Other types of insect envenomation are sporadic. Many insects that normally feed on plant juices occasionally inflict annoying bites. This behavior may be initiated by dehydration of the insect or by unknown factors. Small predatory insects, such as lacewing larvae, anthocorids, and *Sclerodermus* species, occasionally attack humans instead of their normal arthropod prey. Thrips may bite and produce itching macules.^[80] A small hemipteran, *Leptodemus minutus*, caused numerous cases of dermatitis in Kuwait.^[105] The stick insect, *Anisomorpha buprestoides*, a common species in Florida and adjacent states, ejects a noxious fluid from its thoracic region that deters birds and other predators. According to regional folklore, this fluid can be directed toward human eyes with painful consequences. Recently, an outbreak of a blistering disease was reported in a military unit training in the Arizona desert during an unusual heavy rainfall and flooding. Staphylinid (rove) beetles (genus *Paederus*, family Staphylinidae) were collected at the site. These beetles have been responsible for vesicular dermatitis in other parts of the world but were never reported in the United States before this series.^[17]

DIPTERA (TWO-WINGED FLIES)

Insects of the order Diptera are characterized by one pair of wings. The second pair is usually modified to form a pair of drumsticklike structures known as halteres. A typical life cycle consists of eggs, limbless larvae, pupae, and winged adults, but numerous variations exist. Mouthparts are of the sucking type. Females of many species, although free living, take blood or other tissue fluids from vertebrates, injecting salivary secretions that are not intrinsically toxic but are potent sensitizing agents for most humans. Larvae of some Diptera are human parasites. Other adult Diptera feed indiscriminately on feces and human foodstuffs. These habits make them by far the most important arthropod vectors of human disease ([Table 36-1](#)).

Most of these insects are cosmopolitan in distribution, except tsetse flies, which are restricted to Africa, and tropical and subtropical sand flies. Some species of mosquitoes and blackflies are adapted to cold temperate, sub-Arctic, and alpine environments, where their numbers may make areas uninhabitable during peak activity. Other mosquitoes and biting midges are equally abundant and annoying in some coastal areas and on islands.

Mosquitoes are characterized by a fringe of setae along the posterior margin of the wings and delicate scales along the wing veins. Only the female feeds on blood. Her prominent beak contains a kit of piercing and sucking tools. Most mosquitoes have body lengths of 3 to 4 mm, but some large species may be about twice this size (see [Table 36-1](#)). The estimated 3000 species of mosquitoes are cosmopolitan in distribution.

Carbon dioxide, body heat, and sweat gland secretions, especially apocrine, are attractants for mosquitoes; certain skin lipids are repellent.^[55] Children under 1 year of age rarely show a skin reaction to mosquito bites, but by age 5 nearly all are reactors. Both immediate and delayed types of hypersensitivity are induced. Typically, immediate pruritic wheals are followed by red, swollen, and pruritic lesions in 12 to 24 hours. These lesions are associated with both IgE and IgG antibody complexes and a lymphocyte response.^{[87] [96]}

All the classic types of immunologic injury have been reported after mosquito bites, including injury from circulating immune complexes, asthma, and Arthus reaction.^{[38] [46] [120]} Seasonal bullous eruptions in a coastal area of Britain were ascribed to *Aedes detritus*. Most of those affected were women with varicose veins or deep venous thromboses. Intense skin reactions accompanied by fever, lymphadenopathy, and hepatosplenomegaly have been described and are associated with infiltration of skin lesions by natural killer lymphocytes.^[123] Nodular skin lesions lasting up to a month have been reported after mosquito bites in patients with acquired immunodeficiency

syndrome (AIDS) receiving zidovudine.^[26] Papulovesicular lesions with eosinophil infiltration were reported following insect (including mosquito) bites in patients with lymphocytic leukemia.^[21] Among 21 Japanese patients with severe local and constitutional reactions to mosquito bites, seven died of malignant histiocytosis before age 28. Nine others retained hypersensitivity; three lost it.^[46]

Treatment of mosquito bites consists of local application of antipruritic lotions or creams. Antihistamines relieve the itching of early lesions but have no effect on later ones.^[97] Group I corticosteroid creams and ointments may be helpful. Desensitization with insect whole body extract is difficult but occasionally successful.^[72] Prolonged heavy exposure to mosquito bites

TABLE 36-1 -- Major Groups of Biting Dipterans

INSECT	RECOGNITION FEATURES OF ADULT	LARVAL AND PUPAL STAGES
Mosquitoes (Culicidae, subfamily Culicinae)	Prominent proboscis; wings with scales; palps of female much shorter than proboscis; usually rests with body parallel to substrate	Aquatic in great variety of habitats; both larval and pupal stages motile
Mosquitoes (subfamily Anophelinae)	Prominent proboscis; wings with scales and often with dark mottling; palps of females about as long as proboscis; usually rests with head down and body held at an angle to substrate	Same as above
Blackflies, buffalo gnats (family Simuliidae)	Stout; humpbacked; short antennae; wings broad with most of veins faint; body length >2.5 mm	Sessile in flowing water; usually attached to rocks and logs, sometimes to crustaceans
Sand flies (family Psychodidae)	Small (usually >2 mm body length); hairy; wings with straight, prominent veins	In damp crevices, animal burrows, leaf litter
Biting midges, sand flies, no-see-ums (family Ceratopogonidae)	Small (>2 mm body length); wings often mottled; most of wing veins faint	In mud, wet sand, rotting vegetation, larvae very motile

Horseflies, deerflies (family Tabanidae)	Large (5–25 mm body length) with large eyes; usually brilliantly colored; body stout; wings with prominent veins	In mud or shallow water
Stable flies (family Muscidae)	Similar to housefly in size and general appearance; sharp-pointed proboscis projects downward and backward	In decaying vegetable matter or urine-soaked straw
Tsetse flies (family Glossinidae)	Large (6–14 mm); proboscis projects forward; wings fold scissorlike over back	Larvae complete most of development in female; pupate in soil a few hours after birth
Snipe flies (family Rhagionidae)	Long legs; relatively slender body; large eyes; wings with prominent veins	Aquatic, in moist soil or rotten wood

causes some individuals to lose sensitivity, occasionally in less than 1 year. Delayed hypersensitivity is lost more readily than immediate hypersensitivity; with decreases in both IgE and IgG^[88] (see [Chapter 32](#)).

Biting Midges (Culicoides)

Biting midges are very small flies that have a bite out of proportion to their size. Only females feed on blood. The wormlike aquatic larvae usually develop in water-saturated soil; mangrove swamps are a common habitat. Larvae of some species use axils of banana and similar plants. The genus is cosmopolitan but presents the greatest problem in subtropical and tropical coastal regions. Activity is often seasonal. The flies bite most intensely in still air and reduced light.

Bites are immediately painful and result in raised, red, and pruritic lesions that persist from a few hours to a week or more. Some victims develop vesicles, pustules, and superficial ulcers, particularly if bitten by the genus *Leptoconops*. Hypersensitivity is involved, although some persons seem to develop intense reactions on first exposure to the insects.

Treatment of bites is symptomatic and similar to that for mosquito bites. Artificial hyposensitization has not been successful; however, spontaneous decrease in skin reactivity may occur in some individuals (see [Chapter 32](#)).

Blackflies (Simuliidae)

Blackflies are small stocky flies that have a characteristic humpbacked appearance. Adults prefer open and sunny areas and are good fliers. Not all species are anthropophilic. The sessile larvae and pupae are found in flowing water, from large rivers to small brooks. Blackflies are cosmopolitan, but their abundance and medical significance vary widely. They range well into the Arctic and constitute a major problem

for both humans and domestic animals in parts of Europe, Canada, and the northern United States. In the tropics they tend to be more localized, often remaining close to streams.

Blackfly bites are more common on the upper half of the body. They snip the skin and suck the pooled blood, leaving relatively large punctures that may bleed, a symptom rarely seen with bites of other small flies. The local pain, swelling, and redness that follow blackfly bites are unusually intense and persistent. Vesicles and weeping, crusted lesions may last for weeks. Systemic symptoms such as malaise, fever, and leukocytosis may occur. Enlarged indurated lymphatics, particularly in the posterior cervical region, are common in Canadian

877

children living where blackflies are abundant. Hemorrhagic symptoms have been reported in Brazil. Generalized urticaria, bleeding, angioedema, cough, wheezing, toxemia, and even death may occur.^{[51] [60] [135]}

No specific treatment for blackfly bites is available. Hyposensitization has been attempted with little success. Neither repellents nor ordinary clothes provide satisfactory protection against blackflies when they are present in large numbers. Avoidance of heavily infested areas during fly season is often the most practical solution. Control measures have not proved highly effective (see [Chapter 32](#)).

Horseflies and Deerflies (Tabanidae)

Horseflies and deerflies are medium to large (10 to 25 mm body length) stocky flies whose large eyes often are brightly colored. They are strong fliers and prefer open and sunny habitats. The tabanids attack a variety of large mammals, including humans. The predacious maggotlike larvae live in water-soaked soil or shallow water. Bites from these large flies, predominantly the deerfly (*Chrysops* species), are painful and may cause both external and subcutaneous bleeding. An itching wheal up to 1 inch in diameter develops but usually does not last long. In some victims, severe and prolonged swelling of the face or an extremity develops. About 30 cases of systemic anaphylactoid reactions have been reported. One man with a history of systemic reactions to wasp stings had a similar reaction to a horsefly bite.^{[36] [45]}

As with other fly bites, treatment is symptomatic. Hyposensitization has been attempted in a few cases, apparently with some success (see [Chapter 32](#)).

Other Biting Diptera

Snipe flies (Rhagionidae) primarily prey on insects, but some species, such as *Symphoromyia*, feed on the blood of mammals. Their habits and life history are similar to those of tabanids. Reactions to snipe fly bites range from pain to anaphylaxis. A

person who reacts severely may be bedridden for days.

The stable fly (*Stomoxys calcitrans*) is related to the housefly, which it closely resembles. It is plentiful throughout most of the United States, particularly in agricultural districts. Eggs are deposited in piles of decaying vegetation, where the larvae develop. Thunderstorms seem to stimulate fly activity, which accounts for the widespread belief that houseflies bite just before a storm. Bites cause a sharp, stinging sensation, but dermal lesions are uncommon. Itching is brief.

Louse flies (Hippoboscidae) are peculiar Diptera that may lack wings entirely or have them for only part of their adult life. The wingless forms are flat, leathery insects that resemble lice or ticks. They are ectoparasites of birds and mammals. Larvae are carried in the uterus until development is almost complete; the pupal stage may be spent in the soil or on the host. The sheep ked (*Melophagus ovinus*) is a common species in the United States and sometimes bites sheep shearers and handlers. The related deer ked (*Lipoptena cervi*) is a seasonal pest in wooded sections of northern Europe, causing hundreds of cases of dermatitis annually. The pigeon fly (*Pseudolynchia canariensis*) is an avian parasite that sometimes infests buildings and bites the occupants.

Lesions from hippoboscid bites appear 1 to 24 hours after the bites as reddish itching papules that may persist for up to 3 months. Topical corticosteroids may afford symptomatic relief and hasten resolution of the lesions. Repellents are reported to be ineffective against these insects (see [Chapter 32](#)).

Myiasis

The term *myiasis* for parasitism by fly larvae was introduced into the medical literature in 1840, although the condition has been observed since antiquity. More than a hundred species of Diptera have been reported to cause human myiasis.^[77] Some are obligate parasites for which humans are one of several hosts; some are opportunistic invaders that find parasitism an alternative to feeding on decaying tissue or its products. Nevertheless, humans are not a particularly good host for most species of fly larvae, and many infections terminate prematurely. Sensitization of host tissues to fly larvae does not occur as readily as with many other arthropod and helminth parasites.

Myiasis may be classified by clinical manifestations or etiologic agents; neither method is totally satisfactory. This chapter discusses only dermal and wound myiasis. Myiasis primarily involving the gastrointestinal tract, urinary tract, eye, and nasopharynx is not covered.

Furuncular Myiasis.

In furuncular myiasis the fly larva penetrates the skin but remains sedentary, producing a boil-like lesion that usually has a central opening. Here the larva completes its development but typically emerges to pupate outside the host. As a human problem, this form of myiasis is largely confined to the tropics, although imported cases are being

recognized in increasing numbers in other regions of the world (see [Chapter 37](#)).

Autochthonous furuncular myiasis may occur in the United States, usually in children. Most cases are caused by larvae of botflies of the genus *Cuterebra*, whose normal hosts are small rodents and rabbits. The fly eggs are attached to low vegetation and hatch on contact with skin of the host. Adult human skin seems impervious to them, but that of children may be penetrated. There is usually a history of outdoor play in weeds or grass or with a pet rabbit, but in one case, eggs apparently were deposited directly on the skin.^[39] Lesions typically develop on the head, neck, or chest in

1 or 2 weeks. Once recognized, the larvae can often be removed by simple pressure.^[91]^[116] The syndrome may also be caused by larvae of *Wohlfahrtia vigil*, a large fly native to Canada and the northern United States. Its normal hosts are newborn mammals, particularly mink, dog, and fox. The fly deposits larvae on the skin, which penetrates in about an hour. Human infections are typically in infants under 9 months, and the furuncular lesions are usually on the face. Fever, irritability, and loss of appetite are common. Larvae can usually be expressed from the lesion; surgery rarely is necessary. Netting over the crib or pram when outdoors usually affords protection.

Migratory Myiasis.

One type of migratory myiasis is caused by flies of the genus *Hypoderma*. Adult flies are large and hairy, resembling bumblebees. Normal hosts for the parasitic larvae are cattle, deer, and horses. The flies attach their eggs to hairs. Hatching larvae penetrate the skin and wander extensively through the subcutaneous tissues, eventually locating under the skin of the back, where they produce furuncular lesions. The condition has veterinary importance. Humans are abnormal hosts in which the parasite is unable to complete its development. Human infections usually occur in rural areas where cattle and horses are raised and are more common in winter. Larvae migrate rapidly (as much as 1 cm/hr) and erratically through subcutaneous tissues, producing intermittent, painful swellings over months. The person often senses larval movement. Larvae respond negatively to gravity, so the last lesions are usually on the head or shoulders. Eosinophilia (up to 35% eosinophils on white blood cell differential) and angioedema may be seen. Larvae may emerge spontaneously from furuncles or may die in the tissues. In rare cases, larvae invaded the pharyngeal region, orbit, and spinal canal.

Another form of migratory myiasis is caused by larvae of *Gastrophilus*, which normally are gastrointestinal or nasal parasites of horses ([Figure 36-16](#)). In human infections, which are reported more frequently from Europe than from the United States, the young larvae burrow in the skin, producing narrow, tortuous, reddish, and linear lesions with intense itching. Lesions usually advance 1.5 cm/day, but more rapid progress has been reported. Death of the larvae terminates the infection in 1 or 2 weeks without sequelae. This infection is clinically similar to creeping eruption, an invasion of the skin by larvae of the hookworms *Ancylostoma braziliense* and *A. caninum*. The helminthic parasitosis

occurs more often in warm, moist regions, including the southern United States, and is associated with dogs and cats. The myiasis is seen more frequently in cooler regions and is associated with horses. Definitive diagnosis can be made only by removal of the parasite from its burrow and microscopic examination.

Figure 36-16 Larvae of the botfly *Gastrophilus haemorrhoidalis* from a horse's stomach.

Removal of the larvae by surgery or expression is the usual treatment for migratory myiasis, although local freezing of cutaneous burrows is sometimes successful. Ivermectin given to a patient with *Hypoderma* myiasis resulted in expulsion of the larva.^[52] The most effective prevention is control of the infections in domestic animals.

Wound Myiasis.

Opportunistic invasion of wounds by fly larvae is often seen during war and natural disasters, when injured persons are exposed to flies and medical facilities are inadequate to cope with the emergency. Wound myiasis may also be seen sporadically in nursing homes and hospitals and often is not reported for cultural and medicolegal reasons.^[10] Six of 14 cases in one series were acquired in the hospital. Eleven patients were over 63 years of age, and nearly all had underlying problems, such as diabetes or peripheral vascular disease. Most of the infected lesions were on the feet or ankles.^[69] In another series of 16 cases, most victims were debilitated and over age 65. Males were affected more often than females. Seven species of flies were involved.^[75] Fifty *Lucilia* larvae were removed from the nose, mouth, paranasal sinuses, and enucleated eye socket of a hospitalized patient left in a room with an open window.^[20] The most common fly species involved are *Lucilia* (green-bottle flies), *Calliphora* species (blue-bottle flies), *Phorima regina* (black blowfly), *Sarcophaga haemorrhoidalis* (flesh fly), and *Musca domestica* (housefly). The flies, whose larvae normally feed on decaying animal tissues, often deposit eggs or larvae in wounds or around body orifices if a malodorous discharge is present. The larvae feed on necrotic tissue, and damage to healthy tissues and secondary infection are uncommon. They actually may debride wounds, and "maggot therapy" with aseptically bred larvae was briefly used in the 1930s. Recently, laboratory-bred fly larvae have been used to debride venous stasis ulcers and other superficial necrotic areas when antibiotic therapy

and surgical debridement were unsuccessful.^[115] ^[119] Maggots serendipitously present have been used to debride lesions,^[92] but this can be risky. ^[76] Diagnosis is usually obvious on inspection of the wound. Species identification often requires the larvae to

reach maturity. If this is not feasible, examination of the spiracular plates on the last segment of the larva and the chitinized oral structures usually permits adequate identification. Irrigation of the wound and mechanical removal of larvae are generally sufficient for treatment.

LICE (ORDER ANOPLURA)

Species, Life Cycle, and Distribution

Lice are small wingless insects that are ectoparasites of mammals. They are mostly host specific, and two species are human parasites: *Pthirus pubis* (pubic louse) and *Pediculus humanus*, with two varieties, *P. h. capitis* (head louse) and *P. h. corporis* (body louse). They are obligatory parasites, subsisting on blood from the host, and have mouthparts modified for piercing and sucking. The mouthparts are drawn into the head of the louse when not in use.

The adult head louse is about 2 to 4 mm long with an elongated body that is flattened dorsoventrally ([Figure 36-17](#)). The head is only slightly narrower than the thorax. The three pairs of legs are about equal in length and possess delicate hooks at the distal extremities. The entire life is spent on the host's body. The eggs (nits) are deposited on hair shafts, generally one nit to a shaft. The nits hatch in about 1 week, and the freshly hatched larvae, which must feed within 24 hours of hatching or die, mature in about 15 to 16 days. The adult female lives for approximately 1 month and may deposit more than 100 eggs during her reproductive life. Body lice are slightly larger than head lice but are similar in appearance with a similar life cycle, although the nits are deposited on fibers of clothing. Head lice and body lice interbreed.

Adult pubic lice are about 1 to 2 mm long, the head is much smaller than the thorax, and the broadly oval body is flattened dorsoventrally ([Figure 36-18](#)). The anterior legs are much shorter than the second and third pairs, and the insect resembles a miniature crab. Nits are deposited on hair shafts, often several per shaft, and the egg-to-egg life cycle is approximately 1 month.

Lice are found wherever people are found. Able to exist only briefly away from the human body, lice are spread by close personal contact and by sharing of clothing and bedding. The various species not only have a particular host but often prefer a particular part of the host's body, so generalizing about transmission of the three varieties that parasitize humans is impossible. During biting and feeding, secretions from the louse cause a small red macule. Severe pruritus and marked

Figure 36-17 Male of the human head louse, *Pediculus humanus capitis*.

Figure 36-18 Pubic or crab louse, *Phthirus pubis*, grasping a hair.

inflammatory responses to bites are caused by the sensitization that occurs after repeated exposure to bites. Thus a victim may have lice for weeks before pruritus becomes marked. Not all people are equally attractive to lice, possibly because of differences in odor and chemical composition of sweat. Lice are medically important as vectors of systemic illnesses, as well as for dermatitis and discomfort.

Clinical Aspects

The head louse localizes on the scalp and rarely on other hairy areas of the body. Children are most frequently affected, but adults, particularly women, may also be affected. Lice are particularly common in young girls, possibly because of their long hair. Infestation is uncommon in blacks, at least in the United States, probably because the shaft of African hair has an oval cross section that makes it difficult for the louse to grip while depositing eggs. However, pediculosis capitis is found in Africa, where the indigenous head louse is adapted to grip the oval hair shafts. Since nits initially attach to the hair shaft close to the skin and are carried higher as the hair grows, the presence of nits near the tips indicates a longstanding infestation.

Itching is the principal symptom, and physical findings vary with duration and extent of the infestation, cleanliness, excoriations, and degree of secondary infection. Diagnosis is established by identifying nits and lice. It is not always easy to find lice, especially in early and mild cases, when they may be few in number. Lice are very active, but nits are always present and easy to identify. Nits are whitish ovals, about 0.5 mm long, and attached firmly to one side of the hair. Flakes of dandruff, which resemble nits superficially, are not attached to the hair shafts. Occipital and posterior cervical adenopathy is common and may be present even in less severe cases. A pruritic scalp accompanied by adenopathy should prompt a thorough search for lice and nits. In severe cases, oozing and crusting may be present, sometimes with matting of the hair, and lice may be numerous.

The body louse lives chiefly in the seams of clothing and is rarely seen on the skin.

These lice leave clothing to feed on the skin or remain attached to the clothing while feeding, and thus they are most abundant where clothing abuts the skin (e.g., beltline). The bite results in a small red macule with a characteristic central hemorrhagic punctum. Excoriations, crusts, eczematization, and other secondary lesions generally obscure the primary lesions by the time the victim seeks medical attention. Shoulders, trunk, and buttocks are favorite sites for bites, and parallel scratch marks on the shoulders are a common finding. The diagnosis is confirmed by identifying parasites or nits from the clothing. Bands of trousers, side seams, and underarm seams are sites of preference. Untreated cases may persist indefinitely, and massive infestations are sometimes seen in vagabonds who have no ready access to frequent laundering or change of clothing or who cannot bathe regularly.

Pediculosis pubis is usually acquired during sexual activity, although it may result from unchanged bedding or nonsexual activity, either from lice that live briefly away from the human body or from egg-infested public hairs that are shed. The lice localize principally in the pubic hair, but they are found occasionally in eyebrows, eyelashes, and axillary hairs. Adult public lice are not active and hug the skin at the base of the hair shafts, with their heads buried in the follicular orifice. They are not easy to find, but one or more can usually be found if suspicion of the diagnosis is strong enough to prompt a thorough search. A loupe is helpful. Nits are more easily found. Primary bite lesions are almost never seen, but the intense pruritus and public scratching are pathognomonic. The secondary infection, crusting, oozing, excoriations, and eczematization that often accompany head and body lice are rarely seen with public lice. Peculiar steel-gray macules (maculae caeruleae) may appear in association with some cases of public lice. These lesions do not appear until the infestation has been present for several weeks and are most common on the trunk and thighs.

Treatment and Prevention

Treatment of all types of lice strives to eradicate lice and nits and prevent reinfestation. Head lice may be treated with one application of 1% permethrin cream rinse (Nix). Hair should be washed, rinsed, and dried, and the rinse is applied for 10 minutes before being washed off. A fine-toothed comb may be used to remove nits after rinsing. Failure to remove all the nits is a frequent cause of treatment failure. If lice or nits are found after 7 days, retreatment is indicated. Family members and contacts should be treated simultaneously. Hats and scarfs should be machine washed with hot cycle and bed clothing dry-cleaned. Other pediculicides are available if the lice are resistant. Two products, RID (Pfizer, New York, N.Y.) and Triple X (Young's Drug Product, Weatherfield, Conn.) contain 0.3% pyrethrins and 3.0% piperonyl butoxide. One application of either preparation usually eradicates both lice and nits. A few persons may require another application 7 days after the initial treatment.^[6] Lindane 1% (hexachlorocyclohexane, Kwell) may be used on persons who fail to respond or who are intolerant of permethrin. Kwell is the medication used most often in the United States for treatment of louse infestations. Lindane penetrates human skin and has potential for central nervous system toxicity. It is contraindicated in neonates and must be used according to strict guidelines in children, pregnant women, and nursing mothers. Alternative treatments contain pyrethrums and piperonyl butoxide as active ingredients. Ivermectin, a macrocyclic lactone antibiotic highly effective against filarial worms and *Strongyloides*, has recently been demonstrated to be effective against lice both topically

and orally, but it is not approved for this use at present.^[11]

Body lice may be treated with the same medications, but parasites and nits are not generally found on the skin. Eradication of these from the clothing is the primary objective. Treatment includes bathing, laundering all clothing, and changing to fresh clothes free of lice and nits. Dry cleaning eradicates lice and nits, as does ordinary laundering at hot settings. Malathion preparations and γ -benzene hexachloride formulations may be used for mass delousing.

Public lice may be treated with the same medications used for head lice. Treatment consists of permethrin 1% cream rinse applied for 10 minutes or lindane 1% shampoo applied for 5 minutes and rinsed. Sexual partners should also be treated.^[32] Crotamiton lotion rubbed into the affected area daily for several weeks to destroy hatching ova may also be used. Eyelash infestations may be managed with physostigmine ophthalmic ointment using a cotton-tipped applicator. Machine washing

and drying of sheets and clothing at hot settings will kill lice and nits.

FLEAS (ORDER SIPHONAPTERA)

Species, Life Cycle, and Distribution

Fleas are small ectoparasites of mammals and birds. The wingless body, which is covered by a hard shiny integument, is compressed laterally, enabling the fleas to scurry easily among the hairs and feathers of the hosts. They are active insects with legs adapted for jumping, capable of prodigious leaps. Adult fleas subsist on blood. Some species must obtain blood from one particular host, others are less host specific, and all have mouthparts adapted for piercing and sucking. The eggs are laid on or near the host and drop to the ground as the host moves about or shakes. They hatch into small wormlike larvae that feed on droppings from adult fleas, flakes of dried blood from the host, and other organic matter. The life cycle varies among species and may vary considerably within the same species, since each developmental stage is influenced by prevailing temperature and humidity. The customary larval stage of 9 to 15 days may be prolonged for months by adverse conditions, and the pupal stage varies from a week to nearly a year. Individual adult fleas may live for years when circumstances are favorable and can live for months without feeding.

Fleas exist universally, although the distribution of various species is restricted by climate and host. They are of medical importance because of the discomfort resulting from their bites, as a cause of papular urticaria, and as vectors of disease. They are more active in warm weather and cause more problems in warmer climates with a longer breeding season, such as the southwestern United States. They are a particular nuisance in California. High standards of sanitation and personal hygiene in developed countries have discouraged the human flea, *Pulex irritans*, while the same popularity of household pets has been conducive to the proliferation of dog and cat fleas, *Ctenocephalides canis* and *C. felis*. The incidence of other species in mammals and birds remains high. Since dog, cat, and many other fleas are only partially host specific, the fleas associated with many mammals and birds cause disease in humans. Most current flea bite problems are caused by animal fleas. Hungry fleas are more often attracted to people from an area frequented by an animal than from the animal itself. If the family dog is absent, hordes of hungry fleas may persist for months. Consequently, anyone with pet cats or dogs or near domesticated animals is more likely to be bitten, but outbreaks in the absence of pets are common. One epidemic of flea bites among children in a day nursery was traced to dog fleas in a deserted fox nesting area beneath the building.^[102] Another outbreak among poultry workers was caused by an infestation of hen fleas, *Ceratophyllus gallinae*.^[122] Fleas from flying squirrels also have been documented as the source of bites.

Clinical Aspects

The appearance of flea bites is not diagnostic, and the clinical features depend on degree of sensitivity. A bite produces a small, central hemorrhagic punctum surrounded by erythema and urticaria. A small wheal at the bite site may be nonallergic because of primary urticogenic substances in the flea saliva, but increasingly severe reactions are caused by sensitization to substances in the saliva. Bullae or even ulceration may result from flea bites in highly sensitive individuals. Flea bites are intensely pruritic, and scratching often results in crusting and impetiginization. Fleas have a habit of sampling several adjacent areas while feeding, and bites characteristically appear in irregular groups. Feet, ankles, and legs, as well as the hips and shoulder areas, where clothing fits snugly, are favorite targets. Although an individual lesion produced by a flea bite is not diagnostic, the typical clinical picture of grouped multiple bites is generally sufficient to establish a diagnosis, which is usually confirmed by locating and identifying fleas.

Treatment and Prevention

Ordinary flea bites require symptomatic treatment directed at relief of pruritus and prevention of secondary infection. Corticosteroid creams or calamine lotion with phenol, systemic antihistamines, and antibiotics are helpful when indicated, but the management of flea bites consists largely of prevention. The animals that host the fleas must be treated, as well as such places as chicken coops, rat nests, sleeping sites for dogs and cats, and often dwellings where pets live. Many effective insecticides are available. Typically, *N,N*-diethyl-meta-toluamide (DEET), pyrethrins, piperonyl butoxide, and *d*-trans allethrin are ingredients in sprays and foggers. An insect spray containing permethrin may be effective. Spraying or dusting must eradicate not only adult fleas but also the many larvae and pupae in grass, carpet, floorboards, furniture, and beds. Lindane, carbaryl, and malathion are the active ingredients in many sprays and dusts, and the services of professional exterminators may be necessary.

Veterinary prescriptions are available for control of fleas on dogs and cats. Preparations containing 9.1% imidacloprid (Advantage, Bayer) eliminate or reduce fleas on dogs when applied to the skin; 98% to 100% of fleas are killed within 12 hours of application, and reinfesting fleas are killed for 4 weeks after a single application. An oral preparation used for both dogs and cats contains lufenuron, an inhibitor of insect development. Lufenuron does not kill adult fleas but rather

controls flea populations by interrupting the life cycle at the egg stage.

MITES (CLASS ARACHNIDA, ORDER ACARINA)

Species, Life Cycle, and Distribution

Mites make up the largest group in the class Arachnida. Most are small arthropods, and many are barely visible. Mites have two body regions, a small cephalothorax and a larger, unsegmented abdomen. The cephalothorax and abdomen are broadly joined, giving most mites an oblong to globular appearance. Newly hatched larvae have three pairs of legs, and larvae acquire a fourth pair after the first molt. Mites are highly diverse. Some are parasitic, with both vertebrates and invertebrates serving as hosts; some are scavengers, some feed on plants, and many are free living and predaceous. Although most species are oviparous, some are ovoviviparous, and a few are viviparous. They occur worldwide and frequently in great numbers. Mites have been associated with disease transmission, allergies, and dermatologic manifestations. Of the approximately 35,000 species, about 50 are known to cause human skin lesions, and most of the cutaneous lesions are caused by mites feeding or burrowing in the skin. Since children and adults of all races are susceptible to these ubiquitous arthropods, they are responsible for considerable morbidity. The mites of medical importance are some of the sarcoptic mites, some of the trombiculid mites, a number of other acariform mites that infest organic substances such as grains and produce, and the gamasid mites that are vectors of several rickettsial and viral diseases. Dermatologic manifestations of mite bites may be seasonal, as with the trombiculids; individual cases or outbreaks of varying magnitude may be related to contact with mites that infest animals or various foods. Epidemics may occur, as is presently the case with scabies.

Scabies

Life Cycle.

The human scabies mite is *Sarcoptes scabiei* var. *hominis*, an obligate human parasite that completes its entire life cycle in and on the epidermis of humans. Unless treated, scabies can persist indefinitely. The adult female is responsible for the symptoms accompanying the infestation. After impregnation, she burrows into the epidermis and remains in the burrow for a life span of about 1 month. She slowly extends the burrow, feeding during travel, during which time several eggs are deposited daily. The ovoid female mite is approximately 0.3 to 0.4 mm long. Numerous transverse corrugations and dorsal spinous processes are adaptations to prevent backward movement in the burrow. The males are much smaller than females, spend more time on the surface, and have a brief life, dying shortly after copulation. The mite is passed in the vast majority of cases by intimate contact, but adult human scabies mites can survive off the host for 24 to 36 hours at room conditions and still remain infestive.^[2] Thus scabies can

be acquired from infested bedding, furniture, and clothing. Outbreaks not related to sexual activity occur frequently among nursing home patients and personnel; epidemics in schools for small children are also common. Scabies became uncommon after World War II (during the war it was a common problem), but the disease has increased in frequency since 1964 to epidemic proportions worldwide.^[85]

Clinical Aspects.

Severe nocturnal pruritus is the hall-mark of scabies. Itching also may be provoked by any sudden warming of the body and generally does not involve the face. A warm bath or radiant heat may cause a paroxysm of itching. Since the pruritus is caused by sensitization, 4 to 6 weeks may elapse between infestation and the onset of severe pruritus. Reinfestation is common, since eradicating the disease from all contacts simultaneously is often difficult, and reinfestation after cure results in prompt recurrence of symptoms. Cutaneous manifestations are varied. The primary lesion is the epidermal burrow, a tiny linear or serpentine track, rarely longer than 5 to 10 mm. The female mite may burrow anywhere on the body, but sites of predilection include the interdigital spaces, palms, flexor surfaces of the wrists, elbows, feet and ankles, beltline, anterior axillary folds, lower buttocks, and penis and scrotum. The distribution of burrows in infants may be atypical, with burrows frequently found in the scalp and on the soles. In the present epidemic, involving many people with excellent hygiene, cutaneous changes may be almost absent and burrows difficult to find. On the other hand, after the disease has been present for some time, eczematization, lichenification, impetiginization, myriad nonspecific papules and excoriations, and even urticaria may be present. The burrows are often the least conspicuous of various skin changes. The clinical picture varies with differences in personal hygiene, topical treatments used before diagnosis, and individual scratch threshold.

Diagnosis is based on the combination of nocturnal pruritus and cutaneous findings and is confirmed by microscopic examination of burrow contents. The burrow and contents may be collected for examination by scraping with a scalpel blade or by pinching the skin to elevate it and shaving off a superficial layer. Burrows are often inflamed and no longer typical after the disease has been present for some time. The most productive sites to find burrows for examination are finger webs, sides of fingers, wrists, and elbows. Ectoparasites, ova, egg castings, feces, or pieces of mites are diagnostic.

Norwegian scabies is a term describing a particularly severe form of scabies occasionally seen in senile and mentally impaired patients, those with debilitating illnesses, and immunosuppressed patients. Extensive crusting occurs, particularly of the hands and feet. Erythema and scaling may develop, and patients are literally "crawling with mites." This form of scabies is highly contagious resulting from the incredible number of mites on the patient and in the immediate vicinity.^{[13] [61]}

Nodular scabies is another troublesome clinical variation. Persistent pruritic nodules

develop, particularly on the male genitalia or in the groin, but usually on some covered body part. Nodules may be the only finding and may persist for months after adequate antiscabietic therapy.

Treatment and Prevention.

A number of topical treatments are available. In most cases a single overnight application of 5% permethrin cream (Elimite) is curative. Permethrin has the advantages of low mammalian toxicity and high cure rate.^[121] Even after adequate therapy, symptoms may persist more than a month until the mite and mite products are shed with the epidermis. The chemical must be applied even beneath the fingernails, since ova and live mites are frequently lodged there as a result of frenzied scratching. If the itching has not abated in several weeks, the patient should be reexamined for treatment failure or reinfestation. Permethrin may be used for retreatment, or alternative scabicides may be considered. Lindane lotion is highly effective but has the potential for central nervous system toxicity, and percutaneous absorption may occur. It is contraindicated in infants and pregnant women and persons known to be allergic to hexachlorocyclohexane. Sulfur in petrolatum (5% to 10%) or another suitable vehicle applied for three consecutive nights is a suitable alternative. Crothamiton 10% cream or lotion applied for two consecutive nights is also used. In the treatment of Norwegian scabies, salicylic acid ointment may be needed to soften scales and permit penetration of the scabicide. Nodular scabies can be a perplexing therapeutic problem and may necessitate intralesional injections of corticosteroids in addition to adequate antiscabietic therapy. Application of crude coal tar to the nodules has been recommended.

Contacts must be treated simultaneously. Clothing and linens should be laundered the morning after treatment to kill mites that may have strayed from the skin. When many members of a household are infested, live mites may be on the furniture; γ -benzene hexachloride sprays are available.

Control of scabies outbreaks in nursing homes and similar epidemic situations can be almost insurmountable because of the number of patients and contacts that must be treated simultaneously. An uncured case of Norwegian scabies as the focus of an epidemic may be surrounded by millions of mites. Ivermectin is an effective antiscabietic when taken orally. A single dose of 250 $\mu\text{g}/\text{kg}$ cured 10 of 11 patients with Norwegian scabies and all in a group of otherwise healthy persons with scabies; however,^[73] it is presently approved in humans for strongyloidiasis and onchocerciasis.

Zoonotic Scabies.

Other burrowing mites similar to the human scabies mite infest animals such as swine, cattle, horses, mules, sheep, dogs, and wild animals. They are relatively host specific but under conditions of close contact may cause self-limited dermatitis in humans. Because of humans' close association with dogs, the most common animal scabies is canine, caused by *Sarcoptes scabiei* var. *canis*. Studies indicate that the dog scabies mites are able to survive for at least 96 hours on human skin, even burrowing and laying eggs, but whether a perpetual life cycle can be established is not yet determined.^[29] Infested dogs have reddish papules, scaling, crusting, and evidence of scratching.

Humans develop itchy papules, often with some urtication, and scratching may give rise to varying degrees of secondary infection. The initial lesions are most often on areas of skin that come in contact with dogs: forearms, chest, anterior abdomen, and anterior thighs. Outbreaks are frequently traced to a kennel or litter of puppies. In one case, 15 patients developed an itchy dermatitis from five puppies in a single litter.^[16] Human infestation with dog scabies mites subsides spontaneously when contact with dogs is discontinued or when the dogs are cured. The dogs must be treated with scabicides and the human victims with symptomatic therapy for pruritus. Cats, also closely associated with humans, have been known to harbor mites that can infest humans. *Notoedres cati* infestation is seen more often in Czechoslovakia and Japan than is dog sarcoptic scabies.^[14]

Trombiculid Mites

Mites of the family Trombiculidae are distributed worldwide. In the United States the most important species is *Eutrombicula alfreddugesi* (red bug, chigger, harvest mite). Another species, *E. batatas*, is also indigenous to parts of the United States. Adults are free living and predaceous on small arthropods and their eggs, but the larvae are ectoparasites of vertebrates. Wild and domestic mammals, as well as reptiles, serve as hosts. The larval bite causes human dermatitis. Adult mites lay their eggs among vegetation, and newly hatched larvae crawl up on the vegetation, waiting to attach themselves to a passing host. They attach themselves to the skin with hooked mouthparts and feed on blood, falling off when full. However, humans are not good hosts, and larvae usually do not stay long. Severity of the response depends on the species of

trombiculid, the irritating qualities of the mites' saliva, and the host's allergic response. The typical bite is a maddeningly pruritic, hemorrhagic punctum that usually becomes surrounded by intense erythema within 24 hours. Bites may number in the hundreds and can be associated with an allergic reaction. Hypersensitivity causes blisters and weeping of clear fluid with crusting. The surrounding area may be purplish in color, with severe swelling, particularly of the feet and ankles ([Figure 36-19](#)). The lesions regress in 1 to 2 weeks, but pruritus is persistent and often paroxysmal during this time, with secondary infection in excoriated skin.

Treatment is symptomatic and consists of topical antipruritic agents, corticosteroids, systemic antihistamines, and occasionally, pulse therapy with systemic corticosteroids. Superpotent topical corticosteroid creams and ointments, such as 0.05% clobetasol, applied sparingly to individual bites several times daily, are effective but must be used properly. Prolonged application can result in atrophy, and absorption can be significant if excessive body surface is treated. Phenol 1% in calamine often is effective. As in all self-limited conditions with no satisfactory cure, home remedies abound, such as meat tenderizer rubbed into the moistened skin. Application of clear nail polish to the individual lesions is a popular home remedy, even though no evidence suggests that

this is effective.

Preventive measures consist of avoidance and insect repellents used on skin and clothing. Clothing pretreated with permethrin has resulted in 74.2% increase in protection compared with unprotected controls.^[9] Other repellents suggested for treating clothing are ethylhexandiol, DEET, and flowers of sulfur. The symptoms are allergic, and permanent residents in infested areas may develop tolerance to repeated bites.

Miscellaneous Mites

Parasitiformes.

This group contains gamasid mites that are parasites of birds, mammals, snakes, insects, and rarely, humans. In addition to being vectors of disease, gamasid mites are responsible for some cases of dermatitis. The chicken mite, *Dermanyssus gallinae*, is responsible for most of the dermatitis caused by this group. This pest of poultry is widespread and is associated with both domestic and wild birds. Poultry workers are common targets, but other persons may be infested from insidious sources, such as a pet canary or bird nest near an intake for ventilation or air conditioning. The clinical picture is nonspecific, but the diagnosis may be made by identifying the mite. Treatment consists of symptomatic therapy and eradication of the mite source.

The tropical rat mite *Ornithonyssus bacoti* has also been reported to cause dermatitis, from such diverse sources as a rat nest in the attic or a colony of laboratory mice.^[15]^[33] Snake mites have been implicated as a

Figure 36-19 Chigger bites.

cause of dermatitis. Four members of one family developed a vesicobullous eruption from *Ophionyssys natricis* harbored by a pet python.^[106]

Acariniformes.

This huge group includes mites that infest foods, feathers, and furs. Individual infestations and larger outbreaks are common, with increased exposure by occupation, resulting in such terms as *grocer's itch*, *miller's itch*, and *copra itch*. Dogs, cats, and rabbits are primary hosts for mites of the genus *Cheyletiella*, and domestic pets are increasingly the source of mite dermatitis. Pet house cats are often involved.^[100]

Mites of the genus *Dermatophagoides* are said to be the principal inhaled allergen of house dust. *D. schereemetewskyi* is an unusual mite that has been found in kapok and feather pillows, in a sparrow's nest, in monkey food, and on rats and other animals. This mite has been reported as the cause of feather pillow dermatitis.^[3]

The most common type of dermatitis in this group is grain itch caused by *Pyemotes ventricosus*. This tiny mite parasitizes various insects often found in and around grain and straw. It attacks humans when a large mite population has no ready access to normal hosts. Grain itch implies an occupational bias, but outbreaks not involving farmers or rural workers have been described. During a widespread epidemic of *Pyemotes* infestation of farm workers in the midwestern United States in 1950 to 1951, straw used at the Indiana State Fair was infested. During a 2-year period, 642 visitors were treated for grain itch at a dispensary maintained

885

on the fairgrounds, and about 1100 animal attendants and fair workers were treated over the same period at a separate facility. The reservoir of infestation by *Pyemotes* may be quite obscure. Several cases have been reported associated with the common furniture beetle *Anobium punctatum* in the floor joists of a house.^[31] Therapy is symptomatic. Large-scale eradication measures may require services of professional exterminators.

DELUSIONS OF PARASITOSIS

Patients with delusions of parasitosis are convinced, against all evidence to the contrary, that parasites infest their skin and often their homes and clothing. No single cause is known for this condition, although some cases may be associated with proven parasitic infestation. The idea may also be suggested by infestations of relatives or acquaintances. Patients over 50 years are most often female; patients under 50 are equally male and female. Most cases of delusions of parasitosis commence with pruritus, which may be accompanied by crawling, creeping, stinging, and burning sensations. The initial reaction is to scratch, replaced soon by digging to remove the "parasites." Self-mutilation and suicidal behavior may develop. Generally the first contact with a physician is to bring in evidence of the "infestation." Evidence typically consists of scales, lint, crusts, hairs, dust, and small pieces of skin, carefully collected and stored in a small box or folded in facial tissue. Medical attention is often sought not to relieve the symptoms but to eradicate the parasites. Patients may take the evidence to a professional entomologist for identification and may employ professional exterminators for repeated fumigation. Patients may be so convincing that household members or acquaintances come to share the delusion. ^[24] ^[30]

Many patients with parasitophobia know that their fear is groundless but are still unable to overcome it. Other patients with delusions of parasitosis are convinced that they have an infestation and regard as incompetent the physician who makes the correct diagnosis of no infestation. A complete examination of the patient and the evidence is essential, and investigation of the home or workplace may be indicated. Other medical conditions that may produce cutaneous sensations include liver and renal disease, alcoholism and toxic states, diabetes mellitus, cardiovascular disease, lymphoma, anemia, sideropenia, vitamin B₁₂ deficiency, pellagra, peripheral neuritis, dermatitis herpetiformis, drug reactions, and environmental irritants (e.g., arthropods, fiberglass). ^[70] ^[137]

Psychiatric intervention is often unsatisfactory to both patient and physician. Convinced that the physician is wrong, patients often seek repeated opinions and finally become despondent. Pimozide, a neuroleptic medication used to treat other monosymptomatic hypochondriacal psychoses, has been found useful in treating this condition. ^[81] ^[93] ^[98] In one group of 14 patients treated with pimozide and followed for an average of 34 months, seven had complete remissions, three had relapses that responded to treatment with pimozide, and four were treatment failures. ^[65]

IN MEMORIAM

It is with great sadness that we observe the passing of Sherman Minton, MD, who was

an outstanding teacher, scientist, and friend. His contributions to this book and the entire wilderness medicine community were extensive and generous, and we will always be in his debt.

Paul Auerbach, MD

Chapter 37 - Non-North American Arthropod Envenomation and Parasitism

Sherman A. Minton †
H. Bernard Bechtel
Timothy B. Erickson

HYMENOPTERA (BEES, WASPS, AND ANTS)

Hymenoptera insects are worldwide in distribution and often constitute a major part of a region's insect fauna. Honeybees are exploited for their honey throughout the world; even the aggressive *Apis mellifera scutellata* is used for honey production in Africa. Honeybees in southern Asia attach huge nests to limbs of forest trees. The giant bee, *Apis dorsata*, of southeast Asia has a reputation for savagery, and deaths from multiple stings have occurred. Yellowjackets and hornets are common in Europe and the Middle East and have similar medical importance as in the United States. Two species, *Vespula orientalis* and *V. vulgaris*, have recently been introduced into Australia, where they have become a significant problem.^[30] Paper wasps of the genus *Polistes* are plentiful in tropical America and Australia. Another Australian paper wasp, *Ropalidia revolutionalis*, constructs nests that resemble belts of bullets and hangs them from shrubs and fences. Fire wasps (*Polybia*) are found from Mexico to northern South America. The common species are black with yellow markings. They construct globular, cylindrical, or cone-shaped paper nests up to 70 cm long that are usually hung from trees and sometimes under bridges. They may defend these nests with great vigor.

Ants have numerous stinging species in the tropics. Although native to South America, fire ants do not seem to be a major medical problem there, perhaps because of native competitors, predators, and parasites. Two fire ant species are important in areas outside the United States. *Solenopsis geminata* has been introduced into Okinawa and Guam and is widespread in Central America, Mexico, and some Caribbean islands. *S. xyloni* is common in Mexico and also occurs in California and Texas. *S. invicta* has been introduced into Puerto Rico. Amino acid sequences of all fire ant venoms are very similar.^[23] Presumably, all fire ant stings are similar and can be managed medically in

the same manner.

The samsum ant, *Pachycondyla sennaarensis*, is an ecologic counterpart of the fire ant widely distributed in the African tropics and Arabian peninsula. It nests in the ground but does not make a conspicuous mound. In the United Arab Emirates it is plentiful in urban areas and the cause of many stings.^[13] Australian bull ants are large insects (about 20 mm) with prominent jaws ([Figure 37-1](#)). They are ground dwelling and common in suburban areas in southeastern Australia. Many neotropical stinging ants live in trees. The giant black ants (16 to 22 mm) of the genus *Paraponera* are found from Nicaragua to the Amazon basin. Although they nest in the ground, workers forage in trees from almost ground level to high in the forest canopy. They are most active at night. The green tree ant of northeastern Australia makes a leaf nest in trees. It has no true sting but ejects formic acid into wounds made by its jaws.

Clinical Aspects

No unique features distinguish Hymenoptera envenomations in other parts of the world from those in North America. Venoms of the various groups show little geographic variation. This is also true of groups at risk, with the possible exception of a few honey-gathering Asian tribes. The incidence of Hymenoptera sting allergy may be slightly higher in western Europe than in the United States, and fatal allergic reactions may be slightly more common.^[8] Systemic anaphylactic reactions to stings of Australian bull ants and samsum ants are increasing, with reports of a few fatalities. Patients with history of systemic reactions to samsum ant stings have immunoglobulin E (IgE) and positive skin test reactions to fire ant venom.^[13] *Paraponera* ant stings are intensely painful for several hours and may be accompanied by fever and lymphadenitis.

LEPIDOPTERA

The Lepidoptera show high diversity in the tropics with correspondingly greater medical importance, particularly in Latin America. Caterpillars of the genus *Lonomia* native to northern South America can inflict life-threatening stings ([Figure 37-2](#)). These caterpillars are 50 to 70 mm long and have numerous branched dorsal spines. They live in primary tropical forests in groups of up to about 50 individuals. Disturbance of their habitat has resulted in an increasing number of envenomations. Venom of *Lonomia* is a protein that activates prothrombin and is stimulated by factor V and calcium ions.^[21] Stings cause intense pain but not much local reaction. Signs of coagulopathy, such as ecchymoses,

†Deceased.

889

bleeding gums, hematuria, and melana, may develop in a few hours or be delayed a week or more. Fibrinogen, factor V, factor XII, and plasminogen are decreased; fibrin degradation products are increased; and platelets usually are normal. Acute renal failure, cerebral hemorrhage, and pulmonary hemorrhage may occur. Coagulopathy lasts 2 to 5 weeks.

In one series of 33 cases, four were fatal.^{[1] [6] [16]} Treatment with prednisone, plasma, and whole blood is ineffective. An antivenom has been developed, and a preliminary report indicates possible clinical effectiveness.^{[11] [12]}

Neotropical caterpillars of the genera *Dirphia*, *Megalopyge*, and *Automeris* are large, stout, spiny, and sometimes covered with hair. Most are forest species but can adapt to areas of cultivation. Agricultural workers are most often stung; the incidence of stings is higher in the rainy season. Intense, centrally radiating pain with local edema and erythema is typical; lymphadenopathy is often seen. Systemic symptoms include nausea, headache, malaise, chills, and fever. Hypotension, shock, and convulsions have been reported. An *Automeris* caterpillar bite reported from French Guyana produced syncopal pain and edematous infiltration of the thigh lasting several days.^[10] Symptoms usually subside within 24 hours. Treatment is symptomatic. Oral antihistamines are often effective if given within about

Figure 37-1 Red bull ant.

Figure 37-2 A, Caterpillar of *Lonomia achelous*, which can inflict injuries characterized by potentially fatal coagulopathy. **B**, Moth of *L. achelous*, which has no venomous spines.

an hour after the sting. Codeine or meperidine is occasionally needed to control pain.

A chronic granuloma of the hands of Brazilian rubber tappers known as *pararama* results from contact with caterpillars of *Premolis semirufa*. Permanent disability may result. ^[39]

Moths of the genus *Hylesia* occur from southern Mexico to Argentina. The caterpillars have venomous spines, but the greatest problem is created by the moths, which have a coating of spines on their abdomen. The spines or setae are hollow and pointed, contain a toxin of unknown nature, and are freely shed into the air. The moths are attracted to lights in enormous numbers, and their airborne spines can cause great discomfort. Their activity has created serious problems at airports, shipping docks, and tourist resorts. Within a few minutes to a few hours after contact with the spines, victims develop a pruritic, erythematous rash that progresses to urticaria and excoriation. Any portion of exposed skin may be involved, but palms and soles are often spared. Irritation of eyes and mucous membranes is unusual. Symptoms subside in about a week if there is no further exposure. Topical and systemic treatments have had little success. ^[14]

In Korea, outbreaks of dermatitis, presumably caused by setae of the yellow moth *Euproctis flava*, are well known. In the summer of 1980, hundreds of U.S. soldiers were affected. ^[3] The caterpillars feed on hardwood trees; great numbers of moths appear in summer and are attracted to lights. Dermatitis usually involves direct contact with moths or their cocoons or with clothing contaminated with setae. The lesions are similar to those described for *Hylesia* and are equally refractory to treatment. Other outbreaks of dermatitis ascribed to *Euproctis* moths and caterpillars have been reported in Japan and China. One outbreak in Shanghai in 1972 affected about 500,000 individuals. Cases of *Euproctis* dermatitis and ophthalmia have also been reported

in Australia and Great Britain. Sensitization with elevated IgE levels may occur. ^[39] ^[44]

In the Mediterranean region and Middle East the pine processionary caterpillar, *Thaumetopoea pityocampa*, is plentiful and makes silk nests in trees. Its setae cause a maculopapular rash occasionally accompanied by urticaria, bronchitis, and conjunctivitis. Outbreaks typically occur when groups of tourists and military personnel

camp in pine groves. The rash usually results from contact with detached setae rather than with caterpillars. The adult moth stage apparently does not have irritating spines.

Moths of the genus *Calyptra* native to Southeast Asia have a serrate proboscis and feed on mammalian blood, including that of humans. Tropical species of several moth genera feed on human ocular secretions. Their medical importance is unknown.

BEETLES AND OTHER INSECTS

Small rove beetles of the genus *Paederus* are troublesome in many tropical and subtropical regions. The whiplash beetle or Finch Hatton bug (*Paederus australis*) caused evacuation of an entire aboriginal community in northern Australia,^[46] and a large suburban hospital in Sri Lanka had 108 cases of painful dermatitis among members of its staff on night duty.^[27] Staphylinid (rove) beetle dermatitis epidemics have been reported in Nigeria in 1990, Egypt in 1994, and Kenya in 1998 after sudden floods.^[9]

These beetles are slender with elongate abdomens and very short rectangular elytra. They frequent damp habitats and may be plentiful in irrigated crop fields. They usually fly after dark in hot, humid weather and are attracted to lights. Their vesicant secretion is an alkaloid present in greatest concentration in hemolymph; it is usually deposited on human skin when the beetles are pressed or crushed but may occasionally be spontaneously secreted. There is no immediate reaction to the secretion, but after 12 to 24 hours, painful erythematous lesions develop and soon become vesicular. The vesicles last 3 to 7 days and are followed by crusting and pigmentation. Conjunctivitis results if the secretion is rubbed into the eyes. This condition is known in parts of the world as "Nairobi eye" or "Christmas eye."^[9] Some persons with extensive skin involvement may show generalized symptoms. Treatment is symptomatic and not very effective. Prompt soap and water washing after insect contact is recommended. Screening of sleeping and working quarters is the best prevention.

Lady beetles (ladybugs, family Coccinellidae) are widely distributed and highly beneficial as predators on aphids and scale insects. Species in the eastern United States often overwinter in houses and do no harm. However, an Australian lady beetle, *Diomus notescens*, is reported to bite, causing papules with small necrotic centers.^[40] Two cases of human ear invasion by a predaceous beetle, *Crasydactylus punctatus*, or the carabid beetle, have been reported from Oman. One victim had a severe otologic injury caused by biting and chewing on the external auditory canal and tympanic membrane.^[4]

DIPTERA (TWO-WINGED FLIES)

Most dipterans are cosmopolitan in distribution. However, two groups of biting flies and several species involved in human myiasis are largely confined to the tropics and are discussed here (see [Table 36-1](#)).

Sand flies (*Phlebotomus* and related genera) are very small biting flies quite distinct from *Culicoides* and its relatives. They are widely distributed in tropical and subtropical regions. They live in damp, shaded places such as mammal burrows, rock crevices, and cracks in walls of houses and other structures. Favorite habitats in Central America are *gambas*, deep clefts between the buttresses of large forest trees. Larval and pupal stages are found in moist detritus in holes and crevices. The adults usually emerge at night when air is still and temperatures are above 13° C (56° F). They are poor fliers. Sand flies are vectors of leishmaniasis and of *Bartonella bacilliformis* in Peru. Sand fly populations can be controlled with pyrethroid insecticide sprayed into the mounds and burrows. Spraying of a 100-m-wide barrier zone around a campsite can reduce sand fly numbers for an extended period.^[17]

Tsetse flies (*Glossina* species) are of great importance as vectors of human and animal trypanosomiasis in sub-Saharan Africa. Although not closely related to deerflies and other tabanids, they are similar in appearance and habits (see [Chapter 36](#)). Their life history is peculiar in that a single large larva develops in the uterus of the female and is expelled shortly before pupation, which takes place in the soil. Tsetse fly bites produce comparatively little local reaction other than brief pain and itching.

Myiasis

Furuncular Myiasis.

This type of myiasis is caused by flies whose larvae penetrate human skin and develop in that location, producing boil-like lesions with an external opening. Formerly, this condition was encountered almost exclusively in the tropics, but with the growing popularity of ecotourism and other travel to unconventional destinations, cases are being seen in many other parts of the world. A German travel clinic reported 13 cases in travelers returning from tropical countries during a 3-year period.^[25]

The classic agent of furuncular myiasis is the so-called human botfly, *Dermatobia hominis* ([Figure 37-3](#)). Actually, humans are only one of many mammals that serve as suitable hosts for the obligately parasitic larvae of this fly. It is widely distributed in the

tropics and is an important parasite of domestic cattle in many places. Human infection seems to be most prevalent in Central America and northern South America. Adult flies resemble a bumblebee (body length about 15 mm). They do not feed and are infrequently seen. The life cycle of this fly is unique in that the female attaches her eggs to the body of another arthropod for transfer to the host. Large mosquitoes of the genus *Psorophora* are often used (8% were found bearing *Dermatobia* eggs in one study), but about 40 species of insects and ticks have been reported to be egg carriers. When the carrier alights on a mammal, the eggs hatch immediately, and the larvae enter the skin through the bite of the carrier or some other small trauma. Small larvae are fusiform and later become pyriform to ovoid as they reach full development at

Figure 37-3 *Dermatobia* larva.

lengths of 15 to 20 mm. They are encircled by several rings of spines. The larval stage lasts 6 to 7 weeks, after which the larva emerges from the skin and drops to the ground, where pupation occurs.

Infection is fairly common among rural people of Central America. Cases in returned tourists and visitors from Latin America have been diagnosed in many parts of the United States. Six cases occurred in one group of tourists visiting archaeological sites in Guatemala.^{[15] [26] [28] [37] [45]} Lesions may be on any part of the body exposed to insect bites and may be single or multiple. An initial pruritic papule becomes a furuncle, with a characteristic opening from which serosanguineous fluid exudes. Pain often accompanies movements of the older larvae, but the lesion is not particularly tender to palpation. Lymphadenopathy, fever, and secondary infection are rare.

This form of myiasis should be suspected in patients with furuncular lesions and history of residence or travel in endemic areas. It must be differentiated from leishmaniasis and onchocerciasis, which have a different prognosis and treatment. The sensation of movement within the lesion, accompanied by pain but little tenderness or inflammation, suggests myiasis. The tip of the larva may protrude from the central opening, or bubbles produced by its respiration may be seen. Often, simple pressure will extrude the organism, particularly if it is small.^[36] Occlusion of the breathing hole may cause the larva to emerge sufficiently for it to be grasped and withdrawn. An effective folk remedy is binding a piece of fat, such as bacon, over the opening ([Figure 37-4](#)).^[5] This often causes the larva to leave its

Figure 37-4 A, Lateral view of three lesions caused by infestation with *D. hominis* larvae. The nodules were initially assumed to be furunculosis. A central breathing aperture is present in each nodule. Serosanguineous fluid is draining from two of the nodules. Larval spiracles are visible emerging from the uppermost nodule. **B**, The fatty portion of multiple strips of raw bacon were placed over the larval apertures to obstruct the air supply and encourage the larvae's egress from the skin. **C**, After approximately 2 hours of treatment with bacon therapy, the *D. hominis* larvae have emerged far enough from the subcutaneous tissues to be grasped with forceps. The larva is removed intact. (From Felsenstein D et al: JAMA 270:2087, 1993.)

burrow. Another technique is injection of about 2 ml of a local anesthetic into the base of the lesion, thus extruding the larva by fluid pressure.

If these methods are unsuccessful, surgical excision under local anesthesia is indicated. Whatever method is used, care should be taken not to break or rupture the larva. This may cause a strong inflammatory reaction, often followed by secondary infection. Repeated infections tend to confer some immunity that may abort larval development. Screens, protective clothing, and use of insect repellents are helpful in preventing infestation.

Furuncular myiasis in tropical Africa is caused by the tumbu fly, *Cordylobia anthropophaga*. The larval stage of this fly is an obligate parasite of many mammals, of which rats and dogs are most important epidemiologically. The adult is about the size of a housefly, but stockier. It prefers shade and is most active in early morning and afternoon. Females lay eggs on dry sandy soil or on clothing. They are attracted by the odor of urine. The eggs hatch in 1 to 3 days, and hatchling larvae can survive up to 2 weeks waiting for contact with skin of a suitable host. They can penetrate unbroken skin. They become fusiform to ovoid and reach a length of 13 to 15 mm. The larval stage is completed in 9 to 14 days.

Human infections occur in most nations of sub-Saharan Africa. Transmission increases during the rainy season. Among indigenous peoples, infection is most frequent in children; adults evidently acquire some immunity. Infections among Americans and Europeans visiting Africa are reported regularly.^{[24] [25] [43]} Lesions may be on any part of the body but are more common on the legs and buttocks. The furuncles are discrete, elevated, and nontender and have a central opening. The number of lesions, up to about 50, is greater than with *Dermatobia*. Infections in children have been mistaken for chickenpox,^[35] but the course of the infection is much shorter. An exceptionally heavy infection (about 150 larvae) was caused by *Cordylobia rodhaini*, normally a parasite of forest mammals. It was accompanied by lymphadenopathy, leukocytosis, and elevated IgA. Clothing left to dry on the ground was the presumed source of the parasites.^[38]

Principles of diagnosis and treatment are much the same as for *Dermatobia*. Avoidance of skin contact with potentially contaminated soil and ironing of clothing and bedding after open-air drying are preventive measures that often are difficult to achieve.

Hematophagous Myiasis.

The sole cause of hematophagous myiasis is the Congo floor maggot, *Auchmeromyia luteola*. It is dark, distinctly segmented, ovoid, 15 to 18 mm long, and assumes the larval stage of a moderate-size yellowish fly. It is widely distributed in sub-Saharan Africa and is essentially a human parasite. It is unique among parasitic fly larvae in living apart from its host in the earthen floor of native dwellings. It seeks persons lying or sitting on the floor or on mats and feeds intermittently on blood, usually at night. The bites are trivial but may interfere with sleep. Sensitization appears to be uncommon.

Wound Myiasis.

About 85% to 90% of cases are caused by larvae of flies of the family Calliphoridae, which includes both obligate parasites and opportunists. The most dangerous type of myiasis may be caused by larvae of the screw-worm flies *Callitroga (Cochliomyia) americana (hominivorax)* in the Americas and *Chrysomya bessiana* in Asia and Africa. The adults are rather stocky flies, 8 to 12 mm in body length, and metallic blue-green to purplish black.

The parasitic larvae are pinkish, fusiform, and strongly segmented, providing the common name. Length at maturity is 12 to 15 mm. They are obligate parasites whose chief hosts are cattle, sheep, and goats. They are a major cause of economic loss among livestock. Enzootic areas are mostly in the tropics and subtropics; in the past, summer infections have occurred as far north as Colorado and Nebraska. Female flies deposit eggs near any break in the skin or around the nose, mouth, or ears if a discharge is present. Larvae invade healthy tissue, often causing considerable damage. The larval stage lasts 4 to 8 days, and the entire cycle is 15 to 20 days in enzootic areas. Screw-worm has been eradicated in the southern United States and some other areas primarily through the release of large numbers of laboratory-bred male flies sterilized by gamma irradiation. Females mate only once, so mating with a sterile male nullifies the female's reproductive effort, greatly reducing the population.

Flies may be dispersed by prevailing winds. Infection is often acquired while resting outside during the day or may result from trauma.^[32] Lesions may appear on any exposed part of the body. Those on the scalp may be associated with pediculosis capitis. Typical dermal lesions are ulcers or sinuses that may contain up to 200 larvae. These are surrounded by a zone of induration. Pain is variable. Secondary bacterial infection is common. Tissue destruction may be extensive and mortality is associated with nasopharyngeal invasion.

Topical application of 5% chloroform in olive oil followed by irrigation and manual removal of larvae is often sufficient in dermal infections. Deeper nasopharyngeal and orbital infections require surgery. Antimicrobial therapy as dictated by culture and sensitivity tests, is often necessary. The most effective prevention is elimination of the

disease in domestic animals.

BURROWING FLEA

Flea infestations tend to be similar clinically and associated with the distribution of animal hosts. However, one flea, *Tunga penetrans*, is responsible for a distinctive infestation known as tungiasis. The flea has a number of common names: burrowing flea, chigo, sand flea,

893

and jigger. Infestation is common in Central and South America and in Africa, where the burrowing flea is widely distributed, but more cases are seen in the United States as increasing numbers of tourists visit exotic places. One woman resident of New York City developed lesions of tungiasis on her toes after visiting several countries in East Africa, where she frequently wore sandals in rural areas.^[47] The primary lesions of tungiasis are produced by the female flea. As soon as it is impregnated, it burrows into the skin until only the posterior end protrudes. Sucking blood, the insect becomes as large as a small pea and deposits eggs that fall to the ground. Lodged in the skin, the gestating female produces a firm itchy nodule, with the posterior end of the flea visible as a dark plug or spot in the center of each nodule. Lesions occur most often on the feet, buttocks, or perineum of persons who wear no shoes or frequently squat, since the burrowing flea is not a good jumper and abounds in the dusty soil surrounding human habitations. If the infestation is extensive, numerous papules may aggregate into plaques with a honeycomb appearance. Secondary infection around each flea is inevitable, resulting in suppuration, ulceration, and rarely gangrene. The lesions become painful or even crippling, and severe infections may lead to death. If the burrowing flea is not removed, the pustule ruptures, leaving an ulcer. Wearing shoes will prevent most cases of tungiasis.

Cases should be treated promptly. One method is curettage of each nodule under local anesthesia, with concomitant use of systemic antibiotics to prevent secondary infection. Ether pledgets applied to the skin will kill the fleas before curettage is begun. Where burrowing fleas are endemic, eradication is important. Floors must be swept free of dust, and insecticides may be sprayed or dusted.

CENTIPEDES AND MILLIPEDES

Centipedes are elongate, flattened arthropods with one pair of legs for each of the typical body segments, which

Figure 37-5 A, Centipede, *Scolopendra armidale*. **B**, Centipede fangs.

may number from 15 to more than 100. The first segment bears a pair of curved hollow fangs with venom glands at the bases. The last segment bears a pair of filamentous to forcepslike caudal appendages not associated with the venom apparatus. The largest species reach lengths of about 30 cm (12 inches). Most centipedes live in crevices or beneath objects on the ground. Some are burrowers, and others are climbers. Many are nocturnal. *Scutigera coleoptrata*, with body length of 25 mm and long thin legs, is a common house arthropod in much of the United States. *Lithobius* is a cosmopolitan ground-dwelling genus. A species common in eastern U.S. gardens is orange and 30 to 50 mm long. Centipedes prey chiefly on invertebrates, but larger species occasionally eat small vertebrates. Female centipedes of some species curl around their egg clusters and newly hatched young and may actively defend them.

Centipedes use venom primarily to kill prey and only secondarily for defense. Venom may also have a digestive function. Enzymes, including acid and alkaline phosphatase and amino acid naphthylamidase, lipoproteins, histamine, and serotonin, are variably present.^[33] Venom of *Scolopendra subspinipes* produces hypotension followed by hypertension. The major lethal toxin is an acidic protein with molecular weight of 60,000 daltons. It produces vasoconstriction, increased capillary permeability, and cardiac arrest.^[19] ^[20]

As with spiders, any centipede whose fangs can penetrate human skin can cause local envenomation. Centipede bites are typically pointed in shape, a feature that can help differentiate a bite from a large centipede from a snake.^[18] Contrary to popular folklore, centipedes do not inject venom with their feet or caudal appendages. The jaws inject a neurotoxic venom through venom ducts. Centipede bites have been reported from numerous tropical and subtropical regions, but never as a serious medical problem. Most bites have been ascribed to species of *Scolopendra*, which has a wide distribution with several species in the southern United States ([Figure 37-5](#)). Fatalities are almost unknown; however, a death in the United

Figure 37-6 *Spirobolus* millipede.

States was recently mentioned, but with no locality or details.^[29]

Burning pain, local swelling, erythema, lymphangitis, and lymphadenopathy are common manifestations of a centipede bite. Swelling and tenderness may persist for as long as 3 weeks or may disappear and recur. Superficial necrosis may occur at the site of fang punctures. Few bites with serious systemic reactions have been reported in detail. In one case ascribed to *Scolopendra heros* in the southwestern United States, a woman had massive edema of the leg, necrosis of the peroneal muscles, loss of motor function in the foot, myoglobinuria, and azotemia.^[31] An Israeli patient bitten on the neck complained of inability to turn her head, probably because of muscle spasm.^[34] Other cases have been characterized by dizziness, nausea, collapse, and pyrexia.^[7] An infant that ingested a centipede identified as *Scutigera morpha* developed hypotonia, vomiting, and lethargy, presumably from being bitten in the mouth or pharynx. The child recovered spontaneously after about 48 hours.^[2]

Although some centipede bites may be excruciatingly painful, they are not fatal and seldom require more than supportive care. Treatment of centipede envenomation is symptomatic. Infiltration of the bitten area with lidocaine or another anesthetic promptly relieves pain. Antihistamines and steroids have been suggested for more severe reactions. Tetanus prophylaxis is advisable.

Millipedes differ from centipedes in having two pairs of legs per body segment and in lacking apparatus for injecting venom. Several large species of the genus *Spirobolus* are common in the southern United States ([Figure 37-6](#)). Some species are broad and short and roll into a ball when disturbed ([Figure 37-7](#)). Millipedes are generally ground dwelling and secretive. Occasionally, they aggregate in enormous numbers. They generally feed on decaying vegetation.

Millipedes are exceptionally well endowed with defensive chemical secretions that include hydrogen cyanide, organic acids, phenol, cresols, benzoquinones, and hydroquinones. These effectively deter most

Figure 37-7 Giant Madagascar millipede.

predators. Some large species can eject secretions for distances up to 80 cm (32 inches).

Human injury from millipede secretions has been reported from a number of tropical regions. The most common injury is dermatitis that begins with a brown-stained area, which burns and may blister and exfoliate. Millipede secretion in the eye causes immediate pain, lacrimation, and blepharospasm. This may be followed by chemosis, periorbital edema, and corneal ulceration. Blindness has been reported. ^[22] ^[41] Individuals exposed to large millipede aggregations may complain of nausea and irritation of the nose and eyes. No specific treatment is available. Prompt irrigation with water or saline should be followed by analgesics, antimicrobials, and other measures appropriate for superficial chemical burns. Ophthalmologic evaluation is mandatory for eye injuries.

GENERAL TREATMENT OF INSECT BITES

Oral antihistamines can be effective in reducing the symptoms of insect bites. Cetirizine was given prophylactically in a double-blind, placebo-controlled, 2-week crossover trial to 18 individuals who had previously experienced dramatic cutaneous reactions to mosquito bites.^[42] Subjects given the active drug had a 40% decrease in both the size of the wheal response at 15 minutes and the size of bite papule at 24 hours. The mean pruritus score, measured at 15 minutes and 1, 12, and 24 hours after being bitten, was 67% less than that of the untreated controls. These studies have not been done with astemizole, loratadine, or fexofenadine. In highly sensitized individuals, prophylactic treatment with nonsedating antihistamines may safely reduce the cutaneous reactions to insect bites.

A 3.6% ammonium solution (After Bite), relieves the type I hypersensitivity symptoms associated with mosquito bites. In a double-blind, placebo-controlled laboratory trial, 64% of mosquito-bitten subjects experienced complete relief of symptoms after a single application of the ammonium solution, and the remaining 36% had partial relief lasting 15 to 90 minutes.

895

No subjects treated with placebo reported complete symptom relief.^[48]

PROTECTION AND PREVENTION

An integrated approach to personal protection is the most effective way to prevent arthropod bites, regardless of location and species. Insect repellents containing diethyltoluamide (DEET) are the most effective products currently on the market, providing broad-spectrum repellency lasting several hours. Topical insect repellents alone do not provide complete protection. Mosquitoes, for example, can find and bite any untreated skin and may even bite through thin clothing. Deerflies, biting midges, and some blackflies prefer to bite around the head and will crawl into the hair to bite unprotected areas. Wearing protective clothing, including a hat, reduces the chances of being bitten. Treating clothes and hats with permethrin maximizes protection by repelling any insect that crawls or lands on the treated clothing. To prevent chiggers or ticks from crawling up the legs, pants should be tucked into boots or stockings.

Persons traveling to a part of the world where insect-borne disease is a potential threat should be certain to learn about indigenous insects and the diseases they might transmit. Protective clothing, mesh insect tents or bedding, insect repellent, and permethrin spray should be carried.

Chapter 38 - North American Venomous Reptile Bites

Robert L. Norris Jr.
Sean P. Bush

INTRODUCTION

North America is unique in that it is home not only to venomous snakes, but also to the world's only known venomous lizards. Fortunately, bites by venomous reptiles in North America are relatively uncommon, although precise statistics are not available. The only systematic attempt to evaluate the incidence of venomous snakebite in the United States was done in the late 1960s by Dr. Henry Parrish. He estimated that there were approximately 7000 bites by venomous snakes, of which approximately 15 ended in death.^[106] The incidence of venomous snakebite may have changed significantly since Parrish's study, but given that snakebite is not a reportable "disease," no mechanism exists for obtaining reliable data. The incidence of snakebite in Canada is lower than that in the United States because fewer snakes species are found farther north up the continent. In Mexico, however, snakebite takes on increasing medical importance because this country has more venomous snake species than any other nation in the New World.^[16] As many as 150 deaths may be caused by snakebite in Mexico each year.^[46]

Establishing credible estimates of the incidence of venomous lizard bites is even more difficult than for snakes. The vast majority of victims are bitten while intentionally interacting with the lizard, and since these creatures are legally protected, many bites are probably never reported.

Many physicians called on to render acute care to snakebite victims have had limited experience with the potentially complex syndromes of snake venom poisoning. In addition, convincing research sponsors to fund needed studies evaluating prehospital care techniques, hospital management principles, and antivenom development is difficult when the targeted population size is only a few thousand individuals.

Snake venoms are highly complex mixtures of enzymes, low-molecular-weight polypeptides, glycoproteins, minerals, and other unidentified substances. Venoms vary

among species, within a single species depending on its geographic distribution, and even within an individual snake depending on factors such as age, diet, and health. ^[118] The effects of a particular venom may be different depending on the species of prey or research animal that has been poisoned. Such variables make it difficult to conduct meaningful research into snakebite management techniques.

