated and delivered only in verbal-written form; it also requires visual imagery and oral expressions, feedback and user-friendly means, and so on. Such full-scale delivery can be obtained through multimedia technology. With the appearance and advanced development of such technology, people are in a unique position to elaborate and 'place' almost anything into a computer format. As a result, multimedia technology may significantly influence the development of an individual's mind. But the contemporary educational multimedia technologies existing on the global market are far from reaching this goal. An understanding of this issue requires an understanding of the current state of educational multimedia products. However, before proceeding with this topic, we consider existing approaches to instructional technology.

Instructional Technology Innovations

It seems appropriate to distinguish the following approaches in the large and rapidly growing body of literature on instructional technology innovations and their pedagogical outcomes: computer-mediated communication (CMC), virtual classrooms, simulation

training, and intelligent tutoring systems. One of the current tendencies in the field is to combine some of these approaches in developing educational multimedia technologies. For example, Oren, Nachmias, Mioduser & Lahav (2000) used both CMC and virtual classrooms in their Learnnet model. Scardamalia & Bereiter (1994, 1996) did the same in developing computer-supported intentional learning environments (CSILE) technology (articulated below). In part, such intersections of instructional technology approaches can be explained by the endless novelty introduced by modern information and communication technologies. As a result, another distinctive tendency of the field is a lack of consensus about terms, notions, definitions, and conceptual approaches regarding technology-based education.

CMC, a central characteristic of cyberspace, refers to the Internet, the World Wide Web, local area networks, bulletin board systems, electronic mail, and computer conferencing systems (Allen & Otto, 1996; Hiltz, 1986; Jonassen, 1996; S. Jones, 1995; Koschmann, 1996a, 1996b; McAteer, Tolmie, Duffy & Corbett, 1997; Rapaport, 1991; Romiszowski, 1992; Romiszowski & Mason, 1996). CMC links students and employees with one another, with their teachers and managers, respectively, as well as with experts in their fields of inquiry and with the community at large (Sherry, 2000). Such methods of asynchronous (time-independent) communication as e-mail, listservs, and electronic conferences gather participants in on-line discussions together, transmit content, and provide a forum for group discussions. With regard to education, CMC refers to on-line learning and teaching. The fundamental idea behind on-line learning is that learning is a collaborative activity. There are two schools of psychological thought that relate to CMC education: activity theory and situated learning (Tolmie & Boyle, 2000).

Within activity theory, CMC is considered as a mediating tool in an activity system. Drawing on the investigations of Russian psychologists (mainly Leont'ev, 1981; Tikhomirov, 1981), Engestrom (1996) defined the framework of an activity system as consisting of six interrelated components: (a) the subject (e.g. a student, teacher, or expert who is carrying out an activity); (b) the object of activity (e.g. a product or message posted on the Internet); (c) the mediating tools of the activity (e.g. multimedia tools); (d) the community of learners (students, teachers, and all people who are connected electronically by the network and are concerned with the problems and issues discussed on it); (e) the division of labor (the responsibilities commonly associated with the roles of student, teacher, expert, and so on); and (f) the rules and norms regarding appropriate social actions (posting, moderating a discussion, seeding a conference, and so on). Consequently, when exploring CMC as a way of enhancing teaching and learning, one should

consider its effects on the entire sociocultural system into which it is introduced, including the people who compose it, the tools they use, the products and performances they create, the norms and conventions of tool use, the roles and responsibilities of individual group members, and the meanings they share as a cultural group (Engestrom, 1996).

Understanding of on-line learning as a collaborative activity led to the appearance of computer-supported collaborative learning (CSCL), an emerging paradigm of education that emphasizes a delicate balance between the individual mind and socially shared representations developed through ongoing discourse and joint activities that take place within a learning community (Koschmann, 1996b). CSCL uses CMC in both its synchronous (real-time) and asynchronous forms to develop shared knowledge bases and to promote common understandings.