[Table 38-1](#) lists the species of venomous reptiles found in North America. ^[16] ^[46] ^[52] ^[74] ^[115] The medically important North American venomous snakes all fall into the families Viperidae (subfamily Crotalinae, the crotalines or pit vipers) and Elapidae (elapids, the coral snakes). Although there are reports of human envenoming by a handful of species of Colubridae—the family of snakes traditionally regarded as harmless—the cases from North America have all been relatively minor and non-life threatening (see [Chapter 39](#)).

Pit vipers are widely dispersed throughout most of North America below southern Canada (south of 55 degrees north latitude). ^[96] In the United States, for example, all 48 contiguous states except Maine have at least one pit viper species. ^[107] Being poikilothermic and relying on environmental heat energy to support locomotion, feeding, digestion, and reproduction, snakes tend to increase in numbers of species as one moves southward toward the equator. At least 34 species of pit vipers are found in North America, with many more subspecies. Pit vipers can be further divided into rattlesnakes (genera *Crotalus* and *Sistrurus*, approximately 30 species); copperheads, cottonmouth water moccasins, and cantils (genus *Agkistrodon*, three North American species and a number of subspecies); and lance-heads (genus *Bothrops*, with one species in eastern Mexico, *B. asper*). ^[46]

Rattlesnakes are the most widespread of pit vipers, found throughout most of North America ([Figure 38-1](#), [Figure 38-2](#), [Figure 38-3](#), [Figure 38-4](#), [Figure 38-5](#), [Figure 38-6](#), [Figure 38-7](#), [Figure 38-8](#), [Figure 38-9](#)). Copperheads (*Agkistrodon contortrix*) are found in the central and southeastern United States and westward into the Big Bend region of Texas ([Figure 38-10](#)). Cottonmouth water moccasins (*Agkistrodon piscivorus*) are found in the southeast from Virginia to Florida and extend westward into central Texas ([Figure 38-11](#)). In Mexico the copperhead and cottonmouth are replaced by the cantil, *Agkistrodon bilineatus* ([Figure 38-12](#)). ^[52] The pit vipers of North America come in a wide range of sizes. Among the smaller rattlesnakes are the sidewinders (*Crotalus cerastes*), ridge-nosed rattlesnakes (*C. willardi*), and

pygmy rattlesnakes (*Sistrurus miliarius*), whose adult sizes are routinely less than 65 cm.^[74] At the other extreme, the eastern diamondback rattlesnake (*Crotalus adamanteus*) can exceed 2 m.^[74]

Outside of North America the family Elapidae contains a number of extremely dangerous species, such as cobras (genus *Naja*), mambas (genus *Dendroaspis*), and all the potentially lethal snakes of Australia (e.g., *Oxyuranus*, *Notechis*, *Pseudonaja*) (see [Chapter 39](#)). The

Figure 38-2 Western diamondback rattlesnake (*Crotalus atrox*) causes many serious bites in the U.S. Southwest. (Courtesy Michael Cardwell/Extreme Wildlife Photography.)

elapids of North America are all coral snakes and belong to one of two genera, *Micrurus* and *Micruroides* ([Figure 38-13](#) [Figure 38-14](#) [Figure 38-15](#)). These colorful reptiles are found in Arizona (Sonoran coral snake, *Micruroides euryxanthus*), the southeastern United States (eastern coral snake, *Micrurus fulvius fulvius*), and Texas (Texas coral snake, *Micrurus fulvius tenere*). Mexico has 15 species of coral snake, including *M. euryxanthus* and 14 *Micrurus* species. Because of the inoffensive habits of

Figure 38-3 Mojave rattlesnake (*Crotalus scutulatus*) has two geographic populations in terms of venom composition, one with predominantly neurotoxic effects and one with more local sequelae. (Courtesy Michael Cardwell/Extreme Wildlife Photography.)

Figure 38-12 Cantil (*Agkistrodon bilineatus*) is a close relative of the copperheads (*A. contortrix*) and cottonmouths (*A. piscivorus*) of the United States. This pit viper is found in Mexico and Central America. (Courtesy Michael Cardwell and William W. Lamar.)

Figure 38-13 Texas coral snake (*Micrurus fulvius tenere*) has a highly potent venom but is secretive, and bites are uncommon. (Courtesy Michael Cardwell and the Gladys Porter Zoo.)

these fossorial (burrowing) snakes and their less efficient venom delivery device (see later discussion), bites are very uncommon. Although Parrish and Khan^[109] estimated that fewer than 20 coral snake bites occurred in the United States each year, the 1998 report of the American Association of Poison Control Centers (AAPCC) Toxic Exposure

Surveillance System listed 61 cases.^[90]

The only two known species of venomous lizards in the world are found in North America and belong to the genus *Heloderma*. The Gila monster (*Heloderma suspectum*, with two subspecies) is found in the southwestern United States (Arizona, western New Mexico, southeastern California, southern tip of Nevada, extreme southwestern Utah) and northwestern Mexico ([Figure 38-16](#)).^[133] The range of the Mexican beaded lizard (*Heloderma horridum*, with three subspecies) is below that of the Gila monster, south to Guatemala

901

Figure 38-14 Comparison of Texas coral snake (*Micrurus fulvius tenere*) with harmless Mexican milk snake (*Lampropeltis triangulum annulata*). Coral snake (*bottom*) has contiguous red and yellow bands, whereas the milk snake has its red and yellow bands separated by black. (Courtesy Charles Alfaro.)

([Figure 38-17](#)).^[124] The helodermatids are discussed in more detail later in this chapter.

VENOMOUS SNAKES

Anatomy

Pit Vipers.

The term *pit viper* comes from the presence of paired, highly sensitive, thermoreceptor organs (pits) present on the forward portion of these snakes' heads ([Figure 38-18](#)). These structures, also known as foveal organs, serve the snake in locating prey, aiming strikes, and adjusting venom dose ([Figure 38-19](#)). The foveal organs can detect temperature changes of as little as 0.003° C (0.0054° F).^[96] A neurologic feedback loop between the foveal organs and the venom delivery apparatus may allow the snake to adjust the volume of venom it injects into a potential meal or a perceived threat.^[149]

Figure 38-15 Sonoran coral snake (*Micruroides euryxanthus*) is also known as the Arizona coral snake. No documented fatality has followed a bite by this species. (Courtesy Michael Cardwell and Jude McNally.)

Figure 38-16 Gila monster (*Heloderma suspectum*) is one of only two known venomous lizards and the only species found in the United States. (Courtesy Michael Cardwell/Extreme Wildlife Photography.)

Figure 38-17 Mexican beaded lizard (*Heloderma horridum*) is located south of the Gila monster's range in Mexico. (Courtesy Michael Cardwell/Extreme Wildlife Photography.)

The anatomy of the venom delivery system of crotalines is the most sophisticated of all snakes ([Figure 38-20](#)). Bilateral glands located at the sides of the head, above and behind the eyes, produce and store the venom. These glands are connected through ducts to more anterior accessory glands that probably serve to activate or potentiate the venom.^[118] From here the venom is passed forward through other ducts into the

Figure 38-18 Pit viper's head. Note the elliptic pupil and the heat-sensing pit for which these reptiles are named. Viewed from above, the head has a distinctly triangular shape. Many nonvenomous snakes also possess triangular-shaped heads, however, this is not a reliable means of differentiation. (Marlin Sawyer, 1994.)

Figure 38-19 Paired heat-sensing pits of the pit vipers used to help the snake locate its prey, direct its strike, and probably determine the volume of venom to be expended. (Marlin Sawyer, 1994.)

proximal portion of the hollow fangs with which the snake pierces its victim in a stabbing motion. These fangs, found on the anterior surfaces of the maxillary bones, are large (up to 20 mm in large rattlesnakes^[74]) and highly mobile. At rest the snake folds the fangs against the roof of its mouth. For the strike, the fangs are brought into an upright position, perpendicular to the maxilla. The snake has voluntary control over its fangs and can open the mouth without raising the fangs or can raise each fang individually. The fangs are relatively brittle and fracture or become dull with time and use. Replacement fangs at varying stages of development behind the functional set move forward on the maxillary bone when needed ([Figure 38-21](#)). The speed of a pit viper's strike has been clocked at 8 feet per second; the snake can reach distances of approximately one half of its body length.^[149] [Table 38-2](#) lists venom yields for various North American pit vipers.

The fastest crotaline can crawl at a maximum speed of approximately 3 miles per hour, which equates to an average adult walking pace.^[149] Pit vipers do not chase people. Accounts suggesting otherwise can be explained by snakes' poor eyesight; when

threatened, they may retreat in the direction of people.

The characteristic forked tongue of the snake is an olfactory tool and possesses none of the offensive "stinging" function ascribed to in folklore. The snake extends its tongue to detect chemical odors in its environment. The tongue is then retracted and its tips placed into the paired Jacobson's organs, lined with olfactory epithelium, in the roof of its mouth. This sensory

903

system is highly sensitive, allowing the snake to identify potential mates, locate food, and track down a prey item that has been struck and released.

Pit vipers have elliptic, or catlike, pupils, whereas most North American harmless snakes have round

Figure 38-20 Venom delivery apparatus of a pit viper. Venom is produced in large venom glands just posterior to the eyes and is passed through a duct system into the hollow, anterior fangs when the snake bites. (Marlin Sawyer, 1994.)

Figure 38-21 Rattlesnake skull. Replacement fangs are behind the primary, functional fangs. The smaller teeth of the palatine, pterygoid, and mandibular bones are used for gripping food. (Courtesy Michael Cardwell/Extreme Wildlife Photography.)

pupils. A few essentially harmless, rear-fanged colubrids, such as the night snake (*Hypsiglena torquata*) and lyre snake (*Trimorphodon biscutatus*), also possess elliptic pupils but lack facial pits. Although these species possess a special venom gland (Duvernoy's gland) in the rear of the mouth, they are innocuous creatures. They are reluctant to bite humans, and their salivary toxins cause few signs or symptoms, other than slight swelling, bruising, and pain. This contrasts with the truly dangerous rear-fanged colubrids of other parts of the world (see [Chapter 39](#)). The two species of

boas in North America, the rosy boa (*Lichanura trivirgata*) and rubber boa (*Charina bottae*), also possess elliptic pupils, but their body form (more cigar shaped and lacking the broad, triangular head of a pit viper) and skin patterns are very different from any pit viper.

The caudal rattle of the rattlesnake is composed of loosely interlocked plates of keratin that emit a buzzing sound when the snake rapidly vibrates its tail. This characteristic sound serves as a warning to a perceived threat. A new segment to the rattle is added each time

TABLE 38-2 -- Venom Yields of Some Medically Important Snakes of North America

<i>Micrurus nigrocinctus</i>	20	[115]

the snake sheds its skin, which can be from one to several times each year, depending

on its age, health, and feeding success. Newborn rattlesnakes have a single button present at birth. Not until after their first shed do they possess a true rattle that can create a sound. Rattles may be broken off during the snake's life and cannot be used reliably to determine age. Although rattlesnakes are quick to sound out a warning when threatened, it is a misconception that they will always do so before striking in defense.

Another distinct anatomic feature of pit vipers is the scale pattern on the underside of the tail, the subcaudal scales. The junction of the snake's body and its tail can be easily ascertained by viewing its ventral side. At this location is a large scale (sometimes divided) known as the anal plate. Just distal to this in pit vipers is a sequence of single scales that entirely cross the ventral surface. In nonvenomous snakes and in coral snakes the subcaudal scales are paired (i.e., each covers approximately half the width of the tail) ([Figure 38-23](#)). This feature becomes clinically useful when a snakebite

Figure 38-22 Coral snake's skull. Note the slightly enlarged anterior fang that is fixed in its upright position. (Marlin Sawyer, 1994.)

Figure 38-23 Subcaudal scale pattern of pit viper vs. a harmless snake. Pit viper (here, a rattlesnake) has a single scale that spans the ventral side of its tail, just distal to the anal plate, whereas harmless colubrid snake has a double row of scales. Coral snakes also possess a double row of subcaudal scales. (Marlin Sawyer, 1994.)

victim brings in the body of a decapitated snake for identification and when the skin pattern is unfamiliar to the physician. There are very few exceptions to this anatomic rule. The harmless long-nose snake (*Rhinocheilus lecontei*) and the rosy boas (*L. trivirgata*) and rubber boas (*C. bottae*) possess single subcaudal scales.

Coral Snakes.

Coral snakes are identified primarily by color pattern. U.S. coral snakes are banded in a red-yellow-black-yellow-red pattern (see [Figure 38-13](#)), and the bands completely encircle the snake's body. The contiguity of the red and yellow bands distinguishes U.S. coral snakes from a number of harmless mimics (e.g., several king snakes and milk snakes, genus *Lampropeltis*), which generally have red and yellow bands separated by black bands. This can best be remembered by recalling the phrase "red on yellow, kill a fellow; red on black, venom lack" or by considering that the red and yellow lights on a traffic signal are the warning lights. Contiguous red and yellow bands on a North American snake warn of its venomous potential. Exceptions to this rule are found south of Mexico city, including some routinely bicolor (red and black) specimens.^[98] Although one harmless U.S. colubrid has a contiguous red and yellow banding pattern (the

shovel-nosed snake, *Chionactis* species), this is an inoffensive reptile, and its bands do not completely encircle its body. In exceptionally rare cases, coral snakes can be all black (melanistic) or albino.^[94]

The coral snake venom apparatus is much less complex than that of the pit vipers. The paired venom glands connect through ducts to slightly enlarged, hollow, maxillary fangs that are fixed in an upright position in the forward portion of the jaw ([Figure 38-22](#)). In

order for the coral snake to inflict a potentially serious bite, it must chew on the victim to inject a sufficient volume of venom through its relatively small fangs. These animals are not capable of striking out with the stabbing motion of the crotalines. In the vast majority of coral snakebite cases, the victim was handling the creature when bitten.

Venoms

Crotaline venoms contain proteins and peptides capable of damaging vascular endothelial cells, leading to increased permeability to plasma and erythrocytes. This results in translocation of fluids, which may progress to hypotension and shock.^[148] Specific enzymes common to pit viper venom include proteolytic enzymes, hyaluronidase, thrombinlike enzymes, phospholipase A₂, L-amino acid oxidase, collagenase, RNase, DNase, and arginine ester hydrolase. Proteolytic enzymes damage muscle and subcutaneous tissue and are responsible for necrosis. Hyaluronidase decreases the viscosity of connective tissue, allowing venom to spread. Thrombinlike enzymes act by cleaving either fibrinopeptide A or fibrinopeptide B from fibrinogen without activating factor XIII. This results in formation of an abnormal, unstable fibrin clot, which is readily lysed by both endogenous plasmin and proteolytic enzymes in the venom.^[118] This leads to hypofibrinogenemia and increased fibrin degradation products. Phospholipase A₂, common to all pit viper venoms, causes muscle necrosis by damaging cell membranes, which allows calcium influx and release of creatine and creatine kinase (CK). In addition, phospholipase A₂ increases permeability of red blood cell (RBC) membranes, leading to ab-normal RBC morphology and potential hemolysis. Lysolecithin, a by-product of the enzymatic action of phospholipase A₂, damages mast cell membranes and results in histamine release.^[21]

Pit viper venom has both offensive (i.e., food gathering) and defensive functions. In predatory strikes the venom immobilizes the prey, facilitates its retrieval by altering its scent, and accelerates digestion.^{[19] [60] [62]} Defensive strikes are meant to deter predators and tormentors. The amount of venom injected differs from bite to bite. Factors such as prey size and species, duration of fang contact, and time elapsed since last meal influence the amount of venom released.^{[60] [62]} Rattlesnakes have been shown to inject significantly more venom into large mice than into small mice.^[60] The mass of venom expended probably differs between predatory and defensive bites. In preliminary comparisons, venom expenditure by North American pit vipers appears greater in

defensive bites than in predatory bites.^[62] In one comparison the northern Pacific rattlesnake (*Crotalus viridis oreganus*) expended almost 4 times more venom when biting a hand model (defensive) than a mouse (predatory).^{[60] [62]} The most important factor influencing potential venom delivery is the size of the snake.^[62] A direct relationship has been demonstrated between snake length and mass of venom expended in both predatory and defensive bites.^{[58] [62]}

A popular belief is that juvenile rattlesnakes are more dangerous than adult snakes because their venom is more toxic and they are unable to control the volume they release. The venom of some juvenile rattlesnakes may be slightly more toxic, but larger rattlesnakes are capable of delivering much greater amounts of venom in a bite. Juvenile prairie rattlesnakes (*Crotalus viridis viridis*) have venom that is 2 to 3 times more toxic than that of adults.^[33] Large adult snakes, however, deliver an average of 17 times more venom than do juveniles.^[58] The ability to control venom expenditure has been demonstrated in juvenile rattlesnakes. In a series of first exposures to different-sized prey, "naïve" juvenile rattlesnakes injected similar quantities of venom into all size classes. However, in the second series of exposures, "experienced" snakes injected significantly more venom into larger prey.^[59] The clinical relevance of this is uncertain. In many species, venom composition appears to change as the snake ages. Phospholipase A₂ activity decreases with age, probably accounting for some decrease in toxicity. Proteolytic activity, however, increases with age, possibly to aid digestion of larger prey eaten by older, larger snakes.^[58] Coagulopathic effects can be different between juvenile and adult western diamondback rattlesnakes (*Crotalus atrox*), partly due to greater amounts of thrombinlike enzymes in younger snakes.^[113]

Venom characteristics may vary with geographic origin of the snake.^[44] Certain populations of the Mojave rattlesnake (*Crotalus scutulatus scutulatus*) cause human neurotoxicity with severe envenomation while causing minimal local tissue destruction and no hemorrhagic effects.^{[24] [69]} Neurotoxic findings may include respiratory difficulty, generalized weakness, and cranial nerve palsies.^[24] The venoms of these snakes possess a presynaptic neurotoxin, Mojave toxin, and are classified as venom A populations. Venom B populations lack Mojave toxin and are less toxic. Bites by venom B snakes result in consequences more typical of most rattlesnake venom poisoning: soft tissue swelling, necrosis, and coagulopathy. Venom A populations range from California, across western Arizona, Nevada, Utah, New Mexico, and Texas. Venom B populations are found in more eastern parts of Arizona. A zone of intergradation between venom A and venom B populations occurs along a line between Phoenix and Tucson.^{[53] [147]} Toxins with structure and physiologic effects similar to those of Mojave toxin have been isolated from venoms of other species of rattlesnakes, including prairie rattlesnakes (*Crotalus viridis viridis*), midget faded rattlesnakes (*C. v. concolor*), tropical rattlesnakes (*C. durissus*), canebrake rattlesnakes (*C. horridus*), and tiger rattlesnakes (*C.*

tigris).^{[42] [43] [61] [144]} Geographic differences occur in the venoms of other snakes as well. Canebrake rattlesnakes (*C. horridus*) from Florida, Georgia, and South Carolina

possess more neurotoxic and myotoxic "canebrake toxin" than do specimens from Alabama, Mississippi, Tennessee, and North Carolina.^[43] Differences in concentration of this toxin correlate with variable clinical effects seen after bites by this species from different geographic regions.^[17]

Neurotoxicity has been clinically associated with severe myotoxicity in many cases.^[13] ^[17] ^[27] ^[69] Severe rhabdomyolysis and myoglobinuric renal failure have been reported after Mojave rattlesnake envenomation and are thought to be related to Mojave toxin.^[69] The association between neurotoxicity and myotoxicity has been confirmed in laboratory animals.^[3] *C. horridus* specimens possessing significant amounts of the neurotoxin (canebrake toxin) produce a rise in serum CK levels as a biochemical signature of significant venom poisoning. The rise in CK appears to parallel the severity of poisoning by these snakes.^[17] Autopsy findings have demonstrated that myonecrosis in this setting is systemic and not focused at the bite site.^[17] ^[73] Concomitant rises in MB fractions of creatine kinase can occur in the absence of any clinical evidence of cardiac damage. In one such case, troponin-T was measured as negative despite abnormal total CK and CK-MB.^[17] Lesser CK elevations (usually less than 500 U/L) may be seen with other rattlesnake bites, such as that of the eastern diamondback (*Crotalus adamanteus*). In these cases the elevations appear to more closely parallel local effects.^[17]

Mojave toxin is thought to inhibit acetylcholine release at the presynaptic terminal of the neuromuscular junction.^[24] *Myokymia*, or muscle fasciculation, is often considered a manifestation of neurotoxicity. This phenomenon, however, occurs through a different mechanism than Mojave toxin-induced neurotoxicity. Muscle fasciculations are believed to be caused by the interaction of certain venom components with calcium or calcium binding sites on the nerve membrane.^[24] Fasciculations may occur after envenomation by various species of rattlesnakes, including northern and southern Pacific rattlesnakes (*C. viridis oreganus* and *C. v. helleri*, respectively), eastern diamondback rattlesnakes (*C. adamanteus*), western diamondback rattlesnakes (*C. atrox*), Mojave rattlesnakes (*C. scutulatus*), and timber rattlesnakes (*C. horridus*).^[6] ^[24] ^[141]

Coral snake venoms have received less research attention; they are also less complex than pit viper venoms. *Micrurus* and *Micruroides* venoms have minimal proteolytic activity but contain the spreading enzyme hyaluronidase and some phospholipase A₂.^[124] The primary lethal component is a low-molecular-weight, postsynaptic neurotoxin that blocks acetylcholine binding sites at the neuromuscular junction.^[18] ^[139] In addition, the venom contains at least one myotoxic component that may clinically produce a rise in CK levels.^[51]

What coral snake venom lacks in complexity, it makes up in potency. Among U.S. snakes, *Micrurus* and *Micruroides* venom potency, as determined by median lethal dose (LD₅₀) values in mice, are surpassed only by that of the Mojave rattlesnake (*Crotalus scutulatus*).^[118] It is estimated that a full-grown coral snake carries enough venom in its delivery apparatus to kill four to five adult humans.^[34] It is indeed fortunate that these toxic reptiles are shy, inoffensive, and possess a less effective venom delivery device than the pit vipers.

Clinical Presentation

Pit Vipers.

The clinical presentation of pit viper venom poisoning is quite variable, depending on the circumstances of the bite. Important factors include the species, size and health of the snake, age and health of the victim, circumstances that led up to the bite, number of bites and their anatomic locations, and quality of the care rendered to the person, both in the field and in the hospital. Although statistics vary, most accidental bites occur to the lower extremities.^[106] The next most common anatomic site is the upper extremity. Many of these bites occur while the victim is intentionally interacting with the snake (e.g., tormenting the animal, trying to catch it, or working with a captive specimen). Less often, bites occur to the head, neck, or trunk. Most bites occur around dawn or dusk, during warmer months, when snakes and people are more active outdoors.^[106] A young, intoxicated male bitten on the hand while intentionally interacting with a snake is the most common clinical profile in the United States.

About 75% to 80% of pit viper bites result in envenoming. Approximately one in every four to five bites is "dry," meaning no venom has been injected.^[108] ^[118] The snake may voluntarily choose to save its venom for its next meal rather than waste it on a large human. Alternatively, the feedback mechanism may "short-circuit" between the pit organs and the venom apparatus, so that when faced with a huge, heat-radiating mass (a human), the system fails and no venom is expelled. Other possible causes of dry bites include glancing blows that fail to penetrate the skin and an exhausted venom supply. Approximately 35% of cases are mild envenomations, 25% moderate, and 10% to 15% severe.^[108] Given their less efficient venom delivery system, coral snakes only effectively envenom approximately 40% of the time.^[118]

The clinical findings found in crotaline venom poisoning can be divided into local and systemic signs and symptoms ([Table 38-3](#)). After most pit viper bites, severe burning pain at the site begins within minutes. Soft tissue swelling then progresses outward to a variable extent from the bite site. Over hours a bitten extremity can swell all the way to the trunk. Blood may

persistently ooze from fang marks, marking the presence of anticoagulant substances in the venom. Ecchymosis is common, both locally and at more remote sites, as the vasculature becomes leaky and RBCs escape into the soft tissues ([Figure 38-24](#) and [Figure 38-25](#)). Fang marks are usually evident as small puncture wounds, but the precise bite pattern can be misleading.^[100] Most nonvenomous snakebites result in multiple rows of tiny puncture wounds (from the maxillary, palatine, pterygoid, and mandibular teeth), which usually coagulate quickly. Pit vipers also possess palatine, pterygoid, and

Figure 38-24 Mottled rock rattlesnake (*Crotalus lepidus lepidus*) bite in a young man at 24 hours. Note the exudation of red cells into the soft tissues remote from the bite site. The man was bitten on his left thumb. (Robert Norris, MD.)

Figure 38-25 Hemorrhagic bleb at the site of a western diamondback rattlesnake (*Crotalus atrox*) bite at 24 hours. (Robert Norris, MD.)

mandibular teeth, which can result in more than the classic paired puncture marks. Also, a snake may make contact only with a single fang. Thus the associated signs and symptoms should be considered more than the bite pattern in determining whether a bite was inflicted by a pit viper or another snake. Some rattlesnake bites result in little or no local pain despite envenoming; the best example is the Mojave rattlesnake (*Crotalus scutulatus*). Specimens containing significant amounts of Mojave toxin in their venom tend to cause few local findings. This can lead the treating physician to misjudge the severity of envenoming.^[149]

Systemic findings after pit viper bites can be extremely variable because any organ system can be affected. Nausea with or without vomiting is common and may occur early in serious bites. The victim may complain of an overall sense of weakness. An odd sense of taste, such as a rubbery, minty or metallic taste, may be present.^[118] Occasionally the victim complains of a numb sensation of the mouth or tongue. The vital

signs may be abnormal. The respiratory and heart rates may be increased. The victim may experience respiratory

distress due to neurotoxic components of the venom, especially after bites by venom A—producing Mojave rattlesnakes (*C. scutulatus*).^[118] Another important cause of respiratory distress is pulmonary edema from pulmonary artery congestion and translocation of intravascular fluid into alveoli. This can be compounded by myocardial depressant factors in some venoms.^[118] The victim's blood pressure may be elevated; however, hypotension, which may progress to frank shock, is more common in severe cases. In the first several hours, hypotension is usually caused by pooling of volume in the pulmonary and splanchnic beds. Later, as swelling progresses and fluids exude into remote soft tissues, intravascular volume can become significantly depleted. A rare cause of early shock is an anaphylactic reaction to the venom.^{[14] [29]}

Musculoskeletal and neurologic abnormalities can be present. As mentioned, a number of rattlesnake venoms possess a component that can result in local or systemic muscle fasciculations as a sign of significant envenoming. These fasciculations can persist for many hours despite adequate treatment with antivenom. Other findings of neurologic dysfunction can include paresthesias, numbness, and frank motor weakness, especially after bites by some Mojave rattlesnakes (*C. scutulatus*) and eastern diamondback rattlesnakes (*C. adamanteus*).

Although uncommon, hemorrhage can occur at multiple anatomic locations because of the complex procoagulant and anticoagulant fractions of some venoms.^[118] Bleeding can occur in the gingival membranes, renal system (microscopic or frank hematuria), gastrointestinal tract (hemocult-positive stools or frank blood per rectum), pulmonary tree (hemoptysis) or central nervous system.

Laboratory evaluation of a victim of significant pit viper bite may reveal significant abnormalities. The white blood cell count may be elevated. The hematocrit may be elevated from hemoconcentration or may be depressed secondary to bleeding or hemolysis. Serum chemistries may be abnormal. Blood sugar may be elevated. Muscle damage can result in elevated serum potassium and CK levels. Renal dysfunction may result from hypotension, myoglobin and hemoglobin deposition, and direct venom effects.^[22] Hepatic dysfunction with elevations of serum transaminases may be seen.^[93] Coagulation studies may reveal significant abnormalities. Prothrombin time (PT) and partial thromboplastin time (PTT) can be prolonged. Fibrinogen levels may be depressed, along with an elevation of fibrin degradation products and α -dimers.^[4] Major abnormalities may be seen in serum coagulation studies in the absence of any clinically significant bleeding (i.e., more serious than gingival oozing or microscopic hematuria).^[9] This is particularly relevant in determining when to use blood products in treating these victims. Recurrent coagulopathic parameters may persist or recur for as long as 2 weeks after envenomation.^[24]

Urinalysis should be obtained to identify hematuria. Proteinuria and glycosuria may also be seen.^[123] Each time the victim voids, the urine should be evaluated with bedside testing strips for the presence of blood.

If venom poisoning seems severe or if the victim has significant underlying medical problems (e.g., cardiovascular or respiratory disease), an electrocardiogram (ECG), arterial blood gases (ABGs), and chest radiograph should be obtained. The ECG may reveal evidence of myocardial ischemia. ABGs give important information regarding adequacy of tissue perfusion and respiratory status. Pulmonary vascular congestion or frank pulmonary edema may be seen on the radiograph.

Coral Snakes.

The findings of significant coral snake envenoming reflect the predominant neurotoxic effects of these venoms. The victim may have some early, mild, transient pain.^[117] Local swelling is uncommon. Fang marks may be difficult to see and should be carefully sought.^[102] Systemic signs and symptoms may be delayed as long as 12 or 13 hours after significant bites and can then progress rapidly.^[73] The earliest findings may be nausea and vomiting, followed by headache, abdominal pain, diaphoresis and pallor.^[32] Victims may complain of paresthesias or numbness or may have altered mental status, such as drowsiness or euphoria.^[94] The victim may develop cranial nerve dysfunction (e.g., ptosis, difficulty speaking, difficulty swallowing), followed by peripheral motor nerve dysfunction.^[94] In severe cases, respiratory insufficiency and aspiration are significant risks.^[73] Cardiovascular insufficiency may also be seen.^[123] Unlike many crotaline envenomations, coagulopathy is not a feature of coral snake venom poisoning.

Laboratory studies are of little value in the evaluation of a victim of coral snake bite. Occasionally, a rise in serum CK and myoglobinuria occur, reflecting myotoxicity.^[73] ABGs may be useful in evaluating the victim's respiratory status if endotracheal intubation is considered. A chest radiograph is indicated in the setting of apparent cardiac dysfunction or following intubation.

Management

Prehospital Care

PIT VIPERS.

Recommendations for first-aid and prehospital treatment of pit viper venom poisoning are often based on speculation and anecdotal experience. Much of the literature is contradictory. In one large retrospective series, first-aid treatment had no relationship to ultimate envenomation severity.^[148] Some first-aid measures recommended in the past cause more injury than the snakebite itself, and delays in care have been shown

to increase morbidity and mortality.^[29] ^[54] It is inappropriate to use any technique that could potentially injure the patient or impede immediate travel to the nearest facility where antivenom can be administered. General support of the airway, breathing and circulation should be provided based on the capabilities at hand. Oxygen, cardiac monitoring, and intravenous (IV) fluids should be used in the field when available. Although it may be necessary for the victim to hike out from the scene of the incident, activity should be minimized as much as possible. Alternative methods (e.g., helicopter or boat) of extracting the victim from a wilderness setting can be used when available and when conditions such as weather and terrain allow. Jewelry and tight-fitting clothing are removed from the involved extremity in anticipation of swelling. The border of advancing edema is marked with a pen every 15 minutes so that emergency personnel can estimate severity of poisoning by following the rate of progression.

A negative pressure venom extraction device, The Extractor (Sawyer Products, Safety Harbor, Fla.) has been advocated by the Wilderness Medical Society as a temporizing or adjuvant measure before antivenom is available.^[35] ^[45] This device, applied directly over fang marks, delivers approximately one atmosphere of negative pressure and requires no skin incisions.^[53] To retrieve venom, the device needs to be applied as soon after the bite as possible, probably within 3 minutes.^[7] Some recommend that suction continue for 30 to 60 minutes.^[2] As blood, tissue fluid, and possibly venom fill the transparent suction cup, the vacuum is lost. The cup is emptied as needed and reapplied as the victim is transported to the hospital. Two small studies suggest some venom retrieval with this device.^[7] ^[8] Two patients envenomed by *C. atrox* were treated within 1 minute with an Extractor.^[9] The device was applied to each victim a total of 5 times and was left on each time until the suction cup filled. An average of 27.5 μg of venom per milliliter of serosanguineous fluid was removed during the initial suction period, decreasing to 4.4 $\mu\text{g}/\text{ml}$ by the end of the fifth application. This is much less than 1 mg of total venom retrieved and probably was not significant because the average venom yield for *C. atrox* is approximately 250 mg.^[74] Tissue effects and outcome were not described. In a rabbit study, an estimated 34% of artificially injected, radiolabeled rattlesnake venom was retrieved using the Extractor.^[7] The effects on local tissue were not described.

Some suggest the Extractor may exacerbate tissue damage.^[38] A study evaluating use of the device in pigs injected with rattlesnake venom demonstrated no difference in swelling between the Extractor group and controls.^[11] A circular lesion corresponding to the size of the suction cup, however, developed in some animals and progressed to necrosis. This may have been caused by venom sequestration at the site of envenomation or suction-induced tissue ischemia. Use of the device clinically in humans has been documented in a few anecdotal case reports in nonmedical literature.^[55] Its effect on outcome in these cases is difficult to determine, but in two of five cases a dark hemorrhagic bleb conforming precisely to the size of the suction cup formed over the fang puncture sites.

Further research is needed to define the risks and benefits of mechanical suction in

crotaline venom poisoning. Other devices producing lesser degrees of suction, such as kits with small, rubber suction cups, are of no benefit. Mouth suction is contraindicated because of the potential for contaminating the wound with oral flora.

Incising the bite site across fang marks is not recommended. This creates additional injury and has never been shown to be effective. Because viperid fangs are curved, incisions may miss the track along which venom is actually injected. Incisions made by laypersons can cause serious injury to underlying blood vessels, nerves, or tendons. In the face of venom-induced coagulopathy, bleeding from such incisions can be severe.^[53] Furthermore, the lack of sterile conditions in a field setting increases the risk of infection.

Venom sequestration techniques, such as proper application of a lymphatic/superficial venous constriction band or pressure immobilization, inhibit the systemic spread of venom.^[10] ^[135] In a porcine model, lymphatic constriction bands decreased systemic venom absorption without increasing local tissue swelling.^[10] It is not clear, however, whether such measures improve outcome after pit viper envenomation. Some argue that restricting spread of potentially necrotizing venom to local tissues may intensify injury.^[56] Since local sequelae are the predominant complications after pit viper venom poisoning in North America, and since permanent systemic injury and death are extremely rare, such attempts to limit venom to the bite site may be ill advised.^[29] Also, proper placement of a constriction band can be difficult for a lay provider. The band is applied several inches proximal to the bite site and just tight enough (at a pressure of approximately 20 mm Hg) to occlude lymphatic and superficial venous flow while sparing arterial and deep venous perfusion.^[10] Appropriate tightness, however, is difficult to gauge. If applied more loosely, the band would be ineffective. If placed too tightly or with ongoing swelling, the band could become an arterial tourniquet.^[10] ^[56] Tourniquets have worsened injury when used for snakebite and are contraindicated.^[53] Use of a constriction band for a pit viper bite should be based on the situation. If the victim has been bitten by a potentially lethal snake, such as a large rattlesnake (greater than three feet), and is more than 60 minutes from medical care, a constriction band may reduce the chances of a poor systemic outcome, although local

necrosis could worsen. More research is also needed on constriction bands.

Pressure immobilization has been used effectively in Australia for field management of elapid snakebites (see [Chapter 39](#)).^[136] The technique involves wrapping the entire extremity, starting at the bite site, with an elastic or compressive bandage and immobilizing it with a splint. Although one small study suggests this technique is effective in experimental eastern diamondback rattlesnake (*C. adamanteus*) venom poisoning,^[135] the concerns about severely restricting venom movement at the site and worsening local necrosis again apply. Patients bitten by pit vipers often complain of severe pain and do not tolerate pressure immobilization well.^[56]

The Venom Ex device (Arachnodata, Frauentalweg 97, CH-8045 Zurich) combines a constriction band, incision, and suction.^[55] The device consists of six parallel cutting blades (5 mm wide and adjustable to 5 mm in length), a buckled tourniquet (used as a constriction band), and a spring-loaded syringe (20 ml) for suction. The concept is to apply the constriction band, inflict multiple incisions into the bite site, and apply suction to the bleeding wounds. No evidence indicates that this device is beneficial in crotaline bites, and because it uses controversial interventions with potential risks, it is not recommended.

Simple immobilization of the extremity with a splint has not been studied but is unlikely to cause any direct harm. The optimal position for the splinted extremity is not known. The bitten appendage should probably be maintained at heart level, if possible, to balance systemic spread of venom against extremity swelling.

All field management recommendations are based primarily on theory and speculation, with very little science available on which to make an informed decision. This area is open for future research. Until more definitive data are available, the following principles can be used as guidelines. The victim should be calmed, reassured, and transported as expeditiously as possible to the hospital. A splint can be applied en route if materials are immediately available, and the extremity should be kept at heart level unless the victim is required to walk. These measures suffice as adequate prehospital care for the vast majority of cases of pit viper bites in the United States. Decisions regarding the use of a mechanical suction device (e.g., Extractor), a constriction band, or pressure immobilization must take into consideration the risk of worsening local tissue damage.

For the victim of a pit viper bite who is many hours or days from medical care, the best course of action is even less clear and highly dependent on the situation. First-aid measures (reassurance, splint, maintenance of extremity at heart level) should be applied. If present, a companion may hike out for help, if conditions allow for prompt return of a rescue team. At times, if sufficient rescuers are available, the victim can be carried out. The victim who must hike out should use a makeshift crutch (for a lower extremity bite), should rest frequently, and should maximize oral intake of fluids unless vomiting becomes pronounced.

Electrotherapy was proposed in the late 1980s for first-aid treatment of snakebites and subsequently was popularized by the lay press.^[55] ^[63] Guderian et al^[49] described 34 indigenous people bitten by unidentified snakes in Ecuador who were treated with electric shocks. Four or five direct-current (DC) shocks (20 to 25 kV, less than 1 mA) were applied to each bite site. Shocks were given every 5 to 10 seconds and lasted 1 to 2 seconds each. The victims apparently developed no local or systemic effects of envenomation, and the authors concluded that treatment was effective. Early proponents recommended application of high-voltage, low-amperage, DC shocks to the bite site using a source such as an outboard motor or lawn mower engine.^[48] A "stun gun," typically designed for self-defense, was even modified by one company and marketed for snakebite treatment.^[55] This marketing was prohibited by the U.S. Food and Drug Administration (FDA) in 1990 because of total lack of testing or evidence of efficacy. Critics of the Ecuadorian observations suggest many reasons for Guderian's

findings. Many of the bites may have been delivered by nonvenomous species, which closely resemble dangerous reptiles in this part of the world, and many indigenous peoples consider all snakes dangerous. The victims who made it to the missionary hospital from the Ecuadorian jungles may have been a self-selected population with less severe bites that would have done well without any treatment.^[55] ^[125] In subsequent controlled animal studies, electric shock showed no efficacy in reducing morbidity or mortality after rattlesnake poisoning in mice, rats, or rabbits.^[67] ^[70] ^[132] In humans, application of electric shock for snakebite has been associated with acute myocardial infarction and increased local tissue damage secondary to electrical burns.^[28] ^[119] Because of its lack of efficacy and inherent risks, electric shock should not be used in the treatment of snakebites.

Local application of ice to the bite wound as a first-aid measure has not been adequately studied as to its benefits or risks. This should not be confused with "cryotherapy," or packing the injured limb in ice for extended periods. This form of treatment was popularized in the 1950s and 1960s. The results of cryotherapy were a significant increase in tissue loss and amputation rate after pit viper bites, and it has now been completely abandoned.^[116] Whether brief (e.g., less than 1 hour) application of ice is beneficial (by reducing venom activity or decreasing pain) or harmful (by worsening local ischemia and resulting necrosis) is unknown. The American Red Cross recommends that no

cooling measures should be applied in the field management of venomous snakebite.^[141]

Indigenous peoples in many parts of the world have long used plants in the treatment of snakebite, either topically or systemically, but little formal research has been done in this area. No current data support the use of any plants in the management of North American snakebite.^[66]

Other first-aid measures lacking therapeutic value or potentially more harmful than the snakebite itself include scarification of the bite wound, ingestion of alcohol, use of stimulants, and various folk remedies such as application of ammonia, silver nitrate, oil, potassium permanganate, or saliva. Similarly ineffective is the application of poultices made from various parts of the offending reptile (or other creatures), such as the snake's crushed head, bile, or fat.^[118]

Antivenom use in the field can be recommended only when a qualified physician is on scene and when all equipment and drugs are available to manage a potential anaphylactic/anaphylactoid reaction to the serum (including definitive airway management equipment). Newer, potentially safer antivenoms produced using Fab technology (see later discussion) may prove to be safe enough for field use, although monetary costs could be prohibitive.^[31]

Attempts to secure or kill the snake are not recommended because of the risk of additional bites to the victim or rescuer and because precious time can be wasted. Currently the same treatment principles and antivenoms apply for all pit viper bites in North America, so absolute identification of the snake is not necessary. Focus is on "treating the bite, not the snake." Serious morbidity and even death have been reported after envenomation by decapitated rattlesnake heads. ^[17] ^[73] ^[134] In addition, an apparently dead snake or a decapitated snake head can have a bite reflex for up to 1 hour after death. Therefore emergency personnel and hospital care providers should exercise extreme care if handling any specimens accompanying the victim.

CORAL SNAKES.

After a bite by a potential coral snake, the animal's skin color pattern should be noted if possible. Because of the potential delay in onset of signs and symptoms after coral snake envenoming and because the recommendation is to administer antivenom to such victims even in the absence of clinical findings, distinguishing between a coral snake and a harmless mimic becomes important. If the snake can be safely captured and contained, this can be helpful if done quickly.

Although research into field management measures for coral snake envenoming is minimal, the Australian pressure immobilization technique would probably be useful. Being elapids, coral snakes are related to the venomous snakes in Australia for which this technique has been shown to be highly effective in limiting venom absorption (see [Chapter 39](#)).

Hospital Care ([Box 38-1](#))

PIT VIPERS.

As in all emergent medical care, initial attention must be focused on the victim's airway, breathing, and circulation. Most victims should receive supplemental oxygen until it is clear that they are stable. Pulse oximetry and cardiac monitoring should be instituted and two large-bore IV lines established. The initial management of hypotension or shock should include vigorous fluid resuscitation with crystalloids (normal saline or Ringer's lactate). If organ perfusion remains inadequate after vigorous fluid infusion (e.g., 2 L of crystalloid in an adult, 20 to 40 ml/kg in a child), a trial infusion of albumin should be started. Evidence supports the utility of adding albumin early in this setting because of the rapid onset of increased vascular permeability after significant pit viper envenomation. ^[126] Vasopressors should be used to treat venom-induced shock only as a last resort, after adequate volume infusion and initiation of antivenom therapy. Prolonged, inadequately treated hypotension has been strongly implicated in fatal cases of venom poisoning. ^[29] ^[56]

Antivenom is the definitive treatment for serious pit viper envenomation. Antivenin (Crotalidae) Polyvalent (Wyeth-Ayerst Laboratories, Philadelphia, Pa.) has been the only commercially available antivenom in the United States for crotaline envenomation

since 1954. Antivenin (Crotalidae) Polyvalent is derived from the serum of horses immunized to the venom of two North American and two South American pit vipers: the eastern diamondback rattlesnake (*C. adamanteus*), western diamondback rattlesnake (*C. atrox*), South American rattlesnake (*C. durissus terrificus*), and fer-de-lance (*Bothrops atrox*). This antivenom can be used for bites by any North American pit viper, as well as all the Central and South American crotalines and some Asian pit vipers. The degree of protection, however, varies according to the species involved. Since this product is manufactured using only four different snake venoms, its ability to protect against crotalines with significantly different venoms (e.g., the Mojave rattlesnake, *C. scutulatus*) is lessened.

As a heterologous serum product, Antivenin (Crotalidae) Polyvalent carries some significant risks in its use. Early, acute reactions to antivenom can be either anaphylactic (type I, IgE mediated) or anaphylactoid (due to direct complement activation).^[148] These immediate reactions are clinically indistinguishable and may manifest with urticaria, pruritus, flushing, facial edema, vomiting, diarrhea, crampy abdominal pain, bronchospasm, laryngeal edema, and hypotension. Approximately 20% of patients who receive the Wyeth product can be expected to have an early reaction, and

about half of these are serious.^{[28] [71]} Deaths from allergic reactions to antivenom (airway obstruction, cardiovascular collapse) are rare.^{[71] [120]} Risk factors for allergy to antivenom (e.g., previous exposure to equine serum, history of allergy to horses) should be considered when deciding on a course of therapy.

Box 38-1. 38-1 MANAGEMENT PRINCIPLES IN TREATING A VICTIM OF POTENTIAL PIT VIPER BITE IN NORTH AMERICA

Determine: was the snake venomous?

Determine: is there evidence that venom poisoning has occurred?

Assess and support: airway, breathing, and circulation.

Establish two large-bore intravenous lines for crystalloid infusion.

Obtain appropriate laboratory studies.

Measure the bitten limb's circumference at two or more sites every 15 minutes.

If systemic signs or symptoms or laboratory abnormalities are present, obtain and reconstitute an appropriate antivenom.

Obtain informed consent for antivenom infusion if possible.

Have epinephrine (appropriate subcutaneous dose) drawn up at the victim's bedside for possible acute reaction to antivenom.

Perform skin testing for possible allergy to antivenom if indicated.

If the skin test is negative or if antivenom is to be given without skin testing, pretreat with H₁ - and H₂ -blocking antihistamines.

Expand the victim's intravascular volume with crystalloid fluids unless contraindicated.

Dilute the vials of antivenom to be given in crystalloid (1 L for adult, 20–40 ml/kg for child).

Begin antivenom by slow intravenous infusion.

Gradually increase the rate of infusion in the absence of an acute reaction.

If a reaction occurs, stop the antivenom and treat as necessary.

Consider the need for further antivenom:

Further antivenom to be withheld: provide conservative care only.

Further antivenom to be given: dilute the antiserum further; administer intravenous steroids; restart the antivenom at a slower rate.

If reaction continues in the face of severe poisoning:

Further antivenom to be given: dilute the antiserum further; administer intravenous steroids; restart the antivenom at a slower rate.

If reaction continues in the face of severe poisoning:

Admit to the intensive care unit (ICU).

Institute maximal monitoring as needed.

Consult an expert in snake envenomation.

Titrate epinephrine drip against the reaction.

Provide wound care.

Determine management approach:

Apparent dry bite: admit to hospital or observe for a minimum of 8 hours.

Any degree of envenomation: admit to hospital.

Severe venom poisoning: admit to ICU.

Another, more common reaction to Antivenin (Crotalidae) Polyvalent is serum sickness (type III, IgM- and IgG-mediated hypersensitivity reaction), characterized by rash, fever, chills, arthralgias, lymphadenopathy, and malaise. In severe cases, there may be renal or peripheral nerve involvement. Serum sickness may occur in as many as 50% to 75% of patients 3 days to 3 weeks after antivenom administration.^[71]^[149] The likelihood of serum sickness increases with total antivenom dosage and it usually occurs when eight or more vials of Antivenin (Crotalidae) Polyvalent are given.^[71]

The risks of adverse reactions to antivenom must be weighed against the potential benefit of improved mortality and morbidity from its administration. Informed consent should be obtained whenever possible.

Severity grading and dosage of antivenom.

Deciding when to use antivenom in a case of pit viper venom poisoning can be difficult. The risks of adverse reactions to the antivenom must be weighed against the benefits of reducing venom toxicity. Antivenom should certainly be given when evidence indicates serious envenomation (e.g., cardiovascular insufficiency, respiratory difficulty) or imminent risk of an acute complication (e.g., life-threatening bleeding, tissue necrosis, compartment syndrome, rhabdomyolysis). Snake venom poisoning is a dynamic process. Initiation of antivenom or administration of additional vials is indicated in the victim with a worsening clinical course ([Figure 38-26](#)).

Antivenom therapy is predicated on imparting passive immunity to the victim against circulating snake venom antigens. Once these deleterious antigens bind to their target tissues, antivenom is unable to pull them off or reverse their effects. Therefore, to be most effective, antivenom should be given as soon as possible after the bite, preferably

within 4 to 6 hours.^[75] Antivenom may be useful, however, in patients with significant coagulopathy or acute renal failure for days after envenomation.^[121] Venom antigens have been detected as late as 13 days after venomous snakebite.^[39] The clinical implications of prolonged, recurrent, isolated, and mild coagulopathy and the utility of late antivenom administration remain unresolved. No clear endpoints for antivenom's therapeutic window have been established.

Decisions about initial dosing of antivenom in cases of venomous snakebite are based on the apparent or predicted severity of poisoning. The grading scale described in [Table 38-4](#) can be very useful to physicians in determining the severity of North American pit viper bites, but it should not be applied to bites by non-crotaline

Figure 38-26 A, Soft tissue swelling, hemorrhagic blebs, and early necrosis after red diamond rattlesnake (*Crotalus ruber*) bite to the long finger (day 2). Victim received 10 vials of antivenom 6 hours after the bite and 10 more vials for severe thrombocytopenia on day 2. **B**, Seven weeks later. Note the degree of necrosis. (Sean Bush, MD.)

TABLE 38-4 -- Clinical Severity Grading Scale for Pit Viper Bites in North America

SEVERITY	LOCAL FINDINGS	SYSTEMIC SIGNS AND SYMPTOMS			LABORATORY STUDIES
Nonenvenomation (dry bite)	Puncture wounds only	and	None	and	Normal
Minimal envenomation	Puncture wounds	and	None	and	Normal
	Swelling limited to bite site				
	Bloody ooze from bite site				
	Local ecchymosis				
	Local pain (may be severe)				

Moderate envenomation	As for minimal, but swelling may involve entire extremity	and	Mild (e.g., nausea, vomiting, general weakness, mildly abnormal vital signs)	or	Mildly abnormal (e.g., slightly decreased platelet count or fibrinogen; presence of fibrin degradation products; slightly increased PT/PTT; hemoconcentration)
	Severe pain				
Severe envenomation	May be severe (e.g., severe soft tissue swelling and pain)	and	Very abnormal vital signs		
			Shock		
	May be less severe than expected (especially if deep or intravenous deposition of venom)		Respiratory distress	or	Profoundly abnormal (e.g., coagulopathy; hemolysis/severe anemia; renal dysfunction)
			Significant clinical bleeding		

species. A more detailed snakebite severity score was developed as a research tool, but is not intended for clinical use.^[30]

The grade of envenomation at any given time is determined by whichever parameter (local effects, systemic effects, or laboratory abnormalities) is most severely affected. In nonenvenomations, or "dry bites," fang marks are present but there are no other clinical signs or symptoms and no laboratory abnormalities. The victim has only superficial punctures that require

standard wound care, including tetanus prophylaxis as necessary.

Minimal envenomation results in effects confined to the immediate area around the bite site (pain, swelling, erythema, ecchymosis). Systemic effects are absent and laboratory values normal.

In a moderate envenomation, local effects progress beyond the immediate bite area but involve less than the entire body part (arm or leg). Local effects are generally quantified in relation to the extent of involvement of the bitten extremity. Systemic effects begin to appear when venom poisoning reaches moderate severity and may include paresthesias, strange taste sensations, numbness of the mouth and tongue, muscle fasciculations (myokymia), generalized weakness, and mild hypotension. Along with systemic signs and symptoms, laboratory abnormalities occur. Coagulation times (e.g., PT, PTT, international normalized ratio) may be elevated, platelets may drop to less than 90,000/mm³, fibrinogen may fall below 90 mg/dl, and CK levels may exceed 500 to 1000 U/L. Although evidence is limited that antivenom corrects venom-induced thrombocytopenia, rhabdomyolysis, or myokymia, [4] [24] these abnormalities serve as markers of systemic injury and the need for antivenom therapy.

With severe venom poisoning, local effects may rapidly involve the entire body part and may become limb threatening. Systemic manifestations may include shock, clinically significant hemorrhaging (e.g., hematemesis), respiratory difficulty, and multifactorial renal failure. Severe muscle fasciculations may contribute to respiratory difficulty. Profound laboratory abnormalities, such as thrombocytopenia less than 20,000/mm³, coagulopathic parameters associated with potentially life-threatening bleeding, or rhabdomyolysis/myoglobinuric renal failure, also indicated severe envenomation.

Antivenom dosing is directed by clinical severity of venom poisoning. No antiserum is necessary in dry bites, and it is questionable whether the risks associated with the use of Antivenin (Crotalidae) Polyvalent ever justify its use in mild venom poisoning. Some authors recommend a starting dose of 5 vials in mild cases. [118] For moderate poisoning the initial dose should be 10 vials, and for a severe case, 15 to 20 vials. If symptoms, signs, or laboratory parameters continue to deteriorate after the initial dose of antivenom, further dosing in 5- to 10-vial increments every 30 minutes to 2 hours is indicated. A typical total dose of Antivenin (Crotalidae) Polyvalent for a serious rattlesnake envenomation is approximately 20 to 40 vials.

Although few studies have compared children with adults in terms of the effects of crotaline venom poisoning, higher doses of antivenom should be used in pediatric victims.* Children may receive a higher dose of venom per kilogram of body weight, which may predispose them to greater toxicity. With adequate antivenom administration, however, children do not appear any more susceptible to systemic venom effects than adults. [29]

Special bite situations.

Systemic findings may be delayed after bites by venom A-producing Mojave rattlesnakes (*C. scutulatus*), with deceptively minimal local tissue effects. This can lead to underestimation of severity based on the grading scale in [Table 38-4](#). Therefore, in geographic areas where this variant is found, some recommend that antivenom be started empirically for known Mojave bites, regardless of the initial apparent severity of the bite. [12] [148] Antivenin (Crotalidae) Polyvalent provides relatively poor coverage for *C. scutulatus* venom, which supports this recommendation. [122] To compensate for reduced

overall efficacy in these cases, Wyeth's Antivenin (Crotalidae) Polyvalent is usually given early and in larger doses than for most other rattlesnake bites.

Copperheads (*Agkistrodon contortrix*) and cottonmouths (*A. piscivorus*) generally cause less severe clinical effects than do most rattlesnakes. Many *Agkistrodon* envenomations can be treated without Antivenin (Crotalidae) Polyvalent.^{[30] [146]} Severe envenomation, however, regardless of the crotaline species involved, requires antivenom therapy.

Antivenom administration.

Reconstituting lyophilized Antivenin (Crotalidae) Polyvalent can be an onerous task. Each vial must be dissolved in 10 ml of diluent. Although the antivenom comes with a vial of 10 ml of sterile water for this purpose, any typical diluent (e.g., sterile water, normal saline) can be used. Using warm diluent helps facilitate reconstitution. Gentle agitation of each vial for several minutes is required to redissolve the proteins. Care must be taken to not denature the antiserum with overzealous shaking. It may take as long as 30 minutes to fully reconstitute the antivenom, so this process should be started as soon as the need for antiserum has been identified.

Wyeth recommends a skin test for possible allergy to equine-derived products before administration of Antivenin (Crotalidae) Polyvalent. This involves intradermal injection of 0.02 to 0.03 ml of a 1:10 dilution of normal horse serum into an unbitten extremity (e.g., volar forearm). A small vial of normal horse serum is packaged along with the lyophilized antivenom and diluent. A positive test is manifested by a wheal and flare reaction within 5 to 30 minutes. Skin testing, however, is very unreliable. As many as 10% to 28% of persons with a negative skin test still manifest an acute reaction to antivenom, and up to 30% with a positive skin test have no reaction if antivenom is still given.^{[71] [130]} Furthermore, people can develop an acute reaction or delayed serum sickness to the skin test alone.^[130] Since the test takes up to 30 minutes to be called negative, it is reasonable to forego

*References ^[1] ^[14] ^[26] ^[29] ^[142] ^[148] .

testing in a patient with clear indications for antivenom treatment. If antivenom might be withheld with a positive skin test (e.g., non-life-threatening, moderate envenomation), testing can be considered. In these cases, using actual reconstituted antivenom (further diluted to 1:10 or 1:100) rather than normal horse serum may increase the predictive value of the test. Along with the serum skin test, a similar volume of normal saline should be injected intradermally in the opposite arm as a negative control. Skin testing may be useful in predicting immediate hypersensitivity but has no value in predicting eventual serum sickness. Furthermore, skin testing can sensitize individuals to antivenom, making use of this product even more risky in the event of a future venomous snakebite. Skin testing is *not* recommended when antivenom is either not indicated (dry bite) or clearly indicated (severe bite). Antivenom is still indicated for severe venom poisoning, even with a positive skin test. In this case, management

should proceed as for the victim with severe poisoning who reacted adversely to the antivenom during its infusion (see later discussion).

Any time antivenom is given, an acute adverse reaction should be anticipated and preparations made to manage a life-threatening situation. Airway equipment must be immediately available and two functional IV lines secured.

Before beginning antivenom infusion (but after interpreting any administered skin test), the patient may be premedicated with appropriate doses of antihistamines. Both an H₁ blocker (e.g., diphenhydramine, 1 mg/kg) and an H₂ blocker (e.g., cimetidine, 5 mg/kg up to 300 mg) can be given intravenously to prevent or mitigate any acute reaction. Expanding the victim's intravascular volume with an appropriate bolus of crystalloid (e.g., 1 to 2 L in an adult, 20 to 40 ml/kg in a child) may also prevent or blunt such a reaction.^[1]

If the risk of allergy is high (e.g., past history of known allergy to horses or horse serum products), a prophylactic dose of epinephrine can be considered as well. Epinephrine has been shown to reduce the incidence of acute reactions to antivenom. Subcutaneous administration of 0.25 ml of epinephrine (1:1000 aqueous) reduced acute adverse reactions from 43% to 11% in one randomized, controlled, prospective series of 105 patients.^[111] No patients pretreated with epinephrine had severe reactions to antivenom, whereas 8% of patients who did not receive epinephrine had reactions. Epinephrine must be used with caution in persons at risk for ischemic heart disease or stroke. If coagulopathy is present, prophylactic epinephrine should be avoided because of the risk of elevating blood pressure and causing intracranial bleeding.^[145] The very short half-life of epinephrine would certainly limit any potential benefits from its prophylactic use.

Routine premedication with corticosteroids is not common practice in the United States; it is more common in Australia. Since the beneficial effects of steroids in limiting allergic phenomena would not be present for 4 to 6 hours, and since steroids may worsen local effects of venom poisoning by North American pit vipers,^[128] steroids are generally not given unless an acute reaction has occurred.

Once the vials of antivenom are dissolved, each should be further diluted before administration. Many early reactions to antivenom are related to the concentration of the product that is given intravenously^[1]; therefore Antivenin (Crotalidae) Polyvalent should be given in a relatively dilute form. For adults without preexisting cardiac insufficiency the initial total dose can be placed into a liter of normal saline or Ringer's lactate. For children, the total starting dose should be placed into a volume equivalent to 20 to 40 ml of crystalloid fluid/kg up to 1 L.

The infusion should be started at a slow rate (e.g., 1 ml/min) for the first 10 to 20 minutes, with the attending physician monitoring for signs of acute reaction. If no adverse reaction occurs, the rate is increased to complete the infusion over 1 to 2 hours; children should receive approximately 10 to 20 ml/kg/hr.

If an acute reaction develops, the antivenom infusion should be stopped immediately

and the response treated. This may require administration of epinephrine, further antihistamines (both H₁ and H₂ blockers), and steroids. Appropriate ventilatory and circulatory support should be instituted as needed. Once these interventions have stopped the reaction, the physician must determine if antivenom therapy is still indicated. In most cases, antivenom infusion can be restarted, but after further dilution of the antiserum (twofold if the patient's cardiovascular reserve will tolerate the increased volume) and at a slower rate. If the reaction was serious or persists after restarting the antivenom, and if the venom poisoning is life threatening, the patient should be placed in an intensive care setting with maximal cardiovascular monitoring. Invasive monitoring (e.g., arterial line access) is helpful as long as no coagulopathy would make such line placement risky. An epinephrine IV infusion should be established (starting at 0.1 µg/kg/min) and titrated to hold the anaphylactic reaction at bay as further antivenom is infused. Generally, enough antivenom can be administered using this technique to benefit the patient's outcome.^{[13] [91]} Careful reevaluation of the need for antivenom should be made before embarking on this hazardous approach. It is advisable to consult with a specialist who manages difficult envenomations.

New antivenoms.

Much work has been done worldwide to develop new, more effective, and safer antivenoms for snakebite therapy. For North American pit vipers, a new product may be more potent and less allergenic than Antivenin (Crotalidae) Polyvalent.^{[25] [31]}

This antivenom (CroFab, Protherics, London) is derived from four groups of sheep, each immunized to the venom of one of four species of crotaline: eastern diamondback rattlesnake (*Crotalus adamanteus*), western diamondback rattlesnake (*C. atrox*), venom A-producing Mojave rattlesnake (*C. scutulatus scutulatus*), and eastern cottonmouth water moccasin (*Agkistrodon piscivorus piscivorus*). These four genetically dissimilar snakes were chosen to optimize the degree of cross-protection against venoms of all clinically important North American pit vipers.^[25]

The ovine IgG molecules from each resulting monospecific antiserum are papain digested into Fc and Fab fragments. The immunogenic Fc portion is precipitated and discarded. The protective Fab portions are isolated by affinity chromatography to the venom against which they are active. These Fab fragments are subsequently desorbed and combined in equal parts to yield a polyspecific, crotaline, Fab antivenom.^{[25] [31]} This antivenom should cause fewer allergic reactions than Antivenin (Crotalidae) Polyvalent. Ovine IgG is not glycosylated, unlike equine IgG(T), and therefore is less immunogenic. In addition, Fab fragments, with their single binding site, are incapable of cross-linking immune complexes and stimulating the cascade of mediator release that results in anaphylaxis.^[72] Immunologic response is less likely because the immunogenic Fc portion is eliminated and the molecule is smaller.^[129] Also, this ovine Fab for injection, with its smaller molecular size, is more rapidly cleared by the kidneys; thus it may prevent serum sickness by reducing immune complex deposition in tissues. A smaller

molecule may also allow improved tissue penetration and better access to available venom.^[65]

In animal models CroFab has been shown to be 3 to 10 times more potent than Antivenin (Crotalidae) Polyvalent in protecting mice against lethal effects of venom from various North American pit vipers.^[25] ^[95] In clinical trials the initial dosage of CroFab ranged from 4 to 12 vials, with repeated doses of 2 to 6 vials given for recurrence or progression of swelling or systemic effects.^[24] ^[31] ^[127] Venom effects may recur after initial treatment because Fab fragments are cleared before all venom antigens are neutralized.^[127]

In the first 42 patients treated with CroFab, there were 7 early serum reactions (5 with "urticaria," 1 "cough," and 1 "allergic reaction" manifested by urticaria, dyspnea, and wheezing).^[104A] There were also 5 late serum reactions (2 with "rash," 1 with "pruritus," 1 with "urticaria," and 1 "serum sickness" manifested by severe rash and pruritus.)^[104A]

CroFab received FDA approval in October 2000. Per the manufacturer, it is indicated for mild and moderate North American pit viper venom poisoning.^[104A] Almost certainly, the product will be effective in severe cases, as well. The precise degrees of cross protection, however, for crotaline species other than those used in its manufacture remains to be determined. It is intended for IV administration. No skin test is recommended. No premedication is mentioned in the package insert, but appropriate medications (epinephrine and antihistamines) should be immediately available if a reaction occurs.^[104A] The starting dose for CroFab is 4 to 6 reconstituted vials, further diluted to 250 ml of normal saline.^[104A] Similar to Antivenin (Crotalidae) Polyvalent administration, CroFab should be started slowly for the first several minutes while observing the patient closely for any signs of adverse reaction. If all goes well, the rate is increased to get the initial dose administered in 1 hour. The victim should then be observed over the course of an additional hour for evidence that control of abnormalities has been achieved. If there is evidence of progression of local findings or if coagulation studies and systemic signs and symptoms fail to return to normal, 4 to 6 additional vials should be given until such stabilization occurs. Then 2 vials should be given every 6 hours for up to 18 hours (3 doses). Further dosage requirements after that time period have not been determined. There is evidence that patients with significant coagulopathies during the initial phase of their poisoning may have recurrence of these findings during the first 2 weeks after the bite.^[104A] The clinical significance of these findings and the need for additional antivenom remains to be determined. Certainly, patients should be warned of this potential recurrence of coagulopathy and the need to return if there is any evidence of bleeding and to avoid elective surgical procedures during this time period.

Monitoring therapy.

Antivenom administration should continue until the patient is stabilized. This may include reduced swelling, subjective systemic improvement, and stabilization or normalization of vital signs and laboratory values. Muscle fasciculations should not be used as a guide for continued administration of Wyeth's Antivenin (Crotalidae) Polyvalent, since they may be refractory to this therapy. Preliminary reports, however,

suggest that myokymia improves with administration of the new Fab antivenom.^[24] Neurotoxicity has been documented to improve with antivenom administration, even with delayed administration.^{[13] [24]}

The efficacy of antivenom in treating venom-induced coagulopathy and thrombocytopenia is not established. Although Antivenin (Crotalidae) Polyvalent binds to venom antigens responsible for these effects, abnormalities in hemostatic parameters may persist or recur.^{[4] [127]} In several reports, venom-induced thrombocytopenia improved after antivenom infusion.^{[9] [57] [114]} Other reports contradict these findings.^{[112] [138]} In a series of patients envenomed by timber rattlesnakes (*Crotalus horridus*), PT and PTT, but not thrombocytopenia, normalized after antivenom therapy.^[4] In another series, rattlesnake venom-induced thrombocytopenia usually

improved after antivenom infusion, although the degree of improvement was small, frequently incomplete, and did not appear to be related to the total dose of antivenom given.^[15] Seifert et al^[127] reported investigational use of Fab antivenom (CroFab) in a thrombocytopenic victim of western diamondback rattlesnake (*Crotalus atrox*) venom poisoning. Although the platelet counts rebounded from 12,000/mm³ to 227,000/mm³ within 1 hour, recurrent thrombocytopenia was documented from day 5 through day 10, possibly because of more rapid clearance of Fab fragments than venom antigens.

Blood products.

In the rare situation of significant clinical hemorrhage after pit viper venom poisoning (e.g., gastrointestinal bleeding, central nervous system hemorrhage), transfusion of blood products, including platelets, plasma or packed RBCs, may be necessary. Antivenom should always be started before factor replacement to avoid adding further fuel to an ongoing consumptive coagulopathy. Packed RBCs should be considered for acute, severe anemia (e.g., hemoglobin less than 7 g/dl). Solvent/detergent-treated plasma or fresh-frozen plasma may be needed to replace depleted coagulation factors if bleeding is significant, and cryoprecipitate may be added as needed for fibrinogen levels less than 100 mg/dl.^[9] Regardless of the presence or absence of bleeding, platelet transfusion should be considered for a count of less than 20,000/mm³. Any improvement in platelet count after transfusion, however, may be temporary.^{[4] [138]} Patients with dangerously low platelet counts should be placed on bed rest to lower the risk of bleeding until counts rebound.

Analgesia and wound care.

Pain control can be a significant issue after pit viper venom poisoning. Analgesia is best obtained using appropriate, titrated doses of opiates (e.g., IV morphine sulfate, 2 to 10 mg in adults and 0.1 mg/kg in children; repeated as needed if vital signs allow). Aspirin and nonsteroidal antiinflammatory drugs should be avoided because they may

exacerbate coagulopathies.

Wound care for pit viper venom poisoning follows standard principles. Tetanus immunization (diphtheria-tetanus toxoid, 0.5 ml intramuscularly) is recommended if the patient's immunization is not up-to-date. Any wounds should be cleaned and the extremity placed in a well-padded splint with additional padding between the digits. The extremity is then elevated above the heart to reduce swelling. Antivenom, if indicated, should be started before elevating the limb.

Although snakes' mouths are colonized with several potentially pathogenic organisms, such as *Pseudomonas aeruginosa*, *Staphylococcus epidermidis*, Enterobacteriaceae species, and *Clostridium* species, wound infections from bites are uncommon, and prophylactic antibiotics are unnecessary in most cases.^[23]^[143] Pit viper

Figure 38-27 Rarely indicated fasciotomy in a victim of severe rattlesnake bite (*Crotalus viridis helleri*). Compartment pressures were greater than 60 mm Hg despite aggressive antivenom therapy. (Robert Norris, MD.)

venom has antibacterial activity, which may account in part for the low incidence of wound infections.^[137] If misdirected first-aid efforts included incisions into the bite wound or mouth suction, an appropriate broad-spectrum antibiotic (e.g., amoxicillin/clavulanate) should be considered. If secondary infection occurs, appropriate aerobic and anaerobic wound cultures (and possibly blood cultures, depending on the clinical situation) should be obtained. Empiric therapy should then be started (e.g., ciprofloxacin, 500 mg orally twice a day in adults). If anaerobes are suspected, metronidazole or clindamycin in appropriate doses can be added. Children and pregnant women can be treated with an initial dose of ceftriaxone (50 mg/kg up to 1 g IV or IM) followed by oral amoxicillin/clavulanate (40 mg/kg divided 3 times a day). Daily wound monitoring will guide decisions regarding repeat doses of ceftriaxone until culture and sensitivity results are available. Abscesses should be drained as usual. An infected snakebite should prompt further examination of the wounds for potential retained teeth or fangs. Radio-graphs may be helpful but are not particularly sensitive.

Compartment syndrome is a rare occurrence after venomous snakebite.^[36]^[101] The diagnosis can be difficult because an envenomed arm or leg is often very swollen, discolored, tender, and painful on attempted range of motion of the digits. These findings may closely mimic a compartment syndrome. To differentiate the subcutaneous swelling from intramuscular swelling, it is relatively simple to measure intracompartmental pressures using a wick catheter or digital readout device. If compartmental pressures exceed 30 to 40 mm Hg, antivenom should be started or continued while the extremity is elevated above heart level. The hemodynamically stable patient should receive IV mannitol (1 to 2 g/kg) over 30 minutes. These measures may reduce the pressures to safe levels.^[20] If the pressures fail to decrease within 60

minutes, a fasciotomy

is needed ([Figure 38-27](#)). A surgical consultant (hand, orthopedic, or general) should be involved if compartment syndrome is a possibility. Prophylactic fasciotomy, however, is not recommended. In animal studies, prophylactic fasciotomy did not reduce the amount of muscle necrosis when rattlesnake venom was injected intramuscularly.^[37] Muscle necrosis after pit viper envenomation is primarily caused by direct myotoxic venom effects rather than any increase in intracompartmental pressure. Although the fangs of many pit vipers are long enough to penetrate muscle compartments, most crotaline bites result in subcutaneous deposition of venom.^[118]

Management approach.

Disposition decisions for patients bitten by pit vipers are generally straightforward. Admission to an intensive care unit (ICU) is prudent for victims with severe envenomations or with progressive clinical findings and need for further antivenom administration. Persons bitten in the head, neck, or trunk should be monitored in an ICU because of the greater risks associated with these bites. Patients who develop a serious adverse reaction to antivenom, such as anaphylaxis, should also be admitted to the ICU. Victims who require a higher level of care than available at the treating institution should be transferred to an appropriate facility. After antivenom infusion and clinical stabilization, victims of moderately severe poisoning can be admitted to a basic floor.

Admission to the hospital should be strongly considered for all persons with apparent envenomation. In one series, more than half of persons with minimal or no signs of envenomation at presentation subsequently developed significant envenomation with moderate to severe swelling, elevated PT, or thrombocytopenia.^[68] About 25% of these persons deteriorated more than 8 hours after envenomation. Even with apparent resolution of swelling, victims may later develop severe toxicity.^[50] Because onset and progression of signs and symptoms after a pit viper bite vary greatly, all potential victims should be closely watched in the emergency department for a minimum of 8 hours if not admitted. Because of the delayed onset of findings with some Mojave rattlesnake bites, all persons with suspected *Crotalus scutulatus* bites should be admitted to the hospital for 24 hours of observation. Admission is also highly recommended for children with potentially venomous snakebites.

Discharge is considered after 8 hours of observation for victims who apparently sustained a dry bite. These victims have no symptoms or signs other than puncture wounds. All laboratory studies and vital signs must be normal. On discharge, patients should be instructed to return for onset of swelling, increased pain, bleeding, blood in the urine, severe headache, difficulty breathing, rash, joint pain, swollen lymph nodes, fever, or signs of wound infection. The victim should be scheduled for a follow-up reexamination in 24 to 48 hours and should be accompanied and assisted by another if

needed.

At time of hospital discharge, patients who received antivenom should be reminded about the possibility of developing serum sickness and that they need prompt medical attention if they develop fever, arthralgias, myalgias, urticaria or other findings consistent with a type III reaction within the first few weeks after treatment. Serum sickness is usually benign and self-limited. Most patients can be adequately treated as outpatients with steroids (e.g., oral prednisone, 1 to 2 mg/kg/day) and antihistamines (e.g., oral diphenhydramine, 25 to 50 mg 4 times a day in adults and 5 mg/kg/day in divided doses for children). Steroids should be continued until signs and symptoms of serum sickness resolve, then tapered over 1 to 2 weeks. In patients more severely affected, treatment can begin in the hospital with IV steroids in equivalent doses.

Discharge instructions to patients should also include information on ways to prevent venomous snakebite. More than half of bites occur during intentional interaction with the reptiles.^[99] These usually involve attempts to handle, harass, capture, or kill the snake. The bite may be inflicted by a specimen in captivity. Avoiding intentional interaction with venomous snakes can prevent most injuries. Wearing shoes and long pants can prevent some strikes. In areas where snakes are common, young children should be closely supervised and older children educated to avoid snakes. Animal control services should be called to remove snakes found close to human habitation. If a snake is encountered in the wilderness, people should carefully move a safe distance away from the snake.

Assistance with managing a victim of snakebite can be obtained from regional poison control centers, including the University of Arizona Poison and Drug Information Center (520-626-6016), Rocky Mountain Poison Control (303-739-1123), and San Diego Regional Poison Control (accessed via a central number for California poison control centers, 800-411-8080). The *Antivenom Index*, published by the American Zoo and Aquarium Association (8403 Colesville Rd., Suite 710, Silver Springs, MD 20910; 301-562-0777) and the AAPCC list U.S. antivenom sources.

CORAL SNAKES.