The philosophical foundations of CSCL are based on situated learning (Lave & Wenger, 1991; Suchman, 1987), communities of learners (Brown, 1994; Brown & Palincsar, 1989), and cognitive apprenticeships (Collins, Brown & Newman, 1989). Within these closely related approaches, scientists are attempting to expand investigations of human cognition and conceptual change beyond the individual mind to include learning that is built through mediated conversations among members of peer groups and learning communities. CSCL shifts the focus of education from learning as acquisition of knowledge and skills to learning as entry, enculturation, and valued activities situated within a community of practice (Sherry, 2000). Used as a mediating tool, CMC enables students, teachers, experts, and other members of a learning community to share distributed representations (Allen & Otto, 1996) and to use distributed cognition (Norman, 1993) to overcome the limitations of the individual human mind. For instance, Bereiter (1994) pointed out that an important feature of on-line discourse is that "understandings are being generated that are new to the local participants and that the participants recognize as superior to their previous understanding" (p. 4). Hence, participants in on-line communication suspend their individual thinking and begin to share collectively, thus creating commonly shared meaning and constructing a shared purpose that leads to expansion of ways of knowing.

An example of successful on-line learning is the National Geographic Society's Kids' Network. In a study of 36 schools that participated in the network, scientists found that participating students outperformed students in usual classrooms in terms of their grasp of certain scientific concepts and outperformed control group students on issues unrelated to their unit of study (Sherry, 2000).

Oren et al.'s (2000) Learnnet is another example of on-line learning. Learnnet is a virtual community hosted by an appropriate virtual environment and embodying

advanced pedagogical ideas. CyberSchool (<http://www.cyberschool.4j.lane.edu>), Willoway Cyber-school, and Science Learning Network (<http://www.sln.org>; a consortium of museums that defines itself as an on-line community of educators, students, schools, and science museums) can be considered examples of the Lernet model. Therefore, through using CMC as a mediating tool and: (a) sharing information; (b) fostering multiple viewpoints; (c) suggesting promising strategies; and (d) negotiating shared meaning among students, teachers, and experts, on-line learning enhances and expands the traditional types of teaching and provides new opportunities for learning.

The virtual classroom (laboratory, university, or company) is another innovation in today's instructional technology (Hiltz, 1990; Javid, 2001; Jonassen, 1996; Lan & Gemmill, 2000; Oren et al., 2000; Westera & Sloep, 2001). CMC generates a new learning environment, a virtual learning environment, where communities of learners are involved in collaborative learning. The philosophical, theoretical, and methodological foundations of the virtual classroom approach are essentially the same as in the CMC approach (Bereiter, 1994; Brown, 1994; Collins et al., 1989; Lave & Wenger, 1991), because the successful implementation and use of CMC inevitably lead to the development of virtual learning environments.

The term *virtual learning environment* refers to any educational site on the Internet that includes information, learning activities, or educational assignments or projects (Oren et al., 2000). 'Virtual' is typically used in a general form, such as the possibility of accessing a site from any place at any time, thus eliminating some of the physical constraints of the real world. These websites offer a range of instructional modes, from the retrieval of curricular resources to be integrated in regular classroom activities to complete educational units that include information resources, pedagogical approaches, and technological tools; exist only on the World Wide Web; and serve on-line distance learning (Oren et al., 2000). In other words, it is possible to distinguish two types of virtual learning communities: geographically bounded and interest-bounded ones. The first are based on existing communities (e.g. schools and universities), and they use the capability of on-line technology to support these communities. The educational advantages of on-line technology are connected to the support and enrichment it provides to real classrooms. Edmonds and Kamiak Cyberschools (Javid, 2001), the Maryland Virtual High School of Science and Mathematics (Verona, 2001), and Roosevelt Middle School (<http://www.flinet.com/~rms/>) are examples of this type of virtual learning community. Interest-bounded learning communities are established through CMC and use of the Web as a 'meeting place'. The communities are totally dependent on the virtual environment in which they exist and function in a

manner similar to distance learning courses (Schuler, 1996). A successful example of this type of virtual learning community is the CSILE Knowledge forum project (considered in detail later).