Hospital management of coral snake bite victims can be challenging. The first priority in the stable victim is to determine that a coral snake was actually the culprit; photographs of coral snakes and nonvenomous mimics indigenous to the area can be useful. If a coral snake is identified and appears to have inflicted an effective bite, management should proceed in anticipation of a significant envenoming, even if systemic abnormalities are currently absent. Evidence supports

this approach because the progression of neurotoxicity can be extremely difficult to halt once it begins, even with antivenom administration.^[117]

The patient should receive cardiac and pulse oximetry monitoring, and an IV line should

be established. A history and careful physical examination should be performed; local findings are minimal, and fang marks can be difficult to see. The victim typically has little or no swelling and variable local pain. The victim should be carefully assessed for any neurologic abnormalities. Evidence of respiratory dysfunction or difficulty with secretions demands aggressive airway management. Early endotracheal intubation should be considered in such cases to prevent aspiration and its complications.

Laboratory studies have little benefit except for ABGs if respiratory insufficiency is suspected. Bedside pulmonary function testing may be of some benefit in monitoring the patient's status.

If a coral snake inflicted an effective bite, preparation for antivenom administration should begin, even in the absence of systemic signs or symptoms.^[73] Several antivenoms are produced for coral snakes of the Western Hemisphere. The antivenom currently available in the United States is manufactured by Wyeth-Ayerst (Antivenin [*Micrurus fulvius*]) using eastern coral snake (*M. fulvius*) venom. It is effective against bites by the eastern (*M. f. fulvius*) and Texas (*M. f. tenere*) coral snakes. It has no proven benefit against Sonoran coral snake (*Micruroides euryxanthus*) venom. No antivenom is currently produced for this species, but it is a small, inoffensive creature, and no deaths have been reported after its bite. Treatment of patients bitten by the Sonoran coral snake is entirely supportive. There is little information regarding efficacy of Antivenin (*Micrurus fulvius*) for other *Micrurus* species of North America. If a significant bite has occurred by a Mexican *Micrurus*, its use is probably warranted.

Preparation for antivenom administration is similar to that for pit vipers. Informed consent is obtained if possible. Skin testing for potential allergy to horse serums is inaccurate and of little benefit in making therapeutic decisions. The victim's intravascular volume should be expanded with prudent crystalloid infusion and the patient premedicated with intravenous antihistamines (both H₁ and H₂ blockers). The starting dose for the antivenom is three to six vials, diluted in 500 to 1000 ml of crystalloid (in 20 ml/kg for pediatric patients).^[149] IV infusion is begun at a slow rate, with the physician and epinephrine at the bedside, to ensure no adverse response occurs (anaphylactic or anaphylactoid reaction). The rate is then increased to administer the entire dose over approximately 2 hours.

If a reaction occurs, the antivenom infusion should be temporarily halted and the patient treated as necessary (e.g., epinephrine, further antihistamines, steroids). Once the reaction is treated, the antivenom can usually be restarted at a slower rate after further dilution of the dose. If a severe reaction occurs, a difficult decision must be made: whether to continue antivenom administration efforts, as outlined for pit viper antivenom reactions, or to treat the patient conservatively (endotracheal intubation as needed and respiratory support). Respiratory paralysis after severe bites can be prolonged and may require days to weeks of mechanical ventilation.^[73]

All victims of potential coral snake bite should be admitted to an ICU for close monitoring even if a dry bite is suspected. If signs of neurotoxicity progress after initial antivenom infusion, three to five more vials should be administered; rarely are more

than 10 vials required.^[104]

Snakebites in Pregnancy

As with all disease states that can occur in pregnant women, the management approach that optimizes fetal outcome is the one that best supports the mother. Fortunately, snake bites are rare in pregnant women in North America. The potential effects of snake venom on the fetus have not been well studied, although fetal malformation has been described.^[92] Preterm labor and abruptio placentae have also been reported after pit viper envenomation.^[103] ^[150] The anticoagulant and proteolytic actions in most crotaline venoms probably are responsible for disrupting integrity of the placental attachment to the uterus. To inhibit these systemic venom effects, antivenom administration is important, even though antivenom carries an FDA "Category C" designation for safety in pregnancy (i.e., "uncertain safety—animal studies show an adverse effect, no human studies"). Informed consent may be even more important to obtain, if possible, in this situation. Standard doses of antivenom should be used, although the severity rating should be liberally upgraded in pregnant patients.

If an acute allergic reaction develops during antivenom administration, antivenom should be temporarily stopped. Epinephrine should be avoided because of its adverse effects on uterine blood flow. Instead, ephedrine should be given at a dose of 25 to 50 mg by slow IV push.^[105] This dose can be repeated every 30 minutes as needed. Other drugs (e.g., antihistamines, steroids) should be given as for the nonpregnant patient. Antivenom administration can usually be restarted in a more dilute concentration and at a slower rate. Additional consultation is advisable.

Other management principles for snake-bitten pregnant women include early obstetric consultation, fetal monitoring, and early ultrasonography for fetal/placental assessment.

Morbidity and Mortality

Pit Vipers.

Reliable estimates of morbidity and mortality from snakebite in the United States are not available,

TABLE 38-5 -- Snake-Related Deaths Reported to American Association of Poison Control Centers, 1983–1998

YEAR	DEATHS	TOTAL BITES REPORTED*	SPECIFICS
------	--------	-----------------------	-----------

1983	1	717	<i>Rattlesnake</i>
1984	1	1347	<i>Rattlesnake</i>
1985	0	1676	
1986	0	2416	
1987	1	2701	<i>Rattlesnake</i>
1988	0	3076	
1989	1	3851	<i>Prairie rattlesnake</i> : 27 year-old male was bitten on two fingertips by 2-foot-long prairie rattlesnake (<i>Crotalus viridis viridis</i>). He arrived in ED 15 minutes later. Swelling rapidly progressed to upper arm over next 2 ½ hours. He skin-tested positive to antivenom but was pretreated with diphenhydramine, epinephrine, and methylprednisolone; 5 vials of antivenom in 250 ml D5W started. After 20 minutes, with 60% of antivenom given, he developed anaphylaxis. He was given IV epinephrine, and cricothyroidotomy was performed because he could not be intubated secondary to laryngospasm. He arrested. Autopsy revealed bronchospasm but no swelling of the upper airway.
1990	0	4461	
1991	1	5255	<i>Unidentified rattlesnake</i> : 52-year-old male was bitten on thumb by an unidentified rattlesnake in central Oregon at high altitude. In ED 20 minutes later, he complained of circumoral numbness, tingling, and flushing. Vitals were BP 140/94, pulse 92, and respiration 16. Thumb had "two entrance wounds and minimal swelling." No skin test was performed. He was given 6 ml of a solution of 5 vials of antivenom in 500 ml D5W when he became diaphoretic and dyspneic with increased pulmonary secretions. He became near syncopal. Antivenom was discontinued, and he was intubated and given epinephrine and steroids. He became hypotensive and developed asystole within 15 minutes. Studies showed acidosis, hemoconcentration, and mild coagulopathy. Autopsy revealed extensive coronary artery disease.

1992	2	1055	<i>Northern Pacific rattlesnake</i> : 20-year-old male was handling snake when it bit him on the lips. He collapsed, began vomiting, and then was driven 3 miles to hospital. Forty minutes later he was intubated, but arrested during procedure. He was resuscitated with epinephrine, atropine, and 5 vials of antivenom for 30 minutes before recovering a sinus rhythm and BP of 100/60. He developed profound coagulopathy and was given 30 vials of antivenom. He was later determined to be brain dead. Autopsy showed brain edema and herniation. Blood alcohol level was 207 mg/dl.
			<i>Black Indian cobra</i> : 25-year-old male snake expert was bitten on the toe by gravid pet black Indian cobra. He died within minutes. Autopsy revealed bloody pulmonary exudate, cerebral edema, and fine petechial rash.
1993	0	5653	
1994	2	6317	<i>"Presumptive ... Mohave [sic] Green rattlesnake"</i> : 40-year-old male was bitten while working in bushes. He collapsed 20 minutes later. In ED 4 ½ hours later, he was comatose and in atrial fibrillation with labile blood pressure. He was intubated for poor respiratory effort. Fasciculations and metabolic acidosis were noted. Two small puncture wounds 1 cm apart were then noted on the forearm and lower leg. The presumptive diagnosis of <i>Crotalus scutulatus scutulatus</i> bite was made and antivenom administered. He was cardioverted to normal sinus rhythm and dopamine was started, but he remained hypotensive. He developed disseminated intravascular coagulation and died on hospital day 8.
			<i>Rattlesnake</i> : 34-year-old male "snake handler" was bitten on the hand when he picked up a rattlesnake on the road. He collapsed 10 minutes after being bitten, and his family began CPR. Medics arrived 30 minutes later, and he was in full arrest. He was intubated, given IV fluids, dopamine, antivenom, and hydrocortisone. He died within 3 hours. Autopsy revealed hemorrhage in the myocardium, alveoli, pancreas, and kidney. Although the airway was patent, he had laryngeal edema, pulmonary edema, and evidence of aspiration. His right coronary artery was 75% stenotic. Blood alcohol level was 118 mg/dl.

1995	2	7100	<i>Canebrake rattlesnake</i> : 35-year-old male was bitten near radial artery while playing with <i>Crotalus horridus</i> . He was asystolic when medics arrived 30 minutes later. At autopsy, no necrosis was noted. Blood alcohol level was 250 mg/dl.
			<i>Reptile other/unknown</i>
1996	0	7494	
1997	2	7045	<i>Rattlesnake</i> : 4-year-old male bitten on the thigh was treated with 5 vials of antivenom and transferred. He was intubated en route, subsequently developing massive swelling. He arrested, was resuscitated, and given additional antivenom, then arrested again in PICU 7 hours after envenomation.
			<i>Poisonous exotic snake</i>
1998	0	7194	
TOTAL	13	67,358	2 deaths appeared to be caused by anaphylaxis to antivenom.
			All were male.
			Ages: 4, 20, 25, 27, 35, 40, 52.
			10 rattlesnakes, 2 exotics, 1 unknown.
			2 autopsies revealed coronary artery disease.
			3 victims were intoxicated with alcohol.
			Bites: 1 facial, 4 upper extremity, 2 lower extremity, 1 both.
			Time to death varied from minutes to 8 days.

ED, Emergency department; *D5W*, 5% dextrose in water; *BP*, blood pressure; *CPR*, cardiopulmonary resuscitation; *PICU*, pediatric intensive care unit.

*Includes all bites by reptiles (including exotics, nonpoisonous, and unknowns).

but mortality is extremely rare. Extensive work by Parrish in the late 1950s revealed an estimated 7000 venomous snakebites per year with approximately 15 deaths.^[106] No one to date has repeated Parrish's systematic evaluation of the problem. The best current information comes from the AAPCC. In 1997, about 7000 reptile bites were reported to regional centers in the AAPCC.^[89] Only 10 deaths from endemic venomous snakes were reported to the AAPCC between 1983 and 1998 ([Table 38-5](#)).^{[76] [77] [78] [79] [80] [81] [82] [83] [84] [85] [86] [87] [88] [89] [90] [140]}

When the offending reptile was identified, almost all were rattlesnakes. These numbers are underestimates and can be used only as a rough gauge of incidence and mortality.

Not all venomous snakebites, even fatal ones, are reported to the AAPCC. The 1998 statistics, for example, reveal that no fatal snakebite cases were reported to the AAPCC Toxic Exposure Surveillance System.^[90] Snakebite is not classified as a reportable disease, and no reliable government statistics exist.

Mortality from snakebite depends on treatment. Before the introduction of Wyeth's Antivenin (Crotalidae) Polyvalent in 1954, mortality rates were estimated as high as 5% to 25%.^[108] After this time, mortality rates in patients treated without antivenom declined to approximately 2.6%, largely because of improvements in other aspects of care (e.g., ICU, fluid resuscitation). Antivenom, however, further reduces the mortality rate to 0.28%, a statistically and clinically significant tenfold reduction.^[108] This difference should be even more significant when newer, safer, and more effective antivenoms become available.

Other than death, permanent systemic morbidity after pit viper envenomation is rare.^[29] Local sequelae are more common. The reported incidence of permanent local morbidity is less than 10%, although this does not include complications that may follow surgical interventions.^[46] Most patients recover fully after rattlesnake envenomation in the United States, but the incidence of local complications is probably underestimated. Unless careful follow-up is done, including range of motion and sensory testing, permanent disabilities that impact lifestyle and occupation can be missed.^[128]

Although not clearly substantiated, children are probably more susceptible to systemic morbidity and mortality from snakebites.^[1] ^[26] ^[142] Better pediatric supportive care and improved understanding of how antivenom should be administered have blurred any distinction between pediatric and adult prognosis.^[29] Elderly patients appear to have a higher case-fatality rate, probably related to comorbid conditions.^[29]

Morbidity and mortality from snakebites also result from efforts to treat the victim. Significant wound complications can follow ill-advised incisions in and around the bite site and application of mouth suction.^[40] ^[149] Serious burns and systemic complications, such as myocardial infarction, can follow application of electric shocks to the wound.^[28] ^[119] Tourniquets or ice may increase the risk of tissue damage. Equine antivenoms

can precipitate early anaphylactic or anaphylactoid reactions and delayed serum sickness (see earlier discussion).

Coral Snakes.

Although no deaths have been reported from coral snake bites in the United States since Antivenin (*Micrurus fulvius*) was introduced,^[118] the mortality rate if bites were untreated is estimated at approximately 10%.^[109] Prolonged muscle weakness is common after severe envenoming, and victims with respiratory compromise may require mechanical ventilation for many days. There are no reports of permanent sequelae in

patients who survive coral snake envenomation.

VENOMOUS LIZARDS

Anatomy

The two venomous lizards of the world are impressive creatures about which much misinformation has been spread for centuries. They have been thought to possess supernatural features such as poisonous breath, a stinging tail and the ability to spit their venom.^[118] The Gila monster (*Heloderma suspectum*) reaches a maximum length of approximately 50 cm, whereas the beaded lizard (*Heloderma horridum*) is larger, reaching almost a meter. They are both heavily built and possess massive muscles of mastication with powerful biting capacity. The venom delivery apparatus consists of a pair of anterior, multilobed, interior labial glands that open through a series of ducts into the labial mucosa. Their teeth are lancet shaped, grooved, and loosely attached to the jaws. When the reptile becomes agitated, it salivates heavily, producing a flow of venom into the labial mucosa. It bites with a powerful, chewing motion, instilling venom into the wounds by capillary action along the grooves of the teeth. Teeth may be left in the wounds, especially if the lizard must be forcefully removed from the victim ([Figure 38-28](#)). The tenacious creature may still be attached when help arrives. Effective envenomation occurs in only about 70% of bites.^[5]

Venom

Gila monster and beaded lizard venoms are similar in composition and are as potent as some rattlesnake venoms.^[131] They possess enzymatic components, including hyaluronidase (spreading factor), protease, phospholipase A₂, and kallikrein-like substances, and nonenzymatic substances such as serotonin. Venom kallikreins stimulate the release of vasoactive kinins, such as bradykinin, which are largely responsible for occasional hypotension seen after helodermatid bites.^[133]

Clinical Presentation

The vast majority of victims bitten by a lizard are attempting to catch or handle the reptile; accidental bites

Figure 38-28 Teeth of the helodermatid lizards are grooved to aid instillation of

venom during a bite. These teeth are loosely adherent and may become dislodged in the bite wound. (Courtesy Michael Cardwell/Extreme Wildlife Photography.)

are rare. Most bites involve captive animals, and many are not reported.

Significant bleeding often occurs from punctured and torn tissues. Throbbing or burning pain may radiate proximally along the bitten extremity. Local edema may be progressive. Victims may complain of generalized weakness, nausea and vomiting, difficulty breathing, profuse sweating, dizziness, and paresthesias.^{[64] [118] [133]}

On examination the victim may be tachycardic, hypotensive (related to kinin release), and diaphoretic.^[64] The wounds generally reveal significant local tissue trauma with variable bleeding. The site may be cyanotic or ecchymotic with local vasospasm.^[118] Regional lymphadenopathy may be present on arrival to medical care or appear later.^[5]

Management

Prehospital Care.

Data are minimal regarding prehospital care of venomous lizard bites. In some cases the first priority is to detach the lizard from the victim. The lizard can be placed under running hot water, or the jaws can be pried apart using a stick or metal instrument.^[133] Care must be taken not to injure the victim further and to avoid a second bite, perhaps to the rescuer.

Once freed from the lizard, the victim should be placed at rest and the bite site rinsed and cleaned as much as possible. Any bleeding should be stopped with direct pressure. No evidence supports the use of suction devices, ligatures, or pressure immobilization. Some advocate local ice to reduce pain,^[131] but signs of vasoconstriction must be monitored to prevent later tissue loss.^[118] A dressing to stop bleeding and a splint to limit movement may be beneficial. Transport to a medical facility should be carried out as expeditiously as possible. Incisions and electrotherapy should be strictly avoided.

Hospital Care.

Assuming the lizard has been detached before arrival at the hospital, the victim's airway, breathing and circulation are assessed. Vital signs should be obtained while the patient is being placed on oxygen and cardiac/pulse oximetry monitoring. At least one large-bore IV line should be established with either normal saline or Ringer's lactate. If the victim is hypotensive or tachycardic, a second line should be placed. The victim with hypotension should receive an infusion of physiologic saline (1 to 2 L for an adult, 20 to 40 ml/kg for a child). Hypotension rarely persists after volume resuscitation. If necessary, vasopressors can be added after the victim's intravascular volume has been

repleted.^[133]

Laboratory studies include complete blood count, serum electrolytes, renal function studies, and coagulation studies. Total WBC may be elevated, and in severe cases, platelets may be decreased.^[118] Although lizard venoms do not appear to possess anticoagulant fractions, coagulopathy of unclear mechanism has been reported after severe bites.^[5] Hemostatic abnormalities in these victims may not result from the venom but rather from endothelial damage.^[133] Urinalysis is useful to assess for microscopic hematuria or renal casts.

These bites can cause transient electrocardiogram (ECG) abnormalities, such as T-wave anomalies and conduction delays.^[5] ^[64] Myocardial infarction has been reported after Gila monster bites.^[5] An ECG is recommended if the victim shows any sign or symptom of venom poisoning.

Once the victim's overall status is stabilized, attention focuses on wound care. A soft tissue radiograph of the bite site may identify retained lizard teeth but does not replace careful exploration of the wounds.^[64] After an assessment of functional status, the wound can be anesthetized using a local or regional block. The bite site should then be carefully explored for damage to underlying vital structures and for retained teeth. Thorough cleansing and irrigation should follow exploration. The wounds are dressed and splinted with generous padding. The extremity is then elevated to reduce swelling and discomfort. Opiates may be necessary in the management of pain during the victim's initial evaluation and for any pain not controlled by local or regional anesthesia. The victim's tetanus immunization status should be updated. Prophylactic antibiotics are not required.^[133] Daily wound care should include cleansing with soap and water, followed by hydrogen peroxide, application of a topical antiseptic, and redressing. After the first 24 hours a course of physical therapy can be helpful in more rapidly returning the patient to full function.

If the bite appears to be dry (i.e., victim relatively asymptomatic, vital signs/studies/ECG normal), the victim can be discharged home after approximately 6 hours of observation in the emergency department. This assumes the victim has proper resources for care at home and can return if status deteriorates. Proper wound care instructions should be given and the patient scheduled for reevaluation in approximately 24 to 48 hours. An oral opiate analgesic may be prescribed. Evidence of envenoming (i.e., signs or symptoms besides simple wounds; test or ECG abnormalities) or pain that is difficult to control requires admission. Systemic findings (e.g., chest pain, ECG changes, hypotension, coagulopathy) require monitoring for at least 24 hours.^[133]

Morbidity and Mortality

No fatalities from helodermatid bites have been documented in the last 50 years,^[95] but a bite might be fatal if a large helodermatid hangs on to the victim for minutes. Such a bite to a child or ill adult is especially dangerous.

Although pain may be prolonged for several hours or even days after these bites, necrosis is rare.^[95] ^[118] Wound infections are uncommon. If infection occurs, cultures

should be obtained and the victim started on broad-spectrum antibiotic coverage for both gram-positive cocci and gram-negative rods. Culture and sensitivity results should guide further treatment.

ALLERGY TO REPTILE VENOMS

Snake and lizard venoms are highly immunogenic substances, and occasionally, a bitten victim presents with an acute, anaphylactic reaction.^{[47] [110]} The risk of such reactions increases in victims previously bitten by venomous reptiles or who work with snake or lizard venoms (e.g., in a venom production or research facility). The presentation can be typical for anaphylaxis, with bronchospasm, hypotension, and urticaria, but differentiating an acute allergic reaction to venom from direct venom toxicity can be difficult. If the precise etiology for hypotension or respiratory distress is unclear, treatment can be rendered for anaphylaxis while antivenom preparation (in the case of snakebite) and supportive care proceed.

BITES BY EXOTIC SNAKES IN THE UNITED STATES

With the growing popularity of herpetoculture in the United States, bites by captive venomous reptiles have increased. Many involve species indigenous to North America, but an increasing number are caused by exotic species. Russell ^[120] estimated that exotic venomous snakes were responsible for 30 bites in 1984. In 1998, however, 100 such cases were reported to the AAPCC Toxic Exposure Surveillance System.^[90] An emergency physician anywhere in North America may see a victim who has been bitten by a king cobra, black mamba, or other exotic species. Management principles in these cases are similar to those outlined earlier (see also [Chapter 39](#)).

Chapter 39 - Non-North American Venomous Reptile Bites

Robert L. Norris Jr.
Sherman A. Minton †

Snake envenomation is a significant cause of morbidity and mortality in some parts of the world. The only attempt to survey snakebite as a global problem was undertaken in 1954 under the auspices of the World Health Organization.^[72] The estimate was an annual incidence of 300,000 bites with 30,000 to 40,000 deaths. Due to methodologic problems, the estimate of incidence was probably much too low. In more recent estimates, as many as 2.5 million envenomations and 125,000 deaths may occur each year.^[10] Although reporting from many parts of the world is inadequate, the highest incidence of snakebite occurs in regions where dense human populations coexist with a dense population of venomous snakes, people are engaged in agriculture by nonmechanized methods, and most people reside in small villages. Geographically, these regions include Southeast Asia, sub-Saharan Africa, and tropical America.

The epidemiologic patterns of snakebite in the United States and Europe have changed since 1950. Before that time the bites largely involved persons engaged in agriculture or living in rural environments, although the number was far fewer than those reported from tropical regions. Over the past 40 to 50 years the number of bites from handling captive snakes in a hazardous fashion has increased. In Minton's series of consultations in the United States from 1977 to 1995, 54 of 160 venomous snakebite cases involved nonnative snakes, and 53 of these were by animals in captivity.^[48] In addition, 25 of the 106 bites inflicted by native snakes involved captive animals. The popularity of snake keeping as a hobby is increasing. Although most snakes kept in captivity are not dangerous, some people acquire venomous species. In rare cases, venomous snakes may be incorrectly identified and sold as innocuous species. Many snakes in the "pet" trade are not native to the nations where they are sold. Boa constrictors and ball pythons are harmless exotic snakes popular in the United States, whereas the nonvenomous North American king snakes (*Lampropeltis* spp.) and rat snakes (*Elaphe* spp.) are popular in Europe. Venomous species also appear in the international trade. Cobras, large African vipers of the genus *Bitis*, and green arboreal vipers (*Trimeresurus* spp.) from Southeast Asia are among the species commonly sold in the United States,

whereas rattlesnakes are prized by collectors in Europe. An informal survey in southern California indicated that nearly 2000 venomous snakes were kept by herpetologists and snake collectors in that area in the early 1960s.^[60] Before 1960, bites by nonnative venomous snakes in the United States made up approximately 4% of total bites, largely confined to workers in research laboratories, zoos, and other public displays. In 1972, however, 15% of 410 hospital-treated snakebites were inflicted by nonnative species.^[30] An emergency department physician in an urban hospital in the eastern or midwestern United States is almost as likely to be confronted with a bite of an exotic venomous snake as with that of a species native to North America.

Snakebite is a minor hazard for tourists engaged in sightseeing or recreation unless they deliberately capture or handle local reptiles. The risk for those involved in engineering projects, exploration, military operations, scientific fieldwork, and humanitarian activities in regions where venomous snakes are common is somewhat higher but still small. Hardy^[26] reported three bites by the large pit viper *Bothrops asper* during 1.5 million person-hours in the field at four operations in Belize, Costa Rica, and Guatemala.

SNAKES OF MEDICAL IMPORTANCE

Snakes are a distinctive and specialized group of reptiles represented by about 2700 species. However, their classification at the family level and beyond has always presented problems to taxonomists. Recent taxonomic changes involving medically important species include redivision of the pit viper genera *Agkistrodon* (North America and Asia), *Bothrops* (tropical America), and *Trimeresurus* (southern Asia) and recognition that some wide-ranging species, such as the Asian cobra (*Naja naja*) and saw-scaled viper (*Echis carinatus*), are actually groups of several similar species.^{[18] [95]} [Table 39-1](#) summarizes the major snake families. All species in the families Viperidae, Elapidae, Hydrophiidae, and Atractaspididae, plus an unknown but significant number in the family Colubridae, are venomous. [Box 39-1](#) lists the most medically important venomous species for certain areas of the world.

†Deceased.

TABLE 39-1 -- Major Snake Families

GROUP	DISTRIBUTION	REMARKS
Blind snakes	Tropical and warm temperate zones	Very small, wormlike snakes; none venomous
Families: Typhlopidae and Leptotyphlopidae		
Boas and pythons	Mostly tropical and warm temperate zones; pythons in Old World only	Includes both large and small species; none venomous
Family: Boidae		
"Typical" snakes	Almost worldwide except for Arctic, Antarctic, southern Australia, and certain islands	Large and extremely varied family; many species with venom glands and posterior maxillary fangs, but few capable of causing clinically significant envenomation
Family: Colubridae		

Burrowing asps	Africa, limited areas of Middle East	About 15 species, all venomous; rather small burrowers; large maxillary fangs used singly with backward stabbing motion
Family: Atractaspididae		
Cobras, mambas, coral snakes, kraits, and others	Tropical and warm temperate zones	About 180 species, all venomous; fangs at anterior end of maxillae
Family: Elapidae		
Sea snakes	Mostly Southeast Asian and Australian coastal waters	About 50 species, all venomous; fangs similar to those of Elapidae
Family: Hydrophiidae		
Pit vipers	The Americas and much of Asia	About 120 species, all venomous; highly movable fangs on much reduced maxillae; heat-sensing pits between eyes and nostrils
Family: Viperidae		
Subfamily: Crotalinae		
Old World vipers	Africa, Europe, and Asia	About 40 species, all venomous; fangs like those of pit vipers; no heat-sensing pits
Family: Viperidae		
Subfamily: Viperinae		

**Box 39-1. MOST IMPORTANT SPECIES OF VENOMOUS SNAKES IN VARIOUS
REGIONS OF THE WORLD**

UNITED STATES AND CANADA

Diamondback rattlesnakes (*Crotalus adamanteus*, *C. atrox*)

Timber rattlesnake (*C. horridus*)

Prairie rattlesnake (*C. viridis viridis*)

Pacific rattlesnake (*C. viridis oreganus* and *C. v. helleri*)

Pigmy rattlesnake (*Sistrurus miliarius*)

Copperhead (*Agkistrodon contortrix*)

Cottonmouth (*Agkistrodon piscivorus*)

MEXICO, CENTRAL AMERICA, WEST INDIES

Western diamondback rattlesnake (*Crotalus atrox*)

Mexican west coast rattlesnake (*C. basiliscus*)

Tropical rattlesnake (*C. durissus*), several subspecies

Cantil (*Agkistrodon bilineatus*)

Terciopelo, barba amarilla (*Bothrops asper*)

Fer-de-lance (*Bothrops lanceolatus*, *B. caribbaeus*)

Lora, green palm viper (*Bothriechis lateralis*)

Eyelash viper (*Bothriechis schlegelii*)

Hognose viper (*Porthidium nasutum*)

Central American coral snake (*Micrurus nigrocinctus*)

NORTHERN SOUTH AMERICA (TO ABOUT 15° S)

Tropical rattlesnake (*Crotalus durissus*), several subspecies

Central American coral snake (*Micrurus nigrocinctus*)

NORTHERN SOUTH AMERICA (TO ABOUT 15° S)

Tropical rattlesnake (*Crotalus durissus*), several subspecies

Terciopelo, mapana, vibora equis (*Bothrops asper*, *B. atrox*)

Neuwied's lancehead (*Bothrops neuwiedi*)

Amazonian tree viper (*Bothriopsis bilineata*)

Hog-nose vipers (*Porthidium nasutum*, *P. lansbergii*)

Bushmaster (*Lachesis muta*)

Amazonian coral snake (*Micrurus spixii*)

Red-tail coral snake (*M. mipartitus*)

SOUTHERN SOUTH AMERICA

Brazilian rattlesnake (*Crotalus durissus terrificus*)

Jararaca (*Bothrops jararaca*)

Jararacussu (*B. jararacussu*)

Neuwied's lancehead (*B. neuwiedi*)

Urutu (*B. alternatus*)

Southern coral snake (*Micrurus frontalis*)

EUROPE

European viper (*Vipera berus*)

Asp viper (*V. aspis*)

Nose-horned viper (*V. ammodytes*)

NEAR AND MIDDLE EAST

Levantine viper (*Macrovipera [Vipera] lebetina*)

NEAR AND MIDDLE EAST

Levantine viper (*Macrovipera [Vipera] lebetina*)

Palestine viper (*V. palaestinae*)

Saw-scaled vipers (*Echis carinatus*, *E. coloratus*)

Desert horned viper (*Cerastes cerastes*)

INDIAN SUBCONTINENT AND SRI LANKA

Russell's viper (*Daboia russellii*)

Saw-scaled viper (*Echis carinatus*)

Hump-nose viper (*Hypnale hypnale*)

929

Indian krait (*Bungarus caeruleus*)

Asian cobras (*Naja naja*, *N. kaouthia*)

Sea snakes, especially beaked sea snake (*Enhydrina schistosa*), important in some coastal areas

SOUTHEAST ASIA INCLUDING PHILIPPINES AND MOST OF INDONESIA

Russell's viper (*Daboia russellii*)

Malayan pit viper (*Calloselasma rhodostoma*)

White-lipped tree viper (*Trimeresurus albolabris*)

Wagler's pit viper, temple viper (*T. wagleri*)

Mangrove viper (*T. purpureomaculatus*)

Malayan krait (*Bungarus candidus*)

Asian cobras (chiefly *Naja atra*, *N. kaouthia*, *N. philippiensis*, *N. sputatrix*, *N. sumatrana*)

King cobra (*Ophiophagus hannah*)

Beaked sea snake (*Enhydrina schistosa*)

Asian cobras (chiefly *Naja atra*, *N. kaouthia*, *N. philippiensis*, *N. sputatrix*, *N. sumatrana*)

King cobra (*Ophiophagus hannah*)

Beaked sea snake (*Enhydrina schistosa*)

Annulated sea snake (*Hydrophis cyanocinctus*)

Hardwicke's sea snake (*Lapemis curtus hardwickii*)

FAR EAST (EASTERN CHINA, TAIWAN, KOREA, JAPAN)

Mamushi (*Agkistrodon blomhoffii*, *A. halys*, *A. intermedius*)

Hundred-pace snake (*Deinagkistrodon acutus*)

Okinawa habu (*Trimeresurus flavoviridis*)

Chinese habu (*T. mucrosquamatus*)

Chinese green tree viper (*T. stejnegeri*)

Many-banded krait (*Bungarus multicinctus*)

Chinese cobra (*Naja atra*)

Annulated sea snake (*Hydrophis cyanocinctus*)

NORTHERN AUSTRALIA, NEW GUINEA AND ASSOCIATED ISLANDS

Death adders (*Acanthophis antarcticus*, *A. praelongus*)

Taipan (*Oxyuranus scutellatus*)

Mulga snake, king brown snake (*Pseudechis australis*)

Papuan black snake (*Pseudechis papuanus*)

Brown snakes (*Pseudonaja textilis*, *P. nuchalis*)

Ikaheka snake (*Micropechis ikaheka*)

Sea snakes, particularly *Astrotia stokesi*, *Aipysurus laevis*, *Lapemis curtus*

SOUTHERN AUSTRALIA AND TASMANIA

Tiger snakes (*Notechis scutatus*, *N. ater*)

SOUTHERN AUSTRALIA AND TASMANIA

Tiger snakes (*Notechis scutatus*, *N. ater*)
Copperhead (*Austrelaps superbus*)
Death adder (*Acanthophis antarcticus*)
Mulga snake, king brown snake (*Pseudechis australis*)
Red-bellied black snake (*Pseudechis porphyriacus*)
Brown snakes (*Pseudonaja*), several species

NORTH AFRICA TO SOUTHERN EDGE OF SAHARA

Desert horned viper (*Cerastes cerastes*)
Saw-scaled vipers (*Echis pyramidum*, *E. ocellatus*)
North African rock viper (*Vipera mauritanica*)
Puff adder (*Bitis arietans*)
Egyptian cobra (*Naja haje*)
Red spitting cobra (*Naja pallida*)
Burrowing asp (*Atractaspis microlepidota*)

CENTRAL AND SOUTHERN AFRICA

Saw-scaled vipers (*Echis pyramidum*, *E. ocellatus*)
Puff adder (*Bitis arietans*)
Rhinoceros viper (*B. nasicornis*)
Gaboon viper (*B. gabonica*)
Green tree viper (*Atheris squamiger*)
Night adders (*Causus rhombeatus*, *C. maculatus*)
Spitting cobras (*Naja mossambica*, *N. nigricollis*)
Egyptian cobra (*N. haje*)

Night adders (*Causus rhombeatus*, *C. maculatus*)

Spitting cobras (*Naja mossambica*, *N. nigricollis*)

Egyptian cobra (*N. haje*)

Cape cobra (*N. nivea*)

Ringhals (*Hemachatus haemachatus*)

Black mamba (*Dendroaspis polylepis*)

Green mambas (*D. angusticeps*, *D. viridis*)

Burrowing asps (*Atractaspis*), several species

Boomslang (*Dispholidus typus*)

Cobras

Strictly speaking, cobras are snakes of the genus *Naja* ([Figure 39-1](#) , [Figure 39-2](#) , [Figure 39-3](#)), but the term is often applied to other snakes of cobralike habitus, particularly the king cobra (*Ophiophagus hannah*) ([Figure 39-4](#)), ringhals (*Haemachatus*) ([Figure 39-5](#)), water cobras (*Boulengerina*), and tree cobras (*Pseudohaje*). Spreading the neck to form a hood is common to all, although this behavior is seen in numerous other snakes of several families, including some nonvenomous species. Nearly all cobras are large snakes, 1.2 to 2.5 m in total length, with the king cobra occasionally reaching 5 m. Cobras of the genus *Naja* occur throughout Africa and tropical and subtropical Asia, except in deserts. They live in a wide variety of habitats and adapt well to agricultural and

Figure 39-1 Chinese cobra (*Naja atra*). Cobras are among the world's most venomous snakes, dangerous by virtue of potent venom and distribution in densely populated regions. (Sherman Minton, MD.)

Figure 39-2 The monocellate cobra (*Naja kaouthia*) is one of many cobra species whose venom is known to cause significant local necrosis. (Courtesy Michael Cardwell and Carl Barden Venom Laboratory.)

Figure 39-3 The African red spitting cobra (*Naja pallida*) is capable of spraying its venom with great accuracy for distances up to 3 m. (Courtesy Michael Cardwell and Carl Barden Venom Laboratory.)

Figure 39-4 The king cobra (*Ophiophagus hannah*) is the largest of the venomous snakes, can reach lengths of up to 5 m, and is widely distributed in Asia. (Courtesy Michael Cardwell and Carl Barden Venom Laboratory.)

Figure 39-5 Cobralike ringhals (*Hemachatus haemachatus*) of Africa spreads a hood when threatened and can also spit venom. Some specimens feign death, as shown here, causing bites in unsuspecting keepers. (Michael Cardwell and Cape Town Snake Park.)

Figure 39-6 Green mamba (*Dendroaspis angusticeps*). These large, slender arboreal African snakes are quick, alert, and often dangerous. (Sherman Minton, MD.)

suburban situations. The king cobra is restricted to forest areas in southeastern Asia; the ringhals, water cobras, and tree cobras inhabit sub-Saharan Africa. The African spitting cobras, *Naja nigricollis*, *N. mossambica*, *N. katiensis*, *N. pallida*, and *Hemachatus*, have fangs modified for ejecting jets of venom anteriorly and upward for distances up to 3 m with remarkable accuracy. This habit is rarely seen in Southeast Asian cobras.

Mambas

Mambas are slender elapid snakes constituting the genus *Dendroaspis* ([Figure 39-6](#) and [Figure 39-7](#)). They are usually 1.5 to 2.2 m long, although the black mamba (*D. polylepis*) may reach 4 m. The four species inhabit most of tropical Africa. Mambas are at least partially arboreal, alert and active, and aggressive under some circumstances.

Kraits

There are about a dozen species of south Asian elapids of the genus *Bungarus* ([Figure 39-8](#)). Their average lengths are 1 to 1.2 m, with two species reaching 2 m. Kraits have short fangs and highly toxic venom, are nocturnal, and are often found close to human dwellings. Bites are uncommon, but the case fatality rate is high.

Coral Snakes

All medically important species of coral snakes are in the genus *Micrurus*, which includes about 50 species distributed

Figure 39-7 Relatively large anterior fangs of green mamba (*Dendroaspis angusticeps*). Elapids tend to have smaller fangs than do most viperids, but some, as shown here, can be quite large. (Courtesy Michael Cardwell and Carl Barden Venom Laboratory.)

Figure 39-8 Many-banded krait (*Bungarus multicinctus*). Kraits are widely distributed in southern Asia and have highly lethal neurotoxic venoms. They are nocturnal and rarely aggressive. (Sherman Minton, MD.)

from the southern United States to central Argentina ([Figure 39-9](#)). Nearly all are in the 0.6 to 1.2 m size range. Most have tricolor patterns of red, yellow, and black. A few species are bicolor. The rules and mnemonics for distinguishing coral snakes from their

932

Figure 39-9 Amazonian coral snake (*Micrurus spixii*). This South American species demonstrates how color patterns can be misleading in identification of coral snakes outside the United States. its red and yellow bands are separated by black rather than being contiguous. (Courtesy Michael Cardwell and Extreme Wildlife Photography.)

Figure 39-10 Coastal taipan (*Oxyuranus scutellatus*) Australia's largest venomous snake can reach a length of 3 m and can be aggressive. Its range is largely in semitropical Queensland. (Sherman Minton, MD.)

mimics become progressively less reliable from central Mexico southward (see [Chapter 38](#)). Coral snakes are secretive and not often encountered. The dozen or more species of oriental coral snakes (*Calliophis*, *Maticora*) are widely distributed but uncommon and not well studied.

Australian Elapids

Elapids are the dominant snakes of Australia, New Guinea, and proximity islands north to the Solomons. The 85 or more species are closely related and part of one evolutionary radiation, which also includes the sea snakes. The diverse elapids range from small (40 to 60 cm), inoffensive burrowers to the potentially aggressive coastal taipan (*Oxyuranus scutellatus*), which may reach a length of 3.3 m ([Figure 39-10](#)).

Death adders (*Acanthophis*) are viperlike in appearance, with wide heads

Figure 39-11 Death adder (*Acanthophis antarcticus*). This viperlike Australian snake is actually an elapid with highly neurotoxic venom. (Courtesy Michael Cardwell and William W. Lamar.)

Figure 39-12 Tiger snake (*Notechis scutatus*). This highly venomous elapid snake is found in the densely populated eastern part of Australia. (Sherman Minton, MD.)

and thick bodies ([Figure 39-11](#)). Other dangerous species are tiger snakes (*Notechis*), which may be plentiful in well-populated eastern coastal districts of Australia ([Figure 39-12](#)); brown snakes (*Pseudonaja*), which are quick and may be dangerous if cornered; and large snakes of the genus *Pseudechis*, including the red-bellied black snake (*P. porphyriacus*) and the king brown snake (*P. australis*). Venoms of most of these snakes are highly toxic.

Sea Snakes

The 50 or more species of sea snakes inhabit tropical and subtropical sections of the western Pacific and Indian Oceans over the continental shelves, but the pelagic sea snake (*Pelamis platurus*) also occurs on the western coasts of America from Baja California to Ecuador and is occasionally found in Hawaiian waters

Figure 39-13 Pelagic sea snake (*Pelamis platurus*) is the most widely distributed sea snake and the only species found in American waters. (Sherman Minton, MD.)

Figure 39-14 Nose-horned viper (*Vipera ammodytes*) is an important cause of snakebites in Europe, but cases are rarely fatal. (Courtesy Michael Cardwell/Extreme Wildlife Photography.)

([Figure 39-13](#)). Similarity in plasma and venom proteins indicates that sea snakes are closely related to Australian terrestrial elapids (see [Chapter 61](#)).

Eurasian Vipers

The genus *Vipera* includes approximately a dozen species. Dangerous, large species include the Levantine viper (*V. lebetina*), found from North Africa to Pakistan, and the Palestine viper (*V. palaestinae*), which is native to the Middle East. The European viper (*V. berus*) has one of the most extensive ranges of any land snake and is found from the British Isles to Korea and the eastern limits of Russia. *V. berus* is relatively small (60 to 75 cm). Other species important in Europe are the asp viper (*V. aspis*), Iberian viper (*V. latasti*), and nose-horned viper (*V. ammodytes*) ([Figure 39-14](#)). These cause numerous bites, but the case fatality rate is low. The Russell's viper (*Daboia* [formerly *Vipera*] *russellii*) is found from

Figure 39-15 Russell's viper (*Daboia russellii*). Plentiful in agricultural regions of southern Asia, these large vipers are a leading cause of fatal snakebites. (Sherman Minton, MD.)

Figure 39-16 Desert horned viper (*Cerastes cerastes*). These relatively small Egyptian vipers are highly adapted to their desert environment. Bites are rarely fatal. (Courtesy Michael Cardwell and *The Living Desert*.)

Pakistan to Taiwan and is one of the world's most dangerous snakes, having a highly lethal venom ([Figure 39-15](#)). It adapts well to agricultural environments.

Desert Vipers

The saw-scaled vipers (*Echis*) may cause more fatalities than any other snakes in the world.^[83] These snakes live in arid and semiarid regions from India through the Middle

East to west Africa; however, they often thrive on cultivated land. Their name comes from the sawtoothed ridges on the lateral scales that are rubbed together to produce a warning sound. These small snakes are rarely more than 60 cm in length but are highly irritable and quick to strike. The venoms cause severe coagulopathy. *Cerastes* has two species in North Africa and the Middle East, including the horned viper of Egypt ([Figure 39-16](#)). These snakes are highly adapted to desert conditions. They are relatively small, and their

934

Figure 39-17 Puff adder (*Bitis arietans*). This large African viper is widely distributed and extremely dangerous. As shown here, its color pattern allows it to blend into background leaf clutter. (Courtesy Michael Cardwell/Extreme Wildlife Photography.)

Figure 39-18 Gaboon viper (*Bitis gabonica*). This impressive African viper possesses the longest fangs of any venomous snake, up to 5 cm. It can deliver massive quantities of highly toxic venom. (Courtesy Michael Cardwell and Carl Barden Venom Laboratory.)

bites are rarely fatal. Two other species in this group are the Persian horned viper (*Pseudocerastes persicus*) and the leaf-nosed viper (*Eristicophis macmahoni*), both occurring in the Middle East and Pakistan. They are uncommon and of little medical importance.

African Vipers

The genus *Bitis* has 12 species and occurs throughout Africa, exclusive of the northern deserts. The wide-ranging puff adder (*B. arietans*) also occurs in western Saudi Arabia ([Figure 39-17](#)). All are stout-bodied, wide-headed snakes. They vary in size from *B. peringueyi* (rarely exceeds 30 cm) to the Gabon viper (*B. gabonica*) ([Figure 39-18](#)), which may reach a length of 2 m and a weight of about 10 kg. Habitat ranges from desert to rainforest. The puff adder is a major cause of snakebites in most parts of Africa where it is found. It prefers grassland and often lives near villages. *Atheris* is an arboreal African viper genus with eight species. They are usually 50 to 65 cm long, and some have a bizarre appearance that makes them popular with zoos and hobbyists; bites are infrequent. Night adders of the genus *Causus* are widespread in Africa south of the Sahara. They are usually 50 to 70 cm long and may be plentiful around fields and

villages. Bites are numerous, but fatalities are almost unknown.

Agkistrodon Complex Pit Vipers

The 15 species in the *Agkistrodon* pit viper group are found from the eastern United States to Central America and throughout most of Asia. They are characterized by large shields on the crown of the head, a presumably primitive condition in viperid snakes. American copperheads (*A. contortrix*) and cottonmouths (*A. piscivorus*) are discussed in [Chapter 38](#). The closely related cantil (*A. bilineatus*) is native to Mexico and Central America. The mamushi (*A. blomhoffii*) of Japan, Korea, and eastern China, Siberian pit viper (*A. halys*) of Asian Russia and Mongolia; and central Asian pit viper (*A. intermedius*), found from Iran to Korea, are all common snakes, usually 60 to 80 cm long and of moderate build. They are the only venomous snakes in much of central and northeastern Asia and account for many snakebites. The case fatality rate is low. The Malayan pit viper (*Calloselasma rhodostoma*) is a distinctive species of Southeast Asia that inhabits forests at low elevation and is particularly common on rubber plantations. It is a major cause of snakebites. The hundred-pace snake (*Deinagkistrodon acutus*) is a large (1.2 to 1.5 m) snake with a strongly upturned snout. It is native to forests in south China and Taiwan and is dangerous but uncommon.

Asian Lance-Head Pit Vipers

The genus *Trimeresurus* is now subdivided by many herpetologists. It includes approximately 40 species. They are distributed from southern India to Indonesia, the Philippines, and the southern islands of Japan ([Figure 39-19](#)). The most dangerous species are large (up to 2.3 m), slender snakes with very wide heads. They are often called "habu," a Japanese name. They are mostly terrestrial and may have large populations in sugar cane fields and other areas of cultivation. The Okinawa habu (*T. flavoviridis*) accounts for a high incidence of snakebites on the southern Ryukyu Islands.^[63] The Chinese habu (*T. mucrosquamatus*) has a wide range in Southeast Asia and is another plentiful and dangerous species. Arboreal species are often predominantly green, 60 to 100 cm long, and are found throughout the range of the group. *T. albolabris*, the white-lipped bamboo viper, is the most widely distributed member of this group. These vipers cause many snakebites, but fatalities are rare. A third group (*Ovophis* to some) includes five species of stout, short vipers found in mountainous terrain. They seem to be of little medical importance. Wagler's pit viper is a widely

Figure 39-19 Chinese green tree viper (*Trimeresurus stejnegeri*) is found in

southern and eastern Asia. (Courtesy Michael Cardwell/Extreme Wildlife Photography.)

Figure 39-20 Wagler's pit viper, temple viper (*Tropidolaemus wagleri*). This Asian pit viper is popular with amateur snake keepers. (Courtesy Michael Cardwell and William W. Lamar.)

distributed arboreal species usually assigned to the genus *Tropidolaemus* ([Figure 39-20](#)). Its venom contains a peculiar heat-stable toxin, but its bites do not seem to differ from those of arboreal *Trimeresurus*.

Neotropical Pit Vipers

Most of these snakes were formerly assigned to the genus *Bothrops*, which ranges from eastern Mexico to southern Argentina and a few islands of the West Indies ([Figure 39-21](#)). The genus contains approximately 30 species, most of which are of medical importance. These are medium to long snakes (0.7 to 2.5 m) of moderate to heavy build with distinctly triangular heads. Habitat ranges from semiarid grasslands to rainforests; several species adapt well to banana and sugar cane plantations. Among the more dangerous species are *B. atrox*, *B. asper*, *B. jararaca*, and *B. lanceolatus*. They have many Spanish and Portuguese names, but the name

Figure 39-21 Urutu (*Bothrops alternatus*). This large, dangerous South American pit viper is responsible for many severe bites in its distribution. (Courtesy Michael Cardwell/Extreme Wildlife Photography.)

Figure 39-22 Eyelash viper (*Bothriechis schlegelii*) is found in southern Mexico, Central America, and northern South America and is popular with amateur snake keepers. (Courtesy Michael Cardwell and Carl Barden Venom Laboratory.)

"fer-de-lance" is often used for these snakes in English language publications. Species of *Bothrops* account for most of the serious snakebites in Latin America. Fifteen

arboreal species formerly in *Bothrops* are now in the genera *Bothriopsis* and *Bothriechis*. They are slender snakes with large heads and are 50 to 100 cm in length. Most have green in their pattern. The eyelash viper (*Bothriechis schlegelii*) is a well-known example that accounts for about 20% of venomous snakebites in Costa Rica ([Figure 39-22](#)). Fatalities are rare. Fourteen other

936

Figure 39-23 Bushmaster (*Lachesis muta*) is the largest pit viper, up to 3.6 m and is found in southern Central America and northern South America. (Courtesy Michael Cardwell/Extreme Wildlife Photography.)

former *Bothrops* species constitute the genus *Porthidium*, which has been further subdivided by some authorities. These are small to moderate-sized snakes (45 to 100 cm) with heavy bodies and wide heads. They are found from eastern Mexico to northern South America, usually in forests and often in highlands. They are terrestrial. Bites are common but fatalities rare. The bushmaster (*Lachesis muta*) is the largest pit viper, usually 1.5 to 2.5 m long but occasionally reaching 3.6 m ([Figure 39-23](#)). It has extraordinarily rough scales in the middorsal region and a distinct tail spine. It is found in lowland forests from southern Nicaragua to eastern Brazil and is uncommon. Bushmaster bites are rare, but the case fatality rate is high.

Rattlesnakes

The 31 species of rattlesnakes occur from southern Canada to Uruguay and eastern Argentina, although only two species occur south of the isthmus of Tehuantepec in Mexico. All except one insular species in Baja California can be identified by the presence of a rattle (see [Chapter 38](#)).

Burrowing Asps

The 15 species of the genus *Atractaspis* were formerly considered vipers because they have viperlike fangs; however, they have several unique features that justify their recognition as a separate family (Atractaspididae). They are small (50 to 80 cm), moderately slender with small heads, and uniformly black or brown. They are found throughout most of sub-Saharan Africa and in some areas of the Middle East. They frequent habitats ranging from forest to semidesert and are burrowers that may emerge at night and after rains. Bites are fairly common in some parts of Africa, but fatalities are infrequent.

Figure 39-24 Boomslang (*Dispholidus typus*) is the most dangerous of the rearfanged colubrid snakes. This arboreal snake is widely distributed in Africa. (Sherman Minton, MD.)

Colubrid Snakes

The colubrids are a large, taxonomically varied family of snakes that lack anterior fangs and the primitive features (e.g., labial heat-sensing pits, pelvic spurs, and so on) associated with boas and some other snakes. Some herpetologists partition this family, but little agreement exists on recognized divisions. In most parts of the world, colubrids make up the majority of snake species, absent only from the Arctic and Antarctic, southern Australia, and some islands. Many species have grooved fangs in the rear of the upper jaw, and others have enlarged but ungrooved rear teeth. Although the vast majority of these species are harmless, more than 50 species of colubrid snakes in 30 genera have caused human envenoming. Most cases are mild because the venom-injecting apparatus is inefficient and the quantity of venom small; however, serious and fatal envenomations have occurred.^[47] Most colubrid bites involve the handling of snakes believed to be harmless. The more important species include the boomslang (*Dispholidus typus*) ([Figure 39-24](#)), twig snakes (*Thelotornis* spp.), Japanese garter snake (*Rhabdophis tigrinus*), and brown tree snake (*Boiga irregularis*).

VENOM APPARATUS

The venom apparatus of snakes functions mainly to immobilize and kill prey, although it may also be an important means of defense. Dentition is modified in all venomous snakes, although some colubrids have only an enlarged pair of posterior maxillary teeth. The most highly modified dentition is that of vipers, in which a single, large, tubular or deeply grooved fang is attached to a greatly reduced maxillary bone. These fangs have a wide range of rocking movement. Burrowing asps (*Atractaspis* spp.) have large, viperlike fangs used one at

937

a time with a backward stabbing motion as the lower jaw is shifted to the opposite side. They can bite with the mouth virtually closed. Fangs of elapid snakes are short, tubular or grooved, and attached to the anterior end of a longer maxillary bone that may bear additional teeth and has a limited degree of rocking movement. Fangs of sea snakes are even shorter; the maxillary bone is long and usually bears additional teeth. The enlarged teeth or grooved fangs of colubrids are at the rear of the maxillary bone and are typically preceded by additional teeth.

Snake venoms are produced in a pair of glands usually located between the eye and the angle of the mouth. In one genus of oriental elapids (*Maticora*), two species of burrowing asps (*Atractaspis*), and two species of night adders (*Causus*), however, the glands are tubular and extend well back into the body. Histologic and histochemical studies show secretory cells of various types in all snake venom glands.^[3] ^[36] Space for venom storage in the lumen of the gland is greatest in viperids and some elapids (e.g., cobras), less in other elapids and sea snakes, and minimal in colubrids. Musculature for emptying the glands is best developed in viperids, moderately effective in elapids and sea snakes, and relatively ineffective in colubrids. This is reflected in quantities of venom injected in natural bites and amounts that can be obtained by extraction.

SNAKE VENOMS

The biochemistry and pharmacology of snake venoms are well studied. The venoms are colorless to amber liquids with solid content that is mostly protein. Pharmacologically active substances include enzymes, polypeptide toxins, glycoproteins, nucleotides, small peptides, and biogenic amines. Many of the enzymes and toxins are very stable. Dried snake venoms can retain lethality and some enzyme activity after three decades of storage.

The postsynaptic neurotoxins, found in most elapid and sea snake venoms, are probably the best understood snake venom toxins. They bind to the nicotinic acetylcholine receptors competitively with acetylcholine and produce a nondepolarizing neuromuscular blockade. The short toxins have 60 to 62 amino acids and four disulfide bridges; the long toxins have 71 to 74 amino acids and five disulfide bridges.

Presynaptic neurotoxins inhibit release of acetylcholine at the neuromuscular junction. Toxins in this group have phospholipase A₂ activity, occur in a variety of elapid and viper venoms, and are similar to myotoxins in some sea snake venoms. The phospholipases of this group have 110 to 125 amino acids and six or seven disulfide bonds. Their neurotoxicity and myotoxicity are not related to hydrolytic activity.

With the exception of sea snake venom, nearly all snake venoms affect blood coagulation, although not always to a clinically significant degree. Thrombinlike activity that converts fibrinogen to fibrin is characteristic of pit viper venoms; the fibrin is abnormal and easily lysed. Enzymes responsible for this activity have been isolated from a number of venoms, including the Malayan pit viper (*Calloselasma rhodostoma*), eastern diamondback rattlesnake (*Crotalus adamanteus*), hundred-pace snake (*Deinagkistrodon acutus*), Gaboon viper (*Bitis gabonica*), and jararaca (*Bothrops jararaca*). In sublethal doses these enzymes produce nonclotting blood and do not cause platelet aggregation. Prothrombin activation with formation of thrombin is seen particularly with venoms of the Russell's viper (*Daboia russellii*) and saw-scaled vipers (*Echis* spp.), from which the enzymes responsible have been isolated. Prothrombin activation is also seen with venoms of several Australian elapids, some pit vipers, and dangerous colubrids. Some venoms have more than one type of anticoagulant activity.

Hemorrhage and necrosis are often seen with snakebites, particularly those inflicted by vipers. Although attributed to proteolytic enzymes, several hemorrhagic factors have little or no proteolytic activity.^[55] Their main mode of action is disruption of the vascular basement membrane.

Extensive myonecrosis is often seen with bites by sea snakes, some Australian elapids,

and some pit vipers. Myotoxins have been isolated from several venoms. Most myotoxins show phospholipase A₂ activity, which is more pronounced in those derived from elapids.

The so-called cardiotoxin first described from cobra venom and subsequently found in venoms of some other related snakes is a strongly basic polypeptide whose main action is to produce irreversible depolarization of cell membranes. A specific cardiotoxin with quite different structure and action is found in venoms of some burrowing asps (*Atractaspis* spp.). Its action is directly on the heart, producing coronary vasoconstriction and atrioventricular block.^[43] ^[90]

Hyaluronidase is found in most reptilian venoms and facilitates absorption and spread of other venom components. Other enzymes, such as phosphodiesterase, L-amino acid oxidase, 5' nucleotidase, and acetylcholinesterase, are present in many snake venoms, but their roles in envenomation are poorly understood. Most of the clinical effects of envenomation result from several venom components acting in concert, and venom effects may be compounded by endogenous release of autopharmacologic compounds such as histamine and bradykinin.

SIGNS AND SYMPTOMS OF SNAKE VENOM POISONING

The complexity and diversity of snake venoms are reflected in the wide array of signs and symptoms that can occur after envenomation. The precise clinical picture

938

and degree of severity of any specific venomous snakebite depend on many factors, including the species of snake and its age, size, health, and geographic origin; anatomic location of the bite; size and health of the victim; and therapeutic interventions. The treating physician must anticipate multisystem dysfunction in any victim of snake venom poisoning and must remain vigilant for any constellation of signs, symptoms, and laboratory findings, regardless of the species of snake implicated ([Box 39-2](#)).

Box 39-2. SIGNS AND SYMPTOMS AFTER SNAKE VENOM POISONING

ELAPIDS (COBRAS, MAMBAS, KRAITS, AUSTRALIAN VENOMOUS SNAKES, CORAL SNAKES)

Local

- Findings may be absent or minimal
- Significant pain occurs with some species
- Regional lymphadenopathy
- Necrosis occurs with some species

Systemic

- Neurotoxicity (cranial nerve dysfunction, altered mental status, peripheral weakness and paralysis, respiratory failure)
- Cardiovascular failure
- Coagulopathy
- Myonecrosis

Cardiovascular failure

Coagulopathy

Myonecrosis

Renal failure

SEA SNAKES

Local

Trivial

Fang marks may be difficult to identify

Systemic

Neurotoxicity (cranial nerve dysfunction, peripheral weakness and paralysis, respiratory failure)

Myotoxicity with resulting muscle pain and tenderness, myoglobinemia, myoglobinuria, and hyperkalemia (may precipitate cardiac dysrhythmias and renal failure)

VIPERS AND PIT VIPERS

Local

Pain

Soft tissue swelling

Regional lymphadenopathy

Ecchymosis, bloody exudate from fang marks

Early absence of local findings does not rule out significant envenomation

Local necrosis may be significant

SYSTEMIC

Any organ system may be involved

Cardiovascular toxicity (hypotension, pulmonary edema)

SYSTEMIC

Any organ system may be involved

Cardiovascular toxicity (hypotension, pulmonary edema)

Neurotoxicity (cranial nerve dysfunction, peripheral weakness) with some species

Hemorrhagic diathesis

Renal failure

BURROWING ASPES

Local

Single fang puncture

Pain

Some swelling

Occasional local necrosis

Systemic

Nausea, vomiting

Diaphoresis

Fever

Occasional respiratory distress, cardiac dysrhythmias (atrioventricular block)

Rare fatalities

COLUBRIDS (REAR-FANGED)

Local

Mild to moderate local swelling, pain, and ecchymosis

Bloody exudate from fang marks

Systemic

Nausea, vomiting

Coagulopathy and associated complications

Systemic

Nausea, vomiting

Coagulopathy and associated complications

Renal dysfunction

Elapids

Local findings after most elapid envenomations are unimpressive compared with those seen after typical viperid venom poisoning ([Figure 39-25](#)). In many cases it may be difficult to find distinct fang marks. ^[69] ^[93] The degree of pain varies depending on the species involved. Often, local pain is a minor complaint, but it may be significant after bites by certain cobra species, such as the king cobra (*Ophiophagus hannah*) (see [Figure 39-4](#)). ^[22] Regional lymphadenopathy may be present. Although significant, local soft tissue swelling is uncommon after most elapid envenomations. ^[11] Some species, such as the African spitting cobras (*Naja mossambica*, *N. nigricollis*) ^[76] and some Asiatic cobras (*Naja* spp.), ^[58] ^[67] ^[75] may produce early edema as an indication of envenomation. Swelling can progress with time to involve the entire bitten extremity. With some of these species, local tissue necrosis may be profound ([Figure 39-26](#)). ^[59] ^[75] ^[85] Some Australian elapids, such as the taipan (*Oxyuranus* spp.) and tiger snake (*Notechis* spp.), also can induce myonecrosis and coagulopathy. ^[16] ^[59] ^[93] Renal failure has been reported as a complication of envenomation by some elapids. ^[12] ^[28] ^[59]

939

Figure 39-25 Bite of a small Australian elapid snake (*Hemiaspis signata*) resulting in localized swelling with some discoloration but no systemic symptoms. (Sherman Minton, MD.)

Neurotoxicity is seen after most elapid envenomations. The time of onset of neuropathic signs and symptoms after envenomation is quite variable. It is usually most rapid after serious cobra and mamba bites and most delayed after some coral snake envenomations. In certain situations the onset may be delayed for 10 hours or more. ^[59] The earliest systemic manifestations of envenomation by most elapids are signs of cranial nerve dysfunction, especially ptosis, but also difficulty swallowing, dysphonia, and blurred vision. ^[75] Paresthesias, muscle fasciculations, peripheral weakness, and paralysis, including that of respiratory muscles, may soon follow. Mental status (drowsiness, hallucinations) may be altered. ^[75] Associated systemic symptoms include hypersalivation and diaphoresis. ^[11] ^[56] In cases of severe envenomation, cardiovascular depression may result in hypotension and pulmonary edema. ^[59] ^[91]

Eye exposure to venom from any of the spitting cobras or ringhals results in immediate burning pain and tearing. Significant systemic absorption does not occur, but corneal ulceration, uveitis, and permanent blindness can follow untreated cases. ^[59] ^[84] Bites by

spitting cobras often manifest violent local reactions with hemorrhage and necrosis, but rarely neurotoxicity.

Sea Snakes

Local findings at the bite site after sea snake envenomation are usually trivial. In serious cases, systemic symptoms usually appear within 2 hours.^[78] The bite site may show several tiny puncture wounds from the fangs and other teeth, but local pain and soft tissue swelling are negligible ([Figure 39-27](#)). Fang marks may be difficult to see.^[79]

Sea snake venoms demonstrate significant neurotoxicity in animal studies and in human envenomations.^[12]^[59]^[79] Neurologic dysfunction is manifested by hypersalivation, dysphagia, dysarthria, muscle spasm, and paralysis. Victims remain conscious if hypoxia is

Figure 39-26 Sharply demarcated necrosis, sometimes extensive, often follows bites by both African and Asian cobras. (Sherman Minton, MD.)

Figure 39-27 Bite of a Southeast Asian water snake (*Enhydrina plumbea*), generally considered to be nonvenomous. Swelling and ecchymosis were still present after 24 hours. (Sherman Minton, MD.)

prevented.^[79] Envenomation is also characterized by trismus and diffuse myopathic findings.^[56]^[59] The myotoxic components of sea snake venoms may cause significant outpouring of potassium and myoglobin from injured muscle. Hyperkalemia may precipitate cardiac dysrhythmias, and myoglobinuria can lead to acute renal failure.^[5] Untreated sea snake envenomation may result in muscle pain and weakness that persists for months.^[59] Death after sea snake envenomation may result from respiratory failure caused by paralysis of the diaphragm, hyperkalemic cardiac arrest, or acute renal failure^[79] (see [Chapter 61](#)).

Vipers and Pit Vipers (Viperids)

The effects of envenomation by Eurasian and African vipers and Asian and neotropical pit vipers are similar to those seen after bites by the pit vipers of North America ([Chapter 38](#)). Severe pain, local soft tissue swelling, subcutaneous ecchymosis, and bloody exudation from the fang marks usually begin within minutes. Regional

lymphadenopathy may be present within 30 to 60 minutes,

and soft tissue swelling may progress extensively over several hours. The trunk and contralateral extremity may become edematous. Lack of soft tissue swelling, however, does not rule out significant poisoning by some species or after deep intramuscular or intravascular envenoming. After 12 to 24 hours, serum-filled vesicles and hemorrhagic bullae may appear, and ecchymoses may spread throughout the involved extremity.^[12]

Systemic envenomation may result in blurred vision, altered taste, weakness, dizziness, diaphoresis, nausea, vomiting, diarrhea, fever, headache, abdominal pain, and bleeding at various anatomic sites.^{[46] [56] [59]} Hypotension and shock may occur over a variable time course. Early hypotension is caused primarily by pooling of blood in the pulmonary and splanchnic vasculatures. After several hours, transudation of fluid into the bitten extremity and peritoneal cavity, hemolysis, and systemic bleeding may play a role.

Coagulopathy is a characteristic finding after systemic venom poisoning by saw-scaled vipers (*Echis* spp.).^{[46] [57] [59]} It is also seen after bites by some populations of *Daboia russellii* and many neotropical and Asian pit vipers.^[53] Victims can bleed at multiple sites, including the bite wound, soft tissues, gastrointestinal tract, respiratory tract, brain, eyes, and kidneys. The venoms of some populations of *D. russellii* can also cause massive intravascular coagulation and hemolysis.^{[31] [53]}

Neurologic findings after pit viper venom poisoning in North America are uncommon (with the notable exception of the Mojave rattlesnake [*Crotalus scutulatus*]; see [Chapter 38](#)). Neurotoxicity is a major concern, however, after bites by the South American rattlesnake (*Crotalus durissus terrificus*)^[61] and vipers in the Eastern Hemisphere, including the Berg adder (*Bitis atropos*),^[84] Palestine viper (*Vipera palaestinae*),^[81] and some populations of Russell's viper (*D. russellii*).^[82] Signs and symptoms include cranial nerve dysfunction, muscle paralysis, and respiratory failure.^{[29] [52]}

Victims may have an altered sensorium (from lethargy to coma) as a result of hypotension, hypoxia, intracranial bleeding, and possibly direct venom effects. Seizures may occur but are uncommon and probably secondary to cerebral hypoxia.

Renal failure may complicate viperid envenoming, as with North American pit vipers or Australian elapids. Etiologic factors include myoglobinuria, hemoglobinuria, hypotension, and direct venom nephrotoxicity. This is especially common after bites from the Russell's viper and saw-scaled viper (*Echis carinatus*).^{[12] [57] [59]} Onset may be delayed for several days, and any complaints of costovertebral angle pain should arouse suspicion of impending renal failure.^[53]

Local bite site necrosis and myonecrosis may be severe after viperid envenomation and may necessitate surgical intervention (amputations, grafting procedures).^[46] Although most viperid bites result in venom deposition into subcutaneous tissues, subfascial

injection is possible. In these rare cases, direct myotoxicity can produce muscle necrosis. If muscle swelling is significant, a compartment syndrome may develop. The signs and symptoms of compartment syndrome are closely mimicked by the findings after a typical subcutaneous envenomation (swelling, discoloration or cyanosis, pain on palpation, paresthesias). The diagnosis of a compartment syndrome can be confirmed by documenting elevated intracompartmental pressures. This has significant treatment implications, as discussed later.

Burrowing Asps

Envenomation by any of the burrowing asps (*Atractaspis* spp.) may result in severe symptoms, although fatalities have thus far been reported from only *A. microlepidota* and *A. irregularis*.^[14] ^[15] Persons bitten by these snakes may have severe local pain followed by numbness, soft tissue swelling, lymphadenopathy, vomiting, diaphoresis, and fever.^[15] ^[84] Systemic coagulopathies may occur.^[15] ^[24] Local vesicles can be seen at the bite site, and local tissue necrosis occurs rarely.^[8] ^[15] ^[84] The cause of death after experimental *Atractaspis* envenomation has been attributed to venom-induced coronary vasospasm.^[39]

Colubrids (Dispholidus, Thelotornis, Rhabdophis)

Envenomation by some rear-fanged colubrids may have severe consequences. Fatalities have been reported after bites by the boomslang (*Dispholidus typus*), the bird or twig snake (*Thelotornis kirtlandii*), and the Japanese garter snake or yamakagashi (*Rhabdophis tigrinus*).^[38] ^[49] ^[51] Life-threatening envenomation has also occurred after bites by the red-necked keelback (*R. subminiatus*).^[6] ^[20] ^[41] Signs and symptoms of envenomation by these snakes include mild soft tissue swelling and, in severe cases, coagulopathy, similar to that seen with viperid venom poisoning.^[47] ^[89] Associated findings may include variable local pain, headache, nausea, vomiting, ecchymoses, jaundice, and abdominal pain.^[47] Renal dysfunction has been reported after *D. typus*, *T. kirtlandii*, and *R. tigrinus* envenomations.^[38] ^[42] ^[51] ^[66] Onset of signs of serious envenomation may be delayed by many hours and possibly even days.^[11] ^[21]

MANAGEMENT

Prehospital Care

Prehospital management of a bite by any potentially venomous snake involves placing the victim at rest, offering reassurance, and providing expeditious transport to the nearest facility equipped to handle such an emergency ([Figure 39-28](#)). First-aid measures should not cause further harm and should not delay medical care.

941

Figure 39-28 First-aid measures for venomous snakebites.

A proven technique of limiting systemic distribution of venom after most elapid and sea snake bites is the Australian pressure immobilization technique ([Figure 39-29](#)). This involves immediately wrapping the entire bitten extremity with a crepe bandage, elastic bandage, or article of clothing as tightly as for an acute sprain. This is followed by splinting with any available object.^{[19] [26] [71] [78]} The splinted extremity should be maintained at approximately heart level if possible.

The use of pressure immobilization in cases of bites by snakes capable of causing significant local necrosis (e.g., most viperids, certain cobra species) is controversial.^[19] A laboratory study found that pressure immobilization limits pit viper (eastern diamondback rattlesnake, *Crotalus adamanteus*) venom dispersal from the bite site without worsening necrosis.^[70] However, localizing a necrotizing venom in the region of the bite site may exacerbate tissue loss.^{[69] [80]} Clinical experience with pressure immobilization in human victims of viperid envenomation is limited; the rescuer must weigh the risks against potential benefits. If the offending reptile is a small, innocuous species and transport time to medical care will be short, it may be best to avoid pressure immobilization. If a large or particularly virulent snake is involved and the bite may be life threatening, immobilization may be indicated, especially if in evacuation to medical care will be delayed. More definitive recommendations on the use of pressure

immobilization in viperid envenoming must await further research and clinical reports.

Respiratory and cardiovascular status should be supported to the extent possible under field conditions. If the time to reach medical care is prolonged and nausea and vomiting are not present, the victim should be encouraged to drink frequent, small volumes of clear, nonalcoholic liquids to support intravascular volume.

Other first-aid measures occasionally recommended for snakebites lack sufficient laboratory or clinical evidence to prove their effectiveness. Using any sharp instrument to incise fang marks in the field does more harm than good by exacerbating local bleeding (especially in the face of coagulopathy), introducing bacteria into the wound under nonsterile conditions, and further devascularizing the wound when perfusion may already be impaired. Applying mechanical suction to the wound using a device such as the Extractor (Sawyer Products, Safety Harbor, Fla; [Figure 39-30](#)) without incising the bite may remove a small percentage of venom from the site.^[4] ^[5] Further description of the Extractor, including controversies regarding its use, is found in [Chapter 38](#) . Measures such as local cooling, electric shock, and the application of topical agents should be avoided because they lack efficacy

942

Figure 39-29 Australian compression and immobilization technique has proved effective in the management of elapid and sea snake envenomations. Its efficacy in viper bites has yet to be evaluated clinically.

Figure 39-30 The Extractor device. The efficacy of this device for applying mechanical suction to snakebites in the field continues to be studied.

and may actually worsen local tissue damage or the overall clinical outcome. Cold application may drive deleterious venom components deeper into tissues^[60] (see [Chapter 38](#)).

Evacuating a snakebite victim from a remote field situation can be problematic.^[44] The

key principles are applying potentially effective first-aid measures (reassurance, splinting, with or without mechanical suction or pressure immobilization), transporting the victim to medical care as soon as possible, and limiting the victim's physical activity to minimize cardiac output and systemic circulation of venom. If the victim is alone and unlikely to be found for several hours, he or she should attempt to hike out, pausing for frequent rest stops and maintaining oral intake of fluids. If a lower extremity is involved, a crutch can be improvised to assist ambulation. If a single companion is present and prompt transportation to medical care is unavailable, first-aid measures should be applied and the victim placed at rest. If unconscious, the victim should be placed in a *recovery position* (left lateral decubitus position with the head downhill and the left

943

Figure 39-31 Guidelines for the hospital management of venomous snakebite.

knee bent) to keep the airway open and decrease the risk of aspiration. The companion can then hike out in search of help. Any plan to carry the victim out must taken into account the local terrain, weather conditions, and overall distance (see [Chapter 25](#) , [Chapter 26](#) , [Chapter 27](#)).

Hospital Care

Initial hospital management of a victim of snake venom poisoning should involve assessment of respiratory and cardiovascular status ([Figure 39-31](#)). A patient with significant respiratory distress or in extremis should be

944

Figure 39-31

Figure 39-31

promptly intubated to support ventilation and prevent aspiration.

Oxygen should be administered to all victims while rapid assessment takes place. Cardiac and pulse oximetry monitoring should be started. If intubation is required, the treating physician should choose the most familiar method. Nasotracheal intubation may be considered, but epistaxis is a risk in victims with coagulopathy. Rapid sequence intubation (RSI) uses sedative-hypnotics and paralytic agents to facilitate oral intubation and is safe and effective. The depolarizing neuromuscular agent succinylcholine should be avoided in RSI of a victim with potential hyperkalemia (e.g., sea snake bite). A nondepolarizing agent, such as vecuronium or rocuronium, can be substituted.

Hypotension is treated initially with intravenous (IV) fluids. Crystalloid, such as Ringer's lactate or normal saline, should be started through at least two large-bore IV lines. Having two lines also allows simultaneous administration of fluids, drugs, and antivenom when indicated. If hypotension persists after the rapid infusion of approximately 2 L of crystalloid in an adult or 20 to 40 ml/kg in a child, then 5% albumin should be added. Animal research has demonstrated an improvement in physiologic parameters and survival with the use of albumin compared with crystalloids and dextran.^[64] Vasopressors should be used only after intravascular volume has been restored. The inappropriate use of vasopressors when volume is required leads to prolonged hypotension, multiple organ failure, and preventable deaths.^[25]

If a victim reports being bitten by a snake but appears well, providers must first determine whether the snake is venomous. Identifying the venomous species indigenous to an area is important. Hospital emergency wards should maintain color photographs of the local snake species to aid in identification. The keeper of an exotic snake involved in a bite probably knows its identity, although an amateur hobbyist may

know the snake only by its common name. Common names are extremely variable and often applied to a number of unrelated species of snakes. Assistance in definitive identification may be obtained from a local zoo, university, or museum with a herpetologist on staff.

If the snake has been identified as venomous and the victim remains asymptomatic, a careful search for puncture wounds should be made. With bites by sea snakes and smaller venomous snakes, such as coral snakes, identifying fang marks can be difficult.^[54] ^[79]

Many bites by venomous snakes occur without injection of venom. These dry bites occur in 20% to 30% of viper bites and 50% to 70% of elapid bites.^[37] ^[68] The incidence of dry bites reaches approximately 75% with sea snakes^[37] and is even higher with rear-fanged colubrids.^[47] A careful history regarding current symptoms and a rapid physical examination looking for abnormalities should be performed. Careful evaluation and monitoring of the victim's vital signs are important. If a pressure immobilization device has been applied in the field and the patient is asymptomatic, it should be removed (after IV access has been secured and appropriate antivenom has been located) to assess the bitten extremity. If obvious signs of envenomation develop, the device should be immediately reapplied and left in place until antivenom administration has begun. If a totally occlusive vascular tourniquet has been applied in the field, a looser constriction band (only tight enough to impede superficial venous and lymphatic return) should be applied more proximally and IV access secured. The arterial tourniquet can then be removed while closely observing the victim for possible deterioration as stagnant, acidotic blood (with or without venom) is released to the central circulation. If signs of significant envenomation are present on arrival, appropriate antivenom administration should begin before removal of any pressure immobilization device or constriction band. Tourniquets are best replaced by constriction bands as soon as possible, however, to avoid adding ischemic insult to venom-induced tissue damage.

Box 39-3. DIAGNOSTIC STUDIES IN EVALUATION OF VENOMOUS SNAKEBITE VICTIMS

BLOOD AND SERUM

Type and cross-match

Complete blood cell count

Peripheral smear

Coagulation studies (fibrinogen, fibrin degradation products, D-dimer, partial thromboplastin time, prothrombin time)

Electrolytes, glucose, creatinine, blood urea nitrogen, liver enzymes, bilirubin

Arterial blood gases

Myoglobin, creatine kinase

URINE

Bedside tests (glucose, blood, myoglobin [on each voided specimen])

Urinalysis

STOOL

Test for blood

RADIOGRAPHS

Chest (if over 40 years old, history of underlying cardiopulmonary disease, or severe envenomation)

Bite site soft tissue films (if retained fangs possible; poor sensitivity)

Computed tomography of the brain (if presentation suggests intracranial hemorrhage)

Bite site soft tissue films (if retained fangs possible; poor sensitivity)

Computed tomography of the brain (if presentation suggests intracranial hemorrhage)

ELECTROCARDIOGRAM

If patient is over 40 years old, has a history of underlying cardiopulmonary disease, or has a severe envenomation

Snake venom detection kits are available in Australia and in other regions to help detect the presence of venom in a bitten individual and identify the offending indigenous species.^[59]^[73] This technique, which is both sensitive and specific, uses an enzyme-linked immunosorbent assay (ELISA) to identify venom in tissue fluid taken from the bite site or in the victim's urine. The test is less reliable using blood samples.^[93]

The severity of envenomation is assessed. If the victim shows signs of cardiovascular collapse or respiratory distress, prompt action is needed, including antivenom administration. If the patient appears stable, however, the approach is more complicated. Snake venom poisoning is a dynamic process, so a patient who looks well may suddenly develop respiratory distress and hypotension. The physician must anticipate multisystem involvement after snake venom poisoning and be prepared for deterioration in the victim's clinical status. Furthermore, with some snake species, many hours may pass before significant signs or symptoms appear.

The history and physical examination help determine severity. The bitten extremity should be marked at two proximal locations and the circumferences at these sites monitored every 15 minutes for progressive swelling. Rapidly progressive edema indicates a worsening clinical situation. Lack of swelling, however, does not rule out significant venom poisoning.

Laboratory evaluations are also important in judging severity ([Box 39-3](#)). A complete blood cell count may reveal a drop in hematocrit with significant bleeding or hemolysis or evidence of hemoconcentration as intravascular fluids leak into soft tissues. Leukocytosis is common, and platelet count may reflect consumptive coagulopathy. The peripheral blood smear may reveal microangiopathic hemolysis. A sample for blood typing

and screening should be obtained as soon as possible, since both venom toxins and antivenom may later interfere with this procedure. Blood coagulation studies (prothrombin time, partial thromboplastin time, fibrinogen level, fibrin degradation products) can aid in gauging severity in species known to induce coagulopathy. Urine samples should be checked at the bedside with reagent strips for the presence of blood. If positive, formal urinalysis and measurement of urine myoglobin should be performed

as well. Stool should be tested for gross or occult blood. Baseline electrolyte and renal function studies are important when hyperkalemia and renal failure are potential complications. Liver function parameters help assess hepatic toxicity. Creatine kinase level, as a marker for myotoxicity, may help determine the presence of envenomation. If elevated, cardiac markers should also be checked to rule out myocardial involvement. If systemic poisoning is evident, an electrocardiogram and chest radiograph should also be obtained. Arterial blood gases should be measured and followed if there is evidence of respiratory involvement or circulatory embarrassment. Signs or symptoms of intracranial bleeding should prompt computed tomographic scanning.

The key principles of treating significant snake venom poisoning are sound supportive care of the victim's physiologic status and the use of appropriate antivenom when available. Antivenoms are available for the vast majority of the world's medically important venomous snakes. Although most antivenoms are still of equine origin, an increasing number of countries are putting ovine Fab or Fab₂ antivenoms into clinical use. These antivenoms appear to have an increased safety profile in regard to allergic phenomena and may be more effective than their equine predecessors (see [Chapter 38](#) and [Chapter 40](#)).^[18] ^[33]

Currently, no specific antivenom exists for *Atractaspis* species, and the majority of these bites follow a benign clinical course.^[76] Likewise, no antivenoms for colubrid envenomations are widely available, although antivenoms against *Dispholidus typus* and *Rhabdophis tigrinus* venoms are produced in South Africa and Japan, respectively. Management of envenomation by burrowing asps and colubrids relies almost entirely on sound supportive care. The bitten extremity should be splinted and elevated. Mild analgesics may be required in some cases, and antibiotics are indicated if secondary infection occurs. If a coagulopathy develops, careful assessment of the coagulation status of the patient is vital. Fresh-frozen plasma may replace depleted coagulation factors,^[51] ^[62] and blood products may be needed to counter a declining hematocrit. However, adding fuel to an ongoing consumptive coagulopathy may exacerbate intravascular clotting.^[42] IV steroids (hydrocortisone, 15 mg/kg/day) and aminocaproic acid (70 mg/kg initially, then 15 mg/kg/day) have been beneficial in some cases.^[40] The use of heparin for intravascular coagulation has also been recommended but is controversial.^[38] ^[66] These modalities have no effect on any direct venom toxicity to the vasculature or internal organs.^[51]

For an antivenom to be effective in snake venom poisoning, it must contain antibodies to the specific deleterious antigens present in the offending snake's venom. In regions where more than one antivenom is available to treat bites by various indigenous snakes, identifying the specific snake takes on added importance. In Australia, where multiple monospecific antivenoms are available, this task is aided by ELISA kits. In regions where the only antivenom available is a polyvalent product, identifying the specific snake is less critical as long as all medically important indigenous species are covered by the antivenom. In some situations, antivenom produced for a snake in a particular region may be largely ineffective in treating bites by the same species found in a different region because of significant differences in venom composition. Important examples include the carpet viper (*Echis carinatus*) and Russell's viper (*Daboia russellii*). Bites by these species should be treated with antivenoms produced using

snakes from the same geographic region as the responsible animal.^[34]

Using an antivenom developed for unrelated species is generally of no benefit unless cross-protection has been previously demonstrated. Significant risk surrounds use of a heterologous antivenom, however, since all commercially available products carry some variable risks of allergic phenomena (see [Chapter 40](#)). In some instances, however, heterologous antivenoms have demonstrated significant cross-protection.^[45] An excellent example of this is the efficacy of Commonwealth Serum Laboratory's tiger snake (*Notechis*) antivenom against sea snake venoms.^{[2] [65] [78]} This should be considered the second-line agent to be used if specific sea snake antivenom is not available.^[79] Further research and clinical experience will clarify the antigenic relationships between venoms of seemingly unrelated snake taxa, increasing the list of cross-protective antivenoms.

If there is a choice between a polyvalent antivenom developed to counter the effects of venom poisoning by several snake species found in a geographic area and a monovalent serum specific for one species of snake, the monovalent product should be used if the snake has been definitively identified. It will provide more specific protection with a smaller burden of extraneous, allergenic proteins ineffective against the offending snake's venom. Recommendations regarding antivenom choices can be obtained from experts in snake envenomation or from the *Antivenom Index*.^{[1] [2]} This resource contains a list of medically important snakes of the world (scientific and common names), recommended

antivenoms for these species, a list of antivenom inventories maintained by participating institutions in the United States, and a list of manufacturers of antivenoms around the world.

Assistance in locating stocks of antivenom within the United States can be obtained by using the *Antivenom Index* or consulting the University of Arizona Poison and Drug Information Center (602-626-6016). Assistance in obtaining an appropriate, exotic antivenom may be obtained from law enforcement agencies or the military.

Once the decision has been made to administer antivenom and an appropriate agent has been obtained, preparations for administration should begin promptly. The patient's intravascular volume should be expanded using crystalloid infusion unless there is a contraindication (e.g., a history of congestive heart failure). Volume expansion may blunt a hypotensive response as a result of direct complement activation by antivenom proteins. An appropriate dose of 1:1000 aqueous epinephrine (0.01 ml/kg, up to 0.5 ml total) should be drawn up in a syringe and placed at the patient's bedside so that it is immediately available for subcutaneous or intramuscular injection if an allergic reaction occurs to the antivenom.

Although most antivenom manufacturers suggest an intradermal test for possible allergy

to their product before infusion begins, these tests are extremely nonspecific and unreliable; a significant number of false positives and false negatives occur.^{[32] [88]} Furthermore, a positive skin test does not contraindicate the use of antivenom if a significant threat to life or limb exists. If indicated, antivenom should be administered without first performing any test for sensitivity. The treating physician should be at the patient's bedside during the initiation of the infusion in order to intervene immediately if a reaction occurs (see [Chapter 40](#)).

The antivenom package insert should be consulted in determining an appropriate starting dose. Antivenom can generally be withheld in an apparently dry bite or minor envenomation while the victim is closely observed for any development or progression of signs or symptoms. For a few species of snakes, antivenom should be administered after *any* bite by an identified specimen regardless of whether symptoms or signs are present. Examples include bites by kraits (*Bungarus* spp.) or large (greater than 50 cm in length) coral snakes (*Micrurus* spp.). Once symptoms begin in these scenarios, they may be difficult to stop even with antivenom.

The potency of different antivenoms is variable, and it is difficult to make general recommendations regarding dosages. For many antivenoms, 20 to 50 ml (further diluted as above) is a reasonable starting dose in treating moderately severe poisoning. In a severe envenomation, especially with evidence of neurotoxicity, 100 to 150 ml is more appropriate.^[59] If signs and symptoms or laboratory abnormalities continue to progress after the initial dose is given, more antivenom should be administered. Children should receive the same starting doses as adults or even higher, since children receive larger doses of venom in proportion to their body surface area and intravascular volume.^{[50] [59]} In the future, antivenom dosing may be guided by ELISA techniques that quantitate circulating venom.^[9]

Before antivenom infusion the patient should be premedicated with IV antihistamines. Fifty to 100 mg of diphenhydramine (1 to 2 mg/kg in children) and 300 mg of cimetidine (5 to 10 mg/kg in children) or equivalent agents can be given. Where antivenom is clearly needed and risk of anaphylaxis is increased (e.g., history of allergy to horses, prior reaction to antivenom), premedicating the patient with a small dose of subcutaneous 1:1000 epinephrine (0.3 ml in adults, 0.01 ml/kg in children) can be considered if there are no contraindications (e.g., coronary artery disease, severe hypertension).

The total antivenom dose to be administered should be added to a bag of diluent (5% dextrose in water or crystalloid) at a dilution of 1:50 to 1:100. The infusion should be begun intravenously at a very slow rate (a few milliliters per minute) with the physician in attendance. If no reaction occurs after a few minutes, the rate can be progressively increased so that the total dose is administered in approximately 1 to 2 hours. If the patient is in extremis, however, the infusion should be more rapid. Antivenom should not be administered by local or intramuscular injection, because it is less effective by these routes, and if a reaction occurs, the drug cannot be discontinued.^[11]

If an early reaction occurs, the antivenom should be temporarily halted and the reaction treated (see [Chapter 38](#)). The infusion can then usually be restarted at a slower rate.

Further diluting the antivenom may also be helpful.

Patients who receive equine antivenom are at risk for immune complex-mediated delayed serum sickness, usually 1 to 2 weeks after administration. This risk increases in direct proportion to the total dose of antivenom administered.

Victims definitely envenomed, particularly those requiring antivenom, should be admitted for close cardiopulmonary monitoring for a minimum of 24 hours and until overall stability is achieved. Any abnormal laboratory values should be remeasured frequently for at least 24 to 48 hours or until normalized. Delayed coagulopathy after antivenom treatment may result from delayed release of venom from depot sites such as skin blisters.^[59]

Persons who remain asymptomatic after being bitten by venomous snakes create challenging disposition decisions. If a viperid snake is implicated in such a bite,

it is usually safe to discharge the victim after 6 hours of close observation, provided the clinical picture remains normal. For sea snakes, 8 hours is reasonable; for elapids, 24 hours is safer.^{[11] [79]} Suspected boomslang (*Dispholidus typus*), bird snake, or twig snake (*Thelotornis* spp.) bites should be observed in the hospital for 24 hours. If coagulation studies remain normal at that time, the patient can be discharged.

If discharged, the person should be instructed about bed rest for 24 hours, increased fluid intake, and monitoring for symptoms, such as increased pain, swelling, dizziness, shortness of breath, numbness, and weakness. Follow-up within 24 hours should be arranged for reevaluation.

With evidence of clinically significant bleeding in the patient with a coagulopathy, administration of appropriate blood products should be considered. Antivenom should be started if possible before blood products are given to stop the continued activation and depletion of coagulation factors. Many viperid bites have laboratory evidence of coagulopathy *without* significant clinical hemorrhage.^{[46] [57]} Such cases can be treated with antivenom, bed rest, and close observation while withholding blood products.

Other treatment modalities for snake venom poisoning have demonstrated variable anecdotal benefit, but they do not replace proper conservative care and appropriate antivenom use. Edrophonium and neostigmine, for example, can temporarily reverse neuromuscular blockade after cobra envenomation.^{[59] [75] [87]} These agents must be used cautiously because either may stimulate cholinergic crisis. Edrophonium combined with atropine might be effective in reversing respiratory muscle weakness in a victim of cobra or krait bite when antivenom is not immediately available. Attempts to temporize in a patient with impending respiratory failure can result in aspiration.^[35] It is best to proceed with prompt endotracheal intubation before frank respiratory failure occurs.

Ethylenediaminetetraacetic acid (EDTA) has been touted as an inhibitor of snake venom proteases,^[46] ^[60] but its clinical efficacy has not been demonstrated. In fact, increased mortality occurred in animal models when EDTA was given intravenously to treat pit viper venom poisoning.^[60]

Other modalities recommended in the past without evidence to support routine use include topical agents (e.g., potassium permanganate) to "deactivate" venom; routine fasciotomy of the bitten extremity (see following discussion); immediate exploration, debridement, or excision of the bite site; administration of heparin to counter disseminated intravascular coagulation; and high-dose steroids. Renal failure can best be prevented by aggressively treating hypotension, maintaining adequate urine output, and using antivenom appropriately. Myoglobinuria should be treated in standard fashion with sodium bicarbonate, mannitol, or loop diuretics. If renal failure develops, care should be directed at maintaining proper electrolyte balance. Peritoneal dialysis or hemodialysis is often required in such cases. Hemodialysis has been anecdotally reported to improve peripheral muscle weakness in victims of severe sea snake envenomation with acute renal failure, probably by reversing hyperkalemic and uremic effects on venom-damaged muscle fibers.^[65] Dialysis does not remove circulating venom components, however, and the indications for dialysis are the same as for any other cause of acute renal failure.

Wound care of the bitten extremity should be provided (see [Chapter 38](#)). Although controversial, broad-spectrum antibiotics may be used prophylactically for a few days in victims with significant potential for necrosis in an attempt to limit secondary infection. Although the incidence of such infection is low,^[13] the risks increase after misdirected attempts to incise or open the bite site under field conditions.^[94] Early physical therapy aimed at returning the bitten extremity to its maximal level of function is important, especially in patients with significant soft tissue swelling or necrosis.

If concerned about compartment syndrome, the physician should measure intracompartmental pressures using an appropriate device. Sustained pressures greater than 30 to 40 mm Hg in a normotensive patient may exceed capillary perfusion pressure in the muscles. Ischemia may result if the situation is not addressed, usually by means of a fasciotomy. The pressure at which ischemia ensues is even lower in hypotensive snakebite victims, and the threshold for performing a fasciotomy may need to be lowered in this setting. The overall incidence of compartment syndromes after venomous snakebite, however, is low.^[17] ^[23] ^[86] Prophylactic fasciotomies in patients without objectively documented elevated intracompartmental pressures are inappropriate.

The management of a victim with ocular exposure to spitting cobra venom begins with immediate and copious irrigation of the eyes with any readily available, nonirritating fluid.^[59] ^[84] Prompt treatment may help prevent local complications. Close ophthalmologic follow-up is important to rule out corneal ulceration or uveitis.

ACTIVE IMMUNIZATION

Rituals and techniques for immunization against snake venom have been practiced for centuries in various parts of the world.^[49] More recently, modern immunologic methods have been used. Beginning in 1965, 43,446 individuals in the Ryukyu Islands of Japan, an area of high snakebite incidence, were immunized with habu (*Trimeresurus flavoviridis*) venom toxoid. Follow-up after about 5 years indicated equivocal results, and no further large-scale trials were undertaken, but experimental

950

work continues. Individuals have also been immunized against other snake venoms.^[63]
^[77]

MORTALITY

Although mortality rates vary greatly throughout the world, more than 95% of deaths from snakebites occur in underdeveloped countries with inadequate or remote medical resources.^[9] The causes of death in fatal cases of elapid envenomation are respiratory paralysis, coagulopathy, renal failure, and cardiac failure.^[11] ^[60] ^[92] In viperid-related fatalities the cause is usually protracted hypovolemic shock.^[11] This is often related to inadequate fluid resuscitation, inappropriate use of vasopressors, or inadequate or delayed use of antivenom. Sea snake fatalities are related to respiratory failure, cardiac arrhythmias, or renal failure.^[7] ^[59] ^[79] The average time to death after envenomation is 5 hours in elapid bites, 2 to 3 days in viperid bites, and 12 to 24 hours in sea snake bites.^[58]

Chapter 40 - Antivenins and Immunobiologicals: Immunotherapeutics of Envenomation

Rivka S. Horowitz
Richard C. Dart

The ideal therapeutic agent effectively treats or prevents a specific medical condition and is free of adverse effects. Commercially available antivenins (antivenoms) are not ideal. The vast majority of antivenins are equine derived and thus possess the potential adverse immunologic effects inherent in the administration of foreign proteins. Although antivenin lowers the morbidity and mortality associated with envenomation, it may have life-threatening side effects. As a result, many physicians are reluctant to administer antivenin even to patients who have a clear indication for its use.

Worldwide, more than 60 commercial laboratories produce almost 200 different antivenin preparations for the treatment of snake, arachnid, fish, and coelenterate envenomations. Theakston and Warrell^[48] compiled a list of hyperimmune sera available for the treatment of venom poisoning.

The available crotalid antivenin in the United States is effective against all indigenous North American pit vipers. However, zoos and amateur snake enthusiasts are likely to house non-indigenous, exotic snakes for which the anticrotalid antivenin would be useless. Physicians must expeditiously exploit all available resources to identify and acquire the appropriate antivenins for unusual envenomations. One such resource, the *Antivenin Index*, is compiled by the American Association of Zoological Parks and Aquariums and the American Association of Poison Control Centers (AAPCC). The *Index* lists the location of foreign antivenins stocked by zoos in the United States. Guidance for use of these antivenins and general snakebite management may be obtained through an AAPCC-certified poison center.

PRINCIPLES OF ANTIVENIN THERAPY

Historical Perspective

Immunotherapy against snake venom dates to 1887 with the first report of successful immunization in birds. Sewall^[39] reported that pigeons injected with increasing but sublethal doses of *Sistrurus catenatus catenatus* (Eastern massasauga) venom became resistant to venom inoculations seven times the lethal dose. Seven years later, contemporaneous experiments by Calmette^[8] and Phisalix and Bertrand^[33] demonstrated that immunization with cobra (*Naja naja*) and European viper (*Vipera berus*) venoms, respectively, protected animals against inoculation with these venoms.

Within a decade of Sewall's landmark experiment, Calmette^[9] produced the first therapeutic antivenin derived from immunizing horses with cobra venom. Although Calmette overestimated the effectiveness of his antivenin, erroneously believing that it would protect against all neurotoxic venoms,^[8] he recognized an important principle of immunotherapy still operative today: interspecies cross-reactivity.

Another pioneer in the study and production of antivenin, Vital Brazil, further demonstrated both specificity and cross-reactivity through the production of numerous monospecific and polyspecific antivenins. A *monospecific* antivenin is derived from immunizing animals with the venom of a single species, whereas *polyspecific* antivenin is produced either by inoculating animals with the venom of more than one species or by pooling different monospecific antivenins into a final product. Brazil recognized the need for polyspecific antivenins, since snakebite victims were often unable to differentiate among the variety of poisonous snakes indigenous to an area.^[14]

To ensure an adequate supply of venom for his research, Brazil organized a unique exchange network throughout the countryside of São Paulo, Brazil. He convinced government and railroad officials to allow free passage for snakes shipped to his institute and sent devices for snake capture and crates for transport to anyone requesting them. For every snake shipped to him, Brazil would send a vial of serum (antivenin); for every six snakes sent, he would provide a needle and syringe for administering the serum.^[14] After more than a decade of operating his exchange, Brazil claimed a significant decrease in mortality from snakebites.^{[5] [14]}

Neutralizing Antibody

The foundation of antivenin therapy is the antigen-antibody interaction. The component of antivenin responsible for its therapeutic activity is the immunoglobulin G (IgG) antibody molecule. This neutralizing antibody inactivates the antigen by specific,

noncovalent, antigen-antibody binding. Thus a neutralizing antibody to phospholipase A₂, a common constituent of snake venoms, prevents or attenuates the

953

neurotoxic or myotoxic activity associated with this venom component.

Understanding the structure of IgG helps to explain both the mechanism of action and the adverse reactions of antivenins. An IgG molecule weighs approximately 150,000 daltons and is composed of two functional parts: the antigen-binding site, consisting of two Fab portions, and the effector site, or Fc region ([Figure 40-1](#)). Specific binding of the antigen to the Fab sites neutralizes further activity of the antigen. The Fc region of IgG is responsible for binding and activating immune system cells (e.g., phagocytes, macrophages, mast cells) and triggering a host of immunologic responses. These reactions, which include degranulation of mast cells and activation of the complement cascade, are partly responsible for the immediate, life-threatening allergic reactions to antivenin.

The large size of the IgG antibody has important implications for the immunogenicity, distribution, and elimination of these neutralizing antibodies. Large-molecular-weight entities in general (IgG and other large antivenin components) are more likely to trigger immunologic reactions than smaller ones.^[49] The ideal neutralizing antibody would be expected to have a large volume of distribution, implying more extensive tissue penetration and access to venom components. The large size of IgG, however, confines it primarily to the intravascular space and may limit more extensive distribution into tissue compartments. Theoretically, this may limit the effectiveness of IgG in binding antigen within tissue compartments.

Figure 40-1 Schematic diagram of an IgG molecule. The antigen-binding region (Fab portion) is present at the amino-terminal end. The effector region (Fc portion) interacts with the immune system cells and resides at the carboxyl end of IgG. Note the disulfide bridge.

The large molecules that make up most antivenin proteins have long elimination half-lives, and may predispose recipients to further immunologic complications. Large antivenin proteins exceed the threshold for filtration and excretion by the kidneys and therefore are eliminated primarily by the reticuloendothelial system (RES), a much slower process than renal elimination. Theoretically, the longer it takes to clear foreign proteins from the body, the more time they will be available to form immune complexes with the patient's endogenous antibodies. These complexes, composed of infused

antivenin proteins and the patient's own IgG molecules, may precipitate in susceptible tissue, resulting in clinical disease such as serum sickness.

Enzymatic cleavage of IgG with pepsin and papain produces smaller substituent Fab₂ and Fab fragments that are capable of neutralizing venom components. Snake antivenin composed of Fab or Fab₂ fragments avoids many of the serious adverse effects of IgG antivenin and thus represents a significant advance in treatment of envenomation ([Figure 40-2](#) and [Figure 40-3](#)) (see later discussion).

Modern Production of Antivenin

Antivenin (Crotalidae) Polyvalent, the IgG crotalid antivenin manufactured by Wyeth, has been the mainstay of therapy for crotalid envenomation despite its numerous potential deleterious effects. Efforts to maximize the neutralizing potential of antivenin while minimizing its immunogenicity have become the principal goal of modern antivenin production. Despite major advances in our understanding of the biology of antivenin production, the commercial manufacture of antivenin relies on the same principles of host animal immunization with snake venom described more than a century ago.

All antivenins follow a two-step production process. First, a neutralizing antibody is produced by immunization of a host animal with sublethal doses of venom. This antibody is one of many proteins present in the resulting immune serum preparation. Step two involves purification of antivenin with reduction in the fraction of nonneutralizing proteins. The preparation is then concentrated and packaged in its final lyophilized or liquid form.

Antivenin (Crotalidae) Polyvalent Wyeth.

In 2000 the ovine-derived antigen-binding fragment (Fab) anticrotalid antivenin became available for clinical use. Before this, the only available antivenin in the United States against pit viper envenomation was Antivenin (Crotalidae) Polyvalent Wyeth. Manufacture of that antivenin has changed little since its introduction in 1954. In this process, horses are immunized with increasing doses of venom from four crotalid species: *Crotalus adamanteus* (eastern diamondback), *C. atrox* (western diamondback),

Figure 40-2 Proteolytic cleavage of IgG results in predictable substituent fractions. Pepsin digestion produces Fc and Fab₂ fractions. Fab₂ consists of two Fab portions connected by a disulfide bridge. Molecular weight of Fab₂ is 100,000 daltons.

Figure 40-3 Proteolytic cleavage of IgG results in predictable substituent fractions. Papain digestion of IgG yields the Fc and two Fab segments for each IgG molecule. Molecular weight of Fab is 50,000 daltons.

C. durissus terrificus (South American or tropical rattlesnake), and *Bothrops atrox* (fer-de-lance), plus adjuvant for immune system stimulation. The resultant hyperimmune serum is subjected to an ammonium sulfate precipitation, which removes a variety of plasma proteins. Unfortunately, a fraction of neutralizing antibody is also lost in this process, resulting in diminished potency. The product is then precipitated, filtered, resuspended, and lyophilized. The final concentrated antivenin contains 1.5 to 2 g of horse protein, only 15% to 25% of which is IgG.^[43]

ADVERSE EFFECTS

Incomplete purification of Antivenin (Crotalidae) Polyvalent Wyeth results in the presence of significant amounts of nonneutralizing proteins, such as albumin, α - and β -globulins, and IgM. Sullivan^[43] has quantified the relative contributions of nonneutralizing proteins to the final antivenin product ([Box 40-1](#)). The heterologous nature of this antivenin enhances immunogenicity and is responsible for life-threatening anaphylactic and anaphylactoid reactions and the

955

more common, but self-limiting, serum sickness (see later discussion). In addition, since the purification process results in denaturation of a portion of the protective IgG fraction,^[43] multiple vials of antivenin must be administered for adequate reversal of venom poisoning.

IgG	2900 mg/ml
IgM	75 mg/ml
Total protein	9.4 g/dl
Albumin	0.28 g/dl
α_1 -Globulin	0.74 g/dl
α_2 -Globulin	3.50 g/dl
β -Globulin	2.76 g/dl
?-Globulin	2.12 g/dl

Despite these impurities and being prepared from only four species, the Wyeth antivenin

preparation is effective against all crotalids native to North, Central, and South America. This cross-reactivity enables a single preparation of antivenin to be effective against any clinically significant pit viper envenomation.

Anaphylactic and Anaphylactoid Reactions

The spectrum of human immunologic responses to antivenin is well documented. Introduction of heterologous protein may induce type I hypersensitivity (anaphylactic) reactions. This syndrome results from IgE-mediated degranulation of mast cells and release of vasoactive mediators, including histamine, leukotriene, platelet activating factor, adenosine, and neutrophilic and eosinophilic chemotactic factors.^[26] These substances induce vasodilation and increased capillary permeability resulting in hemodynamic instability and hypotension. Bronchospasm, laryngospasm, and death can result without airway management and pharmacologic intervention.

Anaphylactoid reactions are clinically indistinguishable from anaphylaxis but are not IgE mediated. In this syndrome, mast cell degranulation is postulated to result from direct interaction of nonneutralizing antivenin protein or the Fc segment of the IgG molecule itself with mast cell membranes. This is often associated with activation of the complement cascade.^[45] In addition, large nonneutralizing proteins present in antivenin, as well as aggregates of IgG itself,^{[3] [13] [19]} may directly activate the complement system, resulting in release of vasoactive mediators. The subsequent hypotension, bronchospasm, and airway compromise require rapid, appropriate interventions. These life-threatening sequelae may occur whether antivenin is administered as the skin test or in the full antivenin dose.

Management of allergic reactions should include epinephrine (intravenous bolus or infusion), antihistamines (both H₁ and H₂ blockers), and aggressive airway support if necessary ([Table 40-1](#)).

Allergic Reactions

Patients with significant envenomation and a history of allergy to equine-derived antivenin or to horse serum present a difficult challenge. The decision to treat with Antivenin (Crotalidae) Polyvalent Wyeth must be based on strong clinical and laboratory indications and requires careful but rapid risk-benefit analysis. A patient with a history of allergy to antivenin who requires antivenin because of life- or limb-threatening symptoms may be successfully supported with epinephrine, antihistamines, and airway management. Patients who have experienced life-threatening allergic reactions to antivenin may not necessarily have recurrent reactions when rechallenged. Nevertheless, it is prudent to pretreat such patients with epinephrine and antihistamines (diphenhydramine and cimetidine) before antivenin administration (see [Table 40-1](#)).

Serum Sickness

In addition to the acute effects associated with antivenin administration, a delayed type III hypersensitivity reaction is well described. This entity, known as serum sickness, is

common,^{[12] [46]} particularly in persons receiving more than seven or eight vials of antivenin.^{[17] [50]}

The syndrome of serum sickness was originally described in 1905 by two pediatricians, von Pirquet and Schick, who noted that children receiving equine-derived streptococcal antitoxin sometimes developed fever, lymphadenopathy, and rash.^[29] They first used the term *serum sickness* to describe this constellation of symptoms resulting from the administration of heterologous serum. Modern definitions of this syndrome have varied little from the original description. Serum sickness is a spectrum of disease, typically characterized by fever, malaise, urticaria, lymphadenopathy, arthralgias, and less commonly, glomerulonephritis and neuritis. The onset of symptoms usually occurs within 1 to 2 weeks after exposure to foreign antigens, in this case, heterologous protein in antivenin.

The pathophysiology of serum sickness results from nonspecific deposition of immune complexes (antigen-IgG) in susceptible tissue. Under nonpathologic conditions, these complexes are cleared by the RES without sequelae. With abnormal vascular permeability and slight antigen excess, however, precipitation of immune complexes occurs. In addition, immune complex deposition tends to occur in tissues where the vasculature has a filtering function.^[6] These complexes diffuse between endothelial cells and deposit along the basement membrane.^[27] The interaction of immune complexes

TABLE 40-1 -- Treatment Recommendations for Antivenin-Induced Anaphylaxis or Anaphylactoid Reaction

	EPINEPHRINE		ANTIHISTAMINES	
	INFUSION	BOLUS	DIPHENHYDRAMINE	CIMETIDINE
Adult	1–4 µg/min IV	0.5–1 ml of 1:10,000 solution IV	50 mg IV stat, 50 mg IV q6h, prn	300 mg IV stat, then 300 mg IV q6h, prn
Child	0.01–1 µg/kg/min IV	0.01 mg/kg of 1:10,000 solution IV	1 mg/kg IV stat, then 1 mg/kg IV q6h, prn	5–10 mg/kg IV stat, then 5–10 mg/kg IV q6h, prn

IV, Intravenously; *stat*, immediately; *q6h*, every 6 hours; *prn*, as needed.

trapped in the vascular wall with vasoactive mediators results in complement activation, further release of vasoactive mediators, and exacerbation of the inflammatory process. This process characteristically occurs in skin, synovial joints, and the glomerular apparatus, resulting in the clinical manifestations of serum sickness.^{[10] [26] [52]}

Treatment of Serum Sickness

A large percentage of patients receiving more than seven or eight vials of the standard, equine-derived anticrotalin antivenin develop serum sickness. ^[17] ^[50] The spectrum of illness in this syndrome is highly variable and may range from mild urticaria, malaise, and low-grade fever to debilitating arthralgias and myalgias. Fortunately, although well described, glomerulonephritis and neuritis are rare complications. The variability of the syndrome requires that treatment be tailored to individual clinical needs.

Patients with serum sickness should receive antihistamines such as diphenhydramine or hydroxyzine and, except in the mildest cases, a 7- to 10-day course of high-dose steroids. Clinical illness typically resolves within 1 to 2 weeks.

SPECIFIC ANTIVENINS

This section covers general aspects of antivenin therapy following envenomation by the black widow spider, coral snake, and pit vipers. Specific indications for each antivenin are covered in their respective chapters (see [Chapter 34](#) , [Chapter 38](#) , and [Chapter 39](#)), as are specialized or experimental antivenins directed against the venoms of such creatures as scorpions (see [Chapter 35](#)) and stonefish, box-jellyfish, and sea snakes (see [Chapter 61](#) and [Chapter 62](#)).

Arachnid Antivenin: Black Widow Spider

The only nonsnake antivenin approved by the FDA for use in the United States is indicated for envenomation by the black widow spider *Latrodectus mactans* (see [Chapter 34](#)). Antivenin (*Latrodectus mactans*) MSD is derived from hyperimmunizing horses with *Latrodectus* venom and is effective in counteracting the pain associated with severe envenomations. A similar antivenin frequently used in Australia is associated with a low but measurable incidence of anaphylaxis and serum sickness.^[47]

Fortunately, the venom from the black widow spider rarely results in life-threatening manifestations. Patients can usually be managed effectively with adequate doses of narcotic analgesics and benzodiazepines. In certain conditions, however, *Latrodectus* antivenin may be indicated. In general, patients with underlying medical problems, such as coronary artery disease or chronic obstructive pulmonary disease, whose pain may trigger secondary ischemic events, and those who may not be able to tolerate large doses of narcotics or benzodiazepines may be appropriate candidates for antivenin. Pregnancy and extremes of age have often been cited as indications for antivenin.^[28] ^[38] Patients with severe pain who do not respond to narcotics and benzodiazepines, however, will obtain prompt relief with intravenous (IV) administration of one vial of *Latrodectus* antivenin.^[28]

Snake Envenomation

In contrast to black widow spider bites, venomous snakebites do not allow withholding antivenin when signs of envenomation are present (see [Chapter 38](#) and [Chapter 39](#)). No effective alternative therapy exists for clinically significant snake envenomations other than antivenin.^[37] The FDA-approved new, safer anticrotalid antivenin (CroTab) is available for clinical use. Before this, only equine-derived Antivenin (Crotalidae) Polyvalent Wyeth was available for the treatment of crotalid envenomation from indigenous snakebites in the United States.

Coral Snakes (Elapidae).

The AAPCC reported 61 coral snake bites (family Elapidae) in 1998.^[22] An effective antivenin is available only for the Eastern (*Micrurus fulvius fulvius*) and Texas (*M. fulvius tenere*) coral snakes. Envenomation by these two species is associated with more serious systemic findings than typically occurs with their Arizona (Sonoran, *Micruroides euryxanthus*) counterpart.^[20]^[36] Signs of local envenomation are minimal, with neurotoxicity in the form of bulbar and respiratory paralysis developing up to 12 hours after the bite.

957

Immunotherapy for *M. fulvius* envenomation requires IV administration of four to six vials of Antivenin (*Micrurus fulvius*) Equine Origin.^[35] Additional vials may be necessary as clinically warranted.^[20] Antivenin should be given to patients who have been bitten by an Eastern coral snake that has "chewed" on the affected part and who have evidence of fang penetration through the skin.^[20]

Early antivenin treatment is recommended, since cranial nerve dysfunction and respiratory paralysis from Eastern coral snake envenomation may be easier to prevent than to reverse.^[20] Once venom components are bound to neuronal target tissue, they may not be readily removed by antivenin, or the end-organ toxicity may not be readily reversible. Thus early administration of antivenin, preferably within 8 hours of the bite, has been advocated.^[20] As with any equine-derived product, skin testing is mandatory, and preparations for treatment of anaphylaxis must be in place. Skin testing may be omitted if the patient is hemodynamically unstable as a result of envenomation.

Pit Vipers (Crotalidae).

A sheep-derived Fab antivenin, Affinity Purified, Mixed Monospecific Crotalid Antivenom, Ovine Fab for Injection (CroTAb), approved in 2000, represents a major advance in the immunotherapeutics of snake envenomation. Indications for the use of anticrotalid antivenin include signs and symptoms of progressive envenomation, as manifested by increasing local or systemic effects, or laboratory abnormalities consistent with envenomation (see [Chapter 38](#)).

Antivenin (Crotalidae) Polyvalent Wyeth.

A careful history must be elicited from all envenomed patients. This should include allergy to horse dander, history of atopic reactions, and previous allergy or exposure to horse serum. Patients with positive histories may be at greater risk for allergic reactions to antivenin.

Once the decision to administer antivenin has been made, a skin test determines horse

serum sensitivity. Skin testing may be omitted for patients in extremis from snake envenomation, since immediate treatment may be lifesaving. Skin testing should never be done unless a decision to administer antivenin has been made, since life-threatening allergic reactions may occur from skin testing alone. The patient must be in an emergency department or other intensive care setting, with adequate IV access and resuscitation equipment at hand. The attendant staff must be prepared to treat acute anaphylaxis whenever skin testing is performed or antivenin is infused.

PROTOCOL FOR SKIN TEST.

The manufacturer recommends the following protocol for skin testing ^[34] :

1. From 0.02 to 0.03 ml of a 1:10 dilution of antivenin or 0.02 to 0.03 ml of horse serum (provided in the kit as prediluted 1:10 solution) is injected intradermally.
2. A similar control dose of normal saline is injected at a distant site for comparison.
3. Patients with a history of sensitivity to horse serum who require antivenin therapy should be skin tested using a dilution of 1:100 of antivenin or normal horse serum.
4. A positive skin test is usually manifest within 5 to 30 minutes and is characterized by a wheal or without erythema.

A significant percentage of both false-positive and false-negative skin tests occurs. Therefore a negative skin test does not rule out the potential for anaphylaxis associated with the administration of antivenin. Equally important, a positive skin test does not contraindicate the use of antivenin if the patient's life or limb is threatened.^{[25] [34] [37]} The purpose of a skin test is to identify a patient with obvious severe hypersensitivity so that the health care team can be prepared to manage an allergic reaction.

ADMINISTRATION.

In general, the initial dose of this antivenin is 10 vials, although the clinical severity of the bite may necessitate higher initial doses. Eastern diamondback rattlesnake (*C. adamanteus*) envenomations, for example, are typically more severe and may require an initial dose of 10 to 20 vials of antivenin.

Although seemingly a minor detail, dissolving the lyophilized antivenin is yet another challenge in managing the envenomed victim. Provided with each antivenin kit, 10 ml of diluent (bacteriostatic water for injection, USP) is added to the lyophilized antivenin. Gentle swirling and rotating of the vials are mandatory to avoid inactivating the neutralizing component, IgG. Vigorous handling or shaking while solubilizing the antivenin may result in partial denaturation of IgG. Dissolving lyophilized antivenin takes 20 to 30 minutes per vial, so enlisting the help of staff will result in more rapid completion of the process.

Once in solution, the vials of antivenin are diluted in 250 to 500 ml of 5% dextrose in water or normal saline. The initial rate of infusion should be slow, with frequent clinical assessment for evidence of an allergic reaction. If well tolerated, the remainder of the

infusion should be administered over 1 hour.

The initial rate of antivenin infusion in patients with positive skin tests should be even slower than for patients with negative skin tests. We support pretreatment of these patients with epinephrine and antihistamines,^[31] but this is not universally recommended. If no allergic reaction occurs, the residual infusion may proceed over the next 1 to 2 hours.

If anaphylaxis develops during administration of antivenin, the infusion is stopped, and aggressive airway management and pharmacologic intervention are initiated.

Patients should receive epinephrine and antihistamines (both H₁ and H₂ blockers) (see [Table 40-1](#)). Persistent life-threatening, systemic signs of venom poisoning may necessitate restarting the antivenin infusion. Under these conditions the antivenin should be further diluted and given at a slower rate than the initial infusion. The patient should be pretreated with antihistamines and epinephrine, and when required, epinephrine should be simultaneously infused at a second IV site (see [Chapter 38](#)).

Antigen-Binding Fragment.

A major advance in immunotherapy for envenomation involves the use of specific Fab to neutralize venom (see [Figure 40-3](#)). Theoretically, use of these smaller antibody fragments has advantages. The ideal immunotherapeutic agent should have: (1) high specificity and affinity for the antigen, (2) rapid and extensive tissue distribution so that it will reach and bind the antigen in a timely fashion, (3) low antigenicity, and (4) rapid clearance from the body.^[43] Based on clinical and experimental data, Fab appears to satisfy these criteria.

ADVANTAGES OF FAB VS. IMMUNOGLOBULIN G.

Both animal and human experiments, especially with digoxin intoxication, support the efficacy of purified Fab and its superiority to whole IgG. Extensive experience with the digoxin antidote Digibind demonstrates that ovine-derived digoxin-specific Fab fulfills the criteria for an effective immunotherapeutic agent and is superior to whole IgG antibodies.^{[7] [23] [41]}

In baboon and rabbit models, distribution and elimination half-lives for digoxin-specific Fab were significantly shorter (0.28 to 0.32 and 9 to 13 hours, respectively) than those of the digoxin-specific IgG molecules (4 and 61 hours).^[41] In addition, the volume of distribution for digoxin-specific Fab is significantly greater than that of the whole IgG antibody, reflecting its more extensive tissue distribution. In this model, therefore, Fab was more rapidly and extensively distributed to tissue sites than IgG.^[41]

Similar kinetic analysis in the dog model of digoxin poisoning revealed significantly shorter distribution half-lives with Fab than with the whole IgG antibody (0.54 hour vs. 2.28 hours). This correlated with shorter mean time to reversal of digoxin-induced cardiotoxicity in the Fab-treated group (36 minutes vs. 85 minutes in the IgG group).^[23]

Besides its proven efficacy,^{[1] [40] [53]} ovine-derived Fab has not caused anaphylaxis or serum sickness despite its extensive use in clinical practice. Digoxin-specific Fab (Digibind) is safe, effective therapy for the rapid reversal of digoxin-induced cardiotoxicity.

ADVANTAGES AND DISADVANTAGES OF FAB ANTIVENIN.

Clinical manifestations of crotalid envenomation using polyspecific anticrotalid Fab can be successfully reversed based on (1) the effectiveness of digoxin-specific Fab immunotherapy, (2) the successful clinical trials using Fab antivenin directed against *V. berus*,^[18] and (3) the protection against venom-induced lethality in mice after the administration of specific Fab.^[44]

Although successful treatment of digoxin toxicity with Digibind is similar to the use of purified Fab fragment antivenin for snake envenomation, important differences include the following:

1. Unlike digoxin, snake venom is a heterogenous mixture of antigens varying greatly in size and structure. The antigenicity of each venom component may vary greatly depending on its physical characteristics.
2. Unlike snake venom, digoxin does not cause permanent cellular damage to target cells. Thus, once digoxin is released from target tissue and bound to Digibind, the cellular toxicity is reversed. The same may not be true of toxic effects of venom.
3. The relatively small size of the digoxin (781 daltons)-Fab (50,000 daltons) complex permits it to be renally excreted. In addition, evidence supports endogenous renal catabolism of such small complexes.^{[2] [21] [42] [51]}

Venom is a complex mixture of proteins, glycoproteins, and peptides, with molecular weights ranging from several thousand to greater than 100,000 daltons.^[37] Although Fab complexed to small-molecular-weight venom components may be cleared renally, most of venom proteins have molecular weights greater than 20,000 daltons and are too large to be filtered and excreted by the kidney when complexed to Fab. This may result in significantly longer elimination half-lives of venom-Fab complexes. Theoretically, this may allow sufficient time for dissociation of the venom-Fab complex, resulting in the release of active venom components.

ADMINISTRATION.

The new CroTAb antivenom is an affinity-purified, lyophilized preparation of ovine Fab obtained from healthy sheep, each immunized with one of the following North American crotalid snake venoms: *C. atrox* (Western diamondback rattlesnake), *C. adamanteus*

(Eastern diamondback rattlesnake), *C. scutulatus scutulatus* (Mojave rattlesnake), and *Agkistrodon piscivorus piscivorus* (cottonmouth or water moccasin). The final product is prepared by isolating the immunoglobulin from the ovine serum, digesting it with papain, and isolating the venom-specific Fab fragments on affinity columns. This procedure produces four different monospecific antivenoms, which are then mixed in equal proportions to prepare the final antivenom.

In mouse lethality studies, CroTAb averaged 5.3 times more potent than Antivenin (Crotalidae) Polyvalent

Wyeth in neutralizing the venoms of 10 clinically important North American crotalid snakes.^[11] In two prospective, open-labeled, multicenter trials, 42 patients ages 10 and older had minimal or moderate North American crotalid envenomation (excluding copperhead bites) within 6 hours before admission and showed evidence of worsening in the emergency department. Rapid onset of action was noted in both trials, with reversal of progressive swelling, neurologic, and gastrointestinal symptoms, and prolonged prothrombin time (PT) during the initial CroTAb infusion.

The short half-life of Fab compared with IgG resulted in recurrent signs of envenomation. Therefore a novel dosing schedule for CroTAb is recommended. Four to twelve vials of CroTAb are infused to achieve initial control of the envenomation syndrome, followed by two vials every 6 hours for three additional doses (18 hours), particularly in patients with severe coagulopathy.

COMPLICATIONS.

As with all products containing animal proteins, CroTAb causes adverse reactions in about 20% of all reactions during infusion. Nearly all effects were mild. The most severe reaction was bronchospasm, which responded promptly to therapy. No cases of anaphylaxis have been reported. The serum sickness rate is approximately 6%, much lower than with nonpurified serum products, which typically produce serum sickness in 70% to 80% of patients.

Monoclonal Antibodies

Advances in molecular biology have made the use of monoclonal antibodies commonplace in research.^[15] A monoclonal antibody is a single, unique molecule produced in large quantity by a clone of cultured B cells. Reports describe the production of monoclonal antibodies directed against specific venom components and activities. For example, monoclonal antibodies with antithrombin-like,^[30] antihemorrhagic,^[16] ^[32] antimyotoxic,^[24] and other activities have been purified. Preincubation of several classes of antiphospholipase A₂ monoclonal antibodies in mice neutralized the myotoxic activity typically seen with *Bothrops asper* (ferde-lance) envenomation.^[24] Monoclonal antibody-based enzyme-linked immunosorbent assays

can be used to measure the concentration of venom components and may be more accurate and sensitive than other bioassays.^[4] This technique also has diagnostic potential because it can be used to detect unique venom components after envenomation.^[30]

Despite these advances, use of monoclonal antibodies for venom poisoning has significant theoretic problems. Traditionally, an effective antivenin has a broad spectrum of activity and can counteract a wide array of clinical sequelae. Because of the complex and heterogenous nature of venoms with their innumerable antigenic sites, such antivenin would require pooling of many different monoclonal antibodies. A major advantage of a polyclonal antivenin is its ability to neutralize the effects of venoms of related species within the same genus or family. The very specificity that enables monoclonal antibodies to target unique antigenic determinants might render this approach impractical as an isolated therapeutic modality against envenomation.^[25]

Nevertheless, with continued isolation of monoclonal antibodies capable of neutralizing specific clinical effects of envenomation, such as myotoxic effects^[24] and thrombinlike activity,^[30] "libraries" of monoclonal antibodies may target and counteract predominant signs and symptoms of envenomation. Adjunctive immunotherapy with monoclonal antibodies and a broad-spectrum antivenin may provide the exquisite sensitivity against specific adverse reactions typically absent in standard antivenin.

After a slow start, advances in molecular biology are finally being applied to envenomation therapeutics. We can anticipate a multitude of novel immunotherapeutic modalities in the future.

Chapter 41 - Bites and Injuries Inflicted by Domestic Animals

Sean Keogh
Michael L. Callaham

Domestic animal bites are common, and their incidence is rising. ^[15] ^[120] ^[148] Wild animal attacks are often more spectacular, but in the developed world, injuries from domestic animals have a much greater health and economic impact. Humans are not a natural prey of any animal, and most attacks are caused by fear of humans (real or perceived), territoriality, protective instinct, or accident. Occasionally a bite may result from disease (e.g., rabies) or rogue behavior. Injuries range from minimal to fatal, are regularly contaminated with a wide array of pathogens, and may spread systemic disease.

EPIDEMIOLOGY OF BITES AND INJURIES

The 1998 National Pet Owner Survey estimated that more than 39 million households own at least one dog and that 32 million households own at least one cat.^[4] The great majority of bites (about 80% to 90%) are inflicted by dogs.^[92] Domestic cats account for about 5% to 15%, although some studies report a figure as high as 25%.^{[92] [133] [214]}

An estimated 1.8% of Americans are bitten by a dog every year, resulting in 4.5 million bite wounds. More than 750,000 of these bite victims seek medical attention.^{[118] [173]} From 15 to 30 bites per 10,000 population occur per year, based on patient visits to the emergency department (ED).^{[120] [199]} In a survey of 274 million ED visits in the United States between 1992 and 1994, more than 333,000 new dog bite injuries were seen, a rate of 12.9 per 10,000 persons. These injuries produced 0.4% of all ED visits in the United States. Bites to children were common, with boys aged 5 to 9 years having the highest incidence rate at 60.7 per 10,000 persons, which is 3.6% of all injury-related ED visits in this group.^[210] These figures represent only bite victims who sought medical attention; one analysis of dog bite incidence in Pittsburgh showed that 790 bites were reported but that an estimated 1388 were unreported, an annual incidence of 58.9 per 10,000 population.^[33] Urban areas have a higher reported rate of biting, and some studies suggest that dog bite incidence correlates inversely with socioeconomic status.^{[184] [199]}

The victim of a bite is often a pet owner or a member of the owner's family, and injury is frequently sustained while playing with the animal.^[38] Surveys of schoolchildren have shown that 55% of boys and almost 40% of girls have been bitten, with 17% requiring medical attention.^[12] Childhood bites can produce significant psychologic morbidity.^[179] In Thailand, where Buddhist cultural beliefs encourage feeding and protection of stray animals, most dog bites are inflicted by strays and are unprovoked.^[14]

The annual incidence of cat bites is about 400,000 in the United States,^{[5] [76] [92]} which is probably an underestimate. Biting cats are typically stray females, and most human victims are also female.

Human bites on other humans are more common in urban areas, with a reported incidence of 3.6% to 23% of all bites.^{[27] [29] [129]} One district in Brooklyn, New York, has reported a rate as high as 60.9 bites per 100,000 population.^[129] In contrast, human bites in rural communities are less common, with one study reporting that 0.03% of all bites are caused by humans.^[177] Children are frequently both the inflictors and the recipients of bite wounds. In a study of day-care centers, 46% of children were bitten by another child over a 1-year period.^[73]

About 30 million Americans ride horses, 50,000 of whom are treated for horse-related injury in an ED annually, principally because the rider is unrestrained and can fall off while travelling at speeds up to 40 mph. Horses can kick with a force of up to 1 ton^[115] and frequently bite. A 2-year review of animal bites in Oslo revealed that 2% of 1051 recorded bites were caused by horses; 53% of these horse bite victims were children.^[43]

The American Ferret Association estimates 6 to 8 million domesticated ferrets reside in the United States. The risk of attack by a ferret is greatest in infants and small children. Bite statistics are scarce, but in Arizona, 11 ferret bites were reported over 11 months, with the ferret population estimated at 4000, about a 0.3% reported bite to ferret population ratio. During the same period, 2265 dog bites occurred, with the dog population estimated at 100,000, for a bite ratio of 2.2%.^[180]

Certain occupations carry a greater risk for animal bite; U.S. letter carriers reported 2851 dog bites in 1995,^[35] and 64% of veterinarians have sustained a major animal-related injury in their careers.^[119] Incidence of biting species varies with exposure. Among veterinarians, most injuries are inflicted by cattle, followed by dogs and then horses.

Box 41-1. ADVICE TO AVOID BEING ATTACKED AND BITTEN BY COMMON PETS*

DOGS

Do not leave a young child alone with a dog.

Never approach or try to pet an unfamiliar dog, especially if it is tied up or confined.

Always ask owners if you can pet their dog.

Do not lean over a dog or pet it directly on the head; do not kiss a dog.

Avoid quick, sudden movements that may startle a dog.

Never pet or step over a sleeping dog.

Never try to take a bone or toy from a dog (other than your own).

Know the appearance of an angry dog: barking, growling, snarling with teeth showing, ears laid flat, legs stiff, tail up, and hair on back standing up.

Never step between two fighting dogs; if you need to separate them, use a bucket of water or a hose.

Do not approach a female dog that is nursing her pups.

Teach injury prevention advice to children from an early age.

CATS

Be aware that some cats do not like prolonged petting.

Know warning signs of an impending bite: twitching of the tail, restlessness, and "intention" bites (i.e., cat moves to bite but does not bite).

FERRETS

Do not sell or adopt a ferret that is known to bite.

Do not push your fingers through the wires of a ferret cage.

Reach for a ferret from the side, palm upward, rather than from above.

Do not sell or adopt a ferret that is known to bite.

Do not push your fingers through the wires of a ferret cage.

Reach for a ferret from the side, palm upward, rather than from above.

Do not handle food and then handle young ferrets without washing your hands first.

Do not poke a ferret or pull on its tail or ears.

Never leave a ferret alone with a child or infant.

If a ferret bites and locks on very tightly, pour cold and fast-running water over its face.

* Prevention of bites and injuries from other animals is addressed in the appropriate sections.

BITE AND INJURY AVOIDANCE

Domestic animals of any kind rarely attack unless provoked, although unrestrained dogs are exceptions.^[156] Physical attack is often a last resort, but an animal will often fight if it perceives that it is trapped. Reducing the risk of injury is often based on common sense and knowledge of animal behavior. For example, horses kick backward and with both rear feet, whereas cattle kick forward with only one foot. How humans react during a confrontation with an animal is also important. Nonpredator species such as cattle and deer are very susceptible to human intimidation, whereas a direct stare to a dog is seen as a challenge.

Specific recommendations can reduce the chance of being attacked and bitten by a domestic animal ([Box 41-1](#)). Dogs are guided by memory and instinct; fear and self-preservation are very strong instincts, so any perceived threat can lead to an attack. Territoriality is still ingrained in domestic dogs, even if humans provide for them. Protection of food can cause aggression, even in a docile dog. Any threat to a dog's mate, off-spring, or owner may result in an attack. Personality changes may lead to aggression; causes include illness (e.g., distemper) or physiological factors (e.g., female in heat).^[211] Specific actions can be taken when threatened or under attack by a dog ([Box 41-2](#)).

FIELD CARE

Local wound treatment should be initiated at the scene of the bite. This is often more important in determining the course of healing than any later therapy. When skin is unbroken, but tissue contusion is present, treatment should include prompt and liberal application of ice or other cold packs during the first 24 hours. In wounds producing a penetrating injury, pressure usually controls bleeding; the use of pressure point occlusion or proximal tourniquets should be avoided unless blood loss is extreme and cannot otherwise be controlled. If

963

the victim is more than an hour from treatment, the wounds should be cleansed promptly after resuscitation. Early cleansing reduces the chance of bacterial infection and is extremely effective in killing rabies and other viruses. Tap or drinking water is safe to use. Ordinary hand soap adds some bactericidal, virucidal, and cleansing properties; at least a pint of soapy water should be used. The wound should be thoroughly irrigated and then gently debrided of dirt and foreign objects by swabbing with a soft, clean cloth or sterile gauze. This is particularly important if the biting animal might be rabid, since simple irrigation without actual swabbing of the wound edges may not remove rabies virus. If possible, irrigation should be with a syringe under pressure.

**Box 41-2. SUGGESTED ACTION IF YOU
ARE UNDER THREAT OR ATTACKED
BY A DOG**

Stand totally still, and let the dog come to you.

Stand passively, rather than in an aggressive or submissive pose.

Do not pat the dog.

Keep your eye on the dog, but do not stare at it.

To reprimand the dog, say "no" in a harsh voice; do not attempt to hit the dog.

Do not make any threatening or provocative movement.

Do not fight back, especially against a "fighting" dog.

Do not let the dog get behind you; keep turning to face it.

If you are knocked down, feign death and curl up into a ball until the dog loses interest.

If the dog punches you with its nose, ignore it.

If a dog puts one of your legs in its mouth without tearing the flesh, waiting for a reaction, stay still if you can.

If attacked by more than one dog, try and stand with your back to a wall or car.

Modified from Wilson S: Bite busters: how to deal with dog attacks, New York, 1997, Simon & Schuster.

Box 41-3. HUMAN AND DOMESTIC ANIMAL BITE RISK FACTORS

HIGH RISK

Location

Hand, wrist, or foot

Scalp or face in infants (risk of cranial perforation)

Over a major joint (risk of perforation)

Through-and-through bite of cheek

Type of wound

Puncture (impossible to irrigate)

Tissue crushing that cannot be debrided (typical of herbivore)

Carnivore bite over vital structure (artery, nerve, joint)

Biting species

Human (hand wound)

Cat (hand and lower extremity wounds)

Pig

Patient factors

Older than 50 years of age

Asplenia

Chronic alcoholic

Altered immune status (chemotherapy, AIDS, immune defect)

Diabetes

Peripheral vascular insufficiency

Altered immune status (chemotherapy, AIDS, immune defect)

Diabetes

Peripheral vascular insufficiency

Chronic corticosteroid therapy

Prosthetic or diseased cardiac valve (consider systemic prophylaxis)

Prosthetic or seriously diseased joint (consider systemic prophylaxis)

LOW RISK

Face, scalp, ears, or mouth

Self-bite of buccal mucosa (not through-and-through)

Large clean lacerations that can be thoroughly cleansed

Partial-thickness lacerations and abrasions

After thorough cleansing, the wound should be covered with sterile dressings or a clean, dry cloth. Wounds of the hands or feet require immobilization. If the wound is high risk ([Box 41-3](#)), antibiotics should be started if available, preferably within an hour of wounding. In severe cases, antibiotics are worthwhile even if administered many hours later.

EVALUATION OF INJURIES

Many domestic animals are large, heavy and strong. All victims of animal attacks should be evaluated using advanced trauma life support (ATLS) guidelines, except for the most minor and isolated bite injuries. Severe blunt trauma and life threatening injuries may initially be less obvious than a bite wound. Even apparently minor wounds ultimately require meticulous exploration, because injuries that appear superficial may overlie fractures or lacerated tendons, vessels, and nerves, or may penetrate into joint spaces.^[69]

With large herbivores, most of the bite injury may consist of severe contusion without skin disruption.^{[130] [205]} Broken skin may result in local wound infection and the transmission of systemic disease. Infection can be caused by organisms carried in the animal's saliva or nasal secretions, by skin microbial flora carried into the wound, or by environmental organisms that enter the wound during or after the attack. Fortunately, most wounds do not become infected, particularly after adequate wound care. The need for tetanus prophylaxis should be assessed and rabies immunoglobulin and vaccine given if required.

Few tests are routinely indicated in the evaluation of most animal bite injuries. Radiographs are useful to exclude fractures, foreign bodies (e.g., teeth), air in the joint after a deep bite wound to the hand, and osteomyelitis in older bite wounds. Films should be taken after any fight-bite injury (e.g., clenched fist) and also after any cranial or facial bite in an infant or small child to exclude bony penetration of the skull or facial fracture.^[208] In the first few hours after a bite, white blood cell count or wound culture is not helpful.

DEFINITIVE WOUND CARE

The same principles of irrigation and cleansing used in the prehospital environment apply in the hospital.

964

Although tap water^[9] and normal saline are acceptable wound irrigants,^[6] 1% povidone iodine solution should also be used if rabies transmission is a possibility, as it is virucidal.^{[181] [187]} Although 1% benzalkonium has been shown experimentally to kill the rabies virus, no data support its use in humans.^[48] Besides gauze, a finely porous sponge may be used to cleanse the wound.^{[36] [51] [121]} Irrigation is best performed with a 19-gauge needle or plastic intravenous (IV) catheter on a 35-ml syringe.^[30] Puncture wounds tend to have a higher infection rate because irrigation is difficult, but it can be attempted if the wound is large enough to be held open. Irrigation does not remove dead or devitalized tissue common in bites, so thorough debridement may be required.

Fleisher^[69] advises that wounds should be treated and left open initially if they (1) are punctures rather than lacerations, (2) are not potentially disfiguring, and (3) involve the limbs, particularly the hand or foot. Delayed repair is advised if wounds are older than 6 to 12 hours (bites to the arms and legs) or 12 to 24 hours (facial bites). In contrast, many surgeons now advocate primary closure for dog bite wounds of the face, even when several days old.^[105] One study from Ghana, where a delay of several days before hospital presentation after injury is common, indicated that immediate closure of human bite injuries to the face is safe. In 90% of cases, wound healing was complete at suture removal, even though some of the wounds sutured were up to 4 days old.^[53]

Bites of the hand are common and at high risk for infections and impaired healing. Although dog bites to other areas of the body have wound infection rates of 5% to 10%,^[209] dog bite wounds of the hand have infection rates of up to 30%.^{[26] [30] [171]} Treatment of hand bites should be aggressive, with irrigation, debridement, and antibiotic prophylaxis. The wounds are usually left open, although some authors recommend closing nonpuncture hand wounds.^[209] If a dog bite wound to the hand or foot is closed primarily, the part should be immobilized in a bulky dressing and elevated. If infection is present, admission and antibiotics are indicated, with surgical drainage if required. If admission is not possible or practical, the wound should be rechecked daily until signs of infection are no longer present. If there is no evidence of infection, 5 days of splinting and oral antibiotics should be adequate.

WOUND INFECTIONS

Tetanus Prophylaxis

Clostridium tetani is an anaerobic gram-positive rod; its spores are found in the saliva and on teeth of animals and can survive in soil for years. Bite wounds often contain devitalized and crushed tissue, as well as puncture sites. These injuries are particularly suited to the release of the exotoxin *tetanospasmin*, which causes clinical tetanus. The number of cases of human tetanus after bite wounds is small but is double that of bite-related human rabies.^[194] Therefore a thorough immunization history is vital for appropriate immunoprophylaxis^[161] (see [Chapter 66](#)).

Risk Factors for Wound Infection

Risk factors for wound infection after a bite are summarized in [Box 41-3](#) .^[30] ^[49]

Indications for Cultures

Cultures of fresh bite wound surfaces have no value in the prediction of subsequent infection. Many of the pathogens causing infection take several days to grow and may be very fastidious or difficult to identify, particularly by routine diagnostic laboratory methods. The choice of empiric therapy for infected wounds can occasionally be guided by organisms identified on Gram's stain, but therapeutic decisions are usually made before culture results are known.

Once infection is established, wound culture is indicated if prophylaxis or empiric therapy has failed; if the patient has systemic illness with signs such as pyrexia, rigors, or hypotension (in this case, blood cultures are mandatory); or if the wound or patient is at high risk. Cultures should be both aerobic and anaerobic. Gram's stain of pus may be helpful in determining predominant pathogens. The laboratory must be informed that prolonged cultures of up to 14 days may be necessary, depending on the organism sought. Using specific media for fastidious organisms, such as *Brucella*-supplemented agar to culture *Porphyromonas*, may also increase the isolation rate.^[76] This is also important if *Pasteurella* or *Capnocytophaga canimorsus* infection is suspected. Isolates of coliforms should not be dismissed as contaminants and must be identified with antibiotic sensitivities. Reference laboratories, such as those of state health departments or at the Centers for Disease Control and Prevention (CDC) in Atlanta, are more likely to isolate unusual pathogens from bite wound cultures than are local laboratories.^[198]

Prophylactic Antibiotics

Surgical wound care rather than antibiotic treatment is the most important factor in decreasing wound infection,^[136] but whether to administer "prophylactic" antibiotics after bite wounds remains controversial. Some authors still recommend antibiotic prophylaxis for all dog bites.^{[134] [164] [172]} Prospective, blinded clinical trials of dog bite wounds suggest that although persons treated with antibiotics may have lower infection rates, this is not statistically significant.^[28] Such results have been extrapolated to the bite wounds of other animals. Unfortunately, many trials lacked standardization of wound care, antibiotic choice and dose, and evidence of compliance.

965

In 1994, Cummings^[42] performed a meta-analysis of eight randomized trials to determine whether prophylactic oral antibiotics prevent infection in persons with dog bite wounds. The relative risk for infection in persons given antibiotics was 0.56. This means that 14 persons need to be treated to prevent one infection. This conclusion is skewed, however, because one study had an atypically high infection rate of 60%. If this study is excluded, the benefit of prophylaxis in low-risk wounds is even less convincing. Antibiotic therapy is not cost-effective in low-risk dog bites and should be reserved for wounds at high risk for infection.^{[28] [50]} (see [Box 41-3](#)). A small controlled trial of antibiotic prophylaxis in cat bites showed a decrease in wound infection in persons given prophylaxis.^[60] Deep cat bites are prone to infection and mandate prophylaxis, whereas superficial injuries in low-risk areas do not require it.

The bite victim needing prophylactic antibiotic treatment should be identified early in a wilderness setting or during triage on entry to the ED. After a few hours, bacteria bind to proteins and become encapsulated in a blood and fibrin coagulum that protects them to some extent from antibiotics.^{[59] [207]} If infection risk is very high, parenteral antibiotics may be warranted,^[207] but in most cases a 3- to 5-day oral regimen is sufficient.

Previous recommendations for choice of antibiotic often assumed that *Pasteurella*, although common in cat bites, was a rare isolate in wounds resulting from dog bites. Recent work by Talan et al^[198] suggests that this may not be true. Although 42% of dog bite wounds harbored *Pasteurella stomatis*, *P. canis*, and *P. dagmatis*,^[71] 12% of wounds grew the more virulent *P. multocida*.^[198] When infection presents less than 8 hours after injury, *Pasteurella* is probably the infecting organism. Empiric therapy for dog and cat bites should cover at least *Pasteurella*, *Streptococcus*, *Staphylococcus*, and anaerobes (see [Box 41-5](#)). *Pasteurella* isolates appear susceptible to amoxicillin-clavulanate, ampicillin, penicillin, second- and third-generation cephalosporins, doxycycline, trimethoprim/sulfamethoxazole, fluoroquinolones, azithromycin, and clarithromycin, although the latter two are somewhat less effective.^[75]
^{[76] [77] [78] [80] [82] [83] [84] [85]} Common antibiotics often used for soft tissue wound infections, such as antistaphylococcal penicillins and first-generation cephalosporins, are less active in vitro against *Pasteurella*. Erythromycin, often chosen for the penicillin-allergic

patient, is a poor choice for *Pasteurella*; serious clinical failures are well documented.^[81]
^[123] *Pasteurella* is resistant to clindamycin.^[75]

Amoxicillin-clavulanate is recommended as a first-line agent for cat, dog, human, and most other bite wounds. It is β -lactamase stable and therefore covers all *Bacteroides*, *Staphylococcus*, and *Streptococcus* species as well as most gram-negative bacteria. It shows activity against all 173 aerobic and anaerobic isolates tested from one series of animal bites.^[78] Other options are a second-generation cephalosporin with anaerobic activity (e.g., cefoxitin) or combination therapy with either a penicillin and a first-generation cephalosporin, or clindamycin and a fluoroquinolone (e.g., ciprofloxacin).^[198] Azithromycin, which is superior to clarithromycin for treating *Pasteurella*, and the new ketolide antibiotics, such as HMR 3004,^[76] ^[85] show in vitro promise, although this may not translate into in vivo success.

For the penicillin-allergic nonpregnant woman, clindamycin and ciprofloxacin are effective in high-risk wounds. For a pregnant woman whose only history of penicillin allergy is a rash, cefoxitin can be given because the chance of cross-sensitivity is low. In the penicillin-allergic pregnant woman the choice is a more difficult. Because neither azithromycin nor clarithromycin is approved for use in pregnancy, erythromycin may need to be prescribed. Because of its limited effectiveness against *Pasteurella*, careful observation of the patient is warranted. Tetracyclines should not be prescribed in pregnancy; ciprofloxacin and tetracycline should not be prescribed for young children ([Table 41-1](#) and [Table 41-2](#)).

Follow-Up and Indications for Admission

Follow-up of animal bites depends on risk factors (see [Box 41-3](#)) and the victim's response to treatment. With a superficial abrasion, infection is unlikely, so a return visit is usually not needed. With a typical, low-risk bite wound, one follow-up visit (in 2 days, to assess any infection) is sufficient. If the patient is well and no sutures have been placed, this visit may not be necessary.

Infected wounds need close follow-up. In a wound that is at high risk for infection, the initial follow-up should be the next day. If an infected wound fails to respond to 5 days of initial antibiotic treatment, a wound culture is usually advised, although switching to a broader spectrum antibiotic may be considered.

Rarely, the victim requires hospitalization ([Box 41-4](#)). Response to initial or secondary therapy (particularly in a high-risk patient), age, general health, previous medical history, and social circumstance can influence this decision.

**Box 41-4. INDICATIONS FOR
CONSIDERATION OF HOSPITAL
ADMISSION**

Hand bite

Involvement of bone, joint, or tendon

Deep space infection or tenosynovitis

Septicemia from animal bite

Severe wound infection causing systemic toxicity in immunocompetent patient

Cellulitis or local infection in severely immunocompromised patient (diabetes, AIDS, chronic alcoholism, asplenia)*

Cranial injury in an infant

Major trauma inflicted by a large animal

*Possible indication, depending on patient circumstances.

TABLE 41-1 -- Antibiotic Sensitivities of Common Wound Is

ANTIBIOTIC	<i>Pasteurella</i> spp.	BACTEROIDES SP.		<i>Fusobacterium</i>	<i>Eikenella</i>
		ANIMAL ORIGIN	HUMAN ORIGIN		
Penicillin or ampicillin	+++	+++	+	+++	++
Amoxicillin plus clavulanate	+++	+++	+++	+++	++

+++, Very sensitive; ++, moderately sensitive; +, some sensitivity; ±, predominantly insensitive; -, insensitive

*Tetracycline should not be prescribed for pregnant women. Ciprofloxacin and tetracycline should not be prescribed for young children.

†*Bacteroides fragilis* may be resistant to cefoxitin.

TABLE 41-2 -- Suggested Initial Antibiotic Prophylaxis for Domestic Animal and Human Bites

PROPHYLAXIS	ADULT	CHILD
Standard	Amoxicillin-clavulanate	Amoxicillin-clavulanate
If penicillin allergic	Clindamycin plus ciprofloxacin	Azithromycin
		Tetracycline if child is older
	Azithromycin	
	Tetracycline	
If pregnant	Amoxicillin-clavulanate	—
If pregnant and rash only with penicillin	Cefoxitin*	—
If pregnant and penicillin allergic	Erythromycin†	—

In the case of pig bite, ciprofloxacin, when not contraindicated, should be added to amoxicillin-clavulanate.

*Chance of cross-sensitivity with penicillin is low.

†Erythromycin has poor activity against *Pasteurella* species, so close clinical observation is necessary.

Treatment

If inoculated in sufficiently large numbers, aerobic and anaerobic bacteria can cause localized cellulitis and abscess formation, which are the most common forms of infection. Wound infection may progress to sepsis.

Treatment of wound infection from animal bites is the same as that for other traumatic wounds: elevation and immobilization of the affected part, removal of sutures or staples, and antibiotic therapy. Empiric initial antibiotic therapy is the same as that for prophylaxis (see [Table 41-2](#)), except with severe cellulitis or sepsis (see later discussion).

Transmission of Systemic Infection

Approximately 150 systemic diseases of mammals can be transmitted in some manner to humans, but relatively few are transmitted through a bite or scratch. These include rabies, cat scratch, cowpox, tularemia, leptospirosis, infection with *Sporothrix schenckii*, and brucellosis. House cats are an increasing source of human

plague in the U.S. Southwest. Since the onset of the human immunodeficiency virus (HIV) epidemic, *Rochalimaea* infection (bacillary angiomatosis) has also become more prominent and is closely associated with exposure to cats.

Sepsis Secondary to Bite Wounds

Although theoretic risks with any animal bite pathogen, bacteremia and sepsis have been reported with only a limited number of organisms. *Capnocytophaga canimorsus*, formerly CDC alphanumeric strain DF-2, is a fastidious, slender, tapering, and gram-negative rod. This facultative aerobe grows poorly in most standard media, making identification difficult. Growth of *C. canimorsus* from blood often takes a week, making Gram's stain of the blood buffy coat taken on admission a useful diagnostic test.^[117] Most infections occur after dog bites. Some cases have occurred after nonbite exposure to dogs or no animal exposure.^[6] About 80% of persons who become seriously ill with this infection are immunocompromised, particularly because of splenectomy, hematologic malignancy, or cirrhosis. A minor bite in a previously healthy person can also result in catastrophic infection.⁴

Clinical manifestations include cellulitis, endocarditis, meningitis, pneumonitis, Waterhouse-Friderichsen syndrome, renal failure, shock, and death. Purpuric lesions are seen in one third of cases and may progress to symmetric peripheral gangrene and amputation. Malar purpura is characteristic. In some cases, cutaneous gangrene

develops at the bite site, a finding classic to this species of bacteria.