Another successful example of the implementation of a virtual classroom approach is an innovative educational model called the Virtual Learning Company (Westera & Sloep, 2001). This model was developed and implemented at the Open University of the Netherlands. The Virtual Learning Company is a distributed, virtual learning environment that embodies the functional structures of real companies; it offers students a rich and meaningful context that resembles the context of real work in many respects. Although it makes extensive use of advanced information and communication technologies, the true innovative power of the Virtual Learning Company resides in the underlying, new educational framework. Students in the Virtual Learning Company assume professional roles and run the business; that is, they deliver knowledge-centered products and services to authentic, external customers. The approach differs from regular role-playing games, simulations, and various forms of apprenticeship learning in that its processes do not reflect predefined scenarios and outcomes. In the Virtual Learning Company, students are in charge of a business system that freely interacts with the outside world. The educator's role reflects that of an in-company training coordinator: It is restricted to facilitating, monitoring, and supporting the growth of the 'employees'. The Virtual Learning Company strives to bring together the contexts of education and work. It attempts to offer a concrete and meaningful environment that closely resembles students' future workplaces (Westera & Sloep, 2001).

The Virtual Learning Company is built on two entirely different but strongly interdependent processes. First, in the educational process, novice students are transformed into competent students; second, in the business process, the students act on orders of external customers and turn them into knowledge-centered products and services. This duality is not unique to the Virtual Learning Company; it strongly matches modern ideas on knowledge-centered businesses, the importance of human capital, human-resource management, performance improvement and personnel development, and work organized through virtual business teams. The pedagogical principles underlying the Virtual Learning Company include: (a) competence learning rather than reproduction of codified knowledge; (b) custom-made education rather than boring uniformity; (c) student control instead of teacher control; and (d) closing the gap between learning and working. Various studies demonstrate that virtual learning companies are a powerful and promising tool to meet today's educational needs, anticipating a worldwide shift to cybereducation (Westera & Sloep, 2001).

Computer-based simulations represent a special type of innovation in contemporary instructional technology (Bliss & Ogborn, 1989; Ferrari, Taylor & VanLehn, 1999; Gredler, 1990, 1992, 1996; Harper, Squires & McDougall, 2000; Jonassen, 1993, 1996). A *simulation* can be defined as a “classroom experience, typically using a computer, which gives students information analogous to that obtained by working in a specific workplace, requires them to make decisions similar to those that the workplace demands, and experience the results of those actions” (Ferrari et al., 1999, p. 26). For example, flight simulators have been developed for both the aviation and entertainment industries. Businesses and business schools routinely use simulations that place students in the role of a CEO or other high-level decision-maker. Medical schools often allow students to practice diagnosis and treatment with computer-simulated patients. Ferrari et al.’s (1999) detailed analysis of 39 computer-based simulations of workplaces indicated that simulations fell into three main types: role-playing, strategy, and skill.

Role-playing simulations involve a high-fidelity portrayal of the information and activities that a real jobholder would experience in a typical day on the job. Examples are Parkside Hotel (manager of a hotel), Starr Medical (nurse at a large hospital), SWAT (rookie police officer on a SWAT team), and HBM (human resources manager for a large manufacturing company). Another good example is Court Square Community Bank, in which students are placed in a virtual office and play the role of bank vice-president.

In strategy simulations, the information and actions of the student are more abstract and powerful than those of the real occupation so that the student can implement long-range strategies and see their results. Examples are Sim City 2000 (managing the growth of a city), Transport Tycoon (developing a national transportation business), C.E.O. (managing a large conglomerate), and Entrepreneur (developing a start-up company). Another example is Capitalism. The goal of this simulation is to set up a profitable corporation by outwitting the competition and gaining a greater market share while overcoming a number of realistic obstacles.