When the diagnosis is known, optimal treatment is with penicillin or a cephalosporin. *C. canimorsus* is susceptible to cefuroxime, ampicillin, erythromycin, and vancomycin. Ciprofloxacin has been used with success.^[140] Unlike most gram-negative bacilli, *C. canimorsus* is resistant to aminoglycosides, often used in empiric treatment of sepsis. If *C. canimorsus* infection is suspected, the laboratory should be alerted, and additional blood cultures should be sent to reference laboratories (e.g., the CDC) for identification.

Pasteurella multocida can also produce bacteremia.^[143] Usually the source is a cat bite, but dog bites also contribute. Most persons who develop bacteremia, as with those dying of *Capnocytophaga* infection, have cirrhosis, HIV infection, malignancy, or other immunosuppression. The mortality rate can be as high as 36%. Some victims may have been healthy, and even a seemingly trivial bite may produce life-threatening sepsis.^[109]

Several options exist for empiric IV antibiotic therapy in severe cellulitis and sepsis ([Box 41-5](#)). Clindamycin plus ciprofloxacin is an appropriate combination; clindamycin inhibits toxin production in streptococcal infection and covers *Staphylococcus aureus* and anaerobes, and ciprofloxacin has good gram-negative coverage, including *Pasteurella* and *C. canimorsus*. Both drugs can also be given orally, either in the field or as continuation therapy on discharge from hospital.

Imipenem-cilastatin

*May be given orally in the field or on discharge from hospital.

DOG BITES

Dogs are the only species whose bites have been well studied in large numbers. Most factors contributing to dog bites are related to the owner's level of responsibility.^[174]

Although domesticated for at least 12,000 years, dogs retain many of their wild instincts, such as territoriality in a guard dog. Although many people keep dogs to repel burglars, a burglar is a fatal dog attack victim in only 1 of 177 attacks. A fatal dog attack victim is a child in 7 of 10 cases.^[35]

Besides the physical and emotional trauma of a dog attack, the financial impact is huge. Recent estimates put the total annual U.S. national cost of ED services for new dog bite-related injuries at more than \$102 million.^[210] When combined with charges for physician services and subsequent postdischarge care, direct medical care charges for dog bites rise to an estimated \$165 million.^[165]

Dogs under 1 year of age are responsible for the highest incidence of bites.^[215] The incidence of biting increases substantially during the warm summer months. Most bites occur between 1 and 9 PM, probably because more people are on the street.^[95] Many bites are inflicted on children coming home from school or playing outdoors. The increased susceptibility of children results from their smaller size, relative inability to defend themselves, interest in animals, and unintentional abuse of animals. Biting dogs (not necessarily those causing fatal wounds) are more likely to be certain breeds, particularly German shepherd, pit bull, and chow chow in the United States.^{[9] [74] [90]} In a United Kingdom survey of patients receiving plastic surgery for bite wounds, the most common

*References: ^[49] ^[96] ^[100] ^[134] ^[147] ^[170] ^[172] .

biting dogs were Staffordshire bull terriers, followed by Jack Russell terriers, medium-sized mongrels, and German shepherds.^[182]

Pit bulls have become popular in recent years and are often bred for aggressive behavior. Fatal attacks from pit bulls have increased dramatically.^[175] Many towns and counties are passing legislation limiting or outlawing ownership of pit bulls, and owners may be charged with manslaughter after fatalities.^[39]

Wound Pathophysiology

Although most wounds are minor, the jaws of adult dogs can bite with a force of up to 450 pounds per square inch, enough to puncture light sheet metal.^[72] Wounds may comprise a mixture of biting, clawing, and crushing forces. These give a characteristic pattern of lacerations and punctures and may result in avulsion of soft tissues. A dog's bite can break human long bones.^[46] ^[48] Treatment may naturally focus on the crushing component of the wound, but the penetrating component may cause the most morbidity.^[200] The dog may move and shake its head during the attack, further tearing tissue.^[114] Some owners replace their dogs' natural teeth with metal ones to increase their wounding capabilities. Snorting, grunting, or wound manipulation by the biting animal may force air into the tissues.^[72] Besides infective organisms, foreign debris and even teeth may be deposited. In a severe attack the dog may eat tissue and blood or scavenge on an unconscious or intoxicated victim. ^[91] ^[160]

Wound Location

Hand, arm, and lower extremity bites are reported most often in the adult population, with children primarily receiving head and neck wounds.^[49] Injuries are typically centered around the nose, lips, and cheeks, and a bite can fracture the victim's maxilla.^[70] In one large study the leading sites for wounds in victims of all ages were the face, neck, and head (29%), followed by the upper and then lower limbs.^[210] In children up to age 9 years, 73% of injuries were to the face, neck, and head. ^[210] In Germany, 8500 dog bite injuries to the face are reported each year, and more than 50% of victims are infants or children. ^[178]

Microbiology of Dog and Cat Wounds

A comprehensive study that evaluated 50 patients with dog bites and 57 patients with cat bites identified a median of five bacterial isolates per culture ([Box 41-6](#)).^[198] *Pasteurella* species were the most common pathogens in bites of both dogs (50%) and cats (75%), in contrast to many previous studies, where *Pasteurella* was rarely isolated from dog bite wounds.^[28] The association of *Pasteurella* with infections of rapid onset was confirmed. In other studies, *Pasteurella multocida* subspecies *multocida* and *septica* were the most common isolates in cat bite wounds and *P. canis* in dog bites.^[16] ^[62] ^[98] *Streptococcus*, *Staphylococcus*, *Moraxella*, *Corynebacterium*, and *Neisseria* were the next most frequent aerobic isolates. *Eikenella corrodens*, usually associated with human bite infections, was found in only one cat and one dog bite wound.^[198] *Capnocytophaga* species and *Weeksella zoohelcum*, both of which can cause invasive sepsis, were uncommon in this study and may be opportunistic pathogens. *Fusobacterium*, *Bacteroides*, *Porphyromonas*, and *Prevotella* were common anaerobic isolates.

Wound Infection in Dog Bites

Typical nonbite lacerations in an adult ED population have an infection rate of 5% to

15%.^[51] ^[89] The rate is lower in the pediatric population.^[10] This rate is similar to that of typical outpatient-treated dog bite wounds, when managed properly with irrigation and debridement. Dog bites of the head and neck, all sutured and none treated with antibiotics, have an infection rate as low as 1.4%.^[93] Bites of the face and ears, although often requiring extensive plastic surgery, also heal well when treated aggressively and with antibiotics, as do dog bites of the genitalia.^[54] ^[195] ^[213] Therefore, dog bite wounds that are not high risk are probably no more infection prone than nonbite, accidental cutaneous lacerations.

Antibiotic therapy for infected dog bite wounds is initially the same as for prophylaxis, unless prophylaxis failed (see [Table 41-2](#)).

Law Enforcement Dog Bite Wounds

Law enforcement dogs are usually trained to bite and hold onto a victim until commanded to release. This is not the normal pattern for an attacking dog. The bite-and-hold technique results in deep puncture wounds, severe crush injuries, and large tissue avulsions. Attention should focus on the greater risk for deep nerve, vessel, and musculoskeletal injury.^[158] Over 3 years in 486 patients evaluated on a jail ward for police dog bites, 7.2% required angiography of an extremity, and 21% of these had arterial injury.^[188] A change in policy, from a bite-and-hold to a find-and-bark technique has been evaluated in Los Angeles. This resulted in a decrease in bites, injuries, and complications and a reduction in hospital admissions from 52% to 33.8% after police dog bite injuries.^[102]

Fatal Attacks by Dogs

A dog bite-related fatality can be defined as death caused by acute trauma from a dog attack, often from an exsanguinating neck wound.^[72] Fatal attacks by dogs in the United States cause many more deaths than rabies. A vicious attack cannot be predicted from a dog's prior behavior, since most offending dogs revert to normal, friendly behavior after the episode. A review between

1979 and 1988 identified 157 fatalities, a rate of 6.7 deaths per 100 million population per year. Seventy percent of these were in children younger than 10 years.^[175] For infants less than 1 year the annual death rate was 68 per 100 million, with half occurring while the infant was sleeping in a crib. Only a minority of fatal attacks were caused by stray dogs. Most victims died at the scene of the attack. Fatal attacks from pit bulls increased from 20% to 62%. German shepherds, huskies, malamutes, and wolf hybrids were the next most common fatal attackers. A review of fatal dog attacks in the US from 1989 to 1994 revealed 109 episodes.^[174] Fifty-seven percent of the victims were children under 10 years. The rate of death for neonates was twice that for adults. Most attacks involved an unrestrained dog on the owner's property. Pit bulls were involved in 24 deaths, rottweilers in 16, and German shepherds in 10.

Data from Talan DA et al: *N Engl J Med* 340:85, 1999.

In the most recent American review on dog bite fatalities, covering 1995 to 1996, dogs killed at least 25 people, although this is probably a marked underestimate because of death certificate unavailability.^[32] Eighty percent of these deaths involved children,

continuing a worrisome trend. Three were neonates less than 30 days old. The rottweiler was the most common breed involved. Sixty-four percent involved more than one dog. Pack behavior increases the likelihood that social facilitation and pack instinct will prolong the attack.^[18] A report from southern Ireland notes that many dogs are very timid when alone, but when exposed to a pack environment, their behavior deteriorates dramatically. Of the seven pack attacks in the Irish report, five

were by greyhounds.^[114] Packs of aggressive dogs should be avoided and aggressive pack behavior toward humans punished by the owner.^[18]

Dogs represent a significant potential cause of death for infants and small children. A dog may accept an immobile baby but may have an unpredictable predatory response when the child starts crawling. Severe dog attacks on children occur most frequently in those under 5 years old.^[21] Children and severely disabled persons should never be left alone with a dog, regardless of its reputation and prior behavior. Certain breeds (e.g., pit bulls) account for a disproportionate number of cases and should be considered for more effective supervision and controls.

Prevention of Dog Bites

Risk factors for increased biting propensity include male gender and unneutered status. Many dogs that seriously wound or kill humans have long histories of aggressive behavior. Strategies that reduce biting risk include education of owners and the public, selection of dogs, training, care, and socialization.^[74] Other strategies, such as the compulsory trimming of canine teeth of sled dogs in Greenland, are also useful.^[88]

Laws regarding dangerous dogs should be enforced, although these are not a panacea. In 1991 the Dangerous Dogs Act was quickly enacted in the United Kingdom in response to violent attacks by American pit bull terriers and specified tight restrictions. Any offense meant the dog was euthanized and the owner prosecuted. Unfortunately, difficulties in clearly identifying pit bull terriers in the absence of clear breed standards led to confusion, and the act has received much criticism.^[52] It has not yet been shown to decrease injuries by so-called dangerous breeds.^[113]

Animal control programs should be introduced and supported. Animal control associations, veterinary societies, and the Humane Society offer such courses.^[215] Training in bite avoidance and canine behavior is recommended; for example a dog wagging its tail still may attack. This training should be offered to persons at greatest risk, such as animal control officers and postal workers; children might also benefit.^[184] Dog bites should be reported as required by local or state ordinances.

DOMESTIC CAT BITES

Domestic cats are becoming an increasing problem in the United States as the population of strays has exploded, with some estimates at 90 million.^[192] This is important because of the opportunity for exposure to wild vectors of rabies. Cats now account for 50% of animal control calls, which has led to proposals for leash and licensing laws for cats. Little information for cat bites by breed is available.

Women, particularly those aged 30 to 40 years, are more likely than men to be bitten by a cat, and 63% of bites are on a hand or finger, usually the right (dominant) hand.^[133]^[198]^[214] Twenty-three percent of wounds are to the shoulder, arm, or forearm.^[198] Seventy percent of wounds are scratches, and 27% are punctures of the skin.^[214]

Cats have a weaker biting force than dogs, but possess sharp, slender teeth, often producing deep puncture wounds.^[48] Cat bites are notorious for their high infection rate, with 15% to 80% becoming infected.^[47]^[198] Cat bites result in a higher incidence of osteomyelitis and septic arthritis than dog bites.^[75] Cat bites frequently possess two risk factors for infection: location on the hand and increased depth of puncture. Other risk factors associated with wound infections include an older victim, longer delay until ED treatment, wound inflicted by a pet rather than a stray, wound care at home, and a more severe wound.^[47] Wound infections are more likely to develop in patients with lower extremity wounds who did not receive prophylactic oral antibiotics and in those with puncture wounds without benefit of prophylactic oral antibiotics. Scratches very seldom become infected.^[47]

Because the hand and lower extremities are common sites of injury and wounds are deep and penetrating, most cat bites are considered high risk. Such wounds should prompt administration of prophylactic antibiotics (see [Table 41-2](#)). Superficial cat bites and scratches elsewhere on the body are not high risk and should receive standard wound care without antibiotic coverage. Bacteria from cat bites and scratches can seed in distant arthritic and prosthetic joints and cause *Pasteurella* septic arthritis, endocarditis, and even mycotic thoracic aortic aneurysm^[7]^[86]^[99] (see [Table 41-2](#) and [Box 41-6](#)).

HUMAN BITES

Human bites are common, particularly in urban areas. They were previously thought to be associated with a higher incidence of infection than other animal bites, but this may not be true. A study of 434 human bites found an infection rate of only 17.7% compared with 13.4% in 803 lacerations in the same patient group.^[125] Others have cited a 10% infection rate for human bite wounds.^[24] The important high-risk exception is human bites to the hand, especially if treatment is delayed. Unfortunately, bites of the hand often present several days after injury.

Most human bites occur during fights. A wound sustained when human teeth actually bite a part of the human anatomy is termed an *occlusional bite*; in forensic cases this is most common on the hands and arms of men and the breasts and genitalia of women.^[75]^[92] Bites may occasionally be self-inflicted as a result of psychiatric or organic illness.^[166]^[201]

971

Human bite wounds in developing countries pose special problems. Presentation may be significantly delayed,^[127]^[135]^[145] and victims may have advanced infections. Many bites are inflicted by women on other women, and many are bites of the face, particularly the lip.^[34]^[53]^[145] These wounds are intended to be disfiguring and can carry significant social stigma, further delaying treatment. Initial treatment in developing countries may be inappropriate, such as treating fresh bites with very hot water.^[127] In the Micronesian Islands the tip of the nose may be bitten off adulterous wives to provoke shame.^[20]^[124] This form of punishment was known under ancient Roman law and Indian custom, and the art of nasal reconstruction originated in India as early as 1000 BC.^[151] Traumatic love bites to the neck are well documented, as are bites to the face, breasts and penis during sexual activity.^[65]^[212]

Microbiology

At least 42 different species of bacteria have been identified in human saliva,^[128] and 190 species have been found when gingivitis or periodontitis is present ([Box 41-7](#)).^[137]^[138] Anaerobes include *Bacteroides fragilis*, *Prevotella*, *Porphyromonas*, *Peptostreptococcus*, *Fusobacterium*, *Veillonella*, and *Clostridium* species. Anaerobes are found in more than 50% of human bite wounds^[75] and frequently produce β -lactamase, unlike those from animal bites. Studies show that 41% to 45% of *B. fragilis* infections from human bite wounds are resistant to penicillin.^[22]^[81] Common pathogenic

aerobes include β -hemolytic streptococci, *Staphylococcus aureus*, and *Haemophilus* species.^[75] ^[92] *Eikenella corrodens*, a fastidious, slow-growing, and gram-negative anaerobic rod, is found on 8.2% of human tooth scrapings and in 0.6% of salivary samples.^[167] *E. corrodens* is frequently implicated in fight-bite injury infections and has been found in 10% to 29% of human bite wounds^[92] (see [Table 41-2](#)).

Human Bites and Systemic Disease

Transmission of actinomycosis has been reported after a human bite,^[139] as has syphilis, herpes, hepatitis C, hepatitis B, and tuberculosis.^{[45] [66] [67] [68] [110] [193]} Tetanus from a human bite has been documented.^{[1] [144]} Herpetic whitlow (infection of the distal phalanx) from herpes simplex virus is a well-known occupational hazard of nurses, physicians, dentists, and oral hygienists.^[107] Toxic shock has been reported after a clenched-fist injury.^[126]

Human bites had not been thought to pose a significant risk of HIV.^[169] HIV is usually not present in the saliva of infected patients, and when present, the titer of virus is very low. Recent data suggest that a slight risk does exist, however, and a human bite is thought to have been the mode of HIV transmission in at least two cases.

972

In one report from Slovenia, a man was bitten while trying to control the airway of a person with acquired immunodeficiency syndrome (AIDS) who had bitten his own tongue during a seizure.^[206] The second occurred after a lip bite in a male from a female prostitute.^[112]

When bitten by a person who is infected with or at high risk for HIV, the victim should receive unusually vigorous and thorough wound irrigation with a virucidal agent such as 1% povidone-iodine. A baseline HIV blood test and follow-up test in 6 months should be considered.

Human Bites of the Hand

The two forms of bite injury to the hand are the simple, direct occlusional bite to a finger and the fight-bite, or clenched-fist, injury. Osteomyelitis may occur after either injury.^{[87] [204]}

The fight-bite injury is more common and at higher risk for infection. Presentation is frequently delayed.^[204] From 60% to 80% of fight-bite injuries occur in males, most in the dominant fist after striking an opponent's tooth.^[135] In this position the extensor tendon and its underlying bursa are pulled distally over the metacarpophalangeal (MCP) joint. The result is a deep laceration that can disrupt superficial and deep fasciae, the

extensor tendon and its bursa, and the joint capsule. When the fingers are extended, the skin and tendon retract proximally, sealing off the contaminated wound.

Any penetrating injury in the vicinity of the MCP joint should be considered a human fight-bite wound until proved otherwise. Radiographs should be requested, and up to 70% of patients may have positive findings^[56] ([Figure 41-1](#)). Films should be obtained in a

Figure 41-1 Intraarticular fracture of the third metacarpal resulting from a human fight-bite injury.

lateral or steep oblique attitude, since this is the best view for initial soft tissue swelling.^[168] The ideal view is the skyline view of the metacarpal head, taken with the x-ray beam in the same plane as the proximal phalanx, with the MCP joint fully flexed.^[64]

Treatment of clenched-fist injuries should be rapid and aggressive. Significant injuries should be explored and debrided, preferably in the operating room.^[11]^[204] In the wilderness setting the wounds should be thoroughly irrigated and not sutured. These wounds are at high risk for infection, and antibiotics should be prescribed as soon as possible. Oral antibiotic therapy should result in a very low infection rate.^[216] Although evidence is contradictory, few indications exist for primary repair of any type of hand bite. The affected extremity should be immobilized and elevated.

A person with established infection is usually hospitalized and treated with IV antibiotics, although closely supervised outpatient oral therapy is an alternative in the compliant patient after wound cleansing and debridement.^[56]^[191] An appropriate initial antibiotic choice for both prophylaxis and treatment of a clenched-fist injury is amoxicillin-clavulanate.

Human Bites to the Face and Cheek

Facial wounds are at low risk for infection, and a large series of sutured facial human bites treated in a plastic surgery clinic had an infection rate of only 2.5%.^[57] Treatment includes aggressive debridement, irrigation, and suturing. Cosmetic considerations are important. Antibiotics are indicated for the same risk factors as in animal bites (see [Box 41-3](#)).

Self-inflicted bite wounds of the oral or buccal mucosa have not been well studied. Accidental bites of the mouth and lips have low infection rates, possibly because of

protective effects from saliva and resistance of mucosal tissues to the victim's own flora. However, a case of *Haemophilus aphrophilus* vertebral osteomyelitis secondary to an accidental lip laceration was reported in a healthy 36-year-old male despite prophylactic antibiotics.^[97]

The literature suggests that oral-cutaneous (through-and-through) wounds are high risk and may benefit from penicillin prophylaxis.^{[3] [155] [190]} Lacerations that involve only the buccal mucosa, particularly those that do not need suturing, do not require prophylaxis.

Human Bite Forensics

Bite mark evidence has become accepted as a powerful tool in the investigation of crime.^[202] Human bite marks are found most often in cases of murder, rape, child abuse, or altercation.^[106] The examining physician should document the appearance of the bite carefully, including its shape, color, and size. Determining the age of the bite can be difficult but is often a critical legal issue. The healing dynamics of these bite wounds is

973

poorly understood,^[44] and accurate description is better than unsupported speculation. The physician must determine if a criminal act may have occurred; if so, the wound should be photographed. Salivary deoxyribonucleic acid (DNA) can be recovered from bite marks on human skin.^[197] Physical comparison of a suspect's teeth to a bite mark injury using hollow-volume comparison overlays is a common forensic odontology technique.^[196] Since most physicians are not familiar with these procedures, consultation with a forensic pathologist or dentist is recommended and may be arranged through the local law enforcement agency.

FERRET BITES

Egyptians kept ferrets long before the cat.^[154] The two species of ferret in the United States are the common ferret *Mustela putorius furo*, sold as a domestic pet, and the wild black-footed ferret *Mustela nigripes*, which is an endangered species. The pet ferret was domesticated from the wild European polecat and was first introduced into the United States in about 1875.^[131] Ferrets are kept in increasing numbers as domestic pets, especially by urban apartment dwellers.

Because of its speed, an attacking ferret can easily run over the shoulders and head of an adult human and inflict multiple bites without stopping.^[40] Ferrets were bred to hunt and kill small game and rodents in their burrows and are particularly attracted to suckling animals, possibly because of the scent of milk. Along with a mouth containing 34 teeth, sharp claws are found on all four feet.^[8] Severe injuries caused by ferrets are not common. When they occur, an infant is often the victim and typically is sleeping or in a crib. The face, ears, and nose may be mutilated.^[154] Scratches, lacerations, and puncture wounds are seen, and the ferret may chew on a victim (e.g., a baby's ear). The neck is also a common target.

In a comprehensive review of 452 ferret attacks over 10 years, virtually all the unprovoked attacks were on the faces of unattended infants.^[40] Most victims were less than 3 years of age and were attacked while sleeping or lying down. Several injuries were severe, and one child died. Bites were usually multiple, and sometimes the ferret's jaws had to be pried open or the ferret had to be killed to secure release.^[154]

Ferrets are unusually adept at escaping from cages and enclosures, guaranteeing that they will occasionally be loose unsupervised in the house and also that they can escape to the wild, where they will be exposed to endemic rabies. In one study, 4% of biting ferrets were positive for rabies virus.^[40] At the University of Georgia, 50 ferrets were inoculated with rabies virus; no animal with virus in the central nervous system showed any evidence of viral shedding in saliva, and only one had rabies in their salivary glands.^[55] Ferrets are now classified in the same category as cats and dogs regarding rabies pathogenesis and viral shedding patterns, rather than as wild terrestrial carnivores. They may be confined and observed for 10 days rather than being routinely euthanized after biting.^[103] An effective rabies vaccine for ferrets (IMRAB-3) has been available since 1990.

Little is known of infection rates or bacteriology in ferret-inflicted wounds although unusual species such as *Mycobacterium bovis* have been observed.^[108] Initial treatment should be as for dog bites.

BITES AND INJURIES FROM DOMESTIC HERBIVORES

Horses and Donkeys

The horse is inclined to both bite and kick, but most horse-related injuries follow a fall during riding activities. More accidents occur per hour horse riding than motorcycling.^[37] Young females are most often injured by falls,^[23] and head injuries cause the majority of deaths.^[94] When a half-ton horse lands on top of a rider after a fall, pelvic ring injuries and knee ligament injuries are a particular risk.^[58] Appropriate helmets and footwear help to reduce the severity of injury.^[37]

Horse bites are common but not severe injuries. The occlusal surfaces of both lower and upper incisors are flattened. Most male horses possess canines, however, that may be used to grab onto a mare's neck during mounting. A penetrating wound to the chest after a horse bite in a child has been described.^[104] The soft tissue contusions inflicted by a horse can be severe, but in a series of 24 horse bites, 21 healed uneventfully.^[58] Bites can produce significant injury, including muscle rupture and fat necrosis, with no external wound. Ultrasound may be useful in the diagnosis of such injuries.^[205] Horses also have a propensity for biting human nipples, which are at the same height as a horse's mouth.

Horse kicks from the rear legs can be extremely powerful, causing severe blunt trauma, including cardiac rupture.^[19] Kicks have also resulted in massive pulmonary embolism.^[159]

Donkeys also bite. One rural worker was bitten twice the same year by the same donkey. The bites were on different forearms, and both resulted in multiple fractures.^[189] Death has been reported from fat embolism caused by fractures after a donkey bite.^[17]

Cattle and Sheep

Cattle and sheep are usually docile but can inflict a variety of injuries. Serious bites are infrequent, since these animals possess neither upper incisors nor canines. A cow typically weighs 1400 pounds, and a bull can exceed 3000 pounds. Accidental treading on the human victim or butting can cause major crush injuries and fractures. Rams have killed farmers by repeated blunt

trauma.^[146] Farm animals in Wisconsin kill about six people a year.^[25] One hospital in rural Wisconsin treated an average of 22 persons a year for horse and cattle injuries, most of them inflicted by a kick or other assault. Domestic cattle and horses are fairly frequently infected with rabies, but because veterinary workers are immunized against the virus, these animals seldom account for human infection.

Cattle horn injuries (or gorings) present typical and unique damage patterns. The horns are used in an inward hooking motion to butt and fling the victim, or the horn tip can be used for goring. Goring injuries seen in bullfighting typically involve the perineum and thigh; they tend to be deep and sometimes fatal. Scrotal skin avulsion is common in bullfight gorings.^[183] By contrast, bull horn injuries from domestic cattle involve a sweeping arc at the level of the bull's head, which is at the level of the human abdomen. The semicircular motion of the horn often produces a relatively superficial laceration, leaving deeper structures of the abdomen intact. In one series of 29 cases in which the peritoneum was breached, usually producing prolapse of bowel or omentum, 27 laparotomies demonstrated no additional injuries. In only a few cases was the bowel itself damaged.^[183] The wound infection rate in this series was high (54%), probably because of delayed treatment. Gorings to the eye have also been described; in one case a metal horn cover complete with decorative ribbons was impacted in the orbit.^[186]

Farmers or veterinarians examining a sick animal should always have a second person present to assist and warn them.^[31] Bulls should be approached only with a protective device (e.g., a heavy stick) and a preplanned exit. A ring in the bull's nose gives a victim something to hang onto besides the horns and a way to yank the bull's nose up, which may stop the attack. Dehorning the bull will not eliminate the potential for crushing. If struck by a bull or cow, the victim should not attempt to stand, since this will provoke being thrown to the ground again, and should try to crawl to safety. Children must be educated about the risks of large animals and kept away from them whenever possible.

Camels

In regions where camels are used for domestic or agricultural purposes, bite injuries are quite common.^[176] Although herbivores and usually docile, camels are much more likely to bite in the winter rutting season, and bite fatalities have been reported. Camels have 34 teeth, including large backward-inclined upper canines, or tushes. The lower tushes are placed relatively forward, and the resultant mouth grip is very effective. Jerking movements of the head result in severe tissue damage and sometimes limb avulsion. This whipping motion can also break the victim's neck. The forearm is often injured, and bites to the face are well documented.^{[150] [185]} Virtually all bites are single.^[176] Injury or death can also occur if the camel presses the victim to the ground and crushes, after gripping the person in its jaws.

Domestic Deer

The most common domesticated deer are the reindeer and the more recently domesticated red and fallow deer. Female deer bite other deer when fighting. Males bite when testosterone levels are low, because at these times antlers are soft, pain sensitive, and cannot be used as weapons. Foreleg kicks are more common, since the

deer stands on its back legs. Domestic deer only bite humans when threatened. Since they have a dental pad instead of upper incisors, bites are rarely serious and are usually directed at an arm and the back, which are normally well covered by clothing. These bites are usually single nips.

Microbiology of Herbivore Bites

Little is known about wound infection from herbivore-inflicted injuries. Infection after camel bites is common, up to 86%,^[176] although this series did not specify time from injury to treatment. Species of *Actinobacillus lignieresii* and *A. suis*, as well as *Pasteurella multocida*, have been isolated from infected horse and sheep bites.^[13] ^[157] All are common organisms in the mouths of herbivores. *Actinobacillus* and *Pasteurella* are closely related genera, distinguished chiefly by biochemical tests. Most domestic herbivores carry *Pasteurella*, and most are given frequent and regular doses of different antibiotics, especially in their feed, leading to antibiotic resistance of bite wound organisms.^[162] *Pasteurella caballi* has been isolated from a horse bite wound.^[63] *Staphylococcus hyicus* subspecies *hyicus*, a well-known cause of disease in many animals, has been reported as a human wound pathogen after a donkey bite.^[153] One child developed *Acinetobacter anitratus* osteomyelitis after a pet hamster bite to his finger.^[132]

Bites from horses, donkeys, cattle, sheep, camels, deer, and most other herbivores are treated with the same antibiotics as bites from dogs, cats, and humans (see [Table 41-2](#) and [Box 41-5](#)).

INJURY FROM DOMESTIC SWINE

Bites from domestic swine are fairly rare, although pigs have bitten 12% of veterinarians.^[119] When they do attack, domestic swine can be aggressive and inflict deep goring or bite injuries, often on the posterior thigh as the pig approaches from behind.^[11]^[149] Goring wounds may be deep, even while deceptively small on the surface.^[203]

Among veterinarians, pigs have a reputation of inflicting bites at high risk for infection. Thorough wound exploration and debridement are essential. The usual

975

wide range of bacterial pathogens is reported, including *Pasteurella aerogenes*, *Bacteroides*, *Proteus*, and hemolytic streptococci, including *Streptococcus milleri*.^[11]^[122] *Actinobacillus suis* has also been reported.^[61] Like many domestic animals, pigs often carry *Pasteurella multocida*. Unusual gram-negative bacteria, such as *Flavobacterium* group IIb, have been isolated, as has *Mycoplasma*.^[79]^[141] Both these organisms are resistant to amoxicillin-clavulanate, so the addition of ciprofloxacin is recommended as prophylaxis for a serious pig bite wound.^[141]^[142]

INJURY FROM BIRDS

Birds may be kept as domestic pets or on farms. They can inflict serious injuries. Attacks on joggers by non-domesticated birds may also occur. European buzzards, red-tailed hawks, and starlings are known to be aggressive on occasion. On farms, rooster attacks, often by male fowl defending their territory, are well documented. Children, especially infants, are particularly vulnerable to attack. Rooster injuries have included serious clawing to the face and a fractured skull.^[163] A 2-year-old child sustained a ruptured globe from a rooster attack in a petting zoo.^[116] In one report a rooster spur was retained in a wound, resulting in chronic infection.^[41] Septic arthritis was reported in a child after a bite from a domestic fowl.^[101]

The ostrich is responsible for one to two deaths a year, mostly in Africa, where it is raised commercially. Most of the fatal attacks are kicks to the head and abdomen. The ostrich can kick only forward; a sharp toe-nail flicks out like a switchblade and can penetrate the abdomen. Since an ostrich can easily outrun a human, the only protection is to lie prone to protect against disembowelment and to cover the neck to protect against pecks. Eventually, the ostrich loses interest and allows the victim to escape.

MEDICOLEGAL IMPLICATIONS

In certain locations and circumstances, animal bites must be reported to public health authorities. Reporting suspected exposure to rabies is mandatory in most regions. If the offending animal is a pet, the victim may seek compensation from the owner, and that the health care provider may be summoned and the medical record reviewed in court. Injuries and their circumstances should be documented as fully as possible, with line drawings or photographs added to the medical record whenever possible. Hand wounds are particularly prone to infection and can lead to permanent, litigation-prone complications. A legible, precise, and complete medical record is the best protection for the health care provider.

Human bites are often inflicted in assaults or fights and may be a marker for child, spousal, or elder abuse. All these conditions must be reported to law enforcement agents in most jurisdictions. Subsequent criminal investigation may depend heavily on the initial medical record, which must be extensive and complete. Human bites of the hand have a propensity for infection and complications. In addition to providing and documenting thorough and appropriate care of the wounds, the physician should warn the victim of possible complications despite current care.

ACKNOWLEDGMENT

I thank Dr. Marina Morgan for her microbiologic advice and review of this chapter.

Chapter 42 - Bites and Injuries Inflicted by Wild Animals

Luanne Freer

Wild animal bites are distinct from the other assorted injuries suffered by humans. Tearing, cutting, and crushing injuries are sometimes combined with blunt trauma caused by falls. Animal bites may cause local infection, but this complication is hardly unique. Many offending bacteria reside in numerous environmental sources. However, few traumatic lacerations are as regularly contaminated with as broad a variety of pathogens as are animal bites.

Other special features are as follows:

1. Many victims have been terrorized by an attacking animal.
2. Animals can transmit various systemic diseases, many of which induce substantial morbidity and mortality; detailed discussion of zoonoses is found in [Chapter 44](#).
3. In contrast to the extensive scientific literature on traumatic injuries that do not involve bites, the literature on animal bites, especially wild animal bites, is largely unscientific and often simply anecdotal. As a result, rational treatment decisions are often made without a completely satisfactory scientific basis.
4. Many decisions involved in the treatment of wild animal attack victims are based on experience with domestic animal attacks, namely dog and cat bites.
5. Perhaps most importantly, animal attack injuries are usually preventable. When experience allows humans to understand typical behavior for a species, they can take proper precautions in the vicinity of a potentially dangerous animal.

This chapter interprets the present state of knowledge to make logical, specific recommendations for all of these features.

INCIDENCE OF BITES

Neither the annual number of bites nor the base population at risk can be reliably estimated, especially when the human population is only those exposed to a wild animal or in a wilderness setting. The world supports approximately 4600 species of mammals, 10,000 species of birds, and 6000 species of reptiles,^[90] but the actual number of wild animals in the world is estimated to be in the billions. Many people who suffer relatively minor injuries from wild animals do not seek medical attention unless infection or some other complication occurs, or they fear exposure to rabies. If the injury is minor, patients will continue to be treated, released, and unrecorded.

Few studies have examined the incidence of wild animal bites ([Table 42-1](#)). In Sweden, three of 1000 inhabitants were injured by animals each year.^[19] Domestic animals accounted for over 90% of the total, moose accounted for 6% (almost all involved in auto accidents), and all other animals totaled 4%. However, bites were not examined separately, and many injuries occurred during accidents caused by animals. Some officials estimate there are two bites for every one reported, but a survey of children 4 to 18 years old estimated an incidence of more than 36 times the reported bite rate. Such figures are most likely based on domestic bites, although this was not specifically stated. ^[14] ^[15]

No reported statistics exist on the typical wild animal attack victim. If all animal bites (including domestic) are considered, two U.S. state health departments report animal bites most often occurring in male children age 5 to 9 years,^[120] ^[122] but over 90% of animal attacks in these states are caused by domestic animals so this group is probably not representative of a *wild* animal attack. In undeveloped countries, many persons are exposed every day to bites from species considered "exotic" in the developed world.

Persons in certain occupations in developed countries, such as veterinary and animal control workers and laboratory workers, are at greatest risk of wild animal bite. A British survey reported a 70% incidence of animal-handling injuries during a typical veterinarian career; the rate was 42% in veterinary technical staff.^[32] The U.S. Bureau of Labor Statistics reported that in 1 year, less than 0.3% of all occupational injury fatalities were caused by mammals.^[130] In one study of 102 animal control officers, the overall bite rate was 2/57 per working day, 175 to 500 times the estimated rate in the general population (this study did not differentiate between wild and domestic animal bites).^[14] It is difficult to make conclusions about the financial sequelae of *wild* animal bites because the incidence is substantially lower than with domestic animal bites.

In every statistical series of bites, small numbers of exotic animals, such as ocelots,

jaguars, lions, leopards,

§One coyote.

?One kinkajou.

polar bears, wolves, anteaters, and weasels, are represented. Bites from these animals occur from exposure to wild and zoo animals, and from the increasing popularity of wild animals as pets, which are usually kept illegally and without adequate understanding

and training regarding animal care and behavior.

Several thousand people per year are killed by mammalian bites, with most of the deaths inflicted by man-eating lions and tigers in Africa and Asia ([Table 42-2](#)). The World Health Organization (WHO) estimates that roughly 60,000 people per year are killed by snakes and that additional millions are killed by insect-borne diseases.^[143] An estimated 200 Americans are killed by animals each year; 131 of these die in traffic accidents involving deer.^[62] Bees kill approximately 43 persons, dogs 14, and rattlesnakes 10. Wild animals, such as bears and cougars, kill fewer people than do goats, rats, jellyfish, and a captive elephant. Over 3 million people visit the wilderness in Yellowstone National Park every year; the incidence of serious injury by a wild animal at the park is less than the chance of being struck by lightning.^[61]

CIRCUMSTANCES AND PREVENTION OF ANIMAL BITES

Animal Behavior

Prevention of animal bites requires a thorough knowledge of the behavior, personalities, and patterns of various species of animals. A person wishing to avoid the bite of a particular species will often be able to gain expertise about that species' behavior only from those who work with it regularly. Detailed information on animal behavior and the attack patterns of animals is also available on Internet websites listed in [Box 42-1](#).

Basic Principles For Avoiding Animal Bites

Animals rarely attack people without provocation. Exceptions are large carnivores, which may be relatively unafraid of humans, and creatures clinically infected with rabies. However, carnivores do not commonly hunt humans as preferred prey. The animal's perception of provocation may differ from that of the human. Patterns of behavior and

attack differ by species.

People often capture or restrain wild animals, creating stress that may induce even the most benign animal

TABLE 42-2 -- Human Deaths from Animal Attacks

SPECIES	ANNUAL ESTIMATED DEATHS	ANNUAL ESTIMATED ATTACKS	PREDOMINANT AREA	COMMENTS
Humans	200,000		Worldwide	Individual murders only; excludes 1 million/yr by war in recent decades
Humans	34,000	3 million	United States only	Deaths by firearm, both intentional and accidental; attacks include all assaults
Snake	60,000		Worldwide	
Crocodile	1000		Africa	Man eating predominantly
Alligator	<1	7	Florida only	Human encroachment on alligator habitat
Tiger	600–800		India	Frequently man eaters
Lion	300–500		Africa	Frequently man eaters
Leopard	400		Africa, India	Frequently man eaters
Elephant	200–500		Central Africa, India	Occasionally rogue man killers; incidence increasing because of environmental pressures
Hippopotamus	200–300		Africa	Unpredictable; bites and trampling common

African buffalo	20–100		Africa	Only if cornered or wounded
American bison	<1	3–5	United States only	Usually only when approached at close range
Moose	1–2	20	Sweden only	Almost always involves vehicle collision with animal
Hyena	10–50	Hundreds	Africa	Frequently bites off face of sleeping victim
Wolf	20–50	200–500	Eurasia (none in North America)	Hundreds per year in previous centuries
Domestic dog	10–20	1,500,000	United States only	
Gorilla	0	2–3	Africa	Only if cornered; injuries usually not severe
Baboon	0	1–2	South Africa	Usually pets
Ostrich	1–2		South Africa	Disembowelment, kick to head, stomping
Emu	None reported	1–2	Worldwide	Usually on farms
Black rhinoceros	<1		Africa	Easily provoked

to turn on its captor. Allegedly tame animals are very likely to struggle. Even shy animals that are being captured for treatment of an injury may attempt self-defense and can inflict a life-threatening injury such as goring. Therefore all situations of animal restraint and capture are considered high risk, and careful study of the species' behavior, the individual animal, and the physical environment and resources should precede actual attempts at restraint.

Because people seem drawn to raising wild animals as pets,^[84] a large and lucrative market exists, particularly in the United States. No matter how they are raised, these animals remain wild and will never be as predictable, trustworthy, and nonaggressive as animals that have been domesticated for centuries. Often owners demonstrate a lack of common sense, as in the case of a pet Bengal tiger that attacked and killed its trainer, then 6 weeks later did the same to its owner.^[9] ^[39] Many of these mistakes probably stem from a lack of firsthand experience with wild animals.

Most wild species have a strong sense of territoriality. Individuals, pairs, or larger groups

establish a territory that ranges from square feet to square miles and aggressively prevent any intrusion into that territory, particularly by members of their own species. During mating season, this drive may stimulate even small animals to threaten or attack humans, particularly in protection of the nest and young. A Malayan tapir bit off the arm of a zookeeper who came between the usually docile animal and its calf.^[66]

A major principle of animal behavior is that physical attack is often the animal's last resort. Animals generally give ample warning of their intentions. Spectacular contests that occur in the wild are governed by elaborate rituals and rules that encourage a nonviolent solution, so that the victor may successfully defend its territory and itself with little or no injury. Humans can often avoid attack and injury by successfully interpreting visual, auditory, and olfactory warning signs. If a human slowly and carefully backs off without making sudden or threatening gestures, usually no harm will be done. The ideal reaction may depend on the species. For example, mountain lions have been turned from a full charge by an angry human who acted aggressively or fought back.^[16] Given a choice of victims, such a predator prefers the fleeing, panicky victim who demonstrates expected flight rather than unexpected behavior. Nonpredatory species, such as deer, are extremely susceptible to human intimidation, whereas a canine can be provoked to attack by a direct stare, which is regarded as a challenge.

If capture of an animal is essential, detailed preparation should be undertaken. For small animals, using nets or heavy cloth and wearing extremely heavy gloves and other protective clothing are advisable. Desperate animals can bite with tremendous force; large carnivores can easily amputate a gloved digit. A wolf can tear apart a stainless steel bowl with its teeth, and a hyena can bite through a 2-inch plank.^[27] Four men are needed to subdue an adult chimpanzee; an orangutan can maintain a one-fingered grip that an adult human cannot break. Larger animals generally require a team approach by animal control specialists with equipment such as nets, barriers, cages, and immobilizing drugs. Ideal immobilization techniques for various species are detailed in veterinary texts.^[49]

Box 42-2. SUMMARY OF ANIMAL-BITE WOUND TREATMENT

MANDATORY FOR ALL WOUNDS

1. Evaluate for potential blunt trauma and injury to deeper and vital structures by penetrating teeth, claws, or horns.
2. Ensure appropriate tetanus immunization.
3. Irrigate wound with copious volume (minimum 100 to 300 ml) of normal saline or 5% povidone-iodine solution.
4. Debride obviously crushed and devitalized tissue.
5. If the animal is suspected to be rabid (atypical behavior, high-risk species), do the following:
 - a. Infiltrate wound edges with 1% procaine hydrochloride.
 - b. Swab wound surface vigorously with cotton swabs and 1% benzalkonium chloride (Zephiran) solution or other soap.
 - c. Rinse wound with normal saline.
 - d. Assess need for rabies immune globulin and vaccine.
6. Assess risk factors to decide on further (selective) treatment (see [Box 42-3](#)).
7. Do not culture fresh wounds.
8. Do not give prophylactic antibiotics for routine low-risk bite wounds.

SELECTIVE TREATMENT (WOUNDS SELECTED BY RISK FACTORS)

1. Suture, staple, or adhesive strip closure of all skin wounds in the usual fashion unless wounds are high risk (e.g., hand wounds, high-risk species, immunosuppressed patient).
2. Culture infected wounds only if they fail to respond to initial antibiotic therapy, they are very high risk (see [Box 42-3](#)), or there is evidence of systemic sepsis.
3. Consider delayed primary closure of high-risk wounds and administration of prophylactic antibiotics to victims with high-risk wounds.

PREHOSPITAL CONSIDERATIONS

Attacks by domestic and farm animals are fairly predictable and preventable, unlike attacks in the wilderness. In Africa, life-threatening attacks by large animals, such as water buffalo, lions, tigers, and elephants, are common. Attacks by larger animals can result in major blunt or penetrating trauma, with possible major arterial blood loss, airway damage, broken ribs, pneumothoraces, and intraperitoneal bleeding. The victim's condition and the availability of rapid evacuation determine the extent of treatment in the field. Often medical personnel or supplies are not available and the victim must be moved to a hospital or clinic as soon as possible.

Many, if not most, of the complications and serious infections from animal bites are caused by inadequate first aid and significant delays to medical care. Local wound treatment should be initiated at the scene of the bite ([Box 42-2](#)) and can determine the course of healing more than any other therapy. Simple first aid measures must be initiated immediately unless definitive or better treatment is available within a short time. Pressure on the wound or pressure points controls most bleeding; avoid tourniquets unless blood loss cannot be controlled otherwise. If the victim is more than 1 hour from a treatment facility, cleanse the wounds at the scene as soon as resuscitation efforts are complete. Early cleansing reduces the chance of bacterial infection and is extremely

983

effective in killing rabies and other viruses. Potable water, preferably boiled or treated with germicidal agents, is adequate for wound irrigation. Ordinary hand soap adds some bactericidal, virucidal, and cleansing properties. If a 1% povidone-iodine (Betadine) solution is available, it should be used as an irrigant. Thoroughly irrigate the wound with at least a pint of soapy water and then gently debride it of dirt and foreign objects by swabbing with a soft, clean cloth or sterile gauze. Irrigation with a syringe is much better, but syringes are seldom available (see [Chapter 18](#)).

After cleansing, cover the wound with sterile dressings or a clean, dry cloth. Wounds of the hands or feet require immobilization. If the wounds are at high risk for infection, treatment is hours away, and an antibiotic such as amoxicillin-clavulanate, azithromycin, or ciprofloxacin is available, it is reasonable to start immediate treatment with an oral dose^[48] ^[57] ; to be most effective in preventing subsequent wound infection, this should be given within 1 hour of wounding. However, with a severe wound, it is worthwhile to provide the antibiotic even many hours later. If antibiotics are not available, the wound is infection prone, and medical care is hours or days away, a simple remedy such as filling

the wound with honey may be an effective antibacterial strategy.^[106]

When definitive medical care cannot be obtained for a day or more, cleanse and irrigate the wound thoroughly. For some wounds, attempting closure is reasonable. Further discussion of bandaging and wound-repair techniques may be found in [Chapter 16](#) , [Chapter 18](#) , and [Chapter 19](#) .

In addition to treating the bite victim, try to capture the offending animal for examination, if this can be done without risk of further injury. Unusual behavior, such as unprovoked attack by a wild animal in broad daylight or a complete absence of fear of humans, should raise the suspicion of rabies. Live capture is optimal, but freshly killed animals are usually satisfactory for examination for fluorescent rabies antibody (FRA). Avoid damaging the animal's head and brain, because brain tissue is needed for analysis. Availability of the animal can eliminate the need for costly and uncomfortable rabies prophylaxis. If more than 1 hour will elapse before the animal can be transported to a hospital or public health department, refrigerate the body. Do not use preservatives. Rabies is discussed in [Chapter 44](#) .

Examination of the animal is not useful for most other diseases and will not help predict local wound infections. Therefore use good judgment in deciding how much time and energy to expend on capture.

EVALUATION AND TREATMENT OF INJURIES

Evaluate all victims of animal bites for blunt trauma and internal injuries, which may be less obvious than the bite wound (see [Box 42-2](#)). Many animals are large, strong, and heavy, and victims should be treated like any other victim of blunt or penetrating trauma. Internal organ damage, deep arterial and nerve damage, and penetration of joints are all possible. Particularly in children, animal bites can penetrate vital structures such as joints or the cranium ^[20] ^[82] ; radiographs are needed whenever these injuries are suspected. A complete head-to-toe evaluation for trauma is advised in all but the most trivial and isolated bite injuries. Few laboratory tests are of use in evaluating animal-bite injuries. Unless hematocrit is being assessed for evidence of blood loss from occult trauma, the complete blood cell (CBC) count is not useful because it is a nonspecific and unreliable gauge of infection. Definitive trauma evaluation and treatment are discussed in detail in [Chapter 18](#) . Routine wound cultures obtained at the time of initial wounding do not reliably predict whether infection will develop, or, if it does, the causative pathogens.^[48]

The principles of wound care for injuries caused by inanimate objects apply to bite wounds as well. Many bite injuries are simple contusions that do not break the skin. The infection potential of these injuries is low; superficial wound cleansing and symptomatic treatment of pain and swelling suffice. Treatment should include prompt and liberal application of ice or other cold packs during the first 24 hours. However, this is not beneficial in snakebite and is obviously impractical in many undeveloped locations. Snakebite is discussed in [Chapter 38](#) and [Chapter 39](#) .

When skin is broken, the risks of local wound infection or the transmission of systemic disease are incurred. Infection can be caused by organisms carried in the animal's saliva or nasal secretions, by human skin microbes carried into the wound, or by environmental organisms that enter the wound during or after the attack. Virtually any bacterium, virus, or fungus can become a contaminant in bite wounds. Fortunately, most wounds do not become infected.^[59]

Animal bites are not clean lacerations, but are instead crush injuries that usually contain devitalized tissue. Debridement removes bacteria, clots, and soil far more effectively than does irrigation.^[48] In addition, debridement creates cleaner surgical wound edges that are easier to repair, heal faster, and produce a smaller scar. Topical antiseptic ointments, such as neomycin, bacitracin, or polymyxin, are highly effective in promoting healing in minor skin wounds.^[52] ^[80] However, although topical ointments are appropriate for abrasions produced by animal bites, they may be less effective for punctures and sutured lacerations.

A sutured wound is covered by a simple, sterile, dry dressing to protect from rubbing against clothing or repetitive minor trauma. Delayed primary closure requires that the wound be kept moist; this is usually done with a wet saline dressing.

WOUND CLOSURE AND INFECTION RISK FACTORS

Three major considerations govern the decision of whether to suture a wound: cosmetics, function, and risk factors. Cosmetic appearance virtually mandates suturing all facial wounds, which usually are low risk. Similar reasons may dictate closure of wounds on other visible portions of the body. Function is of critical importance in wounds of the hand and foot, which are high-risk areas in which infection can have disastrous consequences. Thus hand wounds should generally be left open. Risk factors are many and complex and provide a useful logical framework in making the decision whether to suture, administer antibiotics, or undertake other treatments. For more information on surgical procedures, see [Chapter 18](#).

The amount of time elapsed after wounding is a critical risk factor; the longer the interval, the more likely the chance for infection. After the first few hours, adequate wound cleansing is unlikely to be carried out. In developed countries, many victims are seen within hours of wounding, and the results are usually very good. In remote and undeveloped areas and countries, wounds commonly do not receive medical attention for half a day or more, putting them into a high-risk category that may eliminate the possibility of suturing. Certain species, including primates, wild cats, pigs, and large wild carnivores, seem to inflict infection-prone wounds, although evidence is incomplete. The presence of one or more of these risk factors may preclude suturing or may suggest the use of delayed primary closure (discussed below). However, most fresh bites can be safely sutured after proper wound preparation. Optimal conditions include prompt medical treatment, which is seldom available in remote and undeveloped areas. In those locations, leaving bite wounds open (or with a drain, although this is also controversial) is the more prudent course.

Box 42-3. RISK FACTORS FOR INFECTION FROM ANIMAL BITE

HIGH RISK

Location

Hand, wrist, or foot

Scalp or face in patients with high risk of cranial perforation; CT or skull radiograph examination is mandatory

Over a major joint (possibility of perforation)

Through-and-through bite of cheek

Type of wound

Punctures that are difficult or impossible to irrigate adequately

Tissue crushing that cannot be debrided (typical of herbivores)

Carnivore bite over vital structure (artery, nerve, joint)

Patient

Older than 50 years

Asplenic

Chronic alcoholic

Altered immune status (chemotherapy, acquired immunodeficiency syndrome [AIDS], immune defect)

Diabetic

Peripheral vascular insufficiency

Chronic corticosteroid therapy

Prosthetic or diseased cardiac valve (consider systemic prophylaxis)

Prosthetic or seriously diseased joint (consider systemic prophylaxis)

Species

Large cat (canine teeth produce deep punctures that can penetrate joints, cranium)

Prosthetic or seriously diseased joint (consider systemic prophylaxis)

Species

Large cat (canine teeth produce deep punctures that can penetrate joints, cranium)

Primates

Pigs (anecdotal evidence only)

Alligators, crocodiles

LOW RISK

Location

Face, scalp, ears, and mouth (all facial wounds should be sutured)

Self-bite of buccal mucosa that does not go through to skin

Type of wound

Large, clean lacerations that can be thoroughly cleansed (the larger the laceration, the lower the infection rate)

Partial-thickness lacerations and abrasions

Species

Rodents

Quokkas

Bats (although high risk for rabies)

Bites of the Hand

Hand bites are common, and infection can be disastrous.^[139] Therefore the hand is considered at risk for complications ([Box 42-3](#)). The hand contains many poorly vascularized structures and tendon sheaths that poorly resist infection. The fascial spaces and tendon sheaths of the hand communicate with each other, and movement seals off the wound from external drainage

and spreads bacteria and soil internally. Because of the unique anatomy of the hand, irrigating hand wounds adequately is often impossible.

Data on hand wound infection have been collected mostly from experience with domestic dog and cat bites. From a retrospective study in Oslo, nearly all hand bite wounds healed uneventfully when the wounds were left open, either without antibiotics or with penicillin after wound treatment.^[35] In another European center, the total infection rate was 18.8% in hand bite wounds; this rose to 25% when the hand wound was closed primarily. The average time from the injury to the first medical treatment was 11 hours in infected wounds and 2 hours in noninfected ones.^[2]

Because of high morbidity and permanent residual impairment from hand infections, treating them aggressively is best (see [Box 42-2](#)). Hand bite wounds should be irrigated, debrided if possible, and initially left open.^[48] ^[139] The hand should be immobilized with a bulky mitten dressing in an elevated position, and the victim usually should be started promptly on intravenous antibiotics. Specialty consultation and follow-up are mandatory for persons with an established infection, and hospitalization should be considered. Persons not hospitalized should be rechecked daily until signs of infection clear. In the patient without initial evidence of infection, 5 to 7 days of splinting and oral antibiotics should suffice if no complications develop. Radiographic examination should be performed on all significantly injured extremities.

Punctures

Punctures may occur from bites, clawings, or gorings. The infection rate is related to difficulty irrigating properly and degree of contamination, which is highest in bites. Usually, attempts to irrigate narrow punctures simply result in rapid development of tissue edema from infused saline, which does not cleanse the wound. However, if the wound is large or can be held open wide enough to permit fluid to escape, irrigation is worth the effort. Large goring-type puncture wounds up to 8 to 10 inches deep from bison have a low incidence of infection when closed primarily after irrigation and debridement.^[30] For most smaller puncture wounds, irrigate or debride as well as possible, suture only if cosmetic or functional considerations require it, and treat as for high risk for infection.^[48] Use delayed primary closure liberally.

Facial and Scalp Wounds

Facial and scalp wounds tend to heal rapidly with little risk of infection; in general, they may be sutured primarily and do not require prophylactic antibiotics. Typical dog bites of the face and neck (including punctures) have an infection rate of only 3%, even when sutured.^[2] ^[35] ^[37] ^[141] In general, cosmetic closure of facial wounds is afforded by the lower incidence of infection, and standard of care in most cases is primary closure of an animal bite to the face.^[141]

A major risk associated with facial and scalp wound victims of large carnivores is that the teeth can easily perforate the cranium, producing depressed skull fracture, brain laceration, intracranial abscess, or meningitis.^[23] ^[104] In young children with such wounds, or with adult victims of large carnivores, computed tomography (CT), or in the

absence of CT, skull radiographs should be routine, looking for evidence of perforation that would mandate immediate neurosurgical consultation and admission to the hospital.

INDICATION FOR CULTURES

Cultures of animal-bite wound surfaces, whether judged quantitatively or qualitatively, are useless as predictors of infection. Some of the pathogens of greatest concern (such as *Eikenella*) can take 10 days to grow out in culture, by which time most therapeutic decisions have been made. Other organisms (such as *Pasteurella*) are fastidious, hard to identify, and frequently missed by the laboratory technician, who rarely encounters them.^[53]

If the victim or wound is very high risk, or if animal bite sepsis is suspected (see the section on sepsis), obtaining cultures would be prudent to guide subsequent antibiotic therapy. In certain cases, cultures should be sent to reference laboratories, such as those in state health departments or at the Centers for Disease Control and Prevention (CDC) in Atlanta, because reference laboratories have successfully isolated more pathogens on identical samples sent to both reference and local laboratories.^[127]

PROPHYLACTIC ANTIBIOTICS

Currently the weight of evidence does not support use of prophylactic antibiotics for other than high-risk wounds. The use of antibiotics is most advisable for wounds of the hand; the speed of development, frequency, severity, and complications of hand wound infections can be impressive.^[48] ^[139] Persons with other risk factors, particularly prolonged time from injury to treatment, complex wounds with massive crushing, or medical conditions, such as asplenia, diabetes mellitus, vascular insufficiency, or immune deficiency, may benefit from prophylactic antibiotics (see [Box 42-3](#)).

In bite wounds, treatment can begin only *after* wounding and bacterial inoculation; thus antibiotics are never truly prophylactic. In major surgery, prophylactic antibiotics are of proven value only in carefully selected high-risk procedures and only if begun *before* surgery.^[135] Several controlled studies of dog bite wounds found no significant benefit for using prophylactic

TABLE 42-3 -- Tetanus Prophylaxis

HISTORY OF IMMUNIZATION (DOSES)	CLEAN MINOR WOUNDS		MAJOR DIRTY WOUNDS	
	TOXOID*	TIG†	TOXOID	TIG
Unknown	Yes	No	Yes	Yes
None to one	Yes	No	Yes	Yes

*Toxoid: Adult: 0.5 ml DT intramuscularly (IM). Child less than 5 years old: 0.5 ml DPT IM. Child older than 5 years: 0.5 ml DT IM.

†Tetanus immune globulin (TIG): 250 to 500 units IM in limb contralateral to toxoid.

antibiotics in low-risk facial and scalp wounds.^{[38] [141]} Other studies recommend the use of prophylactic antibiotics only for high-risk wounds and/or patients.^{[35] [37] [59] [139] [141]}

If used, prophylactic antibiotics must be administered early. The offending bacteria are already present in the wound when the victim is first seen. Therefore bite victims needing prophylactic antibiotic treatment should be identified early, preferably during triage on entry to the emergency department. The victim should receive immediate antibiotics by protocol; the intravenous route is by far the quickest. Although previous practice had led to prescription of prophylactic antibiotics for 7 to 10 days, current knowledge in the surgical literature is that prophylaxis is needed for only a few days after surgery. In animal bites, oral antibiotics are not expensive to continue for a few extra days; thus a maximum period of 5 days of prophylaxis should be more than sufficient with uninfected bites.

Therapy should be tailored to the largest variety of most likely pathogens for a particular type of bite. For most terrestrial mammals, the choice of antibiotic is based on experience with human, dog, and cat bites. However, with alligator or crocodile bite, or other wounds incurred in fresh water, antibiotic choice should be directed against *Aeromonas hydrophila*.^{[63] [89]}

TETANUS PROPHYLAXIS

Recently, about twice as many cases of human tetanus from animal bites have been seen each year as cases of human rabies.^[13] The spores of *Clostridium tetani* are ubiquitous in soil, on teeth, and in the saliva of animals. Therefore the risk of tetanus may be present from any animal injury that penetrates the skin. Because tetanus is preventable, and many persons still do not receive tetanus immunoprophylaxis according to guidelines of the CDC, proper emergency prophylaxis against tetanus remains an important, but often underappreciated intervention.

Tetanus prophylaxis is administered in standard fashion ([Table 42-3](#)). With a clean wound that contains little devitalized tissue and that can be easily irrigated and debrided, a previous full course of immunization plus a booster within the last 10 years is sufficient. In a deep puncture or wound with much devitalized tissue that is difficult to irrigate and debride (predisposing to anaerobic growth), a full series of previous immunizations plus a booster within the last 5 years is sufficient. If there is any uncertainty regarding the status of the victim's prior immunization, a high-risk wound should prompt intramuscular injection of 250 to 500 units of tetanus human immune globulin (TIG), as well as 0.5 ml of diphtheria-tetanus (DT) toxoid booster vaccine. Because many persons do not have full prior immunization against tetanus, questioning the patient thoroughly on this point is critical. The risk of inadequate prior immunization is particularly high for elders and persons reared in underdeveloped countries. In 1995 to 1997, 35% of human tetanus cases occurred in persons 60 years and older.^[11]

If the patient has not been immunized in the previous 10 years, TIG is recommended because most victims have no significant antibody response to a booster dose for at least 4 days.^[13] If a definite history of prior immunization cannot be elicited, the victim must be treated with 250 to 500 units of human TIG intramuscularly in one arm and 0.5 ml of the adult DT toxoid in the other. Booster doses of tetanus toxoid are administered at 30 and 60 days after the initial injection to complete the course of immunization.

FOLLOW-UP CARE

Assuming that the possibility of major or occult trauma has been ruled out, follow-up of animal bites depends on the risk factors present (see [Box 42-3](#)) and the patient's

987

response to treatment. With only a superficial abrasion, infection is unlikely, and no return visit is needed. With an ordinary low-risk bite wound, one follow-up visit in 2 days, to assess any infection, is all that is needed. If the patient is very reliable and no sutures have been placed, even one visit is not necessary. Infected wounds dictate much closer follow-up, the frequency depending on the wound's response to treatment and the patient's risk factors. In a high-risk patient, the initial follow-up should be within 24 hours if the patient is not hospitalized.

COMPLICATIONS OF BITE WOUNDS

Wound Infection

Immense numbers of bacteria inhabit animals' mouths and can be inoculated into a bite wound. The exact pathogens vary depending on the biting species. The major aerobic and anaerobic bacteria are listed in [Box 42-4](#) and [Box 42-5](#). If inoculated in sufficiently large numbers, these microorganisms can cause localized cellulitis and abscess formation, the most common forms of infection. Wound infection is generally diagnosed on the basis of increasing redness, swelling, and tenderness of the wound margins, eventually progressing to production of pus, cellulitis, lymphangitis, and local lymphadenopathy. Lymphadenitis and lymphangitis, which are much less common, occur as local defenses are overwhelmed. Systemic symptoms of infection are rare and suggest bacteremia or sepsis.

Wound infection from animal bites should be treated like infection of any other traumatic wound (i.e., elevate the wound, immobilize the affected part, remove sutures or staples if present, and provide antibiotic therapy [see [Box 42-1](#)]). Based on the 1999 Emergency Medicine Animal Bite Infection Study Group findings, recommended empiric treatment includes combining a β -lactam antibiotic and a β -lactamase inhibitor, a second-generation cephalosporin with anaerobic activity, or combination therapy with either penicillin and a first-generation cephalosporin or clindamycin and a fluoroquinolone.^[127] Additional studies recommend azithromycin, trovafloxacin, or experimental ketolide antibiotics HMR 3004 or HMR 3647, which show good in vitro activity against unusual aerobic and anaerobic animal pathogens ([Box 42-6](#)).^{[53] [56] [57]} ^[127] In 1999 the Food and Drug Administration (FDA) issued a public health advisory statement recommending that the use of trovafloxacin be restricted to treatment of serious infections in hospitalized patients because of the risk of hepatic toxicity.

*1999 FDA recommendations restrict use to seriously ill hospitalized patients.

Extremely rare pathogens can cause infection (see [Box 42-4](#) and [Box 42-5](#)). Culture of debrided tissue is the only reliable identification technique, and sensitivity testing may take weeks. Surgical debridement of all infected tissue is crucial. The organisms are usually sensitive to ciprofloxacin, ceftiofur, and perhaps rifampin. ^[107]

Septic Complications

Bacteremia and sepsis, although theoretical risks with any animal bite pathogen, have so far been reported with only a limited number of species. ^{[4] [46] [76] [104]} Clinical manifestations include cellulitis, endocarditis, meningitis, pneumonitis, Waterhouse-Friderichsen syndrome, renal failure, shock, and death. Purpuric lesions are seen in one third of cases and may progress to symmetric peripheral gangrene and amputation. In some cases, cutaneous gangrene develops at the site of the bite, a finding unique to this species of bacteria.

Allergic Reactions

Allergic reactions to animal bites are virtually unheard of. However, up to 11% of laboratory workers have allergic reactions to laboratory animal dander, hair, and urine. ^[142] One case of proven hypersensitivity to rat saliva after a bite has been reported. ^[142] The patient was subsequently proven allergic to the saliva (presumably because of saliva proteins) and not to other portions of the rat. The bite produced

lymphangitic swelling and itching that subsided within 24 hours.

Transmission of Systemic Infection

Approximately 150 systemic diseases of mammals can be transmitted in some fashion to humans. However, relatively few occur through a bite or scratch. Pathogens may be secreted in saliva, nasal secretions, or tear, or reach the animal's mouth through cleaning activities. The list includes pasteurellosis, leptospirosis, rat-bite fever, cat-scratch fever, tularemia, fish handler's disease, hepatitis A and B, monkeypox virus infection, tuberculosis, toxoplasmosis, bubonic plague, tetanus, gas gangrene, rabies, Q fever, Hantavirus infection,

and sporotrichosis. ^[40] ^[98] [Chapter 44](#) reviews most of the diseases theoretically transmitted by lick, bite, or scratch. Although systemic disease is a valid consideration, 99% of mortality and morbidity arises from local wound infection, including rabies and tetanus. [Chapter 44](#) discusses the diagnosis and treatment of zoonoses.

NEUROTROPIC DISEASE

Rabies

Rabies is discussed in detail in [Chapter 44](#), so comments here are limited to brief remarks about epidemiology, assessment of risk in the bite victim, and local wound treatment.

Rabies is a rhabdovirus that occurs in wild and domestic animals. Migrating epidemics alternate with periods of endemicity. It is generally believed that no true reservoir host exists for rabies; that is, no species harbors a latent and nonfatal infection.

The epidemiology of rabies varies widely in different parts of the world. In the United States, western Europe, and Canada, wild animals are by far the main vectors of rabies, accounting for more than 85% of all reported cases in the past two decades.^[92]^[99] In recent years, rabies in humans has become an extremely rare disease in the United States, with only two cases occurring in 1997.^[131] Since 1980, rabies-infected bats caused 58% of the human cases of rabies diagnosed in the United States.^[99] Of the more than 8000 cases of animal rabies reported in the United States in 1997, the terrestrial animals most represented were woodchucks, raccoons, skunks, foxes, and coyotes.^[92] Foxes are the primary offenders in Europe, although some countries have eliminated rabies in wild populations by using innovative vaccination programs.^[25]

Because of local variations in animal vectors and endemics, consultation with the state or local health department is prudent before a decision is made to initiate antirabies postexposure prophylaxis.^[92] Although the number of human cases has declined, about 18,000 people per year in the United States receive postexposure prophylaxis.^[47] In the rest of the world, virtually all rabies occurs in dogs. Worldwide, dogs account for 91% of all human rabies cases, cats 2%, other domestic animals 3%, bats 2%, foxes 1%, and all other wild animals only 1%.^[25] Each year in India, 25,000 humans die from rabies and a half million receive antirabic vaccine.^[125] In Africa, Latin America, and most of Asia, dogs are the principal vector, although jackals are also a factor. In South America and Mexico, rabid vampire bats cause occasional human infection. In recent years, disruption of the natural ecology by introduction of humans and domestic animals into the rain forest has produced epidemics of rabies caused by vampire bats. In Israel, wolves and jackals are the chief vectors, and the mongoose prevails in Puerto Rico. In eastern and central Europe, the raccoon dog (*Nyctereutes procynoides*) is an increasingly common vector.^[25]

Judgment of risk of rabies exposure rests on several factors. The incidence of rabies in local species is important; in the United States, urban dogs and cats, domestic ferrets,

rodents, and lagomorphs (rabbits and hares) are at low risk. The animal's behavior is sometimes helpful. This is easily evaluated in wild animals because most tend to shun humans. The urban appearance of a skunk, fox, or bat in broad daylight, showing no fear of human beings, is abnormal and should raise the index of suspicion.

In addition to situations involving animal bites, contact of mucous membranes with rabid saliva or an animal scratch should prompt consideration for rabies postexposure prophylaxis (PEP). If a person is found in a room with a bat and is unable to reliably report the absence of contact that could have resulted in exposure (e.g., an unattended child or sleeping or mentally incompetent adult), then rabies PEP should be administered.^[99]

Thorough and rapid early treatment of wounds from animals suspected of being rabid is mandatory. Immediately cleanse all bite wounds and scratches with soap and water and a virucidal agent, such as povidone-iodine solution.^[121] Evaluate all persons exposed to a possibly rabid animal for rabies immunoprophylaxis; CDC guidelines issued in 1999 recommend that for previously unvaccinated persons, *the entire dose* of rabies immune globulin, 20 IU/kg body weight should be infiltrated at the wound site if possible. Three types of rabies vaccine are currently available in the United States: human diploid cell vaccine, rabies vaccine adsorbed, and purified chick embryo cell vaccine. The chosen vaccine is given in 1-ml doses on days 0, 3, 7, 14, and 28 after exposure. Further information on rabies preexposure and postexposure prophylaxis is discussed in [Chapter 44](#).

Other Neurotropic Infections

Although not caused by bites or wounds, oral transmission of Creutzfeldt-Jakob disease has been reported from the regionally common practice of eating the brains of wild goats, pigs, or squirrels, even when cooked. Creutzfeldt-Jakob disease is characterized by progressive dementia, ataxia, and myoclonus, and is untreatable. It is caused by a virus also identified in the brains of domestic sheep and mule deer.^[71]

PSYCHIATRIC CONSEQUENCES OF ANIMAL ATTACK

Victims of traumatic or life-threatening events may develop posttraumatic stress disorder (PTSD). This syndrome has been recognized anecdotally by the author

990

as a result of wild animal attack and is rarely reported in the scientific literature. ^[36] After physical recovery from an attack, the victim may be plagued by recurrent nightmares and flashbacks of the event and may have an aversion to outdoor travel. Critical incident stress debriefing and posttrauma intervention counseling may be important aspects of care for victims of animal attack. ^[36]

BITES OF THE WILD (BIG) CATS

Adult cats have 30 permanent teeth, arranged in rows of 16 upper and 14 lower. The upper teeth overlap the lower, resulting in an overbite.^[32] This helps the animal lock its teeth into prey and exert twisting and tearing forces. The feline bite is much shorter and more rounded than that of a dog.

Big cats typically attack from behind, biting the neck and occiput of their prey and attempting to maneuver their canine teeth between the victim's cervical vertebrae and into the spinal cord.^{[28] [114] [138]} Proprioceptors in the cat's tooth allow it to detect when it has encountered bone. The goal of rapidly paralyzing the prey is also accomplished by a violent shake of the cat's head, which fractures the cervical spine. In a study of fatalities from jaguar attack, 77% of victims were bitten on the nape of the neck and half of the bites were made to the base of the skull.^[28] In 20% of cases, the killing bite was to the head, with at least one canine piercing the skull or ear canal. Cheetahs prefer to attack the throat of their prey, crushing the larynx and strangling the victim, a method also used by lions and leopards.^[83] Big cats also claw their prey, producing deep parallel incised wounds. Several victims have died of exsanguination without evidence of strangulation or cervical spine injury.^{[29] [114]} Because of the growing propensity for people of developed countries to keep exotic animals as pets (or raise them for profit for hunting purposes), injuries by big cats can occur anywhere.

Wound care is the same as for other species, with special attention to evaluation for major internal injury. In particular, observe for penetration of deep structures of the cranium and neck, and rule out injuries of the cervical spine and deep cervical vessels (see [Box 42-1](#)).^[28] One victim with an apparently trivial puncture wound after a bite to the neck from a pet cougar was discharged from the emergency department.^[72] Within hours her voice was hoarse; on return, she recalled that the cougar had shaken her in its jaws when it bit her, and air was found in the prevertebral and retropharyngeal spaces on radiographic examination.

Like domestic cats, big cats usually carry *Pasteurella* as normal flora, and because of the deep penetration of their large teeth, *Pasteurella* septic arthritis, meningitis, and other serious deep infections can occur.^{[51] [70]}

Cat-scratch disease is an uncommon disease; 90% of cases are caused by scratches from domestic cats, and it has been reported in a big-cat attack victim.^{[33] [72]} The average incubation period is 3 to 10 days. The characteristic feature is regional lymphadenitis, usually involving lymph nodes of the arm or leg. In most cases, clinical diagnosis is based on finding three of the following four criteria^[3] :

1. Single or regional lymphadenopathy without obvious signs of cutaneous or throat infection
2. Contact with a cat (usually an immature one)
3. Detection of an inoculation site
4. A positive skin test for cat-scratch disease.

More detailed information on the diagnosis and treatment of this disease is found in [Chapter 44](#).

Tigers

Adult tigers are so powerful that the human victim is often killed instantly. It is not unusual for a limb to be severed with a single bite.^[42] ^[79] A swiping blow to the human head can cause a skull fracture.^[108] Like many big cats, tigers typically strike without warning from behind, biting the head and neck and often shaking their heads violently to sever the victim's spinal cord.^[74]

Big cats are a major threat to the lives of humans in the cats' native regions.^[88] Although the number of tigers in the world is dwindling rapidly, they are still the number one animal killer of humans (see [Table 42-2](#)). Nonetheless, man killing almost invariably results from stress (wounds or old age) or lack of natural prey and habitat that forces the animal to prey on humans. A tiger subsisting solely on human meat would have to kill approximately 60 adults a year, and documented cases in selected regions have approached this rate over periods of up to 8 years. Man-eating tigers in India between 1906 and 1941 ate an estimated 125 persons each, and one had killed 436 persons. However, unlike lions, tigers are not thought to become exclusive man eaters. Some tigers have become opportunistic man eaters in lieu of plentiful natural prey, and tiger biologists hypothesize that these animals have become unafraid of man.^[88]

Over the last 5 centuries, an estimated 1 million people have been eaten by tigers. In the nineteenth century, the tigers' toll in India averaged 2000 victims per year. From 1930 to 1940, the annual number never dropped below 1300. In the late 1940s, this rate dropped to about 800 per year, where it remains. At the same time, approximately 17,000 people per year are killed in India by other wild beasts, which include nonmammalian species.

Lions

Despite their appearance and reputation, lions are not as greatly feared or respected by experienced hunters as are tigers ([Figure 42-1](#)). Lions are primarily scavengers, making fewer original kills than do hyenas. A

Figure 42-1 African lion. (Photo by Cary Breidenthal, RN.)

protected population of 250 Asiatic lions in India has attacked 193 humans, killing 28 between 1977 and 1991; biologists credit lion baiting for tourist shows and drought for this increasing carnage.^[115]

A threatening gesture or shout may repel a lion, although a lioness guarding her cubs is more likely to attack. Experienced hunters find that when a charging lion is faced head on and confronted, it will often turn tail and run. An intended victim who flees is most likely to be attacked. Walking unarmed in lion country is usually safe; most hunters who succumb to lions are killed by wounded or sorely provoked animals, usually in dense brush ([Figure 42-2](#)). Many who survive the initial mauling die later of infection. Details of their treatment are not available. Persons who have survived attacks state that it is unwise to struggle and that the cat should be allowed to chew on an arm or other extremity. With luck, it will lose interest and leave.

Man-eating lions exist, as noted recently in South Africa, where illegal immigrants from Mozambique attempt to cross the border at night through Kruger National Park. In direct proportion to the number of immigrants on foot, the number of humans maimed or killed by lions has increased. Rangers suggest that humans on foot are an easier food source than normal prey for old or sickened lions.^[95] Lions are estimated to eat 300 to 500 Africans a year and rank second to tigers among man eaters. Conversion to man eating has been blamed on drought, famine, and human epidemics in which large numbers of corpses are abandoned in the bush. Lions that become man eaters and subsist exclusively on human flesh need approximately 40 victims a year to stay alive. They usually kill instantly with one bite to the head or neck or with a swipe of the paw, which can break an ox's neck. Lions have tremendous strength and can easily carry a human victim for a mile without rest.

Figure 42-2 Lion attack victim. This African victim was rescued by bystanders as his head was in the lion's mouth. His only injury was a degloving scalp laceration. (Photo by Harold P. Adolph, MD.)

Although most lions in captivity become passive and dull, circus and zoo lions periodically kill attendants. Many such deaths have occurred when keepers accidentally

have backed into or trod upon an animal.

Leopards

Most leopard attacks are provoked by wounds or by a dog attack. When wounded, trapped, or cornered, a leopard is unpredictable and ruthless, attacking the first person within striking distance. Unmolested and in normal health, the leopard is a shy, nervous animal with marked fear of humans. Unlike a lion or tiger, the leopard relies on fast claw work and biting. Like the jaguar, the leopard may go for the neck (in an effort to sever the spinal cord) or attempt disemboweling by raking at the victim's abdomen with the claws. The leopard seems inclined to retreat when much resistance is offered, even in encounters with baboons. There is a documented report of a man armed only with a screwdriver fighting and killing an attacking leopard.^[77] Before the era of antibiotics, three fourths of people mauled by leopards died from wound infection, but modern morbidity is estimated to be less than 10%.^[27]

Mauling by leopards is much more common than killing; estimated casualties are 400 per year, mostly in Africa. The leopard does not often turn into a man eater; when it does, it attacks mainly children or sick adults. In the state of Bihar in India, leopards ate 300 people in 1959 and 1960.^[27] The man-eating leopard of Rudraprayag in India killed 150 people between 1918 and 1926. Becoming increasingly bold, it eventually took its prey by banging down doors, leaping through windows, or clawing its way through the walls of mud huts. Like man-eating lions, man-eating leopards completely change their normal hunting patterns when the prey becomes exclusively human.

992

Cougars

The North American cougar (mountain lion or puma) is a clever, basically shy cat. It is the most widely distributed large animal on the American continent. Recently, cougars are encroaching with increasing frequency into populated areas of the western United States, probably because of human expansion into the wilderness and an increased population of protected cougars.^[73] The combined cougar population in California, Colorado, and Idaho is now estimated at 9000 to 12,000; humans live, exercise, or picnic in cougar country with increasing frequency.^[124] Thus modern suburban dwellers (who typically are ignorant of wild animal behavior) are now in regular close contact with

cougars in their homes and parks—whether they know it or not.

From 1970 to 1990, 31 cougar attacks on humans were documented, with five fatalities.^[16] More people have been attacked since 1975 than over the entire previous century.^[16] ^[124] ^[128] Most attacks occurred in the western United States and Canada. Throughout the United States, cougars took sixteenth place as an animal-related cause of death in recent years, just behind jellyfish or goats.^[110] In California, no attacks occurred from 1925 until 1986, when two children were attacked in a regional park in southern California.^[72] In 1991, a teenager was killed in Colorado, and a cougar killed an adult woman in California in 1994. Both victims were jogging, perhaps evoking a predatory response.^[29] ^[114] Young animals that are forced out by adults and must find their own territory are the most frequent attackers of humans.^[73] Children are the preferred victims (86% of fatalities are children).^[67] There has been only one alleged report of a cougar as a primary man eater, but cougars have sometimes partially eaten victims of their attacks ([Figure 42-3](#)).^[29] ^[114]

The cougar hunts like a domestic cat: crouching, slinking, sprinting, pouncing, and then breaking the prey's neck. The types of injuries to the neck are similar to those described for lions and tigers. Like many potentially dangerous wild animals, the cougar can often be scared off by the victim's aggressive behavior, even after the attack has begun.^[62]

RODENTS

Rodents do not tend to bite unless severely provoked; their bites are usually small and do not cause much disability. The exact number of rodents in the world is unknown, but they probably number in the hundreds of millions, with 1500 species of laboratory and pet rodents. Despite these numbers, they account for only 1.7% to 10% of animal bites brought to medical attention.^[101] Such bites are infrequent, seldom cause any problems for the victim, and often occur among lower socioeconomic groups without good access to medical attention. The other human populations at risk are owners of pet rodents and laboratory workers who handle rodents used in research. Insufficient data exist to determine any difference in outcome between wild and domestic rat bites.

Rats, Mice, and Other Small Rodents

Rat bites show an infection rate of 2% to 10%, even without treatment, and the rate is usually on the low end of this spectrum.^[101] Other than bites inflicted by laboratory animals, the vast majority occur in poverty areas while the victim is sleeping and involve the face and neck, usually in infants or physically or mentally disabled adults.^[100] ^[101] There were 415 reported rat bites in New York City between 1986 and 1994.^[24] Sometimes these can be severe; a week-old infant was bitten around the eyes by a rat, resulting in perforations of the globe, an estimated vascular loss of 55% of red blood cell mass (with an initial hematocrit value of 20%), and eventual blindness.^[96] Despite the rat's reputation for spreading disease, however, infection did not occur. Similar bites in infants have resulted in loss of more than three fourths of the eyelids.^[144]

The bacteriology of a rat bite is similar to other animal species, and the various systemic diseases transmitted by rats are discussed in [Chapter 44](#). Sporotrichosis has been reported; this widely distributed saprophyte is found on various plants, in the soil, and on many animals.^[50]

Although rodents occasionally become infected with rabies, they seldom secrete this virus in saliva; therefore they inflict extremely low-risk bites for transmission of the disease. However, local epidemics can occur, as documented in the 1980s among rodents and lagomorphs on the United States east coast.^[94] In that epidemic, woodchucks constituted 80% of all rabid animals; the remainder were squirrels, beavers, rabbits (lagomorphs, not rodents), and one rat. Some of these

rabid animals were very aggressive; a woodchuck attacked and knocked down an elderly woman in her garden, biting her repeatedly. Rabies was isolated from the buccal cavity of the woodchuck. A reasonable current recommendation is that a biting wild rat in the United States should be caught and examined for rabies and rabies immunoprophylaxis should be initiated only if the rabies test is positive; rabies immunoprophylaxis is probably appropriate for bites of uncaptured rodents inflicted outside the United States and Canada.^[101]

A case has been reported of a cowpox virus-like infection transmitted by a probable rat bite.^[141] Rodents are believed to be the natural reservoir for cowpox virus.

Rat-bite fever is an acute illness caused by *Streptobacillus moniliformis* or *Spirillum minus*, which are part of the normal oral flora of rodents, including squirrels. It may also result from bites by wild and domestic carnivores, such as weasels, dogs, cats, and pigs, which may have become infected when hunting rats and mice.^[118] Carrier rates among wild rats vary from 50 to 100%.^[136] Fewer than 100 cases have been reported in the North American literature; rat-bite fever is not a reportable disease in the United States.^[136] Although relatively rare, cases can occur in any setting and can easily be fatal, particularly when the proper diagnosis is not suspected.^{[34] [117] [136]} Further information is found in [Chapter 44](#) .

Plague is caused by the bacterium *Yersinia pestis*. Wild plague is endemic in many parts of the world, chiefly among rats, mice, moles, marmots, squirrels, hares, cats, and mongooses. One of the larger areas of endemic plague is the western United States (362 cases reported in 50 years), where voles, field mice, ground squirrels, prairie dogs, and pack rats carry the infection. The infection is usually transmitted to humans by the bite of arthropods that infest infected animals. Handling infected animals allows *Yersinia pestis* to enter cuts and abrasions, as seen in veterinarians and in hunters who skin and clean infected rabbits.^[137] Transmission by bite or scratch has never been reported. The disease is mentioned here because of its historical significance and the frequency of occurrence in wild animals. Further information is found in [Chapter 44](#) .

Tularemia represents various syndromes caused by *Francisella tularensis*. This bacterium normally parasitizes about 100 different mammals and arthropods, most commonly cottontail rabbits, rodents, hares, moles, beavers, muskrats, squirrels, rats, and mice. The primary mode of transmission to humans is via a bloodsucking arthropod, such as a tick, or by skin or eye inoculation resulting from skinning, dressing, or handling diseased animals. Other routes of infection include ingestion of water contaminated by urine or feces, and inhalation of dust. Infections after bites or scratches from dogs, cats, skunks, coyotes, foxes, and hogs have been reported, although these are rare.^[109] The disease is an occupational hazard of hunters, butchers, cooks, campers, and laboratory technicians. Humans are quite susceptible, and although tularemia was removed from the national notifiable disease list in 1995, 105 cases were reported in 1997 in the United States.^[91] More information is found in [Chapter 44](#) .

PORCUPINES

Porcupines (a species of rodent) are virtually never reported to bite, but their quills may become embedded in the skin of humans. Because of the structure of quills, they not only embed themselves and are extremely difficult to extract, but they can migrate as much as 10 inches under the skin. The average porcupine has 30,000 quills, which range from less than an inch to 4 inches in length. The quills are barbed and their cores are spongy, so if they are not removed immediately, they absorb body fluid and expand, causing the barbs to flare even further outward. Thus each movement of the victim's body or muscles helps a quill work its way in deeper. Allegedly, such migration has led to injury to internal organs and death in humans. Infection seldom results because the quills have mild antiseptic properties, presumably to protect the porcupines themselves, which sometimes impale themselves.

No medical reports are available of appropriate treatment or complications of porcupine quill injuries, though anecdotal reports of human tetanus from porcupine quill puncture arise from Africa.^[1] Most veterinarians remove quills from animals by simple extraction; the same technique is probably sufficient in humans.

BATS

Vampire bats are a vector of rabies in Central and South America; 177 cases were reported from 1980 to 1990, with 27 of those cases in Brazil.^[134] Sometimes, small "epidemics" of bites occur in isolated villages in the jungle, as in one outbreak of 26 bat bites in Honoropois, Brazil; all were treated with rabies prophylaxis, and no clinical human rabies was reported.^[13] Such clusters of attacks may be triggered by human destruction of wild or domestic hosts (such as pigs) of the bats.^[86] Vampire bats feed at night on animal blood, including that of humans, by making an incision in the skin to lap up the blood from the victims' earlobes, forehead, fingers, or toes. One bat can eat a maximum of 1 oz of blood per night, which is clearly not enough to cause death. However, a cave of 1000 bats needs 15 gallons of blood each night, which amounts to more than 5750 gallons per year.^[27] ^[33] Protection against vampire bats is effectively provided by mosquito nets.

994

Insectivorous bats, such as free-tailed bats, are noteworthy for the nearly undetectable bite wounds they leave on their victims.^[99] All bats should be considered high risk, and exposure—even to sick or "pet" bats that have been in captivity—should be avoided. Some situations mandating rabies prophylaxis are bizarre and reveal more about human nature than about rabies or bats. For example, rabies prophylaxis was initiated after a patient dunked a dead bat in his beer, chewed on the bat's ear, and then drank the beer.^[51] In a similar case, prophylaxis was needed when a miner swallowed a live bat on a bet.^[18] Most bats have small teeth that often cannot penetrate human skin, so the risk of bacterial wound infection is low.

PRIMATES

Monkeys and other primates inflict vicious bites that virtually always become infected, despite use of prophylactic antibiotics.^[54] Although in developed countries this is largely an issue for laboratory workers, in tropical undeveloped countries, large apes (such as baboons) are not only common, but often aggressive. Weighing up to 90 pounds, a large baboon can be dangerous and lethal. These animals have frequent contact with humans and lose most fear of them. There have been numerous recent reports of packs of wild monkeys driven out of the jungle by hunger attacking humans who get in the way of food sources.^{[112] [116] [123]}

Monkeys often bite hands and have been known to amputate parts of fingers. A literature review revealed 132 cases of simian bites in which *Bacteroides*, *Fusobacterium* species, and *Eikenella corrodens* were isolated from some of the wounds.^[54] Three victims of simian bites with infected wounds grew diverse bacteria, including β -hemolytic streptococci, enterococci, *Staphylococcus epidermidis*, and *Enterobacteriaceae*.^[54] At the present time, simian bites should be considered relatively high risk and treated as if they were human bites.

Old World macaque monkeys (rhesus macaque, cynomolgus, and other Asiatic macaque monkeys) are often infected with simian herpes virus (B virus); transmission to humans is rare but the risk is real, especially for animal control and laboratory workers.^{[40] [98]} As with rabies, local wound treatment may be important; of 61 persons bitten by probably infectious monkeys and who received wound cleansing with cetrimide and iodine solution, none became infected.^[129] See [Chapter 44](#) for additional information.

The wild gorilla, despite its reputation and appearance, is shy and avoids humans. Although it may charge in defense, it seldom attacks and can be easily confronted and forced to retreat. When a gorilla attacks, it takes one bite and runs. In Africa, gorillas are responsible for two or three attacks per year, none of which are fatal and few of which are severe. Chimpanzees occasionally attack humans, usually only if provoked or cornered. Rare instances of chimpanzees eating children and women have been reported. The baboon is responsible for one to two attacks per year, almost all in South Africa; these are usually by pets. Occasionally, man eating has been reported. The incidence of hunting and meat eating by these animals has increased over the last century, perhaps paralleling the evolution of humans into hunters and meat eaters.^[27]

COYOTES, WOLVES, AND HYENAS

The coyote has not only survived the onslaught of civilization in the United States, but has thrived and multiplied. Perhaps as a result, more and more coyote attacks on people have been reported, even in urban areas such as Los Angeles and Cape Cod.^[8]^[22]^[64] Occasionally, these animals are rabid, but most are not. Some attacks (especially on small children) are fatal.^[69] Recently, there has been an increase in reports of attacks in national parks by animals captured and found to be disease-free.^[22]^[65] The bite of a coyote should be treated as a dog bite regarding antibiotic and closure issues; if the animal cannot be captured and examined, rabies prophylaxis should be undertaken.

No significant problems or killings by wolves have been reported in North America, where wolves are traditionally timid. However, throughout Europe and Asia, the wolf has a well-documented history of cunning behavior, pack attacks, and human killing. European wolves tend to hunt in packs and attack women and children. Rabid wolves are seen; a substantial number of attacks by rabid wolves in Iran in the last 10 years provided the clinical population on which the human diploid cell vaccine for rabies was tested.^[10] The reintroduction of wolves to wild habitat in the Yellowstone ecosystem and Idaho in 1995 has resulted in the successful proliferation of many new wolves. However, there has not yet been a negative human interaction since their release.^[58]

Two other canines that traditionally hunt in packs are the cape hunting dog of Africa and the Indian "devil dog." Although both are feared in their respective environments, they are not deliberate attackers of humans.

Hyenas have tremendously strong jaws and can leave teeth marks in forged steel. The hyena frequently attacks humans in Africa. In certain areas, Africans leave the dead or dying in the bush for predators (hyenas) to eat, which accustoms the animals to the taste of human meat. Hyenas forage around campsites and villages and are wary of awake people. During the summer months when Africans sleep outside their huts, many are assaulted with one clean, massive bite that removes the face or the entire head. Young children have been dragged from their huts while sleeping when a family member leaves briefly without latching the door, and it

is common for the hyena to injure or amputate the thumb of a sleeping victim as it drags the victim (by the thumb) to a more convenient place for consumption.^[1] Campers are also frequently bitten on the face or limbs while they sleep at night, particularly if they have left food nearby. They usually survive but are massively disfigured. In some parts

of Africa, the hyena is a more consistent man eater than the leopard or lion.

SKUNKS, FOXES, AND RACCOONS

Skunks bite readily when captured and are frequent carriers of rabies.^[49] No data exist concerning the likelihood of other wound infections after skunk bite; in one series, only 21 bites were reported for the entire United States for a 10-year period.^[111]

A skunk's most frequent means of defense is spraying the secretions of its anal sac. A skunk ready to spray directs its hindquarters to the enemy, feet firmly planted and tail straight in the air, often stamping the front feet in warning. The spray is accurate to 13 feet and, contrary to popular belief, can be discharged when the animal is lifted by the tail.

Skunk musk causes skin irritation, keratoconjunctivitis, temporary blindness, nausea, and occasionally convulsions and loss of consciousness.^[49] The chief component of the musk is butyl mercaptan. This can be neutralized by strong oxidizing agents, such as sodium hypochlorite in a 5.25% solution (household bleach), further diluted 1:5 or 1:10 in water. The chlorine forms odorless sulfate or sulfone compounds by oxidizing the mercaptan and breaking the sulfur free from the carbon chain. This solution can be cleansed with tincture of green soap, followed by a dilute bleach rinse. Tomato-juice shampoo has been advocated for deodorizing hair, which can be washed and mildly bleached or cropped short.

Most human attacks by foxes are by rabid animals; fox bites have caused eyelid lacerations in children sleeping in tents and leg punctures in adults.^{[75] [126] [134]} One child died of rabies from fox bites despite adequate postexposure prophylaxis.^[126]

Raccoons are the definitive host of *Baylisascaris procyonis*, a zoonotic nematode parasite that may cause larva migrans syndromes in humans.^{[75] [145]} In the United States, large raccoon rabies epizootics in New England and the middle Atlantic states are spreading. Most rabies-positive animals are taken from near private homes.^{[120] [140]} Raccoons account for more than 50% of all animal rabies in the United States.

SWINE

Although domestic pigs are common, pig bites are rare in developed countries, probably because the total number of farmers in those countries is small.^[12] Domestic swine can be aggressive and inflict deep goring or bite injuries, often on the posterior thigh because they tend to approach from behind.^[12] Wounds are deep (particularly when the boar, with large penetrating tusks, is involved), although sometimes they can be deceptively small on the surface.^[132] Carefully and thoroughly explore and debride these wounds.

Twelve percent of veterinarians have been bitten by a pig, placing it fourth in frequency behind dogs (63%), cats (81%), and horses (87%).^[78] The usual wide range of bacterial pathogens is reported, including *Pasteurella aerogenes*, *Bacteroides fragilis*, *Proteus*, and α - and β -hemolytic streptococci.^[60]^[131] Like many domestic animals, pigs often carry *Pasteurella multocida*. Unusual gram-negative bacteria have been isolated; many other poorly understood species are probably present.^[55]

Wild pigs are even more likely to inflict injury. With a population of over half a million roaming the French countryside, wild pigs cause crop loss and occasionally gore and bite humans.^[85] Swine wounds should be treated as high risk for infection, warranting broad-spectrum prophylactic antibiotics (perhaps parenterally) and close follow-up if the victim is not admitted to a hospital.

WILD HERBIVORES

African Buffalo

The African buffalo is a threat chiefly when provoked, but accounts for many deaths and maimings. Left alone, it does not attack; however, when shot or cornered, it charges, is difficult to avoid or stop, and can hook the victim 10 feet into the air with its horns ([Figure 42-4](#)). Buffalo that charge humans are usually old, solitary bulls that have left the safety of the large herds, most often because of wounds from poachers' snares, spears, or lion attacks. The buffalo is also wily and intelligent; wounded buffalo may lay in wait for trackers or may

Figure 42-4 African water buffalo with calf. (Photo by Cary Breidenthal, RN.)

996

double around and come up behind them on the trail, often with fatal consequences for the humans. The buffalos' hatred of hunters is legendary in Africa; one hunter was treed but could not get his feet high enough to keep them clear of the animal. The buffalo repeatedly hooked the man's feet with his horns, eventually cutting them to ribbons so that the hunter bled to death, still hanging in the tree. In another anecdotal series, a single buffalo injured several humans in one day; all of the wounds were impaling injuries through the anus.^[4]

Once the victim is prostrate, the buffalo gores into the ground with its horns and the heavy horny boss across its forehead and then whips its head from side to side, disemboweling the victim with the sharp horn tips. Such injuries are estimated to be responsible for 20 to 100 deaths per year, mostly in Africa. The horns are always covered with mud, so goring wounds may be heavily contaminated. However, victims who do not have major traumatic injuries generally do well.^[119]

American Bison

Brought back from the brink of extinction, a free-ranging herd of more than 3000 North American bison (American buffalo) now lives on land in and around Yellowstone National Park and is responsible for an average of three tourist injuries per year. Fifty-six injuries and three deaths were documented from 1975 to 1993 in Yellowstone as a result of bison-human interaction.^[30] ^[31] Despite warnings to avoid approaching these animals any closer than 25 feet, most attacks involve close human approaches to obtain photographs. The mechanism of injury in bison attack is usually penetrating injury, with punctures from goring by horns and blunt injury caused by being tossed in the air and falling or being butted by the animal's massive head. Goring injuries most frequently involve the buttock or posterior thigh as the victim turns away from the bison to flee.^[30] ^[31] Gored abdomens and evisceration have been reported. Despite the inevitable contamination of these deep punctures, wound infection is rare if careful operative irrigation and debridement with closure are combined with broad-spectrum prophylactic antibiotics (cephalosporins were used in most cases in one series of reported injuries).^[30]

Elephant

The elephant can be one of the most dangerous wild animals and was until recently probably the greatest killer of hunters. The annual death toll in central Africa was probably between 200 and 500.^[27] In defense of the elephant, most injuries occur when humans accidentally approach elephants too closely, which the animals interpret as a threat. However, elephants turn rogue from time to time, deliberately attacking and killing humans ([Figure 42-5](#)). The incidence of such deaths might decrease as the world becomes progressively less wild, but as humans and elephants compete for the

Figure 42-5 African elephant bluff-charges the photographer. (Photo by Cary Breidenthal, RN.)

same space and humans despoil and devastate the forests, it may also increase. In Sri Lanka, for example, such encounters force some families to sleep in trees, and at least four people a year are killed by elephants in one area with a human population of only 25,000.^[5]

Elephants kill by trampling, goring with the tusks, or striking or throwing with the trunk. Once the victim has been run over or skewered with the tusks, the elephant kneels on them and crushes them. Elephants have been known to use weapons in their attacks; a villager who retreated safely up a baobab tree was hit by a tree branch the bull elephant picked up in its trunk and used as a club. Elephants frequently rip the victim's body apart and scatter the pieces, later covering them with grass and branches. Another elephant tactic is to toss the victim into the trees or straight over the pachyderm's back; a number of victims have survived this experience. Some hunters pursued by elephants

have diverted them by throwing off items of clothing.

Many rogue elephants seem to be injured; others have become intoxicated by eating fermenting marula berries. Persistent hunting has made the elephant more wary and irritable than it was 100 years ago. Its traditional feeding and migration ground is increasingly invaded by farmers, leading inevitably to negative interactions. The elephant is incredibly destructive of plants and trees, and its future in this escalating conflict is in grave doubt. A few rare stories suggest that an elephant may actually be a man eater; one of these occurred in 1944 at the Zurich zoo. Elephants captive in zoos and circuses may cause deaths while temporarily deranged; since 1990, captive elephants have killed 39 and injured more than 100 humans worldwide.^[105]

Hippopotamus

The hippopotamus is a frequent killer in Africa. Its placid and indolent appearance in zoos completely belies its activity and personality in the wild.

997

A hippopotamus can run at speeds of up to 45 mph on land and is relatively unpredictable and made irritable by people. It will attack boats and people in the water if it feels trapped (e.g., between a boat and deep water) or if its calf is threatened. With its large canine teeth, it can chop canoes (and the people in them) in half, and it does so several times a year on the Zambezi River in Zimbabwe. However, these attacks are usually in self-defense, and a hippopotamus will get out of the way if it can. Hippopotamuses graze on land and habitually run along established narrow tracks back to the river, mostly at night but also in the day. They will not change course for anything, and humans who make the mistake of staying in the tracks may be trampled.

Moose

Moose are large and potentially aggressive animals, especially during fall rutting and spring calving seasons. When moose are fed by humans, they become more aggressive when food is no longer available.^[3] Moose are difficult to chase away, but it is easy to flee from a moose to a larger shelter. If the rump hairs are raised, the ears are laid back, or the moose is licking its lips, it is likely to charge. The subject of the attack should get behind a large solid object for protection. If knocked to the ground by a moose, a victim should roll into a ball, protecting the head with hands and arms and remaining still until the moose leaves.^[3] A man was killed in 1995 by a moose in urban Alaska when he approached a cow with a calf who had been harassed by students throwing snowballs.^[97] Moose consider dogs predatory and will attack and kill dogs without other obvious provocation.

Most human injuries caused by moose result from moose-motor vehicle collisions, which are quite hazardous in New England and in Sweden.^{[19] [44]} In a New England report, an average of two persons per year are seriously injured when their vehicle

strikes a moose, usually after dark; 70% of those injured had head and facial injuries, and 26% had cervical spine injuries. The mortality in this series was 9%, and morbidity declined with use of seat belts and rear seat location.^[44]

Deer and Elk

The deer population is burgeoning in parts of the United States, and as a reservoir of the tick that carries Lyme disease, it may be credited with the increasing incidence of human Lyme disease.^[93] Block Island, an 11-square-mile island off Rhode Island that reintroduced one buck and 4 does to its area in 1968 now has a herd of over 1000 animals and has recorded 45 cases of Lyme disease in residents over the past 9 years. In addition, residents have been attacked by deer in their own yards.^[93]

Deer rarely attack humans, but deer-motor vehicle collisions are quite common in densely populated areas. One deer jumped through a window of a law office, injuring an attorney,^[7] and another buck in rut carried a man in its antlers for 45 minutes, then pinned the man on the ground until he was rescued.^[17] A child was gored by a startled buck when he was feeding the animal; the antler penetrated the axilla, lacerated the pulmonary artery, and caused death by exsanguination.^[43] Deer may bite, and like other ungulates may carry *pasteurella* as oral flora.

Similar to moose, bull elk may attack humans when in rut and cows may attack by butting and stomping when protecting their young.^[103] Up to 1% of elk sampled in one study carried *Brucella abortus* and *Mycobacterium bovis*.^[113]

Rhinoceros

The black rhinoceros has been represented as one of the meanest animals in Africa because it charges any moving object, including trains. The click of a camera, a gentle movement, or a scent is enough to induce a charge. Because the rhinoceros has poor eyesight but excellent hearing, it may well be running toward sounds to investigate them. Contrary to the popular belief that because of its nearsightedness it can be easily sidestepped, the rhinoceros can turn on a dime.^[27] At the end of its charge, it usually hooks right and left with its horns and is generally satisfied with tossing the victim high (12 feet) in the air. However, like so many large wild animals, it probably does not desire confrontation. Rhinoceroses often flee once they have identified a sound as originating from something dangerous (such as a human), and persons who have fallen while running from a charge have been investigated with a few typical snorts and then ignored. However, severe injuries can result if the human fails to get out of the way of a rhinoceros. As with the hippopotamus, injuries and death may have more to do with being in the path of a very large, fast-moving object than with malicious intent. The white rhinoceros is docile and has killed few, if any, people.

Other Wild Herbivores

Other wild species, such as the giraffe, may turn rogue, but this is exceedingly rare. The black wildebeest has killed one or two zookeepers, as have the spiral-horned kudu and

bushbuck. Other antelopes have killed or wounded hunters or zookeepers with their sharp horns.

MARSUPIALS

Opossum

The American opossum (*Didelphis virginiana*) inflicts bite injuries both when hunted for food and when accidentally provoked while handled in captivity. Aerobically cultured organisms from the mouths of seven

998

wild opossums included streptococci, coagulase-positive and coagulase-negative staphylococci, *Aeromonas* species, *Citrobacter freundii*, *E. corrodens*, and *Escherichia coli*.^[64] No literature is available on the bites themselves.

Quokka

One of the smallest of the wallaby family residing in western Australia, the quokka typically bites only humans who attempt to feed or pet the animal. Bites tend to occur on the finger or hand. Despite the presence of mixed coliform bacteria in quokka mouth cultures, the incidence of bite-wound infection in this series was zero.^[87]

VENOMOUS MAMMALS

Only two types of venomous mammals are known. The short-tailed shrew (*Blarina brevicauda*) of the northeastern United States secretes a protein venom from its maxillary gland and injects it with the lower incisors. The venom may cause edema, a few days of burning sensation, and pain lasting up to 2 weeks.^[23] No specific antivenin is available, and treatment is symptomatic. No bites have been reported since the 1930s. A similar venom is possessed by the European water shrew (*Neomys fidiens*) and the primitive Cuban insectivore (*Solenodon paradoxus*).^[21] Documented bites are exceedingly rare.

A second type of venomous mammal is the male platypus (*Ornithorhynchus anatinus*), which injects venom from a hollow spur in its hind leg. This venom appears to resemble viperine snake venom and causes local pain, edema, and lymphangitis.^[21] The pain can be excruciating and completely unresponsive to intravenous narcotics. Regional nerve block has been reported to be effective in combination with limb immobilization.^[45] Localized edema also occurs; no specific treatment is available, and the exact pathophysiology is unknown. Functional recovery may be delayed for up to 3 months.^[53] The echidna, or spiny anteater, possesses a similar spur and venom, but envenomation has not been reported.^[49]

LARGE BIRDS

The ostrich is responsible for one to two deaths per year, mostly in Africa, where it is raised commercially ([Figure 42-6](#)).^[6]^[27] Most of the fatal attacks are kicks to the head and abdomen. The ostrich can kick only forward, but when it does, a sharp toenail flicks out like a switchblade and can penetrate the abdomen. Because the ostrich can easily outrun a human being, the only protection is to lie prone to protect against disembowelment and to cover the neck to protect against pecks. Eventually, the ostrich loses interest and allows the victim to escape.

Figure 42-6 African ostrich. (Photo by Cary Breidenthal, RN.)

The cassowary (common in New Guinea) can easily disembowel a hunter with a single kick from its long, sharp toe claws.

Birds of paradise have been found to secrete a venom on their feathers, although cases of human toxicity from this have not been reported and the phenomenon is little studied.

The emu is a large flightless bird native to Australia that may weigh 100 to 150 lb. It is usually docile, but when cornered or frightened may lacerate a human handler by kicking.^[68]

LARGE REPTILES

The Nile crocodile accounts for 1000 human deaths per year in Africa.^[27] Individual crocodiles have been responsible for up to 400 deaths. Most attacks take place in the water, where crocodiles are accustomed to scavenging for the dead, sick, and deformed human babies that are tossed into the water to be disposed of by these reptiles. The crocodile has tremendous grip strength and locks this grip by slotting two lower teeth into holes in the upper jaw. When a crocodile is unable to drag the victim completely underwater, it may grasp a limb and then spin over until the limb is detached.

In a 10-year period in Australia, there were 16 attacks and four fatalities caused by crocodiles; most victims were swimming or wading at night, and alcohol ingestion was present in half.^[89] Wound infections with *Aeromonas hydrophila*, *Pseudomonas pseudomallei*, *P. aeromonas*, and *Proteus*, *Enterococcus*, and *Clostridium* spp. were reported in 6 of 11 survivors in this series.^[116] In Malawi, over a period of 4 years, 60 victims were admitted to hospitals after injury by crocodiles; (40%) had serious injuries resulting in permanent deformity, and one person died from sepsis.^[133]

The American alligator is thriving in the southern United States, and its habitat is so greatly threatened

by human expansion that incidents of alligators appearing in suburban backyards and swimming pools are now common. Attacks on children and pets are increasing, with 127 attacks and five deaths reported in Florida from 1973 to 1990.^[63] The alligator causes crushing injuries to the torso and open extremity fractures, and may roll underwater with the victim, resulting in drowning. Blunt trauma may result from a strike by the animal's massive tail. Prevention of alligator attacks includes avoiding touching or feeding the animal or swimming at feeding time (dusk) with a dog or in waters with heavy vegetation.^[31]

MEDICOLEGAL CONSIDERATIONS

In some cities and regions, animal bites must be reported to public health authorities. Reporting suspected exposure to rabies is mandatory in most regions, and failure to report could become the basis for legal action. Reporting often leads to examination of the offending animal by public health authorities and sometimes to quarantine or destruction of the animal.

Although most wild animals by definition do not have an owner, some exotic species are kept as "pets." An owner's failure to meet local regulations regarding licensure and vaccination can lead to legal action. In addition, the victim may seek compensation from the owner of the animal, with the result that the health care provided and the medical record will be reviewed in court. The injury may be related to the victim's employment, generating worker's compensation or other insurance claims. Therefore injuries and their circumstances should be documented as fully as possible, with line drawings or photographs added to the medical record whenever possible. Certain types of animal bites, particularly those of the hand, are prone to infection and can lead to permanent, litigation-associated complications. A complete medical record is the best protection against such issues and the more ordinary matter of malpractice claims made against the health care provider.

Chapter 43 - Bear Attacks

Steven P. French

Bears are one of the most widely distributed animals in the world. At least one of the eight bear species currently exists in Asia, Europe, North and South America, and the Arctic ([Table 43-1](#)). Bears in Africa became extinct several million years ago. Australia and Antarctica are the only continents where bears have never existed. The koala bear of Australia is a marsupial and not a true bear.

Bears also occupy a wide variety of habitats, including tropical forests, polar ice sheets, swamps, barren ground tundra, bamboo jungles, alpine meadows, and coniferous and deciduous forests. Their range extends from sea level up to about 6100 m (20,000 feet).

Bears are carnivores. Although some bear species practice specialized feeding in response to their habitat, all bears are also omnivores and retain the ability to feed on a variety of food types, including vegetation, insects, and meat.

Modern bears have larger brains than their extinct ancestors,^{[22] [30]} and the relative brain size for bears is larger than that of other carnivores.^[14] This greater brain size probably resulted from a need to increase sensory and perceptual capacities for locating an omnivore food base with both seasonal and annual variations in distribution and abundance.^{[5] [8] [25]} The larger brain size reflected the increased intelligence required by bears to develop a complex foraging strategy. Increased intelligence also allowed them to develop individual behavior, shaped by both experience and memory. Thus they possess a wide variety of behaviors and have been described as playful, lazy, doleful, entertaining, intelligent, caring, powerful, aggressive, terrifying, and vicious.^[33]

The image of bears as "man-eaters" ignites our fear of them. Human injury and deaths from natural phenomena, especially wild animal attacks, are sensationalized. Bear attacks are rare, but the psychologic impact of widespread media coverage inflates their frequency and significance.^{[6] [24]} Every bear attack is traditionally referred to as a *mauling*, regardless of the extent of injuries. This term contributes to the emotional response regarding such attacks and leads to "bearanoia" in many people who visit bear country. This fear of bears may affect how people use wilderness areas with bear

populations and how they view the conservation of bears and their habitat. Better understanding of bears and their behavior helps reduce bear attacks, assists physicians in treating bear attack victims, and promotes conservation of bears.

NORTH AMERICAN BEARS

Grizzly bears (*Ursus arctos horribilis*) are larger and more heavily built than most other ursids, with adults weighing 146 to 383 kg (325 to 850 pounds)^[4] ([Figure 43-1](#)). Polar bears (*Ursus maritimus*) are similar in size and weight but are more elongated in shape ([Figure 43-2](#)). Black bears (*Ursus americanus*) have the same general shape of grizzly bears but are generally smaller than both polar and grizzly bears ([Figure 43-3](#)). Weights for black bears range from 63 to 135 kg (140 to 300 pounds) for adult females and 113 to 293 kg (250 to 650 pounds) for adult males.

Dentition in these three species is bunodont and reflects their omnivorous diet, although polar bears are the most carnivorous of the three ([Figure 43-4](#)). Their canine teeth are sturdy and can reach a length of 7 cm (2 $\frac{3}{4}$ inches). Their legs are of approximately equal length and taper to large, plantigrade feet. The fore claws of a grizzly bear are heavier, longer, and straighter than those of a black bear and can reach a length of 8.75 cm (3 $\frac{1}{2}$ inches) measured along the external curvature^[35] ([Figure 43-5](#)). A large muscular hump overlies the scapulae of grizzly bears, giving additional strength to the forelimbs for digging ([Figure 43-6](#)). The face of a brown bear tends to be more dish shaped than that of a black bear ([Figure 43-7](#)).

The physical strength of bears is tremendous, and they can run at speeds up to 65 kph (40 mph) over irregular terrain. They have a keen sense of hearing and an even keener sense of smell. Their eyesight has been described as poor,^[19] although many field researchers believe that bears can see as well as humans and are especially adept at detecting movement. Evidence suggests grizzly bears have good night vision.^[11]

Grizzly and black bears hibernate about 5 months during the winter, an evolutionary adaptation to reduced food availability. The hibernation of polar bears is slightly different, since their primary food (seals) is available during the winter.^[28] Adult male polar bears tend to hibernate for short periods each winter in response to severe storms, whereas pregnant females have more extended hibernation. During the active (nondenning) season, all bear species wander throughout a general home range in search of seasonal foods.

The guard hairs on brown bears can be lighter in color and lend a "grizzled" appearance. Black bears can be many colors, ranging from white to black, cinnamon, brown, or "blue."^[9]

TABLE 43-1 -- Distribution of Bear Species

COMMON NAME	SCIENTIFIC NAME	DISTRIBUTION
Panda bear	<i>Ailuropoda melanoleuca</i>	Eastern rim of China's Tibetan Plateau
Spectacled bear	<i>Tremarctos ornatus</i>	Andes Mountains in South America
Sloth bear	<i>Melursus ursinus</i>	Nepal, Bangladesh, Bhutan, northern India, Sri Lanka
Asiatic black bear	<i>Ursus thibetanus</i>	Southern Asia from Pakistan across northern India and into China and southeast Asia; separate populations in eastern Russia, Korea, Taiwan, and Japan
Sun bear	<i>Helarctos malayanus</i>	Borneo, Burma, Java, Malaysia, Sumatra, Thailand
American black bear	<i>Ursus americanus</i>	Alaska, Canada, most of lower 48 states
Brown bear	<i>Ursus arctos</i>	Eurasia, Alaska, Canada, northern Rocky Mountain states (including Wyoming, Montana, Idaho, and Washington)
Polar bear	<i>Ursus maritimus</i>	Arctic circle (circumpolar)

Grizzly Bears

The grizzly bear symbolizes wilderness in North America. In certain respects, "grizzlies" define the "wild" in wilderness. They range from Alaska down through western Canada and into the lower 48 states in remnant populations located in relatively undeveloped

Figure 43-3 American black bear. (Courtesy Marilyn G. French.)

Figure 43-4 Grizzly skull, demonstrating canine teeth. (Courtesy Marilyn G. French.)

federal lands, primarily in the northern Rocky Mountains.

Attacks by grizzly bears are relatively rare and sporadic. A total of 162 bear-inflicted injuries (including deaths) were reported from 1900 through 1985 in Canadian and North American national parks.^[19] ^[20] From 1980

1004

Figure 43-7 Silhouette of brown bear, demonstrating hump and "dished" face.

(Courtesy Timothy Floyd.)

to 1994, 21 grizzly bear attacks, including two deaths, occurred in Yellowstone National Park.^[18] In Alaska the number of people injured by grizzly bears in recent times,^[26] possibly from increased recreational use of grizzly habitat, will probably be maintained.

Calculation of an accurate injury rate remains elusive. Earlier records were incomplete, and defining and quantifying those at risk have always been difficult. Injury rates are based on total visitation days to the national parks in Canada and North America.^[20] The average number of grizzly bear-inflicted injuries is 1 in 2,260,276 visitors to these parks combined, with a high of 1 in 317,700 visitors in Kluane National Park and a low of 1 per 6,693,859 visitors in Banff. During this same period the grizzly bear-inflicted injury rate for Yellowstone National Park was 1 in 1,543,287 visitors and for Glacier National Park was 1 in 848,180 visitors.

Not every visitor to a national park is exposed to the same risk of being attacked by a grizzly bear. To calculate an injury rate more accurately for visitors with higher and more uniform exposure, similar rates are reported based on registered backcountry users. However, this method provides an inaccurate injury index because some parks do not register backcountry use and others generally underestimate it. Also, significant and perhaps most backcountry use (and therefore exposure) is by unregistered day hikers.

The number of bear attacks (both black and grizzly) increases in months when more people seek recreation in grizzly country. For national parks the incidence of bear attacks increases during the peak tourist season, July and August. For surrounding national forests another peak occurs during hunting season, September to November. With more people seeking recreation in bear country, greater opportunity exists for human-bear encounters.

Native peoples and grizzly bears occupied the same land for thousands of years in North America in what was probably a neutral coexistence, since neither had a profound influence on the other. However, the European expansion into the west after Lewis and Clark's expedition in the early 1800s tipped the scales heavily in favor of humans, both in sheer numbers and in technology, such as guns, traps, and poisons. Bears were killed in large numbers to appease fear and hatred and to protect life and property. Most of their original habitat was occupied by either people or livestock or was dramatically altered by ranching and agricultural development.

Selection pressures that began with European expansion into the grizzly bears' habitat has probably been altering their behavior. Since that early period and even today in

protected areas such as national parks, aggressive bears have been removed at a higher rate than nonaggressive bears. Bears that were curious

1005

Figure 43-8 Yellowstone grizzly sow with cubs. (Courtesy Brian Ertel.)

about humans and human developments and those that did not readily flee the presence of humans were also removed at a higher rate. Therefore bears that avoided humans survived at a higher rate than other bears and probably passed that trait on to their offspring through genetics and learning.

A built-in safety factor exists for people entering grizzly country because the vast majority of bears now avoid a confrontation if given the opportunity, which probably explains why grizzly bear attacks on humans are so rare. Unfortunately, the available information on grizzly attacks does not always yield an accurate account of the cause-and-effect relationship. The specific sequence of events is not always known and is subjectively reconstructed, although case histories reveal certain patterns.

A sudden and close encounter with a grizzly bear is the primary event leading to human injury. From 1980 to 1994, of 21 people injured by grizzlies in Yellowstone National Park,^[18] 18 resulted from people surprising a grizzly at close quarters. These attacks were often brief, and the bear generally left the area soon after the attack. Although injuries were typically described as a mauling, they were generally much less severe than the bear had the potential to inflict, and victims were rarely killed. This suggests that the bear's behavior in response to a close encounter was to remove a perceived threat.

A close encounter with a female with cubs is considered more dangerous, since she is considered to be more aggressive in defense of her young ([Figure 43-8](#)). Evidence to support this hypothesis is strong. Females with young represent about 20% of a bear population but account for more than 80% of the bears that injure humans. Another explanation, however, is that females with young are more likely to be active during daylight hours when humans are active, whereas males are active primarily in the predawn hours and after dusk.^[11]

Grizzly bear attacks sometimes occur near a carcass on which the bear has been feeding. Grizzly bears may be more aggressive under these circumstances in defense of the carcass. Grizzly bears of all ages and either gender, however, may readily exit when they sense people approaching.^[12] When grizzly bears injure someone near a carcass, the precipitating event may simply be a close encounter with a preoccupied

bear.

Another class of attacks results from provocation, most often when a grizzly bear is shot. Once the bear is injured, its behavioral response is no longer to remove a threat but to fight for its life. These attacks tend to be more prolonged and aggressive, resulting in more severe injuries than those a resulting from a close encounter.

Provoked bear attacks can result from direct harassment by aggressive photographers. Although such incidences are rare, these attacks tend to resemble the response of an injured bear rather than one responding to a close encounter. The injuries tend to be more severe, and a disproportionate number of photographers are killed. Up to 1985, at least 10 photographers were injured, one fatally, and from 1986 to 1992, at least four were injured, two fatally.^[19]

Most people attacked by grizzly bears are injured but not killed; the intent of the bear is simply to remove a perceived threat, not to prey on the individual. From 1900 to 1979, 19 human deaths resulted from grizzly attacks documented in the national parks in North America, and 22 deaths occurred in Alaska outside the parks.^{[19] [24]} Some were victims of defensive attacks and probably would have survived if current medical management techniques had been available. Some deaths, however, resulted from predatory attacks. The question is why grizzlies do not prey on humans more often. As a potential prey species, humans are predictable and abundant, easy to catch and kill, and easy for a grizzly to consume.

Little historic evidence suggests that grizzly bears routinely preyed on humans except in unusual circumstances. In 1860 a smallpox epidemic struck a small band of Stonie Indians (Assiniboin Tribe) camped in the Yarrow Creek drainage in Alberta, Canada.^[32] Grizzlies began scavenging on the dead left on the ground as the tribe moved to the next drainage. Grizzlies followed them to their next encampment and began preying on survivors. For years the Indians avoided this area for fear of being eaten by grizzlies that had "learned" to prey on humans.

Since about 1900, when reasonably accurate records were first kept predatory attacks on humans by grizzly bears generally have been rare, sporadic, and isolated events.^{*} However, a disturbing trend has begun in recent

*References ^[16] ^[26] ^[27] ^[32] ^[36] ^[37] .

times. Between 1967 and 1986, 12 deaths were inflicted by grizzly bears in Banff, Glacier, and Yellowstone National Parks. In each case the bear was conditioned to human foods (regularly seeking out and obtaining it) and/or habituated to human presence (not readily fleeing). Nine of the victims were partially consumed, and eight deaths were classified as predatory events.^[19] During this same period, however, many bears with these same behavioral traits did not prey on humans. Conditioned and habituated behavior may predispose some grizzlies to prey on humans within their

image under certain but still unknown circumstances. The relationship between conditioning and habituation appears strong but is not conclusive. The bear involved was not always known, and the terms "conditioned" and "habituation" are borrowed from learning theory and have never been precisely defined by wildlife biologists. This potential relationship, however, has significantly influenced grizzly bear management. The primary thrust currently is to prevent bears from obtaining human foods and from routinely being around people and human developments.

Grizzly bears may also mistakenly perceive a person as one of their normal prey species. Five such incidents have been documented. Two victims were killed by grizzly bears while making prey calls to lure in other predators. Two victims were attacked while field-dressing a game animal, and the fifth was attacked while carrying the hide of a deer draped over his shoulder. Clearly, persons should not look, smell, or sound like a prey species when in grizzly country.

Black Bears

Black bears are the most numerous and widely distributed of all North American bears (see [Figure 43-3](#)). They occur in more than 30 of the lower 48 states, from Maine to Florida and from California to Washington. They also occur throughout Canada and Alaska, extending up to treeline below the Arctic Circle. They are well adapted to an arboreal habitat and prefer to eat vegetation, carrion, and mast (nuts, acorns), with small mammals and insects accounting for less than 5% of the diet.^[9]

Between 1960 and 1980, more than 500 people were injured by black bears, but at least 90% of these episodes resulted in minor scratches or bites inflicted by bears that were either conditioned to human foods or habituated to human presence.^[19] Injuries as a result of close encounters are extremely rare, and in contrast to female grizzly (brown) bears, female black bears display little aggression in defense of their young and rarely cause injury. They have short, sharp radial claws better adapted for climbing trees than for attacking humans. They will often retreat rather than attack, even in defense; thus hunters using dogs can "tree" black bears.^[9]

Whereas grizzly (brown) bears sometimes prey on humans at night, black bears occasionally prey on humans during the daytime. From 1900 through 1980, 20 people were killed by black bears, with predation considered the motivation in 18 cases. All but one case occurred in remote areas outside park boundaries, an indication that neither conditioning nor habituation was a major factor.

Since 1985, black bears attempted to prey or preyed on humans in 15 episodes, with two fatalities and 7 major injuries.^[19] Details are scant, but at least four occurred at night while the victims were asleep. In one case the bear broke into a camper and pulled the victim out, and in another case the bear entered a wooden teepee ("wickiup") and dragged the victim out by her foot.^[29] In most attacks, the black bears were driven away by aggressive actions by the victims and their companions, such as yelling and throwing objects.

POLAR BEARS

Polar bears are distributed in a circumpolar fashion around the Arctic Circle and subsist almost exclusively on a diet of seals ([Figure 43-2](#)). These bears feed primarily in winter on ice-covered polar seas. Some southern populations live on land during the summer in a state of waking hibernation and starvation. Polar bear-inflicted injuries are much less frequent than those by grizzly (brown) or black bears, primarily because of their remote and harsh environment with relatively little human intrusion. From 1973 to 1987, three people were injured (one fatally) in Norway,^[15] and from 1965 to 1985, 20 people were injured (six fatally) by polar bears in Canada.^[20] The number of injuries would probably be much higher except that most people in polar bear habitat are armed, and in the majority of aggressive encounters the bear is killed before causing injury.

Polar bear-inflicted injuries have been classified into two general categories. The major one is predation, primarily by subadult and adult males. In these instances, five of the six victims who died were probably killed instantly. The other category is injury by adult females thought to be defending their young. These episodes are typically brief and nonfatal, which supports the theory that the bear is removing a perceived threat. In more than 90% of aggressive encounters with polar bears, an attractant, such as food, garbage, or carcasses, was considered contributory.^[20]

BEARS ON OTHER CONTINENTS

The available data on attacks by bears on other continents are much less complete than those for North American bears. In Europe the brown bear has coexisted with humans much longer than those in North

1007

America. (In some parts of North America the brown bear is called a grizzly bear, but they are genetically the same species.) As a result, its behavior is less aggressive and more like that of black bears. Numbers of European brown bears are extremely low, and the animals are highly cryptic and nocturnal and thus are rarely seen or encountered. Human injury by brown bears in Europe today is almost nonexistent.

The brown bears in the former Soviet Union live in vast, relatively undeveloped areas and appear to have aggressive responses against humans similar to those of North American brown bears. Many human injuries from brown bear attacks, including deaths, may be related to bears injured by sport hunters.^[4]

The panda bear (*Ailuropoda melanoleuca*), commonly known as the giant panda, lives in the temperate climate of the bamboo jungles distributed along the eastern rim of China's Tibetan Plateau. It is one of the most recognized bears in the world, with a distinctive white and black coloration. It is a relatively poor climber but will climb trees on occasion to avoid danger. During winter months the panda bear migrates to lower elevations where food remains plentiful, thus avoiding the need to hibernate.

The panda bear is primarily a vegetarian. About 99% of its diet consists of stalks, leaves, and shoots of only two bamboo species.^[33] The panda has an enlarged wrist bone that serves as an opposable digit, much like a thumb. This evolutionary adaptation enables the panda to efficiently hold and strip bamboo stalks. Since bamboo is a poor-quality food, the panda must compensate by eating large amounts. Each day it feeds up to 12 hours. The panda bear is shy and reclusive, representing minimal threat to human safety in the wild.

The spectacled bear (*Tremarctos ornatus*) lives in the tropical climates of the Andes Mountains along the northwest border of South America. It is one of two bear species that live below the equator. The spectacled bear has a distinctive white coloration around its eyes. It is an excellent climber and spends most of its time in trees eating fruit. It often builds nests and rests in trees as well. Because its source of nutrition is

abundant year-round, it does not hibernate. Spectacled bears are relatively small and shy. Encounters are extremely rare, and they pose very little threat to human safety.

The sloth bear (*Melursus ursinus*) lives in the subtropical forests of Nepal, Bangladesh, Bhutan, India, and Sri Lanka. It has a disheveled appearance because of its long, shaggy fur coat. In some of its range the sloth bear coexists with elephants, wild boars, leopards, tigers, greater one-horned rhinos, and Asiatic black bears.

The sloth bear is a special type of insectivore called *myrmecophagous* because it feeds primarily on ants and termites. It is uniquely adapted for this feeding behavior. Without the two upper incisors and with an elongated and raised hard palate, mobile lips, and nearly naked snout, the sloth bear can blow away dust to expose termites and create a strong sucking force to feed. It can dig out insect burrows with its long claws, and its coat protects it from insect stings.

Although the data are limited primarily to anecdotal reports, the sloth bear appears to be the most dangerous bear species in Europe or Asia, next to the Russian brown bear. Approximately one native is seriously injured or killed by a sloth bear in Chitwan National Park in Nepal each year.^[13] In the remote regions of western Nepal, at least one villager is seriously injured by a sloth bear every other year. Most of these injuries are the result of a close encounter, and the victims receive wounds to the head and neck. No predatory behavior has been reported.

The aggression of the sloth bear is between that of the American black bear and grizzly bear. Sloth bear researchers in Nepal work exclusively while riding elephants because of their concern about attacks from rhinos, sloth bears, and tigers, in that order.^[23]

Asiatic black bears (*Ursus thibetanus*) occupy the broad-leafed forests throughout a large portion of south Asia, from Pakistan across northern India and into China and Southeast Asia ([Figure 43-9](#)). Separate populations also occur in eastern Russia, Korea, Taiwan, and Japan. Some of their range overlaps with brown bears, sloth bears, and sun bears. In some localities the Asiatic black bear is called the "moon bear" or the "white-breasted bear" because of the crescent-shaped white coloration on its chest.

The Asiatic black bear is a dietary generalist and feeds on a wide variety of plants, insects, and animal matter. It is a good climber and often forages and rests in trees. Unlike pandas and spectacled bears, these bears hibernate during the winter months. They are hunted extensively for illegal trade of bear parts and rarely present a threat to human safety. There are in fact one to two attacks per year that result in significant injury

Figure 43-9 Asiatic black bear. (Courtesy Marilyn G. French.)

1008

Figure 43-10 Sun bear. (Courtesy Marilyn G. French.)

requiring hospitalization. Although rare, they do occur mostly as a result of a close encounter.

The sun bear (*Helarctos malayanus*) is the smallest of all bear species, rarely weighing more than 45 kg (100 pounds) ([Figure 43-10](#)). It occupies tropical regions in Borneo, Burma, Java, Malaysia, Sumatra, and Thailand. As with the spectacled bear, the sun bear is equatorial because part of its range extends below the equator. It has a white to cream-colored, horseshoe-shaped marking on its chest, providing its common name. In some localities it is called the honey bear. It has a long slender tongue, an adaptation for extracting honey from beehives. Its claws are long and more sharply curved than those of other bears, enabling it to be a proficient tree climber, where it can easily hang upside down from a branch. The sun bear is rarely seen and represents almost no threat to humans.

PREVENTION AND RISK REDUCTION

Much literature about safety in bear country involves attack victims. ^[6] ^[19] ^[20] ^[24] ^[26] Such information is gathered from victims who are generally unfamiliar with bear behavior and whose interpretations of the events reflect their cultural biases. Also, victims often become instant media celebrities. In several cases the circumstances surrounding the attack changed significantly with each telling, usually reducing the victim's culpability. Because of potential litigation, some victims have told their stories only through an attorney. Caution must be used when compiling and analyzing such "data."

Recommendations for avoiding bear attacks have been drawn primarily from what attack victims did "wrong." Because most people who live, work, and regularly vacation in bear country are never injured, it is equally important to understand what they have done "right." Unlike bear attack victims, these people have successfully navigated grizzly country without

Figure 43-11 Bear prints. (Courtesy Timothy Floyd.)

being injured. Although this information is not as readily available as attack records, it is critical to our knowledge of grizzly-human interactions.

From 1900 to 1985, 115 human injuries were reported from black, polar, and grizzly bear attacks in Alaska, but only two victims were natives. ^[26] This strongly suggests that the behavior of people is important in determining how to coexist with bears safely. Safety in bear country involves four levels of interaction: (1) avoiding an encounter, (2) reducing the chances of being attacked after an encounter, (3) reducing the severity of injuries received if attacked, and (4) reducing the chances of becoming prey to a bear.

Avoid an Encounter

The following actions can significantly reduce the chances of having a close encounter with a bear:

1. Make noise so that the bear knows a person is present. This only requires casual conversation to prevent startling a bear at close range. The voice may have to be

amplified somewhat while traveling along a noisy stream or a windy ridge. Foghorns have been used successfully in Alaska; "bear bells" may not be sufficiently loud.

2. Remain alert in bear country and be aware that the terrain and environment may hamper a bear's ability to detect a human by sight, smell, or sound. Likewise, the terrain and environment may also hamper your ability to see or hear a bear before it discovers you. An "upwind bear" is more likely to be surprised by you, as is one in heavy forestation or near loud rushing water, in the rain, or in fog.^[9] Avoid ripened berry patches, streams with spawning fish, and elk calving grounds.^[9] A collection of ravens may indicate carrion and the presence of feeding bears.
 3. Always use good judgment to avoid a potentially dangerous situation. If fresh bear signs are seen, such as tracks ([Figure 43-11](#)), droppings, tree scratchings ([Figure 43-12](#)), or a carcass (or even
-

1009

scavenger activity indicating that a carcass may be nearby), consider that a bear is in the vicinity and take an alternate route. If the bear is seen first, slowly and quietly retreat to safety; consider aborting the trip or taking an alternate route. Do not approach bears, or any wild animals, too closely for a better view or photograph.

Figure 43-13 Yawning behavior may indicate agitation in a bear. (Courtesy Timothy Floyd.)

Bear-bear confrontations demonstrate signs of aggression and annoyance. These include standing or turning in profile to appear larger and intimidating, vocal hissing and jaw popping, "yawning" ([Figure 43-13](#)), and head swinging ([Figure 43-14](#)).^[9]

Avoid Provoking an Attack

Again, the best way to avoid bear-inflicted injuries is simply to avoid surprising a bear in a close encounter situation. However, no set of known responses is guaranteed to prevent injury in a close encounter, although the following generalizations may be useful:

1. Allow the bear to know you are human and not a prey species. Step away from any visual obstruction to allow the bear to see you fully. Any attempt to hide at this point will only confuse the bear, which may approach closer to identify you, thus creating an encounter at an even closer distance. It is probably best to talk in a calm voice to allow the bear to identify you as a human.
2. Although remaining calm is difficult, do not make sudden movements or yell out, particularly with a grizzly bear. The bear may view this as an aggressive action and deal with it by an aggressive response.
3. Do not stare directly at the bear. Look to the side or stand sideways to the bear. Standing your ground is important in determining the bear's response. ^[35] This posture tells the bear you are willing to defend yourself if necessary, and it may prevent further aggressive behavior.
4. Do not consider climbing a tree or running away. Not only is it impossible to outrun a bear, but running may prevent the bear from correctly identifying a human and may initiate a charge. Once a bear charges, you cannot locate a climbable tree and achieve a safe height. Attempting to climb a tree may also prevent the bear from correctly identifying you as a human. Therefore the best defense during a charge is to stand quietly and nonaggressively, and allow the bear to identify you as human and not a prey species.

In most cases the bear aborts the charge after a close encounter without making contact or causing injury. At this point you should also leave the area, retreating opposite

to the direction taken by the bear. If a bear continues to charge, however, resulting in physical contact, your actions should depend on the species, and information from bear attack victims is useful.

Reduce Severity and Extent of Injuries

If attacked by a bear, a victim can take several important steps to minimize injury. The actions taken immediately before, during, and after an attack will influence the type and severity of the injuries.

Humans are rarely killed during an attack precipitated by a surprise close encounter, even though bears can do so easily and quickly. During these attacks, grizzlies are only trying to remove what they perceive as a threat, and their intent is to use only as much force as necessary. When interacting with others of their species, grizzly bears are head oriented, and they usually direct their aggression toward humans in the same manner—toward the head and neck. Therefore the general rules to follow during a grizzly attack are to "help" the bear remove the perceived threat and to protect vital body parts, as follows:

1. Do not run, try to climb a tree, fight, or scream.
2. Drop to the ground and protect the head and neck by interlocking the hands behind the head (ear level) and flexing the head forward, either in the fetal position or flat on the ground face down ([Figure 43-15](#) and [Figure 43-16](#)). Use elbows to cover the face if the bear turns you over.
3. Do not hold out a forearm or hand to ward off the attack. Bears can readily cause significant neurovascular injuries to these structures.
4. Never try to look at the bear during an attack because it could expose you to serious facial injuries.
5. After the attack, stay down until you are sure the bear has completely left the area. This is extremely important. Victims who have gotten up before the bear has left after the first attack generally received more severe injuries during the second one.
6. When you believe the bear has left the area, peek around while moving as little as possible, try to determine which way the bear went, evaluate options, and then leave the area.

Figure 43-15 Curling into the fetal position to defend against a bear attack.
(Courtesy Marilyn G. French.)

Victims attacked from a close encounter situation who immediately protected themselves and did not try to resist typically received minor injuries treated on an outpatient basis. Victims who tried to run or fight the bear and those who left after the initial attack but before the bear had left the area typically received more severe injuries that required multiple surgical procedures, resulting in permanent cosmetic or functional disabilities.

If the attack is by a black bear, a different set of guidelines should be followed. Black bear aggression should be countered with aggression, such as shouting, yelling,

throwing rocks or sticks, or whatever means are available. The victim should never lie down in a protective, submissive position because black bears are more likely to prey on humans they encounter at close range than are grizzly bears.

The data on polar bears are less complete but suggest that attacks by females with offspring are behavioral responses similar to those of grizzly females with offspring. The attacks are defensive, brief, and result in nonlethal injuries. In addition, the bear typically leaves shortly after the incident. If a polar bear is alone, however, a person should assume it is a male, whose behavioral response is predation, and should use any aggressive response available.

Prevent Predatory Behavior

The most important means of reducing the chance of being preyed on by a bear is to avoid anything that

Figure 43-16 Prone position to defend against a bear attack. (Courtesy Marilyn G. French.)

1011

may attract a bear to the campsite while the occupants are sleeping, as follows:

1. Avoid camping along bear travel corridors or at seasonal feeding sites.
2. Avoid campsites littered with human refuse.
3. Use proper food storage to render human food unavailable to bears.
Bear-resistant food storage containers are often provided at designated campsites in bear country ([Figure 43-17](#)).
4. Reduce food odors by cooking and eating at a site away from the sleeping area.
Do not sleep in clothes worn when cooking and eating.
5. Do not leave garbage or food buried or poured into the ground at the campsite.
This can cause problems for future campers at this site.

The chance of a bear entering a campsite to prey on humans is small, but everyone in the camp should be familiar with a contingency plan. Everyone should know the area, even in the dark, and be aware of potential escape options, such as climbable trees or rocky ledges. Everyone should sleep in a tent because it offers a boundary of protection and may deter an inquisitive bear from walking directly to the campers. Although no study has proved its effectiveness, some people build a brush barrier around the tent to

prevent a bear from readily approaching it.

Sleeping bags should be kept at least partially unzipped to facilitate a quick exit. In several instances a victim trapped inside a sleeping bag has been dragged away from a campsite by a bear.

Each tent should be equipped with a flashlight. Pepper spray is useful, as well as a firearm, unless prohibited in that area. Again, a bear that enters a tent or picks up a sleeping camper is trying to prey on that person, so all available defenses should be used.

The behavior of a predatory bear is different than that of a bear responding to a close encounter. During a

Figure 43-17 Standard government-issued bear-resistant food container.
(Courtesy Marilyn G. French.)

close encounter a bear's response is driven by a defensive reaction, which can be aggressive and injurious. In contrast, the behavior of a predatory bear is driven by the desire for food. The bear is not looking for a confrontation or fight but rather a victim to drag from camp, usually only a few hundred feet, and consume. Predatory grizzly and black bears rarely kill their victims before consuming them. They concentrate on soft tissue or visceral consumption, and the victims frequently remain alive for an hour or more. Therefore a quick, aggressive, and unified response by companions may save the victim's life. Surprisingly, yelling, throwing rocks, or striking the bear with a stick has been effective in driving the bear away from its victim. Approaching a predatory bear in the dark while it is feeding on a human is risky, but probably the victim's only chance for survival.

In contrast, the victim of a predatory attack by a polar bear is typically killed instantaneously, so prevention of such attacks is the only chance for survival. In all predatory attacks by polar bears, all defensive measures must be considered, including guns where permitted.

Special Considerations

Menstruation.

In August 1967, two women were killed in separate events on the same night by different grizzly bears in Glacier National Park. The postmortem examination showed that one had been menstruating. The assumption that menstruation may be a precipitating factor in bear attacks has unfortunately become solidly ingrained into

popular opinion. Hysterical coverage by the mass media enhanced this misconception, and the scientific question was left unanswered by both scientists and government officials.^[2]

A study of polar bear response to menstrual odors was published in 1983.^[7] Although it was not designed to adequately test the hypothesis that menstruating women were more likely to be either attacked or preyed on by bears, the press came to this conclusion. The Interagency Grizzly Bear Committee then printed an ambivalent caution in the government's official grizzly bear pamphlet (*Bear Us In Mind*) that said, "Women may choose to stay out of bear country during their menstrual period." Fortunately, this has since been removed from the pamphlet, because no scientific evidence suggests that menstrual odors precipitate grizzly bear attacks. The attack mentioned previously is the only serious attack on a menstruating woman that has been documented in North America, and even the official investigating team at that time concluded that menstruation did not appear to have played a major role.^[19]

Black bear researchers in North America report evidence of black bears attacking or being attracted to menstruating women.^[31] Furthermore, no evidence links menstruation to any of the 21 grizzly bear attacks in Yellowstone National Park from 1980 to 1994.^[18]

Sexual Activity.

A common concern among backcountry users is that sexual activity may attract bears and make them more aggressive toward campers. As with menstruation, these fears are based on hysteria and folklore. No anecdotal or scientific evidence supports this hypothesis.

Pepper Spray.

Based on a concern for protection against aggressive bears, several methods were investigated for backcountry users. In the late 1970s and early 1980s, several compounds were tested for effectiveness in deterring grizzly bear attacks. The most effective method was an aerosol spray containing capsicum oleoresin, a derivative of red pepper. Captive grizzly bears were sprayed in the face at close range when they charged the researchers outside the cage. Under these controlled conditions, red pepper spray was found to be highly effective in deterring a charging grizzly bear.

Pepper spray (5% to 10% capsicum oleoresin) is commercially available as personal protection against aggressive animals. The effectiveness of pepper spray used in the field against aggressive bears has been difficult to assess. It has been used in too few cases to draw firm conclusions. Also, it is impossible to conduct scientific studies testing the effectiveness of pepper spray used in field conditions.

By 1985, pepper spray was used in the field against aggressive black and grizzly bears

in 66 documented cases.^[21] In general, it appeared more effective in deterring bears that charged after a close encounter than against food-conditioned bears in search of food. During the 1990s, however, most professional outfitters and guides in the northern Rocky Mountains began carrying pepper spray to deter aggressive grizzly bears, preferring spray over firearms. Although data are limited to anecdotal reports, pepper spray can be an effective and nonlethal alternative to repel aggressive grizzly bears, perhaps even more effective than firearms.

Carrying pepper spray, however, is not a substitute for knowledge of bear safety and good judgment to avoid aggressive encounters. If carried, spray must always be readily available, either in a belt-mounted holster or on a chest strap. It should be test-fired, and the user should practice drawing and firing it regularly ([Figure 43-18](#)).

Despite a manufacturer's claim that pepper spray has an effective range of 9 m (30 feet), the effective range under field conditions is significantly less due to either head winds or crosswinds. Preliminary field experience indicates that the oil-based pepper spray is more effective than water-based spray. I recommend a pepper spray that contains 10% capsicum oleoresin, has 2 million Scoville heat units, and comes in a 15-ounce pressurized aerosol container.

Figure 43-18 Discharging a canister of pepper spray. (Courtesy Marilyn G. French.)

Unfortunately, people have used pepper spray similar to mosquito spray. Despite its obnoxious and caustic smell, some sprayed it on themselves, as well as their tent, their sleeping bags, and the ground around their campsite. Once the aerosol has been released, the capsicum begins to lose its potency, and soon the active ingredient dissipates. At this point, bears may investigate the smell of pepper. Pepper spray so used thus becomes a bear attractant rather than a deterrent. One manufacturer of pepper spray (UDAP Industries, www.udap.com) provides a detailed instructional pamphlet on its proper use.

Pepper spray should be aimed toward a charging bear and discharged when the bear is within 6 to 9 m (20 to 30 feet). The person should continue spraying until the bear has stopped its charge, keeping the sprayer aimed at the bear in case it charges again. This continues until the bear has left the area. If the pepper spray is depleted, the best defense if the bear attacks is to lay down, cover the face, and offer little or no resistance. Again, there is no guarantee that pepper spray (or anything) will prevent injury by an aggressive bear.

If pepper spray is accidentally discharged into a person's face, it stimulates facial nociceptors and causes eyelid, ocular, and facial muscle spasms, which may result in temporary blindness. The victim should not rub the eyes (to avoid corneal abrasions)

and should irrigate the eyes and skin vigorously with water for at least 15 minutes. Intraoral burning may be relieved by swishing and spitting milk or another casein-containing food product.^[9]

Firearms.

Many people consider carrying firearms for protection when they enter bear country. Guns can be useful in some situations. However, the target area to kill a grizzly with a shot to the head is only about 30 cm² (12 square inches). The cranial vault is narrow and sloped caudally ([Figure 43-19](#)). A bear initiating a

1013

Figure 43-19 Cranial vault of a bear. (Courtesy Timothy Floyd.)

charge from a distance of about 45 to 55 m (50 to 60 yards) will take only 4 to 5 seconds to reach its victim.

Unless a proficient marksman, a person is unlikely to access a weapon, release the safety, aim accurately, fire, and hit a small target in a brief time under incredible emotional stress. Also, even if a shot could be fired, it probably would only wound the bear. Wounding a charging bear changes its behavior and may make its attack even more aggressive. Because of these factors, pepper spray should be considered as a nonlethal alternative to guns, especially when traveling in places where guns are not permitted, such as national parks.

According to most U.S. and Canadian wildlife agencies, the most effective firearms against grizzly bear attacks are a 12-gauge 3-inch magnum shotgun with 1-ounce slugs and a 30-06 rifle with a 200-grain bullet. A pistol is not considered to be an effective weapon against a charging grizzly. A large-caliber pistol, such as a 44-caliber magnum, can be used as a point-blank weapon to kill a bear attempting to prey. The effective range of a pistol and pepper spray is about the same, but it is easier to hit a moving target with pepper spray because of its shotgunlike aerosol pattern.

Dogs.

In most national parks, dogs are not permitted in backcountry settings. Unfortunately, rare and questionable accounts report a dog stirring up a grizzly, then running back to its owner with the bear in pursuit. Most outfitters, guides, and hunters, however, report positive experiences with dogs in grizzly country. Their dogs are generally well trained

and have been raised in wilderness environments. Most of these dogs can effectively deter grizzly and black bears from coming into a camp. Although no study has been conducted on the use of dogs to deter aggressive bears, most people who spend considerable time in grizzly country use their dogs for this purpose.

Horses.

For individuals concerned about an aggressive bear encounter, another option is the use of horses. No one has been injured by a grizzly or black bear while riding a horse. Horses that frequently travel in bear country are the best to use, since they generally do not react unpredictably and endanger the rider when they encounter bears. Although horses may protect against aggressive grizzly encounters, riders still may be injured by the horse. People are seriously injured or killed in horse accidents each year in the northern Rocky Mountains.

Hunter Safety.

Many people participate in sport hunting in bear country each year. Some are hunting for bears, but most hunt for other game species.

For hunters of bears, the risks are obvious. Bear hunters intentionally break bear safety rules to close in on their prey. The most dangerous situation, however, is after they shoot and injure a bear. They have an ethical obligation to track the wounded animal and kill it, but this is when most bear hunters are injured. This confirms that guns are not completely effective in preventing bear injury. An injured bear may take refuge in heavy cover, then charge when the hunter is at close range. With little time, a surprised hunter often cannot fire a lethal round, and even when shot, the bear can continue its attack and cause significant injury before it dies.

Hunters of other game species in bear country are at significant risk of close encounter and injury. Besides violating bear safety rules, they frequently become preoccupied with the stalk and forget they may encounter a bear. During the 1990s, more than half the people injured by grizzly bears in the Yellowstone Ecosystem have been elk hunters. Some injuries occurred during the stalk, but other factors contributed. Grizzly bears in this ecosystem have learned the association between gunfire and available food. After an elk or other game (moose, deer, bighorn sheep) has been killed, hunters field-dress their kills and leave edible remains (gut piles) on the ground. In several cases, bears approached the kill site before the hunters completed this process. In other cases, an elk or animal was field-dressed late in the evening, then hung in a nearby tree. When the hunters returned the next morning, they encountered a grizzly bear that had claimed the gut pile or the carcass. Hunters must assume that under these circumstances, at least one grizzly bear will be at the site, and they must approach cautiously, preferably on horseback.

Bow hunting represents another high-risk activity. In most states, bow hunters are not allowed to carry a firearm as a backup weapon. They also tend to violate bear safety rules to set up a shot. Elk hunters blow an artificial elk call (a bugle) to lure in bull elk.

This also alerts grizzly bears that prey on adult male elk (bulls)

1014

Figure 43-20 Bite wound injuries typical of a bear attack. (Courtesy Luanne Freer.)

during the breeding season. For protection, bow hunters should (1) hunt from a tree-stand, which provides some protection from grizzly bears, who are poor tree climbers, and (2) carry pepper spray and be prepared to use it.

BEAR-INDUCED INJURIES

Bear-inflicted injuries range from minor, treated on an outpatient basis, to complex, requiring hospitalization and surgery, typically resulting in significant cosmetic and functional disability. In this regard, bear attacks are similar to most other animal attacks, particularly those inflicted by large animals.

The character of such injuries is determined in part by the three main sources: teeth, claws, and paws. The teeth of bears, especially the canines, are large and sturdy. Although the teeth are not particularly sharp, the power of the jaw muscles allows the teeth to penetrate deep into soft tissues and fracture facial bones and bones of the hand and forearm with ease. The trauma characteristically results from punctures, with shearing, tearing, and crushing forces ([Figure 43-20](#)).

The claws are another important source of trauma. Although the claws on the front pads can be as long as human fingers, they are not particularly sharp on grizzly and polar bears. The bear's shoulders, however, provide the force and speed that allow claws to cause significant soft tissue damage in a scraping maneuver that results in deep, parallel gashes. Because black bear claws are sharper and more curved, the cuts tend to have sharper, less ragged edges.

The bear paw is capable of delivering a powerful force, resulting in significant blunt trauma, particularly to the head and neck, rib cage, and abdominal cavity, especially solid organ rupture. Therefore victims of bear attacks should be evaluated for occult blunt trauma.

Several victims of a bear attack were further injured when a companion accidentally shot them while trying to kill the attacking bear. Others were injured when they fell out of a tree while escaping a bear; some sustained long-bone fractures. At least two persons in North America have been killed by such falls, and in both incidents the bear did not attack the victims once they fell to the ground.

WOUND MANAGEMENT

The specifics of initial wound treatment are determined in part by the available medical equipment and location in which the victim is first received. Stabilization of the victim remains the primary objective. All victims of bear attacks should be considered to have major trauma and should be transported to the most appropriate facility after stabilization.