In skill simulations, students practice a specific skill or task that is one component of an occupation. Examples are TRACON (controlling air traffic from an airport tower), Microsoft Flight Simulator (flying a small plane), Train Dispatcher (routing trains between Washington, D.C. and Boston), and M1A2 Abrams Tank (driving an army tank). Another good illustration of a skill simulation is the flight simulation Apache. Throughout this simulation, the student is in the cockpit of an Apache helicopter and uses the joystick to steer the helicopter while using the keyboard to control the weapons, radar, and other systems.

Simulations can be used not only for training purposes but also in traditional educational settings, to

assist students in acquiring basic academic skills such as math or science. The constructivist educational perspective is especially applicable for the development of educational simulations (Jonassen, 1993). Many writers have expressed the hope that constructivism will lead to better educational software and better learning (J. S. Brown, Collins & Duguid, 1989; Papert, 1993). They stress the need for open-ended exploratory, authentic learning environments in which learners can develop personally meaningful and transferable knowledge and understanding. These writers have proposed guidelines and criteria for the development of constructivist software (Grabinger & Dunlap, 1995; Hannafin & Land, 1997; Honebein, Duffy & Fishman, 1993; Rieber, 1992; Savery & Duffy, 1995; Squires, 1996). A main thesis of these guidelines is that learning should be authentic. Harper et al.’s (2000) review of the literature indicates three important concepts originating from the notion of authenticity: credibility, complexity, and ownership.

If students are to perceive that an environment offers realistic learning, they need to be able to explore the behavior of systems or environments; one way to do this is through working with simulations. The environment should provide the student with intrinsic feedback, which represents the effects of the student’s action on the system or environment. Students should be able to express personal ideas and opinions, experiment with them, and try out different solutions to problems (Ainsworth, Bibby & Wood, 1997).

Grabinger & Dunlap (1995) emphasized that learners should be presented with complex environments that represent interesting and motivating tasks rather than contrived, sterile problems. Only in complex, rich environments learners will have the opportunity to construct and reconstruct concepts in idiosyncratic and personally meaningful ways. Learners may need help in coping with complexity. Strategies to help learners include scaffolding, anchoring, and problem-based environments (Cognition and Technology Group at Vanderbilt, 1990).

A sense of ownership should be a prominent feature of learning. The established idea of locus of control (Blease, 1988; Goforth, 1994; Wellington, 1985) is relevant in this context. Working in software environments, which provide high levels of user control, will help students perceive that they are instrumental in determining the process of the learning experience. Metacognition, in which learners reflect on their own cognition to improve their learning, is also appropriate here (Scardamalia, Bereiter, McLean, Swallow & Woodruff, 1989). The point is that, through a conscious, personal appraisal of cognitive processes, an individual can improve his or her capacity to learn. If this is to be effective, however, the learner must feel a sense of ownership of the learning.

The use of simulations as learning environments has a long history. Initial claims for the educational

benefits of using simulations tended to emphasize pragmatic solutions to classroom problems. Both lengthy processes (e.g. population growth or genetic change) and short processes (e.g. changes in impulsive force during a collision) are possibilities for simulation. Difficult, dangerous, or expensive processes are also candidates for simulation (e.g. experiments with radioactive materials).

Gredler (1996) categorized simulations as either symbolic or experiential. Symbolic simulations are dynamic representations of the behavior of a system or set of processes or phenomena. The behavior that is simulated is usually the interaction of two or more variables over time, and the learner can manipulate these variables to discover scientific relationships, explain or predict events, or confront misconceptions. A simulation of a laboratory experiment is a classic example of a symbolic simulation.

Experiential simulations aim to establish a particular psychological reality and place learners in defined roles within that reality. The main elements of an experiential simulation are as follows: (a) a scenario of a complex task or problem that unfolds in part in response to learner actions; (b) a serious role taken by the learner in which she or he executes the responsibilities of the position; (c) multiple plausible paths through the experience; and (d) learner control of decision making (Gredler, 1996, p. 523). Role-playing simulations of environmental planning are classic examples of experiential simulations. For instance, the CD-ROM, *Investigating Lake Iluka*, an experiential simulation, is based on the concept of an information landscape that incorporates the biological, chemical, and physical components of a range of ecosystems that make up a coastal lake environment. Users are given problem-solving strategies to investigate this information in a variety of ways using the range of physical tools provided (Harper et al., 2000).