By the time most bear attack victims reach medical care, their injuries are relatively "old." Bear-inflicted injuries are often occult, producing greater tissue necrosis than initially expected. Deep structure involvement is typically more prevalent than is initially apparent. Internal injuries from either direct penetration (claws, teeth) or blunt trauma are common. Neurovascular injuries must be considered with trauma to the extremities, and neurosensory and cosmetic injuries are common with trauma to the face.

ANTIBIOTIC THERAPY

Little information is available about the organisms in bear-inflicted wounds, but anecdotal evidence suggests that bear attack victims do not develop unusual or rare septic complications from unknown pathogens. In one study, cultures of the mouths of black bears revealed a bacterial spectrum similar to that in dogs, with the majority

1015

TABLE 43-2 -- Animal Bite Risk Factors

LOCATION	TYPE OF WOUND	VICTIM CHARACTERISTICS
HIGH RISK		
Hand, wrist, or foot	Punctures	Older than 50 years
Scalp or face in infants	Tissue crushing that cannot be debrided	Asplenic
Over a major joint		Chronic alcoholic
Through-and-through bite of cheek	Bites over vital structures (e.g., artery, nerve)	Altered immune status
		Diabetic
		Peripheral vascular insufficiency
		Chronic corticosteroid therapy
		Prosthetic or diseased cardiac valve
		Prosthetic or seriously diseased joint
LOW RISK		
Face, scalp, ears, or mouth	Large, clean lacerations that can be cleansed	Younger than 50 years

Self-bite of buccal mucosa		Good medical health
	Partial-thickness lacerations and abrasions	

of species being *Micrococcus* and *Streptococcus*.^[10] *Staphylococcus aureus* was found in only 8%, and *Pasteurella* and *Eikenella* were not found. In a similar study of the bacterial flora in the oral cavities of grizzly bears, *Escherichia coli* was found in 98% of the samples taken.^[12]

The use of antibiotics shortly after the injury but before clinical evidence of infection remains controversial. The usual risk factors should be assessed ([Table 43-2](#)).^[3] However, the blunt trauma, deep punctures, and shearing-tearing forces that are typical of bear attacks create significant tissue ischemia and necrosis that are not apparent on the initial examination. Therefore antimicrobial prophylaxis should be considered for all bear-inflicted wounds pending culture results and before clinical evidence of infection.

Before culture results are available, penicillin is suggested for relatively clean superficial injuries. A third-generation cephalosporin should be added to cover gram-negative organisms for deeper and more contaminated wounds.^[10] However, adequate wound debridement and cleansing are the primary means of reducing the infection rate among these victims. Antibiotics should be administered parenterally for at least 3 days after wounding and at least 2 days after each debridement.^[9]

RABIES

No case of rabies has been reported or documented in either wild or captive bears. The Centers for Disease Control and Prevention (CDC), however, recommends rabies immunization for victims attacked by wild carnivores. Therefore all victims of bear attacks should receive the standard informed-consent discussion of the risks and benefits of rabies immunization.

Chapter 44 - Wilderness-Acquired Zoonoses

Eric L. Weiss

A zoonosis is a disease of animals that may be transmitted to humans under natural conditions. There are more than 200 zoonotic pathogens. The risk of acquiring zoonoses increases proportionately with the frequency and intensity of contact. For example, hunters and trappers who handle and are exposed to the blood, viscera, secretions, and excretions of wild animals are at much greater risk than are recreational campers. Similarly, international travelers who frequent locations with a much higher density of infected animals are at greater risk for infection. The trekker in Nepal is more likely to confront rabies than the hiker in California. Disease severity is important in human infections.

This chapter emphasizes diseases in which wildlife plays a significant role in transmission to humans. Although glanders and melioidosis do not fit this pattern, they are also discussed. Zoonoses acquired primarily from domestic animals that also have a minor reservoir in wildlife are mentioned briefly; standard texts of veterinary public health^{[111] [194] [207]} and infectious disease^{[99] [139]} provide further discussion.

RABIES

Rabies is one of the most ancient and feared diseases, with the first apparent reference found in the Eshnunna Code of Mesopotamia, circa 2000 BC. Aristotle (322 BC) recognized that dogs transmitted the infection to other dogs through bites, and Galen (200 AD) recommended surgical excision of bite wounds to prevent rabies. Celsus (100 AD) subsequently recommended cauterization to prevent the infection; this remained the prophylactic treatment of choice until 1885, when active rabies immunization was introduced by Louis Pasteur. In 1882 Pasteur successfully transmitted rabies experimentally, spinal cord inoculums, from one dog to another. By using the attenuation method of air drying rabbit spinal cords, he discovered that he could provide protective immunity in dogs. While hesitant to apply his findings to humans, on July 6, 1885, a 9-year-old bitten by a rabid dog was brought to his office. The boy was immunized with rabbit spinal cord vaccine and did not develop rabies. By 1886, 726 persons had similarly received "postexposure" immunization; only 10 developed rabies.

Virology

Rabies is caused by a ribonucleic acid (RNA) virus in the family Rhabdoviridae. Rhabdoviruses are bullet-shaped with RNA coiled inside an outer envelope covered with glycoprotein-containing surface spikes ([Figure 44-1](#)).^[155] The rabies virus contains five proteins, including this glycoprotein and a nucleocapsid protein^[192] ; each has a molecular weight of 60,000. The glycoprotein induces neutralizing antibody, which can confer immunity and protection against the disease. The nucleocapsid protein induces antibodies that do not appear to be protective, but are useful diagnostically. The fluorescent antibody technique, widely used to demonstrate rabies antigen in tissues, is directed largely against the nucleocapsid protein.

Transmission

Rabies is almost always transmitted by the bite of infected animals, most often wild and domestic carnivores. Eight cases of rabies have been transmitted to the recipients of transplanted corneas from donors who subsequently died from an illness that was compatible with or shown to be rabies.^{[43] [46] [109] [116] [223]} In two cases of rabies, transmission was by accidental aerosol in a laboratory,^{[231] [232]} ²⁸³ and in two others by inhalation in a bat-infested cave.^{[68] [69]} In such caves, aerosols of rabies virus are created from the saliva, secretions, and excretions of large numbers of infected bats concentrated in a dark, humid environment that favors survival of the virus outside the host. Transmission occurs through the nasal neuroepithelium. Because the virus is sensitive to desiccation and ultraviolet light, once any contaminated materials are dry or

exposed to sunlight, they can be considered noninfectious.

Carnivorous animals can acquire rabies by eating infected prey. Skunks can transmit rabies to their young transplacentally,^[110] and one probable case of congenital rabies^[21] has been reported in a calf.^[146] A congenital human case has also been reported, with mother and child dying of rabies within 48 hours of delivery.^[201] The mother had been bitten by a dog 33 days before she became ill. The diagnoses were made by finding Negri bodies in the brain of mother and child.

Epidemiology

Although all mammals are experimentally susceptible to rabies, the major reservoir and vectors of transmission are wild and domestic carnivores, particularly the dog (Canidae), cat (Felidae), weasel (Mustelidae), mongoose (Viveridae), raccoon (Procyonidae), and bat (Chiroptera) families. In the United States, Canada,

and most of Europe the principal reservoir is wildlife ([Figure 44-2](#) and [Figure 44-3](#)). Between 1980 and 1996, approximately 85% of rabies cases reported in the United States and Puerto Rico occurred in wild animals. In 1996, 49 states, the District of Columbia, and Puerto Rico reported 8509 cases of rabies in animals and four cases in humans to the Centers for Disease Control and Prevention (CDC). Nearly 93% (7899) were wild animals, with 7% (610) domestic species. The breakdown by species was raccoons 50.5%, skunks 24%, bats 11.3%, foxes 5.3%, cats 3.5%, dogs 1.5%, and cattle 1.4%. The epizootic of rabies in raccoons expanded into Ohio in 1997 and now includes 19 states and the District of Columbia. Only Hawaii reported no cases of

rabies. The four cases in humans

Figure 44-3 Cases of rabies in the United States by year, 1955 to 1991. (From Krebs JW et al: *J Am Vet Med Assoc* 201:1836, 1992.)

resulted from infection with rabies virus variants associated with bats.^[128]

Vaccination and leash law enforcement have greatly reduced the incidence of rabies in dogs in the United States and Canada. Since 1981, rabid cats have outnumbered rabid dogs in the United States ([Figure 44-4](#)).^[127] In most developing countries, however, dogs remain the principal reservoir of rabies and the most common source of rabies among humans. In 1991, 81.6% of 8528 reported rabies cases in Mexico occurred in dogs.^[127] Of the cases of human rabies reported to the CDC between 1980 and 1997, 12 (33%) of the 36 cases appear to have been related to rabid animals outside the United States.^{[60] [159]}

The significant wildlife reservoirs of rabies vary geographically. The mongoose is important in Puerto

Figure 44-5 Human rabies in the United States from 1950 to 1989. Figure includes two Americans who contracted and died of rabies outside the United States (1981 and 1983). (From Fishbein DB: *Infect Dis Clin North Am* 5:53, 1991.)

Rico, jackal in much of Africa, red fox in Europe, wolf in Iran and neighboring countries,

raccoon dog in Eastern and Central Europe, and vampire bat in certain Latin American countries. More than 50 countries reportedly have no rabies cases, including most islands in Pacific Oceania, most Caribbean islands, the United Kingdom, Cyprus, Finland, Iceland, Norway, Portugal, Spain, Sweden, Japan, Korea, Malaysia, Singapore, New Zealand, and Taiwan. The largest land mass reported free of rabies is Australia. ^[59]

Because human contact with dogs is much more intimate than with wildlife, dogs offer a greater threat of rabies transmission. Countries with significant domestic canine rabies also have the highest incidence of human rabies; 48 human cases were reported in Mexico in 1991. ^[127] In India, estimates of annual human rabies cases range from 15,000 to more than 25,000. ^[230] No more than five cases of human rabies have been reported in any year since 1960 in the United States. Twenty (36%) of the 55 human cases of rabies reported in the United States (including two Americans who acquired and died of rabies abroad) from 1960 to 1991 were acquired in foreign countries; most resulted from dog bites, with definite recollection of a bite ([Figure 44-5](#)). ^[92] More recently, however, most victims had no definite history of an animal bite or other event associated with rabies virus transmission. Only seven of 32 patients had a definite exposure history; six were bitten by dogs in foreign countries, and one by a bat in the United States. Rabies in the United States is rare but probably underdiagnosed, and should be considered in the differential diagnosis of any acute, rapidly progressing encephalitis, even if the patient does not recall being bitten by an animal. ^[159]

Mammalian species vary in their susceptibility to rabies. In general, the animals most susceptible also have the shortest course of infection. Wolves, foxes, and jackals, which are highly susceptible, generally have acute disease. Skunks and raccoons are less susceptible, and the duration of illness tends to be more prolonged. Opossums are very resistant to infection, and the only consistent way to induce rabies in them is by intracerebral inoculation.

Although rabies is considered an almost uniformly fatal infection once symptoms have developed, some cases of spontaneous recovery or of chronic, asymptomatic infection have been recorded in various wildlife species and dogs. ^[19] ^[21] ^[63] ^[77] ^[89] Bats that harbor and shed the virus may not be overtly ill, especially to the casual observer. This affects the practice of quarantine and observation of animals that have bitten humans as means to determine if or not they are rabid.

The pattern of human rabies reflects the epidemiology of animal bites. ^[17] As for animal bites in general, a disproportionately large number of rabies cases occur in males less than 18 years of age. All cases of animal bites and of rabies in people or animals should be reported to local public health authorities.

Pathogenesis

After the rabies virus is inoculated by a bite, it is first sequestered in skeletal muscle. The virus travels through neuromuscular spindles and motor end plates to the peripheral nervous system, then travels in the

axons of peripheral nerves at an estimated rate of 3 mm/hr to the central nervous system (CNS). Thus, rabies resulting from a bite on the foot has an average incubation period of 60 days, but only 30 days after an infective bite to the face. The incubation period varies greatly and affects decisions about postexposure treatment of patients with a relatively distant history of an animal bite. Rabies has been described in humans more than 1 year after the infecting bite.^[78]

The virus moves across synapses and multiplies within neurons. The brain may be diffusely involved or may have concentrations in different parts, depending on species, resulting in differing clinical manifestations of the disease. For example, the hippocampus is frequently involved in humans; Purkinje's cells of the cerebellum are typically involved in herbivores, such as cattle. After multiplication within the CNS, centrifugal spread along cranial and peripheral nerves occurs out to the skin, cornea, salivary glands, and other tissues. Terminally, rabies virus can be found in many organs of the body, including the nervous system, skin, eyes, salivary glands, pancreas, kidney, and myocardium. Saliva can contain up to 1 million virus particles per milliliter. Rabies is not disseminated in the body by viremia, and contact with blood of a rabid animal is not considered an exposure risk.

Clinical rabies develops in approximately half of untreated persons bitten by rabid dogs. Although controlled clinical trials are impossible, retrospective examination of situations in which rabid animals have bitten multiple persons in an environment with no available postexposure treatment provides some insight. The probability of the disease developing seems to vary with the size and depth of the inoculum, from 0.1% with salivary contamination (e.g., licking) of a minor wound to 80% after a severe rabid wolf bite.

Symptoms

The incubation period of rabies varies from as little as 9 days to more than 1 year. For the great majority of human cases, the incubation period is between 2 and 16 weeks.^[21] Claims of incubation periods as long as 19 years are difficult to substantiate, but reports suggest incubation periods longer than 5 years.^[24] Long incubation periods are confirmed by identifying the strain of virus as coming from an area where the patient last visited or resided years ago. For example, in three immigrants to the United States who died of rabies, the viral nucleic acid pattern matched strains from their native countries, the Philippines, Laos, and Mexico, which they had left 6 years, 4 years, and 11 months before, respectively.^[204]

The initial symptoms of rabies are usually nonspecific and include malaise, fatigue, anxiety, agitation, irritability, insomnia, depression, fever, headache, nausea, vomiting, sore throat, abdominal pain, and anorexia. The only true "early" symptom is pain, pruritus, or paresthesias at the site of the bite, which occurs in approximately half of

patients.

After the prodromal period, which lasts approximately 2 to 10 days, more specific neurologic symptoms develop related to localization of the infection to the limbic system, with relative sparing of the neocortex. In lower animals and in humans this can take one of two forms, either furious or paralytic (dumb) rabies. Humans are more likely to suffer from "furious" rabies with its violent outbursts, whereas dogs more commonly suffer from "dumb" rabies and become increasingly lethargic and eventually actually paralyzed. Furious rabies is characterized by increasing agitation, hyperactivity, seizures, and episodes in which the animal or person may thrash about, bite, and become aggressive, alternating with periods of relative calm. Rabid human patients may hallucinate. Between fits the victim is often aware of impending death. Severe pharyngeal spasm of respiratory muscles may occur when the individual attempts to drink. Later this reaction may be triggered merely by the sight of water, giving rise to the synonym "hydrophobia." A truly rabid patient often attempts to drink because of thirst. A hysterical patient mimicking rabies does not make the attempt. Pharyngeal spasm and choking may also occur when air is blown on the patient's face or when a breeze blows in through an open window (aerophobia).

In the initial phases of furious rabies, animals may appear unusually alert and responsive. Later they show some discomfort and restlessness and may vocalize with unusual frequency. Animals become hypersensitive and hyperresponsive to external stimuli, such as sound or touch. Certain behavioral changes develop, and wild animals that normally shun association with humans may appear unusually friendly and approach people without apparent fear. Friendly dogs or cats may begin to bite. Animals may act ferocious and may salivate excessively, "foaming at the mouth" ([Figure 44-6](#)). The key to maintenance of this infection in nature is the behavioral change in animals that causes them to bite. Skunks are particularly dangerous because they tend to bite and hold on viciously. Eventually, animals and people go into a coma and die, either from cardiac arrhythmia or secondary complications such as pneumonia, sepsis, or congestive heart failure. Untreated, the average human victim survives 8 days. With intensive supportive care, life may be extended for up to 28 days. The mortality from rabies is virtually 100%.

Dumb rabies is associated with progressive lethargy, incoordination, and ascending paralysis, starting as posterior paraplegia. In animals, cranial nerve palsies can result in protrusion of the tongue and nictitating membrane and abnormal vocalization. The tone and pitch of the animal's voice may change, probably because of involvement of laryngeal muscle innervation.

Figure 44-6 Dog-wolf cross-species from Canada with furious rabies. It has a ferocious appearance, excess salivation, and anisocoria. (Courtesy Merieux Institute.)

Dumb or paralytic rabies in animals and humans follows a progressive course, with eventual coma and death.

Because of progressive paralysis without biting behavior, dumb rabies is usually not transmitted further in nature. However, people may be exposed while taking care of such patients, whether animal or human, through exposure to saliva (e.g., attempting to clear oral secretions).

Preexposure Immunization of Humans

People at high risk for rabies, such as veterinarians, wildlife biologists, trappers, taxidermists, and laboratory personnel working with the virus, should be immunized before any potential exposure. Other possible candidates for preexposure immunization include spelunkers, professional hunters, and long-term travelers (especially hikers and bikers) to intensely enzootic areas. Children, especially "toddlers," are at risk because they are more likely to pet stray dogs and less likely to heed warnings. The CDC recommends preexposure rabies immunization "for persons living in or visiting (for more than 30 days) areas of the world where rabies is a constant threat."^[59] This recommendation should be followed more aggressively if the individuals' activities are likely to put them at significant risk of exposure or if they are likely to have difficulty receiving appropriate medical care, including safe, effective biologics administered with a sterile needle and syringe, within a few days of exposure. If appropriate care is available, it may be more cost-effective to forgo preexposure immunization and administer postexposure treatment to persons in need.^[191] Preexposure immunization also protects against inapparent or unknown exposure.

Three vaccines have thus far been approved for human use in the United States: human diploid cell vaccine (HDCV) (Imovax), rabies vaccine adsorbed (RVA), and purified chick embryo cell vaccine (PCEC) (RabAvert). Due to concerns regarding the manufacturing process, the Food and Drug Administration (FDA) has recently suspended the production of RVA, and its future availability on the U.S. market is uncertain. All these vaccines contain virus inactivated with β -propiolactone.^[55] Preexposure immunization consists of three injections given on days 0, 7, and 21 or 28. All can be given intramuscularly, 1 ml in the deltoid muscle (or anterior thigh muscle in children). An alternative route for preexposure HDCV (only) is intradermal (ID), 0.1 ml in the lateral aspect of the upper arm.^{[27] [35] [52] [79]} The ID dose for HDCV is significantly less expensive than the intramuscular (IM) route but may be less immunogenic. When patients are concurrently taking chloroquine phosphate for malaria prophylaxis the antibody response to ID HDCV decreases.^[162] Although interference with the immune

response of other antimalaria drugs, such as mefloquine, has not been studied, precautions for persons taking these medications should also be followed. IM administration of the routine series of three doses provides a sufficient immune response.^[26] Also, if the ID route is used in a traveler taking chloroquine or mefloquine for malaria, a full month must pass after completing the three-dose series before beginning the antimalarial medication. Despite the cost savings, this is usually impractical, and most travelers receive the IM series. The frequency of booster doses for preexposure immunization depends on the antirabies titer of the individual and the likelihood of exposure to infection.^{[55] [91]}

Pain, erythema, or pruritus occurs at the injection site in many of those receiving primary rabies immunization.^{[27] [55]} Malaise, headache, dizziness, fever, and nausea occur in 5% to 40% of vaccinees. Marked local induration and regional lymphadenopathy are occasionally seen. Booster doses with HDCV at 1 year can cause malaise, headache, fever, myalgia, and arthralgias in 26% of recipients.^[27] Boosters with HDCV can also cause an immune complex-like disease characterized by urticaria, macular rash, angioedema, or arthralgia in 10% of recipients.^[80] The incidence of such delayed hypersensitivity seems to be less with the newer PCEC vaccine.^[55] Immediate hypersensitivity reactions, with bronchospasm, laryngeal edema, and rashes after primary immunization with HDCV, are rare. Three cases of Guillain-Barré paralytic syndrome with complete recovery within 3 months have been reported associated with HDCV.^{[25] [30]}

Concurrent use of immunosuppressive drugs, such as corticosteroids, interferes with immunization. If possible, such drugs should not be given at the time of immunization. If preexposure immunization must be given while the person is taking an immunosuppressive drug, the vaccine should be given by the IM rather than the ID route and titers checked to determine if immunization is effective.

Postexposure Procedures

Because no specific or effective rabies treatment is available for symptomatic disease, all effort should be directed at prevention, which consists of adequate wound cleansing and prompt immunization. Evaluating exposure and the need for prophylactic immunization may be difficult, which results in considerable overtreatment.^[107] Considering the prognosis and the relative safety of prophylaxis, however, overtreatment is understandable and inevitable.

Significant exposure risk is associated with bites that penetrate the epidermis or contact with saliva, other secretions, cerebrospinal fluid (CSF), or animal tissue with open wounds or mucous membranes. In general, the deeper the inoculation (e.g., by bite, scratch) and the larger the inoculum, the greater is the risk of contracting rabies.

If a dog, cat, or ferret bites an individual, the animal should be quarantined for 10

days.^[157] Rabies prophylaxis can be started and discontinued if the animal remains well for 10 days. If the animal dies or neurologic symptoms develop within that time, the brain should be examined. The brain should be double bagged in plastic and sent refrigerated (e.g., on ice, not chemically fixed, frozen, or on dry ice) in a leakproof container to an appropriate diagnostic laboratory, such as that maintained by the state department of health. If quarantine is not possible or practical, the dog or cat can be killed immediately and the brain sent for examination. Any wild animal that bites a person should be killed immediately and the brain sent for diagnostic laboratory studies.^[157] Wild animals are not kept under observation because their period of infectivity is usually unknown, and some species, such as skunks and bats, may shed virus in saliva for 2 weeks or more before they appear ill. If the biting animal is rabid, postexposure prophylaxis should be continued or instituted immediately.

If the biting animal is not available for examination, which is usually the case, act on the statistical probability that it was or was not rabid. If rabies is known to occur locally in that species, the person should be treated. If rabies has not occurred in the region for many years and the animal likely was not exposed to rabies, the local public health department can be consulted for regional and individual case guidelines.

Unvaccinated dogs and cats bitten by a rabid animal should be destroyed immediately. If the owner is not willing to have this done, the unvaccinated animal should be kept in strict isolation for 6 months and vaccinated 1 month before being released.^[157] Dogs and cats that were currently and appropriately vaccinated before exposure should be given a booster dose immediately and kept in confinement for 45 days.^[56] Local authorities will define the exact conditions of quarantine.

Domestic livestock (e.g., sheep, cattle, goats) exposed to rabid animals should be slaughtered immediately. If they are slaughtered within 7 days of being bitten, their tissues can be eaten without risk of infection, providing that the area around the bite is discarded. Animals that were exposed to rabies more than 7 days and less than 8 months previously should not be used for food. Meat, milk, or any other organ product of a clinically rabid animal should not be consumed; however, pasteurization or adequate cooking kills the virus, and inadvertent consumption of properly heated food should not be considered a rabies exposure.^[157]

Although rodents are experimentally susceptible to infection, naturally acquired rabies is extremely rare in small rodents (e.g., mice, rats, gerbils, hamsters, guinea pigs, squirrels) and in lagomorphs (e.g., rabbits, hares). Exceptional cases in rabbits and a case in a squirrel have been reported.^[34] With rare exceptions, a bite from a lagomorph or a small rodent should not be considered a rabies exposure, and postexposure prophylaxis should usually be withheld. Local public health officials or infectious disease specialists should be consulted about individual problem cases.

Some cases of rabies in woodchucks and beavers, which are large rodents, have been reported in the United States.^[50] ^[53] Most of these cases have occurred in the Middle Atlantic states, probably from exposure to raccoons. Bites from bats and wild carnivores, such as skunks, foxes, and raccoons in the United States and jackals, wolves, and mongooses in other enzootic countries, should be considered possible

exposures. Prophylaxis should be given if the biting animal escapes.

Information about the biting animal and incident helps determine the likelihood of rabies exposure. The risk is greater if the biting incident was unprovoked. The question of provocation should be asked from the perspective of the animal rather than of the victim. For example, feeding a wild animal or attempting to separate fighting animals is likely to result in a bite. In an unprovoked attack the person did not intrude on the animal's territory or behave aggressively. The question of provocation indicates relative risk, because a provoked animal can also be rabid; a normal animal is not likely to bite unless provoked.

The animal's behavior and appearance should be described. Most rabid animals have obvious behavioral and neurologic abnormalities, such as staggering gait,

1023

excess salivation, uncontrolled rage, abnormal eye movements or pupillary reflexes (see [Figure 44-6](#)), altered vocalization, bizarre behavior (e.g., wild animals approaching humans), convulsions, or paralysis.

The physician should inquire about the animal's vaccination history. No vaccine is perfect, but the likelihood of rabies is greatly reduced if the animal was given an appropriate vaccine within the proper time frame. Rabies has occurred in immunized dogs^[54] and in two people bitten by dogs that supposedly had been immunized in Nigeria^[50] and Mexico.^[134]

A history taken on the animal should include recent bites or involvement in a fight with another animal and travel outside the region within the past year. For example, the likelihood of a dog that stays in a nonenzootic area being rabid is small, but the risk increases if it is taken to enzootic areas to hunt.

Specific Postexposure Care.

Postexposure prophylaxis consists of three steps. The first is adequate wound washing with soap (which is somewhat virucidal) and water. Studies in animals have shown that wound cleansing alone, without any other postexposure prophylaxis, can greatly reduce the likelihood of rabies.^[74] This should be done as soon as possible, preferably within minutes after the bite or scratch, and definitely before seeking medical attention. Immunization can be delayed for hours or 1 to 2 days; washing a wound cannot be delayed.

The second component of postexposure prophylaxis is administration of rabies antiserum. In some parts of the world, this product may be of equine origin. Modern purified equine antirabies serum is effective, well tolerated, and approximately one-tenth the cost of human rabies immune globulin (HRIG). The incidence of adverse reactions is low (1% to 6%), and most are minor.^[229] Earlier products, which were less well purified,

carried a higher risk of serum sickness.^[228] Equine antirabies serum in various countries may be the newer, nonreactive type or the older, more dangerous variety. Review of the package insert is recommended. It may also be advisable to test for hypersensitivity by intradermally injecting 0.1 ml of the product diluted 1:10 with saline before giving the full dose.^[215]

In many Western countries, including the United States, rabies antiserum is made from the blood of immunized human donors (HRIG). HRIG contains 150 IU of neutralizing antibody per milliliter. It is given as a single dose of 20 IU/kg body weight. Recently the recommendations regarding the administration of HRIG have changed. Rather than administering half in the wound and half at a different site, the new recommendations call for the full dose of HRIG to be thoroughly infiltrated in the area around and in the wound.^[62] If anatomy precludes full dosing, remaining product is injected intramuscularly at a site distant from the vaccine administration. A different syringe and different anatomic site are always used for vaccine and HRIG administration. HRIG is a safe product, not associated with anaphylaxis, serum sickness, or transmission of hepatitis or human immunodeficiency virus (HIV).

Theoretically, antiserum may be effective at any time before development of symptoms and should be given regardless of the time since the biting incident. The antiserum is given at the same time that active immunization is started, as described later. With recommended doses, no interference between passive and active immunization should take place. If HRIG was not given when active immunization was started, it can be given up to 7 days after the first vaccine dose.^[55]

The third component of postexposure prophylaxis is active immunization with rabies vaccine. HDCV and PCEC are inactivated by β -propiolactone. Although ID vaccination with HDCV is acceptable for preexposure prophylaxis, this vaccine should always be administered intramuscularly, in the deltoid, for postexposure prophylaxis. PCEC should always be given in the deltoid muscle, whether used before or after exposure. HDCV or PCEC can be given in the midanterior thigh muscles of infants and small children. Either vaccine is given on days 0, 3, 7, 14, and 28 as a 1-ml dose, regardless of the age or size of the patient. The vaccines should not be given with the same syringe or in the same site as HRIG. They should *not* be given in the gluteal region, since the vaccine might be deposited in fat and be poorly immunogenic. Rabies has occurred in a person given postexposure prophylaxis using gluteal injections.^[200]

After exposure, individuals previously immunized should receive booster doses of HDCV or PCEC on days 0 and 3. An effective booster response has been documented in people given primary immunization many years earlier,^[87] including those given duck embryo vaccine, providing they had an appropriate immune response after the primary series. Such individuals should not receive antiserum. This is the principal advantage of receiving "preexposure" prophylaxis.

After vaccination, antirabies titers need to be checked only in individuals who may be immunosuppressed. A person who does not show a satisfactory antibody response (titer of at least 1:25 or 0.5 IU 2 to 4 weeks after immunization series) should receive additional booster doses of rabies vaccine weekly until antibody response is

satisfactory. This is more important for postexposure than for preexposure immunization. Nursing and pregnancy do not contraindicate postexposure rabies prophylaxis.

In developing countries, HDCV and RVA as used in the United States may be prohibitively expensive for general use. Modified protocols for these products or other vaccines are often used to reduce the amount of

vaccine and number of follow-up visits. None of these protocols is approved for use in the United States.

A purified Vero cell rabies vaccine has been used with success in Thailand.^{[55] [92] [230]} This purified duck embryo cell rabies vaccine is more immunogenic and safer than the duck embryo vaccine widely used in the United States in the 1960s.^[230] A purified chick embryo fibroblast rabies vaccine is used in Japan and a hamster kidney cell vaccine in China,^[230] with good results.

Inactivated rabies vaccines prepared in animal brains, collectively known as Semple vaccines, are used for 93% of all postexposure rabies treatment worldwide because they are relatively cheap. They have relatively low immunogenicity and a high incidence of significant side effects, the most serious being neuroparalytic reactions because they induce antineural antibody and cellular response.^[230] Earlier reports suggested a risk of such neurologic reaction in 1:3000 to 1:7000 vaccinees; however, another study from Thailand reported the rate of neurologic complications after receiving Semple vaccine to be a minimum of 8.31 cases per 1000 persons vaccinated (1:120). This complication rate was about 25 times higher than the overall complication rate of 0.33 per 1000 (1:3018) determined from 14 previous reports,^[211] giving added motivation to seek preexposure immunization before travel.

Treatment of Infected Persons.

Treatment of infected persons who have clinical rabies is directed toward the symptoms and consists of intensive care support of vital functions. α -Interferon, vidarabine, ribavirin, corticosteroids, inosine pranobex, multiple doses of vaccine, antithymocyte globulin, and large doses of rabies immune globulin have been used unsuccessfully in treating rabid persons.^[230] The only three persons known to have survived clinically evident rabies (two with major neurologic sequelae) had received at least partial preexposure or postexposure immunization before they became symptomatic.^{[105] [169] [232]}

Diagnosis

The differential diagnosis of rabies is extensive, including viral encephalitis, poliomyelitis, postinfectious encephalitis, vaccine reaction, Guillain-Barré syndrome, brain abscess, cerebrovascular accident, brain tumor, tetanus, phenothiazine toxicity,

psychosis, rabies phobia, respiratory tract infection, pneumonia, sinusitis, otitis media, viral infection, gastroenteritis, myocardial infarction, hypertension, dissecting aortic aneurysm, arteritis, dehydration, lumbago, and headache.^[6] Presumptive diagnosis of rabies depends on the exposure history and compatible neurologic signs, as noted earlier.

Definitive diagnosis is made by demonstration of the virus before or after death from saliva, neurologic tissue, CSF, urine sediment, or other body tissues. One of the most reliable means of demonstrating the infection before death in the symptomatic individual is by direct immunofluorescent staining of a skin biopsy from the back of the neck. The biopsy sample should contain as many hair follicles as possible because the virus reaches the site by peripheral nerves to these follicles. Direct immunofluorescent staining of corneal impression smears may also be positive.^[90] Rabies viruses can be isolated from saliva or CSF by culture on murine neuroblastoma cells or inoculation of mice.^[230] These tests have great specificity but limited sensitivity. They become positive a week or more after the onset of illness.

Rabies can be indirectly diagnosed by antibody studies on serum or CSF.^[90] The rapid fluorescent focus inhibition test (RFFIT), an in vitro neutralization procedure, is the standard diagnostic test used in the United States. Approximately half of persons with untreated rabies show antibody by day 8 and close to 100% by day 15. Titers resulting from actual rabies infection are generally much higher than those attained after immunization. No currently available diagnostic technique used before death can absolutely rule out rabies.

Definitive diagnosis of rabies is usually made by direct immunofluorescent antibody test on brain tissue. This test demonstrates fluorescent viral antigen particles within neurons ([Figure 44-7](#)). Confirmatory testing can be done by intracerebral inoculation of mice with saliva, brain, or other tissue from suspect human or animal patients.^[90] Infected mice die in approximately 2 to 3 weeks. The diagnosis is confirmed by using direct immunofluorescent test on the brains of any mice that die or show neurologic signs. Mouse inoculation is reliable but takes time. Virus isolation on murine neuroblastoma cells takes only 24 hours but is not widely available.

Rabies can also be diagnosed by immunofluorescence and by peroxidase-antiperoxidase techniques on formalin-fixed brain tissue.^[161] These methods should be used when only formalin-fixed tissues are available

Figure 44-7 Brain impression smear (direct fluorescent antibody preparation) positive for rabies from a Canadian fox. (Original magnification 400x.) (Courtesy Centers for Disease Control and Prevention.)

and should not be considered substitutes for the immunofluorescence technique and mouse inoculation with fresh brain tissue.

Pathology of Rabies

On gross examination, the brain may appear normal or slightly swollen and hyperemic. Histologic features include multifocal polioencephalomyelitis. Perivascular cuffing by lymphocytes is common, and there may be diffuse glial proliferation. Neurons may appear swollen, and some may be undergoing neuronophagia. Glial cells may accumulate in clusters called Babe's nodules.

Negri bodies are intracytoplasmic inclusion bodies, 0.25 to 27 μm in diameter, containing nucleocapsid material. They are diagnostic of rabies when correctly identified ([Figure 44-8](#)). They are absent in approximately 20% of cases, and some animals, such as cats, have neuronal changes associated with aging that can be mistaken for Negri bodies. Seller's stain is used to demonstrate Negri bodies in impression smears of the brain.^[90] Several special stains have been used for tissue sections, but the inclusion bodies are usually demonstrable with standard hematoxylin and eosin staining.

Pathologic changes are best seen in the brainstem, including the substantia nigra, periaqueductal gray matter, and hypothalamus. The hippocampus (Ammon's horn) is commonly affected in humans and carnivores. Purkinje's cells of the cerebellum are commonly affected in ruminants. Pathologic changes are also commonly found in the gasserian ganglion. This may be a useful site for examination if the rest of an animal's brain has been destroyed.

Infection Control

Human-to-human transmission of rabies by bite, scratch, saliva, or aerosol has never been documented. Nevertheless, medical personnel should avoid contact with secretions from persons suspected of being rabid. Gloves, masks, and eye protection should be

Figure 44-8 Negri bodies in the cytoplasm of neurons in the hippocampus of a dog. These inclusion bodies show some internal structure. (Hematoxylin and eosin, original magnification 1000 \times .) (Courtesy Merieux Institute, Inc.)

worn for such procedures as tracheal intubation. Rabid patients may have to be sedated and restrained if they attempt to engage in dangerous behavior, such as biting.

Postexposure prophylaxis should be given only to personnel who are involved in the care of a rabies patient and had percutaneous or mucous membrane contact with saliva, respiratory secretions, tears, CSF, or tissue.^[175]

LEPTOSPIROSIS

Leptospirosis is an infectious disease caused by *Leptospira interrogans* that can be acquired by animals and humans, usually by exposure to contaminated urine of wild or domestic animals. More than 170 serovars, or serologically distinct strains, are known. These serovars were given separate species status, as designated here. *Leptospira* organisms are spirochetes with hooked or curved ends, 6 to 20 μm long by 0.1 μm wide. They can grow on artificial media containing rabbit serum, such as Fletcher's semisolid and Stuart's liquid media, or on media containing albumin and fatty acids, such as Ellinghausen, McCullough, Johnson, Harris (EMJH) medium.^[210]

In describing outbreaks with shared epidemiologic or clinical features, several syndromes were ascribed to different serotypes, such as Fort Bragg fever caused by *L. autumnalis*, swine herd disease caused by *L. pomona*, and Weil's disease caused by *L. icterohaemorrhagiae*. Such terms are no longer commonly used because of overlap in the symptoms and epidemiology associated with various *Leptospira* serotypes.

Adolf Weil first described the clinical picture of human leptospirosis in 1886. He described four febrile men with "particularities of an acute infectious illness with spleen tumor, jaundice, and nephritis." In addition, each had "severe nervous symptoms" and an enlarged liver. All recovered, and three had a "biphasic" clinical course with fever recurring after an afebrile period of 1 to 7 days. The term *Weil's disease* was coined by Goldschmidt in 1887. The carrier status was described in asymptomatic field mice by Ido and co-workers in 1915. Since then the infection has been recognized both as a disease and as an asymptomatic carrier state in hundreds of animal species.

Epidemiology

Leptospirosis is found throughout tropical and temperate areas of the world. It is particularly common in Southeast Asia and parts of Latin America, including some Caribbean islands.^[85] Approximately 40 to 100 cases are reported annually in the United States ([Figure 44-9](#)). Undoubtedly, many cases are unreported. Active surveillance on Kauai and the east coast of the big island of Hawaii revealed a high incidence, accounting for a large proportion of flulike illness.^[183] In 1996 five of 26 travelers returning from a white water

rafting trip in Costa Rica developed a febrile illness and were found to have

leptospirosis. [58] In 1998 leptospirosis was implicated in an outbreak of acute febrile illness among athletes from 44 states and seven countries who participated in triathlons (which involve open water swims in fresh water) in Springfield, Illinois, and Madison, Wisconsin. Eighty-four (11%) of Illinois participants and 20 (5%) of Wisconsin participants were infected and had their diagnosis confirmed by the CDC. [61] Both these reports highlight the potential risk to those with occupational, avocational, or recreational (including travel) exposure to contaminated fresh water.

Leptospirosis is a zoonosis in which certain serovars tend to have host specificity (Table 44-1). Dogs are usually associated with *L. icterohaemorrhagiae* and *L. canicola*, and swine and cattle more frequently involved with *L. pomona* and *L. grippityphosa*, although all four of these serovars or serotypes have been isolated from each host species. The major reservoir for *Leptospira* infections for humans and domestic animals is wildlife, principally wild mammals, although the organism has also been isolated

Figure 44-9 Reported annual cases of leptospirosis in the United States, 1955 through 1991. (From MMWR 40, 1991.)

TABLE 44-1 -- Leptospire Isolates from Humans in the United States, and Their Animal Reservoirs

SEROGROUP	SEROVAR	DOMESTIC ANIMALS	WILDLIFE
Icterohaemorrhagiae	<i>Icterohaemorrhagiae</i>	Dogs, cattle, swine	Brown rat, house rat, cotton rat, Pacific rat, house mouse, muskrat, gray fox, red fox, opossum, striped skunk, woodchuck, nutria
Canicola	<i>Canicola</i>	Dogs, cattle, swine	Striped skunk, raccoon, armadillo, mongoose
Pomona	<i>Pomona</i>	Dogs, cattle, swine, goats, sheep, horses	Striped skunk, raccoon, wildcat, opossum, woodchuck, red fox, deer, armadillo

Grippytyphosa	<i>Grippytyphosa</i>	Dogs, cattle, swine	Muskrat, fox squirrel, gray squirrel, bobcat, cottontail rabbit, swamp rabbit, raccoon, striped skunk, red fox, gray fox, vole, opossum
Hebdomidis	<i>Hardjo</i>	Cattle	None

from frogs and snakes, and serologically positive fish and turtles have been found. ^[140]

Animals contaminate the environment by shedding organisms in their urine. Most human cases are environmentally acquired by contact with contaminated water or soil, and discovering the original animal source is difficult. A wet, alkaline environment favors survival, with tropical, unpolluted, nonsaline water with a slightly alkaline pH providing an optimum environment for infection. Heavy tropical rains increase infection risk by saturating soil, flushing leptospire into surface water, and drawing rodents and other small mammals into swampy areas. Infection can also be acquired by contact with infected animal blood and tissues. Factors strongly associated with acquiring leptospirosis in Hawaii include household use of rainwater catchment systems and the presence of skin cuts at the presumed time of exposure. ^[183]

Leptospirosis is an occupational problem for veterinary, agricultural, sewer, slaughterhouse, laboratory, and military personnel.^{[86] [106] [183]} Dairy farmers are at risk in milking parlors, probably through exposure to cow's urine. ^{[7] [115]} Leptospirosis poses an avocational risk for hunters, trappers, hikers, and persons who swim in fresh water, such as ponds and streams that may be contaminated with infected urine. It is acquired by ingestion or by entry through abraded skin or through the mucous membranes of the eye and mouth.

Symptoms

The incubation period is usually 7 to 12 days (range, 1 to 26 days).^[182] The disease characteristically is biphasic. ^{[117] [177]} The primary stage lasts 4 to 7 days and is characterized by organisms in blood, CSF, and various body tissues. During the initial phase, more than half of victims have fever, chills, severe malaise, myalgias, headache, lymph node enlargement, and conjunctival injection, usually without exudate. Nausea, vomiting, and abdominal pain may occur. A nonproductive

cough is common. The initial clinical differential diagnosis includes meningitis, hepatitis, influenza, nephritis, encephalitis, and viral illness. The rickettsioses, typhoid fever, brucellosis, relapsing fever, toxoplasmosis, dengue fever, malaria, yellow fever, septicemia, Kawasaki syndrome, and toxic shock syndrome are also differential

diagnoses.^[106]

The primary stage, is usually followed by an afebrile period of 1 to 2 days. The onset of the second stage coincides with development of immunoglobulin M (IgM) antibodies. The organisms usually cannot be cultured from blood or CSF during this phase but can be isolated from urine for weeks or months. During the second stage the victim may have fever, but it is lower than in the primary stage. Headache is persistent, severe, and unresponsive to analgesics. It often heralds the onset of meningitis, one of the common complications of the secondary stage.

Myalgias, abdominal pain, nausea, and vomiting can occur in the second as well as in the primary stage. In addition to the conjunctival injection seen in the primary stage, uveitis (iridocyclitis) can be seen in the secondary stage. This can cause long-term ocular damage.^[193] Occasionally, pharyngitis and a macular, purpuric, or ecchymotic rash occur ([Figure 44-10](#)). Rarely, endocarditis or myocarditis occurs. In a clinical study of leptospirosis on Barbados, cardiac arrhythmias

Figure 44-10 Hemorrhagic macular rash in a case of leptospirosis. (Courtesy University of Massachusetts Medical School.)

and myocarditis occurred in 18% and pericarditis in 6% of patients.^[81]

Splenic enlargement develops in approximately 20% of patients in the second stage. Hepatomegaly is sometimes found, especially if the patient is icteric.

Jaundice is a serious prognostic sign. Mortality in cases with jaundice exceeds 15% but is rare in anicteric cases. The overall case-fatality rate is approximately 5%. Mortality depends on the patient's prior condition and is higher in older individuals than in young adults. Death can occur from hemorrhagic manifestations as a result of vasculitis, renal or hepatic failure, cardiogenic shock, or myocarditis.

Diagnosis

Laboratory findings in leptospirosis include moderate leukocytosis, usually caused by an increase in neutrophils, elevated erythrocyte sedimentation rate, and thrombocytopenia. Elevated bilirubin level (up to 65 mg/dl, mainly direct bilirubin), greatly increased serum creatine kinase level (often 5 times normal), and less than fivefold increase in aspartate transaminase suggest the diagnosis. Elevated blood urea nitrogen level is a common

finding. Serum amylase concentration may also be elevated.

Definitive diagnosis of leptospirosis can be made by culture of the organism on Fletcher's, Stuart's, EMJH,^[210] or Tween 80-albumin medium. Blood and CSF should be cultured during the first week of illness; urine should be cultured thereafter. The likelihood of obtaining a positive culture is greatly diminished once antibiotics have been given. Oxalated blood samples can be sent to the laboratory for culture because the organisms can remain viable in oxalated blood for up to 11 days.

Some physicians have relied on darkfield examination for identification of the organisms, but this method is not considered reliable. Artifacts such as fibrin are readily mistaken for leptospires. The spirochetes can be demonstrated in tissue sections with silver stains ([Figure 44-11](#)).

Figure 44-11 *Leptospira icthohemorrhagiae* in the kidney of an experimentally infected dog. The organisms are indicated by the arrows. (Warthin-Stany silver stain, original magnification 1000x.)

1028

Leptospirosis can be diagnosed serologically based on demonstrating a fourfold rise in antibody titer.^[221] The commercially available macroscopic slide agglutination test, using killed organisms of multiple serovars, or the complement fixation test is useful for screening purposes. The macroscopic agglutination test may become positive within the first week of illness and can persist for several months. Complement-fixing antibodies are detectable between days 10 and 21. Acute and convalescent sera should be tested 2 weeks apart because false-positive reactions can occur in single samples.

Specific serologic diagnosis of the serovar of infection can be made with the microscopic agglutination test (MAT), which uses live organisms but is available in relatively few reference laboratories. A genus-specific MAT employs a single broadly reactive antigen.^[223] An IgM-specific, dot-enzyme-linked immunosorbent assay is comparable to the MAT in its ability to detect recent exposure to leptospires and is rapid and simpler.^[163] Latex agglutination and indirect hemagglutination have high specificity and sensitivity and are especially useful early in the infection.^[166] Although still investigational, a urine dipstick test shows promise as a rapid screening test for the diagnosis of leptospirosis.^[197]

Treatment

Treatment of leptospirosis with antibiotics is most effective when begun during the first

week of illness, preferably within 4 days of symptom onset. Although antibiotics were thought to have little value after this time, more recent studies indicate that they may still have some usefulness.^[224] The treatment of choice is doxycycline, 100 mg orally twice a day for 7 days.^[151] Alternative antibiotics include tetracycline, 2 g/day orally in three or four divided doses, or penicillin G, 3 million units/day parenterally. Amoxicillin, ampicillin, a cephalosporin, or erythromycin could also be used. Doxycycline and tetracycline should not be given to pregnant women or to children less than 9 years old.

A Jarisch-Herxheimer reaction may occur after treatment. This is a response to release of endotoxins, usually occurring within 2 to 6 hours after initiating therapy, with sudden onset of fever, chills, malaise, headache, and tachycardia. The reaction typically resolves spontaneously within 24 hours.

Other than antibiotic treatment, therapy for leptospirosis is supportive, including fluid therapy, dialysis for renal failure,^[119] and transfusion for hemorrhagic complications.

Prevention

Prevention of human leptospirosis depends on avoiding infected animal tissues and areas contaminated by animal urine, blood, or tissue. Individuals who are at particularly high risk should be educated about prevention and encouraged to wear protective clothing, such as rubber gloves, when handling infective material. Swimming in freshwater ponds and streams likely to be heavily contaminated by urine from livestock or wildlife should be discouraged.

Doxycycline, 200 mg once a week, effectively prevented infection in U.S. soldiers training in Panama.^[214] Such prophylactic treatment could be given to individuals at unusually high risk.

Although *Leptospira* vaccines have been experimentally produced for human use, no product is approved and commercially available in the United States. Vaccines are available for animals. Immunization of domestic animals primarily has a veterinary benefit, in that the animals are protected from clinical disease. Immunity lasts about 6 months, but immunization does not guarantee that the animal cannot become infected. Several human cases have been traced to immunized dogs that apparently were still able to shed organisms.^[68] Since then, some veterinary vaccines have been shown experimentally to reduce the renal carrier state.^[120]

Veterinary Symptoms

Leptospirosis may be asymptomatic in animals, as is usually the case in wild animals, including rodents. Animals that acquire clinical disease have fever, appear depressed, lose appetite, may become jaundiced, develop hemorrhages on mucous membranes, and in late stages of the disease may have renal failure.^[103] In cattle, leptospirosis can cause stillbirths, hemoglobinuria, and thickened yellowish or blood-tinged milk. Leptospire have been isolated from the milk of cattle and goats. A theoretic risk exists that leptospirosis could be transmitted by consuming such milk. Pasteurization should

destroy organisms. Stillbirths or delivery of weak piglets is a common sign of leptospirosis in swine.

Cats are rarely affected by leptospirosis. They may be resistant to the disease because they are frequently exposed to infection through catching mice and other rodents.

Leptospirosis has been suspected as a cause of recurrent uveitis in horses. This is of more interest in comparative pathology than in public health, since horses infrequently transmit the infection to humans.

Prognosis

Recovery from leptospirosis apparently leaves serovar-specific immunity. Individuals can become infected with other serovars. Assuming that the infection and hemorrhagic complications can be controlled, the long-term prognosis after successful treatment is good. Renal and hepatic function usually returns, but headache and ocular damage may persist.^[193]

HANTAVIRUS PULMONARY SYNDROME

Hantavirus pulmonary syndrome (HPS) is a rodent borne viral disease characterized by severe respiratory illness and a case-fatality ratio of 43%. The causative

1029

agent has been identified by serologic tests, polymerase chain reaction (PCR) to RNA, and immunohistochemistry.^[61]^[132] The Sin Nombre virus is the primary hantavirus causing HPS in the United States, with the deer mouse (*Peromyscus maniculatus*) as its predominant carrier.^[63] Other small mammals may be infected, such as piñon mice, brush mice, and western chipmunks.

Hantaviruses of the Bunyaviridae family cause the hemorrhagic fever with renal disease syndrome (HFRS). This is predominantly a disease of East Asia, where it has been called Korean hemorrhagic fever or epidemic hemorrhagic fever.^[129] Wild rodents are the vectors of Hantaan, Puumala, Prospect Hill, and Seoul viruses. Hantaviruses have been isolated from the lung tissues of bats.^[122]

Epidemiology

Although most cases of HPS have been clustered in the western United States, particularly the Four Corners area (Arizona, New Mexico, Colorado, and Utah), the virus may be present across the entire country.^[158]^[170] The CDC had confirmed 217 cases of HPS in 30 states by mid-1999. From January through May 1999, seven cases of HPS were confirmed in Colorado, New Mexico, New York, and Washington. An additional 11 suspected cases with preliminary clinical and serologic evidence of HPS were reported in Arizona, California, Idaho, Iowa, Montana, New Mexico, and Washington. Eight of the confirmed and suspected cases are from Arizona, Colorado, and New Mexico. In the same 5-month period during each year from 1995 through 1998, this area averaged approximately two cases each year.^[63]

Since 1994 the CDC has sponsored continuous monitoring studies of rodent populations at nine sites in Arizona, Colorado, and New Mexico. Hantavirus antibody prevalences in deer mouse populations surveyed during spring 1999 were 35% to 45% in some populations in New Mexico and up to 40% in Colorado. In comparison, prevalences during the population peaks of spring 1998 were less than 10% in New Mexico and approximately 20% in Colorado. These figures were comparable to a prevalence of 10% to 15% in deer mouse populations throughout the United States

since 1993; during the 1993 outbreak, prevalences of 30% were detected.^[64]

The hantaviruses do not cause apparent illnesses in the reservoir hosts, but the animals shed virus in saliva, urine, and feces for weeks. Human infection probably occurs when infective saliva or excreta are inhaled as aerosols, or when excreta are directly inoculated through the skin or perhaps ingested. Persons have been infected with hantavirus via rodent bite. There is no known transmission from arthropods or human to human.

Symptoms

A prodrome of fever, myalgia, and variable respiratory symptoms may include cough and shortness of breath with minimal bronchospasm. Acute respiratory distress rapidly follows. Other early phase symptoms include headache, chills, abdominal pain, nausea, and vomiting. Patients have often shown hemoconcentration and thrombocytopenia, leukocytosis, hypoalbuminemia, and lactic acidosis.

Rapid deterioration occurs, coincident with marked bilateral pulmonary infiltrates identified on chest x-ray examination. Fever, hypoxia, and hypotension may culminate in death; survivors have few or no sequelae. Autopsies have demonstrated intense pulmonary infiltration, with marked accumulations of hantavirus antigens in the endothelial cells.

Diagnosis

Laboratory evidence of acute hantavirus infection can be obtained by any of the following tests: IgM antibodies to hantavirus antigens, fourfold or greater increase in antibody titers to hantavirus antigens in paired serum specimens, positive immunohistochemical stain for hantavirus antigen in formalin-fixed tissues, or positive PCR from frozen tissue specimens (usually lungs).

Any person with a severe and sudden respiratory illness should be suspected to have been infected with hantavirus. CDC screening criteria are febrile illness in a previously healthy person characterized by unexplained adult respiratory distress syndrome or bilateral interstitial pulmonary infiltrates developing within 1 week of hospitalization, with respiratory compromise requiring supplemental oxygen.

Treatment

Treatment is supportive. Previously isolated hantaviruses have demonstrated in vitro sensitivity to ribavirin. The CDC has made the drug available as an investigational agent through an open-label protocol for treatment of patients with HPS. The protocol calls for administration of a 2-g loading dose of intravenous ribavirin, followed by 15 mg/kg body weight every 6 hours for 4 days and then 7.5 mg/kg every 8 hours for another 4 days. Ribavirin contributed to a patient's survival in at least one case.^[172]

Prevention

According to the CDC, hantavirus transmission to humans may be epidemiologically associated with planting or harvesting field crops, occupying previously vacant dwellings, disturbing rodent-infested areas while hiking or camping, inhabiting dwellings with indoor rodent populations, or residing in an area with an increasing rodent density. Most persons with HPS who had high-risk exposures are thought to have been infected in and around their homes; limiting opportunities for domestic exposure is important. Measures to prevent HPS can be divided into four areas ([Box 44-1](#)).

1030

Box 44-1. CDC RECOMMENDATIONS FOR PREVENTING HANTAVIRUS PULMONARY SYNDROME

1. Eliminate rodent harborage.
 - a. Keep cooking, eating, and food storage areas clean.
 - b. Cover human food and animal feed.
 - c. Contain and elevate garbage.
 - d. Seal holes and cracks in dwellings to prevent entrance by rodents.
 - e. Clear brush and trash from around homes and outbuildings.
2. Control rodent populations by maintaining snap traps and using rodenticides; in areas where plague occurs, control fleas with insecticides.
3. Safely clean up rodent-infested areas.
 - a. Air out infested spaces before cleanup.
 - b. Spray areas of infestation and all excreta, nesting, and other materials with household disinfectant or 10% bleach solution, then clean up, seal in bags, and dispose.
 - c. Avoid sweeping, vacuuming, or stirring dust until the area is

materials with household disinfectant or 10% bleach solution, then clean up, seal in bags, and dispose.

- c. Avoid sweeping, vacuuming, or stirring dust until the area is thoroughly wet with disinfectant.
 - d. Wear rubber gloves; disinfect gloves before removal, and wash hands afterwards.
 - e. In areas where plague occurs, spray insecticide on trapped rodents and nesting materials to prevent fleas from abandoning rodents to find new hosts.
4. Avoid rodents when outdoors.
- a. Do not disturb rodent droppings or camp or sleep near burrows or areas where trash is present.
 - b. Avoid feeding or handling rodents, even if they appear friendly.

TULAREMIA

Tularemia was first described in 1837 by Homma Soken, a Japanese physician who wrote of a febrile illness with generalized lymphadenopathy in persons who had eaten infected rabbit meat. In 1911 McCoy described a disease resembling plague in California ground squirrels. In the following year, McCoy and Chapin isolated the organism from rodents in Tulare County, California; this geographic site gave rise to the name of the disease. Edward Francis did much of the landmark bacteriologic and clinical investigation, and the genus of the causative organism, *Francisella*, is named after him. The role of ticks as vectors of the disease was discovered by Parker and Spencer in 1924. In 1929 they described transovarial transmission of the bacterium in ticks.

Microbiology

Francisella tularensis is a nonmotile, gram-negative coccobacillus measuring 0.2 by 0.3 to 0.7 μm . It must be grown aerobically on media containing cysteine or other sulfhydryl compounds. The organism is best grown on glucose cysteine agar with thiamine or on cysteine glucose blood agar. The organism has also been isolated in thioglycollate broth, charcoal yeast extract, and Thayer-Martin agar.

Two varieties of the organism are recognized in North America. Type A can ferment glycerol and has citrulline ureidase activity. It generally causes more severe disease than does type B, which is found in Europe and Asia as well as North America. Type B does not ferment glycerol and does not have citrulline ureidase activity. Type A is more frequently recovered from rabbits and various bloodsucking arthropods. Type B is often recovered from water, voles, muskrats, and beavers. However, the two varieties sometimes share an ecologic niche.^[145]

Transmission

Before 1950, most reported cases of tularemia were associated with direct contact with rabbits. Tularemia is now most frequent transmitted by ticks.^[31] Many different species of ticks are potential or proven vectors. A common vector in the United States is the dog tick, *Dermacentor variabilis*. The lone star tick, *Amblyoma americanum*, is the main vector in the southern United States. Because the infection can be transmitted transovarially, ticks are an important natural reservoir. Ticks may transmit the bacteria through their feces, since the organism has not been isolated from their salivary glands. Deerflies and other biting flies may also be suitable vectors.^[124] In the United States the second most common source for human infection is rabbits. The infection can be acquired by skinning, eviscerating, or handling the tissues of infected rabbits or by

eating improperly cooked infected meat. Transmission can also occur by direct contact with or ingestion of infected soil, water, or fomites. Infection can occur by inhalation of dust or water aerosol^[73] or in the laboratory. Organisms remain viable in mud samples stored as long as 14 weeks, in tap water for 3 months, in dry straw for 6 months, and in salted meat for 31 days.^[18]

Occasional cases of tularemia have been transmitted by cat bite^[48] ^[173] or by handling infected tissue from animals other than rabbits, such as bear,^[44] deer,^[41] beaver, and muskrat.^[235] Person-to-person transmission is rare.

Epidemiology

Transmission by ticks and other arthropods usually occurs in the spring and summer. Transmission from rabbits most often occurs during the fall and winter hunting seasons.

The reported incidence of tularemia has been steadily decreasing in the United States since its peak at 2291 cases in 1939 ([Figure 44-12](#)). Other tick-borne infections, such as Rocky Mountain spotted fever and Lyme disease, have increased. Empiric use of antibiotics may have aborted undiagnosed cases.

1031

Figure 44-12 Reported cases of tularemia in the United States, 1955 through 1991. (From *MMWR* 40, 1991.)

Most cases in the United States have been reported from the South and Midwest, particularly Arkansas, Illinois, Missouri, Oklahoma, Texas, and Tennessee. The disease is also widespread in Europe, Canada, the Middle East, Russia, and Japan.

Symptoms

Classically, tularemia occurs in one of six clinical presentations: glandular, ulceroglandular, oculoglandular, oropharyngeal, pneumonic, or typhoidal.^[18] ^[145] Evans et al^[84] simplified this classification into two major categories: ulceroglandular and typhoidal. Patients are considered to have *ulceroglandular tularemia* if they have lesions of the skin or mucous membranes, with or without associated lymphadenopathy, with affected lymph nodes at least 1 cm in diameter. Patients without lesions of the skin or mucous membranes and with lesser enlargement of lymph nodes are considered to have *typhoidal tularemia*. In this classification, pharyngitis or pneumonia can occur in

either the ulceroglandular or the typhoidal form of the disease.

The ulceroglandular form accounts for approximately 80% of tularemia cases. The typical skin lesion begins as an erythematous papule or nodule that indurates and ulcerates. It is frequently painful and tender. Ulcers associated with handling infected animals are usually located on the hand, with associated lymphadenopathy found in the epitrochlear or axillary regions. Infections transmitted by tick bites are usually located on the lower extremities, associated with inguinal or femoral lymphadenopathy.

So-called glandular tularemia is characterized by the presence of enlarged, tender lymph nodes without an associated skin lesion. However, the skin lesion may have healed or gone unnoticed before the development of lymphadenopathy.

In the oculoglandular form, unilateral conjunctivitis occurs with concentration of inflammatory response in and around a nodular lesion on the conjunctiva and with enlargement of the ipsilateral preauricular lymph node.^[102] The oculoglandular form constitutes 1% to 2% of tularemia cases.

The typhoidal form occurs in approximately 10% of tularemia cases. It is characterized by fever, chills, and debility. As the disease progresses, weight loss may be significant. Hepatosplenomegaly can occur, especially in children.^[114] Pericarditis occurs rarely.^[84] Exudative pharyngitis can occur with either the typhoidal or the ulceroglandular form. There is usually associated cervical lymphadenitis.

Pneumonia is a fairly common complication of tularemia. The pulmonary infection can be acquired by inhalation of aerosol or from bacteremia. Symptoms include cough, chest pain, shortness of breath, production of sputum, and hemoptysis. Radiographic abnormalities of the chest may be found in patients without pulmonary symptoms. Chest films may reveal infiltrates, most often of the lower lobe; hilar lymphadenopathy, and pleural effusion. Tularemia patients with pneumonia are more likely to be older, less likely to have a known source of infection, and more likely to die than those without pulmonary infection.^[196]

Severe complications of tularemia, such as bacteremia, pneumonia, and rhabdomyolysis, are most likely to be seen in patients with significant underlying disease, such as lymphoma, other forms of cancer, or diabetes.^[165] From 1981 through 1987 the case-fatality rate of tularemia in the southwestern and central United States was 2%.^[216]

Diagnosis

Ulceroglandular tularemia can be confused with cat-scratch disease, streptococcal and staphylococcal skin diseases, sporotrichosis, and plague. Typhoidal tularemia can mimic septicemic plague, brucellosis, salmonellosis, typhoid fever, other forms of Gram-negative sepsis, and leptospirosis. Tularemic pneumonia can appear similar to other forms of bacterial and nonbacterial pneumonias, including Q fever, psittacosis,

and legionnaires' disease.^[179] ^[196]

Oculoglandular tularemia resembles Parinaud's syndrome (granulomatous conjunctivitis with preauricular lymphadenitis) caused by other bacteria, such as *Leptothrix* species, *Mycobacterium tuberculosis*, syphilis, and cat-scratch disease.^[102]

The differential diagnosis of oropharyngeal tularemia includes infectious mononucleosis, streptococcal pharyngitis, and plague pharyngitis. The disease most likely to be confused with tularemia is plague, because both diseases occur under similar epidemiologic circumstances and are characterized by certain similar clinical syndromes.^[39] ^[202] The bacteria causing plague and tularemia share morphologic and cultural features but can be differentiated serologically and with appropriate microbiologic techniques.

1032

Definitive diagnosis of tularemia is usually based on antibody studies.^[126] ^[213] The most common test is agglutination, either tube agglutination or microagglutination.^[188] Enzyme-linked immunosorbent assay (ELISA) is also used for diagnosis. An advantage of ELISA is identifying IgM, IgA, and IgG antibodies.

Diagnosis is established serologically by demonstrating a fourfold or greater rise in titer between acute and convalescent sera taken 1 or more weeks apart. Titers of 80 or greater are generally considered significant in the agglutination test. Values rarely reach that level during the first week of infection but usually reach or exceed that by day 16 of infection. Agglutinating antibodies remain detectable for 10 to 30 years after infection. IgM, IgA, and IgG antibodies also remain detectable by the ELISA technique for at least 11 years after infection. Because of this long persistence of antibody, single titers cannot be used for definitive diagnosis.

Tularemia can also be definitively diagnosed by isolation and identification of the organism from blood or lesions. Samples for culture, however, are not routinely taken in suspect cases, and they are not encouraged because of the high frequency of contamination and infection of laboratory workers using this organism in vitro.

Treatment

Streptomycin, the drug of choice, should be given in a dose of 30 to 40 mg/kg/day, in two divided portions intramuscularly every 12 hours for 3 days, followed by half that dose for another 4 to 7 days. Rate of cure for streptomycin is 97%, with no relapses. For gentamicin and tetracycline, respectively, the rates of cure were 86% and 88%, rates of relapse 6% and 12%, and rates of failure 8% and 0. The duration of therapy with gentamicin and a delay in its initiation may have affected outcome in severe cases.^[165] For chloramphenicol and tobramycin, cure rates were 77% and 50%, relapse rates 21% and 0; and failure rates 2% and 33%, respectively. Treatment with imipenem/cilastatin was successful in one case and with ciprofloxacin or norfloxacin successful in six cases;

in contrast, therapy with ceftriaxone was ineffective in eight cases.^[83]

Prevention

Prevention of tularemia includes avoidance of ectoparasites such as ticks and appropriate hygiene in the handling of infected animal tissues. Insect repellents should be applied when going into areas where ticks, deerflies, and other possible vectors are found. Persons walking in tick-infested brush should wear long pants, with the bottoms of trouser legs tucked into socks or boot tops. Individuals should check frequently for the presence of ticks while in the field. Ticks should be removed as quickly as possible, preferably with pointed forceps grasping the mouthparts, taking care not to break them or to squeeze the body of the tick in the removal process.

Persons handling suspect animals should wear rubber or plastic gloves. Reservoir animals such as rabbits or muskrats that appear ill should not be handled. When handling sick animals is necessary, infection control procedures should include the use of gloves, face masks, and disposable gowns.

Attempts at culturing the organism should be done only in laboratories that have appropriate containment facilities for handling such dangerous organisms. Laboratory work with *F. tularensis* should always be conducted under an appropriate microbiologic hood. Standard halogen-containing phenol or alcohol-based antiseptics can be used for disinfecting surfaces.

Although person-to-person transmission is rare, reasonable infection control measures should be taken to reduce exposure to aerosols from patients with oropharyngeal or pneumonic tularemia, and exposure to exudates should be avoided.

A live attenuated vaccine is available as an investigational new drug from the U.S. Army Medical Research Institute for Infectious Diseases at Fort Detrick, Maryland. Physicians using this vaccine must register as collaborative investigators and follow a prescribed protocol in advising the patient, administering the vaccine, and reporting on its use. The vaccine is made available only for those who are at high risk, such as laboratory personnel who frequently work with the organism. The vaccine is effective in preventing the typhoidal form of tularemia^[184] ^[185] ^[186] ^[187] but will not prevent cutaneous lesions forming at the site of an inoculation. The vaccine, when administered by scarification, induces humoral and cell-mediated immune responses.^[220]

PLAGUE

Plague, a bacterial disease caused by *Yersinia pestis* and transmitted by the bite of infected fleas, has occurred in explosive epidemics. Probable epidemics of plague occurred during the Peloponnesian War, as described by Thucydides, in approximately 400 BC. It ravaged the Roman Empire and western Europe during the age of Justinian and continued through the seventh century. The best-known and most devastating epidemic started in 1348. Known as the Black Death, the infection spread from Asia throughout Western Europe, killing one third of the population.^[95] Plague is a reportable disease under the International Sanitary Regulations.

Plague is carried by various rodent reservoir hosts and transmitted by rodent fleas. Most of the outbreaks in Europe have been ascribed to importation of plague from enzootic foci in Asia, by ships bringing infected rats and people to port cities. A matter of considerable historical and epidemiologic interest is how and why the various epidemics eventually subsided. Theories include development of mutant bacteria; changes in patterns of shipping, building, and hygiene; replacement

1033

of *Rattus rattus* by *R. norvegicus*; and development of immunity in animals and humans.^[82]

Bacteriology

Y. pestis is a gram-negative, nonmotile, nonsporulating rod with a bipolar, or "safety-pin," appearance in smears stained with Giemsa's or Wayson's stain.^[38] The appearance is somewhat variable by Gram's technique.

Most standard bacteriologic media support the growth of the organism aerobically or under facultative anaerobic conditions. Optimal in vitro growth occurs at 28° C (82.4° F), at which temperature colonies become visible on plain agar in approximately 48 hours.

Virulence factors encoded by the bacterial chromosome include surface capsular material that is antiphagocytic, ability to synthesize purines even if phagocytosed, and a surface component needed for iron uptake. Virulence factors mediated by a plasmid include dependence on environmental calcium for growth at 37° C (98.6° F) and production of v⁸³ and w¹³⁷ antigens. The relationship between calcium dependence and

virulence is under investigation.^[95]

Transmission

Plague is normally a flea-borne disease of rodents, although other animals, including humans, can become infected. Humans are generally infected by the bite of an infected flea; but direct contact with and percutaneous inoculation from *Yersinia pestis* organisms can lead to disease. Rarely, inhaled infective droplets cause pulmonary plague; human-to-human transmission can occur and is a threat in developing countries and in the United States.

The black rat is highly susceptible to plague and dies with severe septicemia. The concentration of organisms in the rat's blood ensures infection of the biting flea. When the rat dies, the flea leaves to seek other hosts. This cycle is unusual in that the infection kills the reservoir host and vector, but the nature of the infection in the flea and rat guarantees further transmission and survival of the microorganism. The bacteria multiply so extensively in *Xenopsylla cheopis* that they block its proventriculus, or foregut. The flea cannot feed effectively, becomes ravenously hungry, and regurgitates large numbers of bacilli when it bites.

Epidemiology

The epidemiology of plague is complex. Various fleas can transmit the infection between reservoir rodent hosts and humans. In major epidemics the prominent carriers were the tropical rat flea (*X. cheopis*) and the black rat (*R. rattus*).

Smoldering foci of infection are maintained in nature in wild rodents and their fleas. In the United States, enzootic (maintenance) hosts include deer mice (*Peromyscus maniculatus*) and various voles (*Microtus* species). Epizootic (amplifying) hosts include the prairie dog (*Cynomys* species) ([Figure 44-13](#)) and ground squirrel (*Spermophilus* species). Other rodents and lagomorphs that maintain infection include chipmunks (*Eutamias* species), marmots (*Marmota* species), wood rats (*Neotoma* species), rabbits (*Sylvilagus* species), and hares (*Lepus* species).^[168]

Enzootic foci of plague remain in parts of Asia, Africa, and South America,^{[36] [168]} as well as the western United States. The major enzootic states in the United States are New Mexico, Arizona, California, Colorado, Oregon, Nevada, and Utah. From 1944 through 1993, 362 cases of human plague were reported in the United States; approximately 90% of these occurred in Arizona, California, Colorado, and New Mexico. Seven confirmed cases of human plague were reported in 1995 (three in New Mexico, two in California, one in Arizona, and one in Oregon). Five of the seven cases were "bubonic," one was "septicemic," and one a fatal "pneumonic" case.^[137] In many foreign areas the exact species of rodents and fleas involved in transmission and maintenance are not known. Vietnam is the only country considered a threat for the international introduction of plague.

Carnivorous mammals can acquire plague by ingesting infected rodents or by being

bitten by their fleas. Dogs usually do not become very ill with plague, but cats can acquire severe, often fatal, forms of infection, resembling syndromes seen in humans. Bubonic plague in cats is usually manifested as severe submandibular lymphadenopathy. Cats can also acquire pneumonic plague, characterized by a subacute febrile course with cough and respiratory distress. Cats can transmit plague to humans by bite, respiratory droplets, or carrying fleas to people. Plague is an occupational risk for veterinarians who handle sick cats or their tissues.^[118] ^[178]

Although dogs are usually not as severely affected as cats, at least one human case was associated with a

Figure 44-13 Thrombus in a vein in the subcutis of a prairie dog naturally infected with plague. Many organisms (fine stippling) are present in the thrombus. (Hematoxylin and eosin stain, original magnification 1000x.)

1034

Figure 44-14 Reported cases of plague in humans in the United States, 1955 to 1999. (Modified from *MMWR* 40, 1991.)

dog that apparently died of plague.^[180] Dogs may be significantly involved in the epidemiology of plague in Tanzania, as reservoirs of vector fleas or bacterial infection.^[121] In the United States, one person acquired plague while skinning an infected coyote^[40] and two from skinning bobcats.^[45] Other carnivores, such as skunks, badgers, and raccoons, have been found with antibody to the plague bacillus and presumably were exposed while hunting infected rodents. Exposure to infected rabbits, their fleas, or both has been associated with human plague.^[38] Plague is not generally recognized as a disease of farm animals in modern times, but a recent report ascribed one outbreak of plague in a Libyan village to contact with a sick camel and another to contact with two goats.^[65]

In the United States the major epidemiologic factor associated with acquiring plague is living in a rural or suburban area where the enzootic disease occurs ([Figure 44-14](#)). People who hike, camp, or perform field studies in such areas are subject to this disease. Its diagnosis should be considered in anyone with a compatible history who

has recently been in an enzootic area.

Symptoms

The three most common forms of plague are bubonic, pneumonic, and septicemic. Less common forms are meningeal, pharyngeal, and ophthalmic.

In the most common form, *bubonic plague*, buboes develop, which are greatly enlarged and very tender lymph nodes proximal to the point of percutaneous entry, such as a flea bite or a cut infected by handling infected tissues. Inguinal nodes are most often involved because fleas usually bite on the legs. Skinning an infected animal or handling its tissues often results in axillary buboes. Frequently, cervical, hilar, or mesenteric lymph nodes are enlarged.

The incubation period for bubonic plague is usually 2 to 6 days. In mild or early stages of infection, seeding of the blood occurs intermittently, causing a low sensitivity to blood culture testing. Later, if disease becomes severe, all blood cultures are positive. Victims usually have high fever, chills, severe malaise, headache, and myalgias. Toxicity, cardiovascular collapse with shock, and hemorrhagic phenomena may occur. Blackened hemorrhagic skin lesions gave rise to the name "Black Death" during the pandemic of the fourteenth century.

Victims with bacteremia and significant symptoms but no buboes are considered to have *septicemic plague*. Such cases may be difficult to diagnose unless the physician suspects plague based on epidemiology. As with other forms of gram-negative sepsis, victims have fever, chills, malaise, headache, and gastrointestinal (GI) symptoms such as nausea, vomiting, and diarrhea, and the disease can result in cardiovascular collapse. Thrombosis (see [Figure 44-13](#)) and disseminated intravascular coagulopathy may be present. Untreated septicemic plague progresses to pulmonary involvement and death. However, transmissible pneumonic infection is estimated to occur in only 5%, since victims die before alveolar pneumonitis and the potential for droplet spread.

Pneumonic plague can result from inhalation of droplets from another pneumonic patient or by pulmonary seeding from the blood. Pneumonic plague runs an acute and fulminant course and is almost uniformly fatal if not treated. The incubation period is 2 to 3 days and disease is characterized by the sudden onset of fever, cough, bloody sputum, headache, and shaking chills. Radiographs reveal progressive consolidation of pneumonic patches in the lung, often with pleural effusion.