Therefore, the possibilities afforded by new multimedia technology, combined with contemporary ideas about learning, have opened up new perspectives for educational simulations. In particular, the use of sophisticated multimedia environments has led to the design of experiential simulations in which the learner plays an authentic role, carrying out complex tasks.

Intelligent tutoring systems (ITS) approaches also provide new ways of teaching and learning (Anderson, Corbett, Koedinger & Pelletier, 1995; Costa, 1992; Frasson & Gauthier, 1990; Merrill, Reiser, Ranney & Trafton, 1992; Park, 1996; Psotka, Massey & Mutter, 1988; Schofield & Evans-Rhodes, 1989; Shute & Psotka, 1996; VanLehn, 1999). ITSs are adaptive instructional systems developed with the application of artificial intelligence methods and techniques (Park, 1996). ITSs are developed to resemble what actually occurs when student and teacher sit down one on one and attempt to teach and learn together (Anderson et al., 1995; Shute & Psotka, 1996). ITSs have compo-

nents representing content to be taught, the inherent teaching or instructional strategy, and mechanisms for understanding what the student does and does not know (Park, 1996; Park & Seidel, 1989). These components are referred to as the problem-solving or expertise module, the student-modeling module, and the tutoring module. The expertise module evaluates the student's performance and generates instructional content during the instructional process. The student-modeling module assesses the student's current knowledge and makes hypotheses about the conceptions and reasoning strategies he or she used to achieve his or her current state of knowledge. The tutorial module usually consists of a set of specifications for the selection of instructional materials the system should present and how and when they should be presented (Seidel & Park, 1994; Shute & Psotka, 1996). Artificial intelligence methods for the representation of knowledge (e.g. production rules, semantic networks, and script frames) make it possible for ITSs to generate knowledge to present to the student on the basis of his or her performance on the task rather than selecting the presentation according to predetermined branching rules (Anderson et al., 1995; Park, 1996; Psotka et al., 1988; Schofield & Evans-Rhodes, 1989).

There are many types of ITSs (VanLehn, 1999). One common type is the coached practice environment. The tutor coaches the student as the student solves a multistep problem (e.g. solving a complex algebra word problem or discovering the laws governing a simulated economy). The student works with software tools, such as spreadsheets, graphs, and calculators. The tools are often designed especially for the task; an example is a kind of scratch paper that facilitates entering of the types of equations or other notations that the task demands. To solve the problem, the student must complete many user interface actions. After each action, the coach remains silent or may make comments. These comments represent one main form of instruction. When the problem is finished, the coach may review certain key steps in the solution, a process called reflective follow-up. This is another important form of instruction (VanLehn, 1999).

Examples of ITSs include the LISP tutor (e.g. Anderson et al., 1995), which provides instruction in LISP programming skills; *Smithtown* (Shute & Glaser, 1990), a discovery world that teaches scientific inquiry skills in the context of microeconomics; *Bridge* (Shute, 1991), which teaches Pascal programming skills; the *Geometry Tutor* (Anderson, Boyle & Reiser, 1985), which provides an environment in which students can prove geometry theorems; and *WITS* (Whole-course Intelligent Tutoring System; Callear, 1999), which provides an environment to teach a course on solid-state electronics. In general, results from evaluation studies demonstrate that these tutors do, in fact, accelerate learning with, at the very least, no degradation in outcome performance relative to appropriate

control groups (Shute & Psozka, 1996). However, there are criticisms that ITS developers have failed to incorporate many valuable learning principles and instructional strategies developed by instructional researchers and educators (Park, Perez & Seidel, 1987). Cooperative efforts among experts in different domains, including learning—instruction sciences and artificial intelligence, are required to develop more powerful ITSs (Park & Seidel, 1989; Seidel, Park & Perez, 1988).

Therefore, even a brief analysis of contemporary innovations in the field of instructional technology demonstrates that CMC, virtual classroom, simulation training, and intelligent tutoring systems approaches involve new methods of teaching and learning, expanding the resources of the human mind and broadening the conventional boundaries of education. However, none of these approaches incorporate the specificity of HICEMTs described subsequently.

The First Generation of Educational Multimedia Technologies

Today, many people are accustomed to the advanced educational tools included in existing educational multimedia products. Strong development of multimedia technology leads to rapid emergence of a great number of educational off-line and on-line applications. Because, for example, they are easily accessible, educational multimedia products and services are becoming international. The first question that should be addressed is: What is really out there on the global educational multimedia market?

We have come to the conclusion that the current educational multimedia products constitute, in fact, the first generation of educational multimedia (Shavinina, 1997a, 1997b, 1998a; Shavinina & Loarer, 1999). Five types of educational multimedia products within this first generation can be identified. The first is learning manuals used in the framework of traditional school or college curricula and higher education (i.e. history, chemistry, physics, mathematics, biology, and languages). An example would be “history in the university: from the ancient times to the beginning of the 20th century”. It is necessary to note that the great number and diversity of language multimedia products lead some authors to place them in a separate category of educational multimedia applications. This seems to be inappropriate, because the main purpose of these educational multimedia titles is the learning of native or foreign languages.

The second type is multimedia products focusing on general knowledge in various domains (e.g. automobiles). The third type is reference sources (i.e. various encyclopedias, dictionaries, and atlases). An example would be an encyclopedia of the human body. The fourth type is edutainment (i.e. different games with educational aspects, multimedia versions of famous tales, and interesting stories). The final type is cultural

cognition (i.e. on-line and off-line multimedia applications on arts and culture). An example would be ‘the best museums of the world’.

Analyzing today’s educational multimedia applications from the viewpoint of their content, we found that they are ‘domain-specific’ products and that they now dominate on the international market (Shavinina, 1997a, 1997b). Domain-specific educational multimedia products are directed toward knowledge acquisition and skill development in a particular domain (e.g. language, arts, history, physics, literature, biology, and so on) and, very often, one narrow topic (Shavinina, 2000). As argued earlier (Shavinina, 1998a), these domain-specific educational multimedia applications are, in reality, computer versions of printed content (i.e. textbooks and learning manuals). In other words, they are simply ‘placed’ on CDs or the Internet, or both. Of course, contemporary multimedia technologies change the mode of presentation of traditional manuals and textbooks. However, the nature of their content has not changed. The lack of such transformation can be considered the main shortcoming of today’s educational multimedia technologies and the biggest problem for their future. It should be emphasized that, in their current form, domain-specific educational multimedia products do not have realistic chances for further, more advanced development. Content continues to be a problematic issue; in many cases, so-called ‘educational multimedia’ products are nothing more than simple applications of pure multimedia technology in education. A solution can be found in the development of PMTs and HICEMTs (Shavinina, 1997a, 1997b, 1998a).

Analyzing current educational multimedia products from the standpoint of multimedia technology (i.e. specific features of multimedia), we concluded that contemporary educational multimedia applications simply use multimedia effects without any attempt to present or perhaps modify these effects in accordance with users’ psychological organization (Shavinina, 1997b, 2000). It seems that companies develop educational multimedia applications simply because they have the required multimedia technology. This is also not a promising direction for the development of educational multimedia technologies.

The first generation of educational multimedia will undoubtedly be replaced by the second generation: PMTs and HICEMTs (Shavinina, 1997a, 1998a). The future belongs to HICEMTs, which will be distinguished by new principles in the creation of their content. The content of educational multimedia products and services is exceptionally important for the advancement of the field, because the most innovative breakthroughs can be accomplished in this area. From this standpoint, it is not surprising that executives of multimedia companies see successful developments in their firms in terms of substantial improvements in the content of their products. For example, the president of

Quebecor Multimedia, Monique Lefebvre (1997), has insisted that “we must stop putting the emphasis on electronic might and more on content” (p. 20).