Of 71 cases of plague reported in New Mexico between 1980 and 1984, 18 were septicemic.^[113] The victims were significantly older and more likely to die than those with bubonic plague. The white blood cell counts in the New Mexican septicemic cases were low, normal, or elevated (range, 3000 to 68,700/mm³), but all patients had relative or absolute neutrophilia with a left shift. Bacteria were demonstrable on direct blood smears in 3 of 17 septicemic patients. Plague is most common in persons less than 40 years old, perhaps because of their greater outdoor activity, but the risk of the septicemic form increases in individuals over age 40 years. In patients with septicemic plague, mortality was greater in younger patients, perhaps because of greater delay in

diagnosis and decreased likelihood that they would receive antibiotic therapy on an empiric basis.^[113]

Abdominal pain was present in nearly 40% of the patients in New Mexico. Hepatosplenomegaly occurs in plague and may be a source of abdominal pain, but it was not found in the patients reported in this series. The presence of abdominal symptoms in plague should be emphasized because the disease could be mistaken for other forms of GI illness. A review of the 71 plague cases in New Mexico from 1980 to 1984 revealed that GI symptoms occurred in 57% of patients, with vomiting (39%) the most frequent symptom. Nausea (34%), diarrhea (28%), and abdominal pain (17%) were also observed.^[112]

1035

Plague should be suspected in patients who have various combinations of lymphadenopathy, high fever, malaise, tachycardia, tachypnea, hypotension, and abdominal symptoms and who have come from an endemic area. If the suspicion is reasonable, antibiotic therapy should be instituted immediately. Treatment should not be delayed to await laboratory confirmation of the diagnosis.

Rare forms of plague include pharyngeal, meningial, and ophthalmic. Pharyngeal and ophthalmic plague can be acquired by exposure to droplets expelled by a pneumonic patient. Endophthalmitis can also be secondary to septicemia. Meningitis is acquired by direct seeding while the patient is bacteremic.

Diagnosis

Definitive diagnosis is based on culture of the organism from sputum, transtracheal aspirate, blood, or aspirates of buboes. The best staining technique to demonstrate bipolar morphology of the organism is Giemsa's or Wayson's technique.

Direct fluorescent antibody (FA) stain of aspirates and smears provides a reasonably rapid diagnostic technique. Although cross-reactions with *Yersinia pseudotuberculosis* have been recorded, and occasional strains of the plague bacillus do not stain well with FA, a positive FA test in a patient with a compatible epidemiologic and clinical picture is a reasonable basis for making a diagnosis of plague and instituting therapy.

Material from buboes should be obtained by fine-needle aspiration rather than excision or incision and drainage. This reduces risks of transmission to medical personnel and of iatrogenic septicemia.

Treatment

Patients with suspected plague should be treated immediately without awaiting definitive laboratory studies. The best available drug is streptomycin. If given too rapidly,

streptomycin can cause a severe reaction as a result of rapid killing of organisms and release of endotoxin. The recommended dosage is 30 mg/kg/day intramuscularly in four divided doses every 6 hours for 5 days. A less preferred alternative to streptomycin is gentamicin, 5 mg/kg/day intravenously in four divided doses every 6 hours, reduced to 3 mg/kg/day after clinical improvement. Patients with impaired renal function should have their dosage of streptomycin or gentamicin modified appropriately.^[168]

Tetracycline is often used concurrently with streptomycin. The recommended loading dose is 15 mg/kg orally, up to 1 g total dose. This is followed by 40 to 50 mg/kg in six divided doses every 4 hours on the first day. Thereafter 30 mg/kg is administered orally in four divided doses every 6 hours for 10 to 14 days. If the patient cannot tolerate treatment by mouth, tetracycline can be given intravenously, using one third of the calculated oral dose until oral therapy is tolerated.

An alternative to tetracycline is chloramphenicol, administered in a loading dose of 25 mg/kg orally, up to 3 g total, followed by 50 to 75 mg/kg orally in four divided doses for 10 to 14 days. If the patient does not tolerate oral therapy, chloramphenicol can be given intravenously, 50 mg/kg in four divided doses every 6 hours until oral therapy is tolerated. It is preferable to use chloramphenicol in the event of meningitis or endophthalmitis because of good penetration into affected tissues. Whichever drug combination is selected, antibiotic therapy should be given for at least 10 days, or for 3 or 4 days after clinical recovery.

Sulfadiazine is a less satisfactory alternative. A loading dose of 25 mg/kg is given orally, followed by 75 mg/kg orally in four divided doses every 6 hours for 10 to 14 days. Co-trimoxazole (320 mg of trimethoprim and 1600 mg of sulfamethoxazole) twice or three times a day for 10 to 17 days was found effective in treating plague^[2] but much less experience has been accumulated with this medication than with other antibiotics.

Infants born to plague-infected mothers may have congenital infection. They should be treated with kanamycin, 15 mg/kg/day intravenously or intramuscularly in four divided doses every 6 hours, or streptomycin, 10 to 20 mg/kg/day in four divided doses every 6 hours.

Quarantine and Infection Control

The greatest risk of contagion is by aerosol transmission from patients with the pneumonic form of plague. All persons with suspected plague should be placed in strict quarantine and isolation for a minimum of 48 hours of specific antibiotic treatment. If no respiratory signs develop within 48 hours, wound and skin precautions will suffice for the rest of his or her hospitalization. Patients with plague pneumonia or pharyngitis should be kept under strict respiratory quarantine for at least 4 days of antibiotic treatment, until the pharyngeal culture is negative for the organism or respiratory signs abate. Contact personnel should wear gloves, gowns, masks, and eye protection. Strong^[209] dramatically illustrated effective protective clothing during a pneumonic plague epidemic in Manchuria in 1911.

The greatest risk of acquiring plague from a patient with the septicemic or bubonic form

is by inoculation of blood or exudate; therefore strict needle precautions should be taken. Buboes should not be incised and drained. In theory, fleas harbored by a septicemic patient should be capable of transmitting the disease, but CDC recommendations for control of plague do not cover eradication of fleas from human patients.^[225] No pesticides have been FDA approved for this use. Products effective against lice may have limited effectiveness because most fleas do not remain long on a human host.

Household contacts and individuals exposed to patients with pneumonic plague should be prophylactically treated with antibiotics. Tetracycline, 500 mg

1036

orally every 6 hours for 6 days, can be given to adults. Trimethoprim-sulfamethoxazole can be given to children under 8 years of age and to pregnant women. Streptomycin, chloramphenicol, and sulfadiazine are alternative prophylactic medications, given in therapeutic doses for 1 week to 10 days.

Household contacts of individuals with bubonic plague do not have to be treated prophylactically. They should have their temperature recorded twice daily, and if it exceeds 37.7° C (100° F) orally, they should report immediately to a physician for evaluation. Careful surveillance is indicated for persons who have had face-to-face contact with patients with pneumonic plague. Their well-being should be confirmed daily.

The incubation period for primary pneumonic plague is 1 to 3 days and for pharyngeal plague 3 to 6 days. Precautionary follow-up observation of contacts should be maintained throughout this time. All cases of suspected or confirmed plague should be reported to the state health department.

Prevention

Residents and visitors to plague endemic areas should be advised of the risks of infection. They should avoid contact with rodents and other possible animal reservoirs of infection that are found sick or dead in the wild. Disposable plastic or rubber gloves should be worn when skinning or dressing a possibly infected animal. Cats and dogs should be kept indoors, leashed, or otherwise restrained. Owners of pets that have access to wild rodent populations must maintain flea control. Veterinary personnel working on animals that could have plague should follow strict infection control procedures.

Health departments in enzootic areas should maintain surveillance for plague in local reservoir species. At times of increased plague activity, insecticide sprays and powders can be applied to rodent burrows. Ectoparasite control is essential before any attempt is made to kill the rodents, because killing the rodents without control of their ectoparasites

causes fleas to seek other hosts, including dogs, cats, and people.

Immunization

A killed bacterial vaccine is available in the United States but is rarely used. Its application is limited to persons who have intensive, usually occupational, exposure to the infection. Many of these persons prefer to rely on sanitation, protective clothing, and prophylactic or therapeutic treatment rather than use the vaccine, since it has short-term (6- to 12-month) efficacy and has a significant incidence of side effects, such as fever, malaise, and pain at the site of injection.^[47]

Clinical and epidemiologic assistance for problems relating to plague can be obtained from the Plague Branch, Centers for Disease Control and Prevention (PO Box 2087, Fort Collins, CO 80522; 303-221-6400). After-hours consultation can be obtained from the CDC in Atlanta (404-639-8107).

GLANDERS

Glanders, although little known in the Western world today, is one of the classic infectious diseases. Its greatest historic impact has been through its effect on cavalry horses during military campaigns, influencing battles from before the time of Christ through the Crusades and World War I.

Theories and disputes about the origin, nature, transmission, and treatment of glanders figured prominently in the development of veterinary science in Europe in the latter half of the eighteenth century. In 1795 Erik Viborg published an account that is remarkably close to our understanding of the disease today. He demonstrated that equine "farcy," characterized by cutaneous lymphangitis, and the respiratory form of the disease in horses, classically referred to as "glanders," were different manifestations of the same infection. He demonstrated that the disease was transmissible from one horse to the next by infectious exudates, and that the causative organism could be carried by fomites and killed by heat.

Transmission of glanders from horses to humans was documented in France and Germany during the first three decades of the nineteenth century. The causative organism was isolated by Loeffler and Schütz, as well as by Bouchard, Capiton, and Charrin in 1882. In 1891 Kalning and Helmann independently discovered mallein, derived from the glanders bacillus. Like tuberculin, mallein was thought to have therapeutic or prophylactic value. This turned out to be erroneous, but mallein provided a means of diagnosing the infection in clinically ill and carrier animals and provided a basis for test and slaughter techniques, which have largely eliminated glanders from most parts of the world.

Bacteriology

The causative organism is *Burkholderia mallei*, a member of the newly renamed *Burkholderia* genus, which includes *B. pseudomallei*, the cause of melioidosis, and *B. cepacia*. It is a gram-negative, nonsporulating, obligate aerobic, and nonmotile bacillus that requires glycerol for optimum growth in vitro. ^[174] ^[206] In 1992 Yabuuchi et al^[234] proposed that seven species formerly of *Pseudomonas* RNA group II should be transferred to a new genus, *Burkholderia*, with *B. cepacia* as the type species. The genus included *B. caryophylli*, *B. gladioli*, *B. mallei*, *B. pseudomallei*, *R. pickettii*, and *R. solanacearum*; the latter two species were transferred to the genus *Ralstonia*. ^[234]

Epidemiology

Glanders occurs in a few Asian and African countries, such as India, China, Mongolia,

It is primarily a disease of horses and is spread most rapidly when large numbers of horses, mules, or donkeys are kept in proximity. Many carnivorous mammals are also susceptible to infection, and outbreaks have occurred when infected horse meat was fed to lions, tigers, and other wild animals in zoos. Occasionally, infections occur in dogs, cats, sheep, and goats.

Humans are usually infected by exposure to sick horses. Infection can occur by inhalation of respiratory droplets or by contact with infected discharges. Human infections have also occurred from direct contact in the laboratory and from patients.

Symptoms

Equids.

Horses may have unilateral or bilateral mucopurulent nasal discharge. There may be enlargement and induration of lymphatics, with ulceration and discharge, especially involving the legs. Nodules, pustules, and ulcers may be seen on the horse's skin. The cutaneous form of the disease is often referred to as "farcy," the thickened, inflamed lymphatics as "farcy pipes," and the enlarged lymph nodes as "farcy buds." Horses also have pneumonia, with mild respiratory embarrassment in early stages, and more severe respiratory difficulties and cachexia in later stages. Septicemia with lesions in multiple internal organs can occur.

Glanders can run an acute and fulminant course in equids, most often in donkeys and mules, or a more chronic course, more often in horses. The case-fatality rate is high, especially with more virulent strains of the organism.

Humans.

The incubation period of glanders in humans can be as short as 1 to 5 days. Cases with apparent incubation periods of several months may have represented smoldering, unrecognized infection. The severity of disease can vary from mild to fatal, and the course can be acute and fulminant or chronic. Relapses can occur after quiescent periods of up to 10 years. As in horses, manifestations in humans usually involve the skin and respiratory tract. There may be pustular cutaneous eruptions, thick indurated lymphatics that may ulcerate, mucopurulent discharge from the eyes or nose, pneumonia, and metastatic abscesses in internal organs. Depending on the severity, the patient may have anorexia, fever, weight loss, headache, nausea, diarrhea, or septicemic shock. Lobar pneumonia, bronchopneumonia, or nodular densities may be seen on chest radiographs. Cases recently reported from Southeast Asia have been relatively mild, indicating that the local strain of the organism appears to have moderate

pathogenicity for humans.

Diagnosis

Clinical diagnosis in horses based on symptoms can be confirmed by reaction to mallein with a cutaneous hypersensitivity test. Mallein, a filtrate derived from culture of the organism, is injected into the eyelid of a horse. A positive reaction, read 48 hours later, consists of marked local swelling and purulent conjunctivitis. Several serologic tests are also available. Complement fixation (CF) is often used. A dot-enzyme-linked immunosorbent assay is a more sensitive test.^[218]

Clinical diagnosis in humans is based on compatible symptoms in an individual exposed to horses in an endemic area. The diagnosis can be confirmed by culture of the organism from lesions or by serologic testing, using CF or agglutination tests. Agglutination titers are often detectable by the second week of infection. The CF test is less sensitive but more specific than agglutination. CF tests become positive during the third week of infection.^[174]

Laboratory diagnosis can be made by injection of infected material intraperitoneally into male guinea pigs or hamsters. The animals develop peritonitis that extends into the scrotal sac with severe inflammation, the Strauss reaction.

Pathology

In acute phases of the disease, abscessation occurs. Later the inflammatory focus is surrounded by a granulomatous reaction, but central karyorrhexis remains a prominent feature of the lesion. The lungs are the internal organs most typically involved ([Figure 44-15](#) and [Figure 44-16](#)), but septicemic glanders can involve liver, spleen, bone, or brain. With chronic infection, multiple subcutaneous and intramuscular abscesses may develop.

Treatment

Early studies indicated that sulfadiazine, 100 mg/kg/day in three divided doses given for 3 weeks, is effective. Treatment with tetracyclines and streptomycin is also recommended.^[174] The organism is sensitive in vitro to sulfamethizole, sulfathiazole, trimethoprim-sulfamethoxazole, gentamicin, kanamycin, streptomycin, and tetracycline.^[4] Ciprofloxacin and ofloxacin, but not norfloxacin, were found to be effective in treating experimentally infected guinea pigs and hamsters.^[15] Therapy should be based on culture and sensitivity testing of isolates and on clinical response to treatment.

Prognosis

Acute untreated septicemic cases are almost uniformly fatal within 7 to 10 days.^[174] The prognosis is better in chronic forms of the disease, which can last for years, but deaths are still likely without adequate treatment.

Prevention and Control

The only significant reservoir of infection in nature is equids. If the disease were eradicated in them, it would disappear. National programs should be instituted in

1038

Figure 44-15 A bronchus filled and surrounded by pus in the lung of a horse with glanders. (Hematoxylin and eosin stain, original magnification 100x.)

Figure 44-16 Gangrenous pneumonia with characteristic karyorrhexis in the lung of a horse with glanders. A multinucleated giant cell is in the center of the figure. (Hematoxylin and eosin stain, original magnification 250x.)

enzootic countries to eradicate the infection, by mallein or serologic tests of all horses, donkeys, and mules and slaughter of reactive animals. Persons who handle horses in enzootic countries, including trekkers who pack gear into the wilderness on these animals, should be advised of the signs of glanders in equids and warned to avoid contact with sick animals.

Glanders can be transmitted from one person to another, so strict infection control should be exercised with suspected infected patients. Personnel should avoid contact with all secretions and respiratory droplets. Transmission is also a risk in the laboratory, so if this organism is being cultured, all work should be done under appropriate microbiologic hoods.

MELIOIDOSIS

Melioidosis is an infection caused by the bacterium *Burkholderia* (formerly *Pseudomonas*) *pseudomallei*, which lives freely in soil and water.^[234] Disease is spread from the environment to both humans and other animals. The causative agent and disease process in humans were first described by Whitmore and Krishnaswami^[227] in Rangoon, Burma, in 1912.^[131]

1039

Bacteriology

B. pseudomallei is a bipolar, gram-negative, aerobic rod approximately 0.5 to 1 µm in width and 3 to 5 µm in length. It is readily grown on standard laboratory media at 37° C (98.6° F). After 48 to 72 hours of growth, distinctive wrinkled colonies with a "daisy head" appearance are formed. These give off a pungent, putrefactive odor.^[130] The organism is oxidase positive and nonpyocyanogenic. It is resistant to colistin and gentamicin in vitro.^[101] In 1992, Yabuuchi et al proposed that seven species formerly of *Pseudomonas* RNA group II should be transferred to a new genus, *Burkholderia*, with *B. cepacia* as the type species.^[234]

Transmission and Epidemiology

Melioidosis is a saproozoonosis transmitted to animals and humans from the environment; transmission does not generally occur between living organisms. There is a singular case of presumed transmission by the venereal route.^[152] Disease is reported much more often in adults than in children.

Most cases of melioidosis have been reported in areas between 20 degrees north and 20 degrees south of the equator.^[100] A majority of cases have been reported from Southeast Asia and tropical Australia. The most heavily endemic areas include Myanmar (Burma), Malaya, Vietnam, Singapore, Cambodia, Thailand, Java, Borneo, New Guinea, and northern Australia. Occasional human and animal cases have been reported from Central India, Sri Lanka, Niger, Madagascar, Ecuador, Panama, Aruba, and Mexico. Cases from the Western Hemisphere have been reviewed.^[12] *B. pseudomallei* survives during Australia's dry season in the clay layer of the soil, 25 to 30 cm below the surface, and can be brought to the surface and distributed by water seeping through this layer during the wet season.^[101]

Clinical and subclinical infections occur in a variety of animals, most often sheep, goats, and swine. Infections in animals offer no direct threat to human health but are epidemiologic indicators that the organism is in a given geographic area.^[100]

Transmission is thought to occur by direct percutaneous inoculation through wounds contaminated with soil or water, by ingestion, or by inhalation of infective droplets. A high incidence of pulmonary melioidosis in helicopter crew members in Vietnam was ascribed to inhalation of dust and aerosols raised by the helicopters operating in highly endemic areas.^[100]

Symptoms

Most human infections are asymptomatic, as indicated by the high prevalence of seropositivity without clinical disease within endemic areas. Active disease is most likely to be seen in individuals with predisposing conditions, particularly diabetes mellitus, alcoholism, neoplasms, malnutrition, and various forms of immunodeficiency.

Clinical disease can occur in acute, subacute, or chronic forms. The lungs are the organs most frequently involved. Pulmonary melioidosis can mimic tuberculosis in that the upper lobes are most frequently involved, cough is productive, sputum often contains blood, and patients complain of chest pain and fever. However, calcifications in the lung and hilar lymph nodes typically seen in tuberculosis are rarely seen with melioidosis. An entire lobe or major segment of a lobe may be consolidated, and multiple pulmonary abscesses may be scattered in the lung parenchyma.

Septicemia can develop in the acute form of the disease and may mimic other forms of gram-negative sepsis in its manifestations. Multiple abscesses can form in skin, lungs, liver, spleen, kidney, and bone, but the CNS is rarely involved. Without treatment the case-fatality rate exceeds 90%.

In the subacute and chronic forms of disease, abscesses can form in internal organs and may drain through sinus tracts.

Melioidosis has been referred to as a "medical time bomb" because infection can lie dormant for months or years, only to become manifest when resistance is lowered. An incubation period as long as 26 years has been reported.^[148] The infection should be suspected in anyone with a compatible clinical picture, including fever of unknown origin, who has resided in an endemic area.

Diagnosis

The only definitive diagnostic procedure is culture of the organism from blood, bone marrow, sputum, pus, or infected tissue. Several serologic tests are available but are not reliable, because many individuals from endemic areas have antibodies to the organism without any evidence of clinical disease. An indirect hemagglutination antibody titer of 1:40 or greater is considered compatible with infection, as is a CF titer

of 1:10 or greater. Rising titers by IgM indirect FA are probably the best immunologic indication of infection.

No pathognomonic lesions are seen histologically. The abscesses consist of central areas of necrosis without unique or distinctive features permitting definitive histopathologic diagnosis.

Treatment

Combinations of antibiotics have been used, almost always including chloramphenicol, 40 mg/kg/day in adults and 50 to 75 mg/kg/day in children.^[164] Even with combination therapy, however, mortality can reach 80% in disseminated septicemic melioidosis. Tetracycline is also used in adults and in children over 8 years of age, 50 mg/kg/day in four divided doses six times a day orally. Kanamycin, 15 to 20 mg/kg/day in two divided doses intramuscularly, and amikacin, 15 to 20 mg/kg/day in two divided doses every 12 hours intramuscularly, have also been recommended for

1040

treatment. Co-trimoxazole may prove useful, but experience is too limited. The antibiotic treatment should be given for several weeks in acute cases and for approximately 6 months in chronic cases. Dosage of kanamycin and amikacin should be modified appropriately if there is renal impairment.

Ceftazidime has largely replaced combination antibiotic therapy and is now generally recognized as the drug of choice.^[227] It has reduced mortality in disseminated septicemic melioidosis to 35% to 40%.^[130]

In vitro sensitivity tests do not always correlate with clinical response to antibiotics. Therapy must be given at sufficient dosage and long enough to avoid recurrence of infection and emergence of resistant organisms.

Prevention and Control

In the field, prevention consists of avoiding ingestion or inhalation of potentially infective soil or water. Wounds, burns, and other injuries should be thoroughly cleaned to avoid infection through contamination. No evidence exists that transmission is likely to occur from person to person, so isolation of hospitalized patients is not necessary. Reasonable care and precautions should be taken in handling purulent drainage of blood, sputum, and other materials from patients with melioidosis.

TRICHINOSIS

Trichinosis is an infection caused by nematodes in the genus *Trichinella*. In the past, only one species, *T. spiralis*, was recognized. Isoenzyme and DNA analysis indicate that the genus is polyspecific. ^[171] Eight gene pools, T₁ through T₈, have been identified. T₁ is classic *T. spiralis*; the principal reservoir is in domestic swine, but some wild animals can also be infected. T₂, *T. nativa*, is found primarily in terrestrial mammals such as the bear, walrus, or fox in Arctic and sub-Arctic regions. Most human infections are caused by T₁, fewer by T₂. Relatively few data are available on how frequently the other species infect people. T₃ occurs in bears (Ursidae), T₇ and T₈ in African Hyenidae and Felidae. Only T₄, *T. pseudospiralis*, can infect mammals and birds.

Unless stated otherwise, the rest of this discussion relates to trichinosis generically or to *T. spiralis* specifically.

Trichinella cysts were first noticed by Paget during an anatomic dissection in 1836 when distinct white lesions were found throughout a muscle specimen. The association of the encysted organism and the ingestion of contaminated meat was not made until 1850. In 1862 Friedrich diagnosed and described the first clinical case of acute trichinosis. Outbreaks in Germany in 1849 and 1865 were associated with mortality rates of 19% and 30%, respectively. Examination

Figure 44-17 Reported cases of trichinosis in the United States, 1950 to 1999. (Modified from MMWR 40, No. 53, 1991.)

of diaphragmatic muscle samples in the United States between 1936 and 1941 revealed *Trichinella* organisms in 1 out of every 6 samples tested (16.7%). National reporting of trichinellosis began in 1947. The incidence of this disease has decreased significantly over time due to the passage of legislation prohibiting the feeding of raw sewage to swine (Federal Swine Health Protection Act of 1980), widespread freezing of pork, and increasing public awareness of the dangers of eating inadequately cooked pork products ([Figure 44-17](#)).

Life Cycle

The life cycle is unusual in that every host is necessarily both a definitive host, harboring the adult stage of the parasite, and an intermediate host, harboring the larval stage.

The infection is acquired by ingestion of larvae encysted in skeletal muscle. The worms mature within a few days in the small intestine. The female burrows into the mucosa and deposits larvae in the tissue, starting around the fifth day after infection. Most larvae are deposited within 4 weeks, but they can be produced for as long as 4 months. The larvae enter the circulation and invade skeletal muscle within 7 to 14 days ([Figure 44-18](#)). They become encapsulated around day 21 after infection and are then infective for the next host that ingests them.

Epidemiology

All carnivorous and omnivorous mammals are susceptible to trichinosis, but most human infections are acquired by eating raw or undercooked pork. Game animals can harbor the parasite. Trichinosis was found in 1.3% of black bears in New England. ^[104] It can infect other species of bears, raccoons, opossums, seals, walruses, peccaries, and wild swine.

Rodents, such as mice and rats, are commonly infected in nature. Except in certain cultures, these small

1041

Figure 44-18 Trichinosis in a polar bear. A larva is seen within a muscle fiber in the center of the picture. The parasite found in Arctic mammals is highly resistant to freezing and has been given a separate species status, *Trichinella nativa*. (Hematoxylin and eosin stain, original magnification 100x.)

rodents are rarely eaten by people, unlike their larger cousins, squirrels, woodchucks, muskrats, agoutis, and capybaras. These larger rodents are primarily herbivorous but can still be an occasional source of human infection.

Although experimentally susceptible to trichinosis, herbivores, such as members of the deer and antelope families, are almost never infected naturally, and consumption of their flesh is not associated with this infection. Interestingly, some outbreaks of trichinosis have occurred in people who consumed horseflesh. ^[51] The horses could have become infected by consuming mice, dead or alive, in their feed. Alternatively, larvae passed in the stool of infected rodents could have been ingested in the horses' grain or

hay.

Swine that are privately raised and slaughtered are a continuing source of human infections in many areas, including the northeastern United States. ^[10] Bears, walruses, and feral swine have been the principal nondomestic sources of trichinosis in the United States. ^[149] From 1991 to 1996, three deaths in 230 cases were reported to the CDC (average of 38 cases per year), including 14 multiple case outbreaks from 31 states and Washington, D.C. Information on the suspected food item was available for 134 (58%) of the 230 reported cases. Pork was implicated in 80 (60%) cases, bear meat in 31 (23%), walrus meat in 13 (10%), and cougar meat in 10 (7%). Sausage was the most frequently implicated pork product (i.e., 57 of the 64 cases for which the form of the pork product was identified). ^[154] Wild boars are a source of infections in Germany. ^[108]

Twenty-six cases of trichinosis reported in the United States from 1975 to 1989 were acquired during foreign travel. Seventeen of these persons had traveled to Mexico or Asia. ^[150]

Symptoms

The signs and symptoms of trichinosis are closely related to the activities of the parasite in its life cycle. The severity of disease is proportional to the number of adult and larval worms present. GI symptoms predominate during the first week after ingestion of infected meat. The worms mate and invade the intestinal mucosa during the first 48 hours. The female worm is capable of producing up to 1500 larvae during her lifetime. Larvae are deposited starting on approximately the fifth day after ingestion. This activity results in irritation of the bowel, with nausea, vomiting, variable diarrhea, and abdominal pain. Fever may occur. These symptoms are often mistaken for various forms of food poisoning. GI symptoms may continue until the females are cleared from the intestinal tract at approximately 4 to 6 weeks after infection.

Larval production reaches a peak during the second week after infection. The larvae start to invade skeletal muscle as early as the seventh day. During larval migration, direct capillary damage occurs, resulting in facial edema, especially involving the periorbital area, which may be accompanied by photophobia, blurred vision, diplopia, and complaints of pain on moving the eyes. Splinter hemorrhages may appear in the nailbeds, and there may be cutaneous petechiae. Hemorrhagic lesions can also occur in the conjunctivae and retinae. The temperature may reach 40.5° C (105° F).

Eosinophils start to increase in peripheral blood during the second week, often exceeding 20% of the total white blood cell count after the third week of infection.

The eosinophil count returns to normal from 6 to 12 months after infection. GI symptoms may continue during this period, until the females are cleared from the intestinal tract approximately 4 to 6 weeks after infection. During the second phase of infection,

migrating larvae can cause pulmonary damage, resulting in cough, dyspnea, and pleuritic pain. There may be hemoptysis. Myocarditis can occur and may be life threatening. Damage to the brain or meninges by migrating larvae can cause encephalitic or meningitic symptoms. A spinal tap may reveal eosinophils in CSF. The third phase of infection is encystment of the larvae within skeletal muscle, starting about the second or third week after infection. This can cause significant myalgias and stiffness in affected muscle groups. The final phase of infection occurs as the larvae die and become calcified. This is a period of convalescence, which is usually asymptomatic, and typically occurs between 6 and 18 months after infection.

Trichinosis in the Inuit population of northeastern Canada, associated with eating raw walrus, is characterized by prolonged diarrhea and brief muscle symptoms. High peripheral eosinophilia and high *Trichinella* antibody titers occur. The disease is probably caused by *T. nativa*, and at least some cases may be associated with reinfection.^[136]

Diagnosis

Larvae are sometimes passed in the stool in the early stages of infection, but this occurs infrequently and inconsistently and cannot be used for diagnosis.

Trichinosis is definitively diagnosed by biopsy of the gastrocnemius muscle or of clinically affected (painful, tender) muscles. The larvae are demonstrable in muscle beginning about the seventh day after infection. Diagnosis can also be made serologically, using the bentonite flocculation test (BFT), latex particle agglutination, or countercurrent immunoelectrophoresis. The BFT involves a suspension of aluminum silicate particles (bentonite) to which *Trichinella* antigen is bound and incubated with dilutions of serum from the patient. All these tests usually do not become positive until 3 to 4 weeks after infection. Newer ELISA tests are available that measure reaction by different immunoglobulin classes. Most ELISA tests offer greater specificity and sensitivity and become positive earlier than many of the other tests.^{[9] [189] [217]} An ELISA IgG test, using the excretory-secretory antigen of *T. spiralis* larvae, had specificity and sensitivity of 100% at days 57 and 120 after infection but was negative at day 23.^[138] An experimental "dissociated enhanced lanthanide fluoroimmunoassay" (DELFLIA) can detect as little as 1 ng of antigen/ml of serum. Circulating antigen was detected in mice as early as 7 days after infection.^[125]

Treatment

No satisfactory, safe, and effective drug is available for elimination of larvae, which are responsible for most of the pathologic changes and symptoms of trichinosis. Thiabendazole (25 mg/kg twice a day for 5 days, maximum 3 g/day) is effective against adult worms in the intestine. Its efficacy against larvae is questionable, however, and it can cause serious side effects, such as fever, increased edema, and myocarditis.^[123] Mebendazole (200 to 400 mg three times a day for 3 days, then 400 to 500 mg three times a day for 10 days) is better tolerated,^[160] but poor intestinal absorption reduces its use in extraintestinal trichinellosis. Albendazole or flubendazole are well absorbed and

may be more effective, but the supporting data are scarce.

Steroids (e.g., prednisone, 30 to 60 mg/day orally for 10 to 30 days) can be given for relief of severe illness, such as myocarditis caused by migrating larvae.^[123] The dose and duration of treatment are individually determined by clinical response. Steroids reduce the inflammatory response to larvae but can also interfere with rejection of adult females in the intestine, thus prolonging the period of larva deposition.

Prevention

Trichinosis is prevented by cooking meat to an internal temperature of 65.6° to 77° C (150° to 170° F). Most *Trichinella* larvae are killed by freezing. The time required depends on the thickness of the meat and the freezing temperature. Holding meat at -15° C (5° F) for 20 days, -23.3° C (-10° F) for 10 days, or -28.9° C (-20° F) for only 6 days is recommended. Salting, drying, and smoking are not always effective. Note that *T. nativa* found in Arctic mammals ([Figure 44-18](#)) is resistant to freezing.

CAT-SCRATCH DISEASE

Cat-scratch disease (CSD) is transmitted through a break in the skin (bite, scratch, or other injury) caused by a cat. First recognized by Robert Debre at the University of Paris in 1931, the disease was not officially reported until 1951. CSD is relatively rare but is probably the most common cause of unilateral lymph-adenopathy in children.^[205] The current etiology of CSD is thought to be the gram-negative rod, *Bartonella henselae*.^[33]

Epidemiology

About 90% of cases are caused by scratches from cats, but dog and monkey bites, as well as thorns and splinters, have also been implicated.^[71] The organism may be on the claws or in the oral cavity of the offending cat. Most cases occur in children, particularly boys who tend to play more aggressively with domestic animals. CSD has been reported from all countries and in all races. An estimated 24,000 cases are recognized each year in the United States.^[144] Patients are more likely than healthy cat-owning control subjects to have at least one kitten 12 months of age or younger, to have been scratched or bitten by a kitten, and to have at least one kitten with fleas.^[236]

1043

Symptoms

The average incubation period is 3 to 10 days. The characteristic feature of CSD is regional lymphadenitis, usually involving lymph nodes of the arm or leg. In one series, 54% of lymphadenopathy occurred in the axilla, with the remainder in the neck.^[205] Often only one node is involved. The nodes are often painful and tender, and about 25% suppurate.^[222] Adenopathy may spread proximally; occasionally, cervical adenopathy is mistaken for Hodgkin's disease. In most cases a characteristic raised, erythematous, slightly tender, and nonpruritic papule with a small central vesicle or eschar that resembles an insect bite is seen at the site of primary inoculation. Constitutional symptoms are mild, with approximately two thirds of patients manifesting fever, which is rarely greater than 38.8° C (102° F). Chills, malaise, anorexia, and nausea are common. Infrequent evanescent morbilliform and pleomorphic skin rashes lasting for 48 hours or less have been reported. This typical clinical course occurs in 88% of victims; the remainder seek medical treatment for complications such as encephalopathy, atypical pneumonia, and severe systemic disease. Parinaud's oculoglandular syndrome of granulomatous conjunctivitis and an ipsilateral, enlarged, tender preauricular lymph

node occurs in about 6% of cases.^[142]

Serious complications are rare and include encephalitis, seizures, transverse myelitis, osteolytic bone lesions, arthritis, splenic abscess, mediastinal adenopathy, optic neuritis, and thrombocytopenic purpura.^{[32] [142] [156] [167]} Although encephalopathy is rare, CSD is becoming a more common cause of encephalopathy as other viral infectious diseases disappear; the incidence of CSD-associated neurologic complications now ranks with those of varicella and herpes simplex infections, Lyme disease, Rocky Mountain spotted fever, and Kawasaki disease.^[37] CSD encephalopathy should enter the differential diagnosis of patients (especially young ones) with unexplained coma or seizures (half of whom may be afebrile). The prognosis of encephalopathy generally is good.

Diagnosis

Results of routine laboratory studies, including urinalysis and complete blood cell count, are usually normal, although mild leukocytosis may be seen. An indirect FA test to *B. henselae* is now commercially available.

Immunity is thought to be largely cell mediated.^[97] An intradermal skin test of 0.1 ml of CSD antigen is positive in approximately 95% of victims, although 10% of the population has a false-positive reaction. In confusing cases, biopsy of lymph nodes can yield characteristic findings of areas of granulomatous change and necrosis with central neutrophilic infiltration, a peripheral zone of histiocytic cells, and an outermost zone infiltrated by small lymphocytes and plasma cells.^[141] This picture is not diagnostic, however, and is also seen in lymphogranuloma venereum (LGV), histoplasmosis, tularemia, brucellosis, sarcoidosis, and tuberculosis. Thus lymph node biopsy is most useful to rule out malignancy. Warthin-Starry or Brown-Hopps staining of the nodes or the primary skin lesion usually demonstrates the small, pleomorphic bacilli.^[142]

In most cases, clinical diagnosis is based on finding three of four criteria: (1) single or regional lymphadenopathy without obvious signs of cutaneous or throat infection, (2) contact with a cat (usually an immature one), (3) detection of an inoculation site, and (4) a positive skin test.^[39]

The workup should exclude other causes of regional lymphadenopathy, such as tuberculosis, tularemia, LGV, lymphoma, brucellosis, and sporotrichosis.^[190] In general, only sporotrichosis and LGV demonstrate localized unilateral lymphadenopathy; LGV usually occurs in the groin. Cat scratches are normally found on the upper extremities. Skin tests, cultures, serologic tests, and biopsies are available for the differentiation of these other diseases.

Treatment

CSD usually resolves spontaneously in weeks to months, although in 2% of persons (usually adults) the course is prolonged and involves systemic complications.^[142] Systemic CSD in an adult has been successfully treated with gentamicin^[133] and in a

child with cefuroxime.^[96] Trimethoprim/sulfamethoxazole was used in a retrospective series of 71 patients with good results; this was not the case with other antibiotics.^[66] The best study, of 202 patients, is also retrospective, but found a response rate of 87% with rifampin, 84% with ciprofloxacin, 73% with IM gentamicin, and 58% with trimethoprim/sulfamethoxazole.^[143] Antibiotics that were of no benefit included amoxicillin-clavulanate, erythromycin, dicloxacillin, cephalixin, tetracycline, cefaclor, ceftriaxone, and cefotaxime.

Antibiotics should be reserved for persons with severe or very prolonged disease.^[143] Symptomatic treatment and reassurance that the prognosis is excellent are the best therapies. No sequelae of CSD other than the rare complications mentioned are known.

BACILLARY ANGIOMATOSIS

Bacillary angiomatosis was first described in 1983 during the early years of the acquired immunodeficiency syndrome (AIDS) epidemic and forced a reconsideration of CSD, bartonellosis, and trench fever.^[208] In the early 1990s it was determined that organisms of the genus *Rochalimaea* caused a diverse array of clinical syndromes, including cutaneous bacillary angiomatosis, bacillary peliosis hepatitis, fever with bacteremia (*Rochalimaea* bacteremic syndrome) and CSD. Whether the different clinical syndromes result from subtle differences in the infecting organisms or in the response of the immune system remains unclear. Each of these conditions can be caused by the bacteria now known to

1044

be *Bartonella* (formerly *Rochalimaea*) *henselae* and *B. quintana*, also the agent of trench fever.

Epidemiology

Although clinically different from CSD, bacillary angiomatosis is also closely associated with recent cat scratch or bite. The vast majority of victims are HIV positive, but a few are not and appear otherwise well. In 34% of cases, this infection was the first one to establish the diagnosis of AIDS in a given patient. AIDS patients with bacillary angiomatosis can die if untreated, but erythromycin is usually effective.^[23]

Symptoms

Most cases of bacillary angiomatosis involve cutaneous or subcutaneous lesions. The lesions are typically elevated, friable, red granulation tissue papules resembling pyogenic granulomas, numbering a few to thousands. Deeper subcutaneous nodules are seen in about half of victims. Similar lesions can occur in other body tissues.^[23] Visceral lesions may be the first sign of infection; patients often have fever, weight loss, and malaise.^[75] Hepatic involvement can lead to hepatic failure or even rupture (bacillary peliosis hepatitis). This usually presents with GI symptoms (nausea, vomiting, diarrhea, or abdominal distention), fever, chills, and hepatosplenomegaly. Histopathologic examination of liver biopsy specimens reveals dilated capillaries or multiple blood-filled cavernous spaces. The organism can also cause bacteremia, even in immunocompetent patients. *Rochalimaea* bacteremic syndrome is characterized by a prolonged symptom complex of malaise, fatigue, anorexia, weight loss, and recurring,

everincreasing fevers.^[14] ^[20] ^[22] No site of focal infection is apparent. The symptoms are usually present for weeks to months before the diagnosis is finally made by isolation of the organism in blood cultures.^[203]

Diagnosis

B. henselae and *B. quintana* can be isolated from blood using lysis-centrifugation blood cultures, ^[13] ^[14] ^[29] but both species have also been isolated with traditional blood culture systems.

Serologic diagnosis can also be made using techniques of indirect FA testing. Serum samples can be sent (for both *B. henselae* and *B. quintana*) to the CDC. An enzyme immunoassay for the detection of IgG antibodies to *B. henselae* is now commercially available and is reportedly 5 to 10 times more sensitive than the indirect FA test.^[76] Positive results should be interpreted cautiously, taking into account the clinical context, since the meaning of positive serologic results awaits further evaluation with stricter epidemiologic methods.

Diagnosis of bacillary angiomatosis is usually made from clinical features and biopsies of lesions, with characteristic histopathologic findings in tissue sections. Blood cultures should be obtained and incubated for a prolonged period. As more is learned about the growth requirements of the causative organisms, they may become easier to culture directly from skin lesions and lymph nodes. Serologic analysis will become an important means of diagnosis.^[1]

Treatment

Treatment is with erythromycin. If patients cannot tolerate this therapy, rifampin and doxycycline or trimethoprim-sulfamethoxazole should be given. Norfloxacin, gentamicin, and ciprofloxacin are also clinically effective.^[195] Penicillin and first-generation cephalosporins are not beneficial. Therapy is for a minimum of 6 weeks and may have to continue indefinitely in an immunosuppressed patient.

COWPOX AND CATPOX INFECTION

Poxviruses are large DNA viruses that are implicated in a variety of human diseases, including smallpox, monkeypox, cowpox, catpox, and molluscum contagiosum. Infection is rare because of the history of smallpox immunization. Vaccinia virus results in a local skin lesion after "vaccination" against smallpox. Because this immunization provides cross-protection against other poxviruses, cases of monkeypox, cowpox, catpox, and other infections will now increase, since smallpox has been eradicated and immunization is no longer recommended.^[219]

Cowpox has been reevaluated because new epidemiologic evidence suggests that cowpox is not enzootic in cattle, that the cow has a minor role, that feline cowpox is important as a source of human infection, and that wildlife, principally rodents, are virus reservoirs.^[16] Although poxvirus infection in the domestic cat has only recently been described, the incidence has increased steadily, and cats are now the most frequently reported hosts of poxvirus in Britain.^[219] The infection occurs mostly among hunting cats in the late summer and early autumn; infection in humans usually is reported after close contact with or a scratch from a sick cat. The infection is manifested as an inflamed vesicular nodule with lymphadenitis, systemic symptoms (e.g., fever) and a rapid but self-limited course, similar to the orf poxvirus carried by sheep, cattle, and goats. This disease has not yet been reported in immunosuppressed persons. No effective treatment is available, but normally the disease is self-limited.

RAT-BITE FEVER

Rat-bite fever is an acute illness caused by either *Streptobacillus moniliformis* or *Spirillum minus*, which are part of the normal oral flora of rodents, including squirrels. It may also result from bites by wild and domestic carnivores,

1045

such as weasels, dogs, cats, and pigs, which may have been infected when hunting rats and mice.^[199] Carrier rates among wild rats vary from none to 50%.^[28] ^[212] Fewer than 70 cases have been reported in North America, with at least half caused by *S. moniliformis* in laboratory workers. At least 10%, and up to 100%, of rats are nasopharyngeal carriers of *Streptobacillus*.^[5] ^[49] ^[98] Victims of disease caused by *S. minus* are primarily children of lower socioeconomic groups with poor sanitation and heavy rodent populations.^[153] Rare cases can occur in any setting and can easily be fatal, particularly when the proper diagnosis is not suspected.^[153]

Streptobacillary Type

Streptobacillary rat-bite fever (Haverhill fever) is caused by *S. moniliformis*, an aerobic, nonmotile, gram-negative bacillus. The onset usually occurs within a week of the bite, but the incubation period may extend to several weeks, during which time the original wound usually heals completely. A bite need not be present, since the disease can also be transmitted by contaminated food, milk, or water.^[93] It has also been transmitted by simply playing with pet rats, with no history of bite or injury.^[181] Initial symptoms include fever, chills, cough, malaise, headache, and less frequently, local lymphadenitis. These are followed by a nonpruritic morbilliform or petechial rash, which frequently involves the palms and soles. Migratory polyarthritides develops in approximately 50% of victims. Generalized lymphadenitis may be present; splenomegaly and hepatomegaly are rare.^[212] 25% of victims have a false-positive Venereal Disease Research Laboratories (VDRL) test. Leukocytosis with left shift is common, and agglutinating antibodies for the bacillus appear during the course of the disease. On autopsy, interstitial pneumonia, fibrinous endocarditis, mononuclear meningitis, hepatosplenomegaly, and mononuclear cell infiltrates in regional lymph nodes have been found.^[198]

When a history of animal bite is lacking, the differential diagnosis must include rickettsial and viral infections. The fever and rash may suggest meningococemia, but meningeal signs are lacking in rat-bite fever. Definitive diagnosis requires demonstration of rising antibody titers or culture of the bacillus from the blood, joint fluid, pustules, or original

bite location. This can present a difficult differential diagnosis. Typically, identification by culture requires experienced laboratory workers who are seeking the organism.

Untreated, the disease runs a course of several weeks; prolongation of symptoms should raise the suspicion for endocarditis. The mortality in untreated persons is 10%, with most deaths caused by endocarditis and pneumonia. Although mortality is low, the disease can be fulminant; an infant bitten by a wild rat died 4 days after the bite and 2 days after the onset of symptoms.^[198] The drug of choice is procaine penicillin, 600,000 units intramuscularly twice a day for 7 to 10 days.^[212] Effective alternatives for penicillin-allergic patients are tetracycline, 30 mg/kg/day orally in four divided doses, or streptomycin, 15 mg/kg/day intramuscularly in two divided doses. Erythromycin is not effective. Complications such as endocarditis should be treated with high-dose intravenous potassium penicillin G, 10 to 20 million units a day. The organism has both a bacillary and a cell wall-deficient L phase, which is thought to account for some of the antibiotic failures. The bacterial phase responds to penicillin, streptomycin, and tetracycline, whereas the L phase is resistant to penicillin.^[198]

Spirillar Type

Spirillar rat-bite fever is caused by *Spirillum minus*, a gram-negative, tightly coiled, spirillar microorganism. It is usually transmitted by infected wild rats, although cats have also been implicated. The general setting of socioeconomic deprivation in which this disease occurs is the same as in the streptobacillary form; cases in laboratory animals are unusual. The incubation period is 7 to 21 days, during which the bite lesion heals. The onset of illness is heralded by chills, fever, lymphadenitis, and a dark-red macular rash. Myalgias are common, but arthritis is absent, which helps in the differentiation from streptobacillary fever. Leukocytosis and a false-positive VDRL test are often present. The disease is episodic and relapsing, with a 24- to 72-hour cycle. The differential diagnosis includes rickettsial and viral diseases when the history of animal bite is not present. In addition to the absence of arthritis, the manifestations at the bite site are more pronounced than in the streptobacillary variety (usually involving lymphadenitis, and still present when systemic illness occurs), and the fever and illness are relapsing in nature.^[212] Definitive diagnosis rests on demonstrating the presence of *S. minus* in a darkfield preparation of exudate from an infected site. The patient's blood can be inoculated into mice, which may be tested for subsequent infection. The mortality from untreated disease is considerably lower than for streptobacillary fever. The untreated course spans several months. Antibiotic therapy is the same as for streptobacillary fever.^[98]

BRUCELLOSIS

Brucellosis is an anthroponozoonotic disease with a broad clinical spectrum caused by a number of species of *Brucella*, a small, gram-negative bacterium. The bacterium can survive in soil for up to 10 weeks, in goat cheese for up to 180 days (at 4° to 8° C [39.2° to 46.4° F]), and in tap water up to 60 days. It is however very sensitive to heat, most disinfectants, and entirely killed by pasteurization.

1046

Brucellosis usually results from the ingestion of contaminated milk or milk products or by direct skin contact. *Brucella* organisms are carried chiefly by swine, cattle, goats, and sheep and may be recovered from almost all tissues in a sick patient. Most animals used as livestock are susceptible to brucellosis, while the occurrence in wild animals is rather small.^[147]

Epidemiology

Brucella in domesticated animals tends to be species specific, with *B. abortus* infecting cattle, *B. melitensis* goats, *B. suis* swine, *B. canis* dogs, and *B. ovis* sheep. The disease is found worldwide and has an annual attack rate of approximately 500,000; U.S. cases number less than 200. Internationally, most cases are transmitted by ingestion of fresh, nonpasteurized goat cheese and raw goat's milk. The disease caused by *B. melitensis* has a higher attack rate and is more severe, whereas brucellosis in the United States is usually caused by *B. abortus* from cattle, which produces mild clinical disease and is usually occupationally acquired. A proven case of transmission by dog bite has been reported, and dogs carry their own pathogenic species.^[176]

Symptoms

Many organ systems may be involved, with a wide range of disease severity and acuity.^[79] The disease can be classified into three forms: acute, subacute, and chronic. In "acute" brucellosis, the victims complain of headache, weakness, diaphoresis, myalgias, and arthralgias. This is the most common presentation. Anorexia, constipation, and weight loss are often seen in the first 3 to 4 weeks. Physical examination reveals hepatomegaly and splenomegaly. Bacteremia in the early stages typically induces lesions of the viscera, bones, and joints; osteomyelitis, particularly spondylitis, is a common complication.

In *subacute*, or *undulant*, brucellosis, symptoms are milder, but with more frequent arthritis and orchitis. The clinical picture is more varied, and the diagnosis considered in any "fever of undetermined origin." In the preantibiotic era, most patients spontaneously cleared their disease in 6 to 12 months.

In chronic brucellosis, symptoms have persisted for more than 1 year. It is rare in children, but increasingly common as the patient ages. Many describe arthralgias and extraarticular rheumatism. Chronic brucellosis can mimic chronic fatigue syndrome.

Diagnosis

Brucellosis is most often diagnosed by serologic testing, including rose bengal, immunofluorescence, CFT, and ELISA.^[135] After acute infection, high titers may persist for 18 months. False-positive results may be caused by *Francisella tularensis* or *Yersinia enterocolitica* infection. The isolation of *Brucella* organisms by blood culture is also used for definitive diagnosis. Blood cultures in 10% carbon dioxide is a common method, with sensitivities of 50% to 80%.^[11] Bone marrow biopsy and culture can be used in patients with clinically suspected brucellosis, but negative serologic tests and blood cultures.

Treatment

Oral tetracycline, 50 mg/kg/day in four divided doses for 21 days, is used to treat brucellosis. Doxycycline may also be used. In severe cases, streptomycin, 20 to 40 mg/kg intramuscularly once a day for 1 week, is added to this regimen. The next week, streptomycin is continued at a level of 15 mg/kg. Alternatively, rifampin can be added to doxycycline.^[67] The role of quinolones has been investigated.^[3] The prognosis is generally excellent, with only two deaths reported in several thousand cases.^[94]

ACKNOWLEDGMENT

I thank Leonard Marcus for his fine work on a previous version of this chapter.

Chapter 45 - Emergency Veterinary Medicine

Murray E. Fowler

The wilderness experience often involves animals other than humans. Such domestic animals as horses, llamas, elephants, camels, and yaks may be used for packing or pulling supplies, relieving hikers of this burden. Dogs may accompany owners into the wilderness as companions, as trackers of game, or in the Arctic and Antarctic as primary draft animals. Any of these animals may become injured or fatigued or fall ill with a variety of ailments that may require emergency treatment and management by trek personnel.

Observation of wild animals in their natural habitat enhances the wilderness experience, but encounters between wild animals and animals accompanying the trekkers cause problems. Healthy wild animals usually try to avoid humans, but they may show interest in domestic animals.

WILD ANIMAL ENCOUNTERS

Medical and paramedical personnel who may be called to render emergency medical care or assist in the rescue of injured or diseased humans or support animals should recognize that wild animals may be involved. Experienced trekkers can usually recognize when they are intruding into an animal's domain. Unfortunately, some people lack a sense of courtesy for animals. When trekkers in the wilderness behave as if they are entering the home of a human friend, they show appreciation for the rights of wild animals and have less risk of injury or illness to themselves or their support animals. Understanding the biology and normal behavior of wild animals known to live in the wilderness areas to be visited enhances enjoyment and diminishes exposure to potentially dangerous situations.

Others who may be at risk are wildlife biologists, hunters, and people who choose to live in remote areas. Hunters come into intimate contact with wild animals as they pursue, dress, and eat game. Plant scientists, paleontologists, geologists, and other nonanimal scientists may inadvertently encounter wild animals. Wild animal biologists conducting field investigations may capture or immobilize wild animals to collect data. Such individuals are at potential risk of injury or disease, not only as a result of wild animal contact, but also from drugs and firearms used to administer the drugs.

[Chapter 42](#) and [Chapter 43](#) provide more details on why and when wild animals are dangerous. Although few wild animals stalk humans, they may prey on support animals. Most wild animals fear humans and, given a choice, avoid human contact. Injuries to humans by wild animals usually result from human judgment errors, such as approaching too closely, ill-advised handling of diseased wild animals, or unlucky exposure to highly aggressive or protective animals. Such animals may be natural predators seeking food, prey species fearful for their lives or the lives of their young, or diseased and irrational animals (e.g., with rabies). Attacks on support animals usually occur at night or when humans are absent.

Animals are most likely to respond adversely if startled from sleep or if their flight distance is violated. Flight distance is that distance at which, if approached by an enemy, an animal will either fight (attack) or flee. The distance is species specific for a given region and may become greater if animals in the area have been recently hunted. Flight distance may be greater for a person walking or carrying a gun than for a person riding on horseback or in a vehicle. Cornered animals occasionally attack or risk injury trying to escape. Any animal may attack if its offspring are in danger. With any large animal, accidental or intentional positioning between a mother and her infant invites attack.

Equal danger exists for a person who comes between a territorial male and one or more females. Many wild animals are territorial. Males and females may establish feeding, breeding, and home territories. An animal may share feeding territories with other members of the same species or different species, but home territories may be defended against any intruder, including humans.

Injuries have been inflicted on hunters who approached a recently shot animal, believing it to be dead, only to have the animal revive explosively in a final effort to fight or flee.

Humans should not fraternize with wild animals. Food scraps should not be left to tempt wild animals closer for photographs. Any wild animal that will allow touching is a spoiled park animal or is diseased; neither type should be hand fed. Travelers in the wild should be observant for animal signs (e.g., feces, tracks, trails, resting areas) and should respect the behavioral characteristics of animals. Knowledge of the biology and habits of local animals obviates most avoidable close encounters and dangerous situations.

Wild animal attacks on support animals usually occur when the animal is tied on a picket line or staked

1052

out for grazing. The animal may injure itself trying to escape the attack or be bitten and mauled by its attacker. One frightened llama broke loose from a stake, but the lead rope snagged between rocks, fracturing the animal's cervical spine.

Treatment of animal-inflicted injuries that require specific therapy include lacerations, contusions, punctures, or abrasions (see [Chapter 42](#) and [Chapter 43](#)).

SUPPORT ANIMALS

Expedition leaders and participants should consider the well-being of support animals and understand their physical capabilities, including maximal load, speed, and endurance. They should also be able to recognize signs of exertional stress.

Exertional stress is more likely to occur in horses that are ridden than in packhorses that are led. A horse can generally match or exceed the physical endurance of a hiker. Adverse metabolic conditions may develop in horses pushed beyond their limits of endurance. The type of syndrome arising from excessive exercise depends on intensity and duration, degree of prior conditioning, and nutritional status. Mules, donkeys, and llamas are less prone than horses to develop problems, because they usually refuse to be pushed to extremes of exertion.

The animal best suited to the terrain, climate, and task should be selected. Horses, mules, and donkeys are traditional beasts of burden in North America, wherever sufficient forage and water are available. Each animal has both admirable and undesirable qualities. Horses are usually the largest and can carry the heaviest loads. Mules and burros tend to be more difficult for novices to handle. No animal should be used on a trek unless at least one member of the party has considerable experience in handling and caring for the chosen animal.

In South America the llama is the beast of burden. Adventurers traveling into rugged and remote areas above 3000 m (9843 feet) will probably use llamas for support. Llamas have also become popular support animals with backpackers in North America. The llama requires less feed, can subsist better on sparse native forages, and is less damaging to the environment than is the horse.

Dogs are necessary support animals for winter travel in the Arctic. In other regions they function more as companions.

Many expeditions are mounted in countries unfamiliar to both leaders and participants. In various parts of Asia the horse is replaced by the elephant, water buffalo, Bactrian camel, or yak. In North Africa and the Middle East the dromedary camel carries the load. Each species has specialized requirements for handling, packing, and health care.

Expedition physicians may be asked to treat the ailments of support animals. Basic medical training provides the foundation necessary to diagnose and treat many conditions that may be encountered on the trail. If in doubt, expedition members should handle an ailing support animal as if it were human. With support animals carrying all or

part of the load, a more sophisticated emergency medical kit may be carried.

Pretrip Animal Health Considerations

Health certificates are needed for travel and entry into the state or province of destination and possibly intervening states. Regulations are extremely variable, and inquiries should be made at least 4 weeks before departure. Each animal should receive a physical examination by a qualified veterinarian before an extended trip. Conditioning is as important for trek animals as for human participants. Training should be in terrain similar to that expected on the trek, with special attention to toughening the footpads of llamas and dogs by appropriate exercise.

Immature animals should not be taken on expeditions. Dogs should be at least 1 year old. Llamas and equids should be 3 years old. Well-conditioned and trained horses, mules, donkeys, or dogs can carry approximately 30% of their body weight. Llamas usually carry only 25% of their body weight ([Table 45-1](#)).

Frequently, arrangements are made to contract for support animal service from suppliers in the trek locale. Persons providing these services do not always understand the trek requirements and may supply animals that are poorly shod, unconditioned, poorly trained, or otherwise unsuitable for the needs of trek participants. Trek leaders must clearly describe specifications and be adamant about compliance, well in advance of the trek.

Horses, Mules, and Donkeys.

A tetanus booster should have been given to equids within the past year. Vaccination against rabies is appropriate if the trek itinerary includes traveling in an endemic area. Encephalomyelitis vaccines should be used in endemic areas, especially during the insect seasons of summer and fall. Internal parasite levels should be evaluated by fecal flotation and appropriate medication given to reduce the parasite burden.

The feet should be trimmed and shod properly at least 2 weeks and not more than 4 weeks before a trek begins. Extra shoes for forefeet and hind feet of different-sized horses should be carried, along with the appropriate nails and hammer to reattach a shoe.

Llamas.

Llamas should have been given a tetanus toxoid booster within the past 6 months. Other basic immunizations should include *Clostridium perfringens* toxoid, type C and D, within the past 6 months, as well as vaccinations against leptospirosis and rabies if entering an endemic area.

TABLE 45-1 -- Vital Statistics of Trek Animals

ANIMAL	BODY WEIGHT		HEART RATE/MIN	RESPIRATORY RATE/MIN	BODY TEMPERATURE	
	POUNDS	kg			° C	° F
Horse	800–1200	360–540	28–40	10–14	37.2–38.0	99.0–100.5
Mule	600–1200	275–540	28–40	10–14	37.2–38.0	99.0–100.5
Donkey	300–600	136–275	28–40	10–14	37.2–38.0	99.0–100.5
Llama	300–450	136–200	60–90	10–30	37.2–38.7	99.0–101.8
Dog	20–100	9–45	65–90	15–30	37.5–38.6	99.5–101.5
Camel	880–1200	400–550	40–50	5–12	36.4–42.0	97.5–107.6
Elephant	5000–8000	2300–3700	25–35	4–6	36.0–37.0	97.5–99.0
Yak	2200	1000	55–80	10–30	37.8–39.2	100.0–102.5

*For sustained trekking: 24 to 40 km (15 to 25 miles) per day on moderately difficult trails. This includes tack. Animals in training should be expected to carry only one half to two thirds of this weight.

Toenails should have been trimmed within the previous 2 months. Internal parasitism is debilitating in llamas. Ova levels should be checked, but treatment with an anthelmintic (ivermectin, 0.2 mg/kg subcutaneously, or fenbendazole, 5 mg/kg orally) usually is desirable within the previous 2 months.

Dogs.

Dogs are routinely immunized against canine distemper, canine adenovirus, leptospirosis, and rabies. Vaccinations should be current. A check should be made for internal parasites and fleas and appropriate action taken. Although dog fleas do not permanently infest humans, they bite and may cause mild to severe local dermal reactions in sensitive individuals. Dogs should be bathed with a shampoo containing a pyrethrin insecticide before a trek. Any pyrethrin-containing dusting powder may be carried on an extended trek to relieve dogs of flea burdens. It is unlikely that the fleas involved in the sylvatic plague cycle will infest a dog, so the dog is not a source of plague infections for humans in a trek situation.

Rest

Support animals require less sleep than human trekkers. Horses can sleep while standing because they have a special locking mechanism of the tendons and ligaments of the limbs. Horses may also lie in sternal or lateral recumbency. Llamas usually rest in a sternal position but may also assume lateral recumbency. Llamas enjoy taking a "dust bath" by rolling in dirt soon after packs are removed. A few may try to roll with the pack still in place.

Watering and Feeding

All animals require daily access to potable water. It is not possible to filter or disinfect water for large animals except in extremely filthy conditions. Dogs may be susceptible to giardiasis and theoretically should drink filtered water, but no one can prevent a free-running dog from drinking from a stream or lake. Heavily mineralized or silted water may be as unpalatable for animals as for humans and may cause similar gastrointestinal problems.

The basic fluid requirement for a horse or other large trek animal is approximately 40 ml/kg/day, or 18 L (5 gallons) for a 450-kg (1000-pound) horse. Work and heavy sweating may triple the requirement. Llamas and donkeys may require one-third less water than a horse.

Llamas and donkeys tolerate dehydration better than other species, but they function better if well hydrated. The camel is noted for its ability to tolerate a number of days (2 to 7) without drinking water. Equids sweat profusely and should be given the opportunity to drink along the trail. Some llamas refuse to drink until evening.

Horses, Mules, and Donkeys.

Equids consume approximately 2% to 2.5% of their body weight daily (for a 1000-pound horse, 20 to 25 pounds of total feed). When the animals are working hard, half this amount should be concentrates (grains such as rolled oats, barley, or cracked corn, or mixed grains and molasses in loose or pellet form). If forage is unavailable, alfalfa pellets should be carried. Animals should become accustomed to eating pellets before the journey begins. Concentrates should be reduced on days when the animals are not working.

Llamas.

Llamas require only 1% to 1.5% of their body weight in food daily. Given the opportunity, llamas will graze and browse to satisfy their requirements. Many packers carry a supplement mixture consisting of half alfalfa pellets and half grain mix (same as for horses),

Figure 45-1 Sequence halter tie.

used as required. Some llamas are reluctant and must be trained to eat pellets or grain. Training should take place at home, not during the trek.

Dogs.

A dog should be accustomed to high-quality dry dog food. The quantity fed should increase by half when the dog is exercising.

Emergency Restraint

One or (preferably) more persons on the trek should be acquainted with the general care and handling of any domestic species involved in the expedition. Methods of haltering and leading are specific for each animal. Securing animals at night may require hobbling or tethering. Skill and experience are necessary to accomplish this without risk of injury to the animal or handler. Animal handlers should be able to examine and clean the feet and hoofs of their charges. All people who deal with animals should know how to create a halter tie at rest stops and when an animal is tethered ([Figure 45-1](#)). A knowledge of temporary rope halter construction is desirable in the event of loss or breakage of halters ([Figure 45-2](#)). ^[7]

Horses, Mules, and Donkeys.

Large animals can inflict serious or lethal injuries on people. When in pain or panicked, they may not respond even to their accustomed handlers. If a horse is down and entangled in rope, wire, or bushes, it should be approached from its back and its head held down until it can be extricated. The handler should stay out of the reach of both fore and hind limbs. ^[7]

A horse's defensive and offensive actions are to strike with the fore limbs, kick forward and backward with the rear limbs, and bite. The safest place to stand is close to the left shoulder. Persons examining the feet and legs of a standing horse should keep their head above the lower body line to avoid having the horse reach forward with a rear limb and strike it.

Additional restraint for painful procedures may be accomplished by grasping one or both

ears of the horse. The method of "earring" a horse is as follows:

1. Stand at the left shoulder and grasp the halter or lead rope with the left hand.
2. Place the right hand palm down with the fingers together and the thumb extended, on the top of the neck.
3. Slide the hand up the neck until the thumb and fingers surround the base of the ear ([Figure 45-3](#)).
4. Squeeze tightly, but do not twist the ear.
5. The horse usually tries to pull away as the ear is grasped. Be prepared to move with the horse while maintaining a firm grip.

Llamas.

Pack llamas are usually docile. Although most allow the feet to be lifted for inspection or treatment, some try to lie down. One or two people should stand on the side opposite the limb being lifted, or the llama should be placed next to a tree or large rock to prevent the animal from moving away. The limb should be firmly grasped. It may be necessary to semisupport the body if the animal tries to lie down.^{[7] [8]}

If a llama refuses to get up, the rear limbs should be pulled out behind it. If it still refuses to rise, an injury or illness that inhibits rising should be suspected.

Rarely a llama "spits" against an annoyance. The "spit" is actually stomach contents, the foul odor of which remains until thoroughly washed off. Spitting is

1055

Figure 45-2 Temporary rope halters.

usually directed toward other llamas to express displeasure, but handlers may be caught in the cross fire. If a llama becomes irritated during an examination or treatment procedure, spitting can be controlled by draping a cloth over the nose and tucking the top around the nose piece of the halter. Llamas also dislike the odor of stomach contents on their noses. Llamas can be "eared" in a manner similar to horses.^[8]

Dogs.

Dogs usually accompany their owners, who are able to handle them under difficult circumstances. If mildly painful medical procedures must be performed, the head and mouth should be secured. The dog's body can be securely held against the handler's body by reaching across the back of the dog and grasping the base of the neck while pulling the opposite shoulder with the elbow toward the handler. The other hand should tuck the dog's head under the handler's arm.

Figure 45-3 "Earing" a horse.

1056

Figure 45-4 Placing a muzzle on a dog.

Figure 45-5 Completed muzzle on a dog.

Alternatively, a muzzle can be constructed from a nylon cord or even a shoelace. A loop should be formed with an overhand knot on one side. The loop is placed over the muzzle of the dog, with the knot on top, and tightened ([Figure 45-4](#)). The ends of the loop should be wrapped around the muzzle, crossed beneath the jaw, and tied behind the ears ([Figure 45-5](#)).

COMMON PROBLEMS

Support animals may injure each other or their human handlers, or may spread disease, such as ringworm or lice (see [Chapter 41](#)).

Trauma

Contusions, abrasions, and lacerations are the most common conditions encountered in support animals. Falls, stumbling on sharp rocks, brushing against branches, and encounters with other animals are frequent causes of injury. Such wounds should be handled similar to human injuries. Hair or wool should be trimmed from the margins of wounds before treatment or suturing to prevent matting with exudate. The skin may be sutured with any suture material suitable for humans. Antibiotics are not necessary unless vital structures, such as synovial or serosal membranes, are exposed.

Rope burns may occur in all species but are more likely to occur in horses because they tend to struggle against entanglements and their skin is quickly burned by abrasive action. Therapy is similar to that for human burns. Thermal burns are unlikely unless animals are caught in brush or forest fires.

Foot, Hoof, and Nail Problems^[2]

Foot injuries may incapacitate an animal, and possibly the expedition. The hoof of the horse covers the distal extremity and third phalanx (P3). The specialized horn of the hoof and nail is analogous to the human nail. Horses are digitigrade, walking on the tip of P3. In llamas, P2 and P3 lie in a horizontal plane within the foot, with only P1 in the vertical position. The nails of the llama and dog are inconsequential in weight bearing but are extremely painful if torn or contused. The weight-bearing surface of the horse's hoof contains the firm sole and more flexible frog, overlying soft fibroelastic tissue called the digital cushion. Dogs have footpads similar to those of llamas.

The structures of the foot are subject to contusions, abrasions, lacerations, and penetration by foreign bodies (e.g., nails, stones, sticks). Segments of the hoof wall and nail may be avulsed, exposing the sensitive laminae. Infection may invade the foot and undermine the outer layers, with abscess formation. Not all lesions are visible. Stone bruises of the sole or frog of a horse may be evident only when pressure is exerted on the site of the contusion. Foreign body penetrations and abscesses may cause reluctance to place any weight on the limb. The penetrating object may have been withdrawn or may still be in place; in either case a discolored tract leads to the depth of the wound. Erosions and ulcerations of the footpads are common in unconditioned dogs and llamas. Dogs working in ice, snow, mud, and water may develop maceration,

cracks, erosions, lacerations, and frostbite.

Foot and limb trauma is accompanied by varying degrees of lameness (limping). It may be difficult to establish which leg is painful, but the principles are similar to evaluation of such pain in humans, with two extra limbs to evaluate.

Cellulitis may develop on the limbs or body. The signs include heat, swelling, and redness and are the same in all species, as is therapy.

Therapy for foot injuries includes providing drainage of infected lesions, disinfection, and protection of exposed sensitive structures. Antibiotics are not indicated for most wounds unless a joint surface

1057

is exposed. It may be necessary to bandage the foot to provide protection while in camp and to fashion special shoes or boots to keep an animal functioning on the trail. Special booties are available commercially for dogs, but a temporary moccasin may be constructed from soft leather, such as that used for human moccasins.

Hyperthermia (Heat Stress, Heat Exhaustion)^[8] ^[9]

Hyperthermia is elevation of the core body temperature above normal limits. As with humans, animals on a trek may become overextended and develop hyperthermia (see [Chapter 10](#) and [Chapter 11](#)).

Etiology.

The primary cause of hyperthermia in pack animals on treks is excessive muscular exertion, especially during periods of high environmental temperatures and high humidity. Animals that struggle for prolonged periods in swampy terrain or in snow or mud may also produce excessive heat. Although high ambient temperature is a contributing factor, excessive muscle exertion in any climate may increase body temperature. Pack animals may also develop fever as a result of infectious diseases. Dehydration from inadequate supplies of potable water exacerbates the problem.

Inadequate physical conditioning is a common problem and contributes to a cumulative heat load. Other contributing factors may include lack of salt in the diet, preexisting cardiovascular insufficiency, obesity, and trauma.

Clinical Signs.

Signs may vary according to species and the stage of hyperthermia, but all affected animals have an increased heart and respiratory rate, usually accompanied by open-mouth breathing. Rectal temperatures may vary from 41.1° to 43.3° C (106° to

110° F). Horses, mules, donkeys, and llamas sweat in the early stages of hyperthermia, but sweating may cease if the animal becomes severely dehydrated. Sweating is evident in horses but imperceptible in llamas because most sweating occurs on the ventral abdomen in what is known as the thermal window, where the fibers are less dense and the staple is short.

Dogs cool themselves by evaporation of respiratory fluids while panting. The mouth is held open and the tongue lolls from the mouth. The respiratory rate increases from a normal of 30 breaths/min up to 200 to 400 breaths/min. Moisture may be observed dripping from the tongue. As dehydration intensifies, salivation and dripping may slow or cease.

Hyperthermia causes a shift of blood volume from the viscera and muscles to the skin, resulting in hypovolemia and varying degrees of hypotension. Hypotension causes hypoxemia of the brain, resulting in dullness, restlessness, and incoordination. Hypoxemia may lead to convulsions and collapse. The shift of blood from the gastrointestinal tract may cause decreased motility and the potential for ileus and tympany. Colicky signs (kicking at the belly, looking back at the side, treading, attempting to lie down and roll) in horses and llamas may be noted.

A 1° C (1.8° F) rise in body temperature requires 10% more oxygen for the body's energy systems. When body temperature reaches 41° C (105.8° F), the respiratory system is no longer able to supply sufficient oxygen by normal respiration. Respiratory acidosis and electrolyte imbalances associated with sweating may produce a syndrome similar to septicemia.

Hyperthermia can affect most organ systems. The severity of the syndrome cannot be assessed in the field. It is important to recognize the conditions that lead to hyperthermia, watch for early signs of heat stress, and stop any activity that contributes to the problem. Mules and donkeys are not likely to become severely affected because they refuse to go on if stressed. Horses may be driven past their endurance and die of thermal stress.

Treatment.

Cessation of excessive muscular activity may be all that is necessary if hyperthermia is mild. If streams or lakes are nearby, the animal can be walked into the water and water splashed on its underbelly. Contingencies for hyperthermia are part of all plans for capture operations for wildlife translocation and reintroduction projects. Water is carried for cooling and intravenous fluids for heat stress. Cold-water enemas are the most effective and rapid way to cool the body of a large animal.

Plant Poisoning^[4] ^[10] ^[12] ^[15]

Certain highly toxic plants that grow in wilderness areas of the United States should be recognized ([Table 45-2](#)) (see [Chapter 48](#) and [Chapter 49](#)). Cooperative extension offices at federal land grant institutions frequently publish booklets on local poisonous

plants.

Horses may be less at risk than llamas because horses are primarily grazers and not likely to eat trees and shrubs. Llamas eat small quantities of almost anything within reach.

Animals are not affected by poison oak (*Rhus diversiloba*) or poison ivy (*Rhus toxicodendron*). However, horses, dogs, and llamas may transmit the toxic oils of these shrubs to susceptible people through contact with contaminated hair.

Few specific antidotes are available for plant poisons. Symptomatic and supportive treatment includes removal of the poisonous material from the gastrointestinal tract by administration of a cathartic or adsorbing the toxin with a nonspecific substance such as activated charcoal (See [Table 45-3](#)).

1058

TABLE 45-2 -- Poisonous Plants That May Affect Horses or Llamas on Trek

COMMON NAME	SCIENTIFIC NAME	POISONOUS PRINCIPLE	SIGNS OF POISONING	HABITAT	SPECIES
False hellebore, corn lily	<i>Veratrum californicum</i>	Alkaloids	Vomiting, salivation, convulsions, fast irregular pulse	High mountains, meadows	Llama
Death camas, sandcorn	<i>Zigadenus</i> spp.	Alkaloids	Foaming at mouth, convulsions, ataxia, vomiting, fast weak pulse	Hillsides, fields, meadows, in spring of year	Horse, llama
Water hemlock	<i>Cicuta douglasii</i>	Resin	Frothing at mouth, muscle twitching, convulsions, death in 15–30 minutes	Standing or running water, obligate aquatic	Horse, llama
Nightshade	<i>Solanum</i> spp.	Alkaloidal glycoside, solanine	Vomiting, weakness, groaning	Ubiquitous	Horse, llama

Jimson weed	<i>Datura stramonium</i>	Alkaloid, atropine	Dry mucous membranes, dilated pupils, mania	Waste places	Horse, llama
Tobacco, tree tobacco	<i>Nicotiana</i> spp.	Alkaloid, nicotine	Stimulation of CNS, then depression; sweating, muscle twitching, convulsions	Waste places	Horse, llama
Lupine, blue bonnet	<i>Lupinus</i> spp.	Alkaloid	CNS depression, dyspnea, muscle twitching, ataxia, frothing, convulsions	Ubiquitous	Horse, llama
Dogbane, Indian hemp	<i>Apocynum cannabinum</i>	Cardioactive glycoside (similar to digitoxin)	Dyspnea, cardiac arrhythmias, agonal convulsions, vomiting, diarrhea	Ubiquitous	Horse, llama
Oleander	<i>Nerium oleander</i>	Same as dogbane	Same as dogbane	Ornamental	Horse, llama
Castor bean	<i>Ricinus communis</i>	Ricin, water solution	Anaphylactic shock, diarrhea	Ornamental	Horse, llama
Rhododendron	<i>Rhododendron</i> spp.	Andromedotoxin glycoside	Vomiting, colic, severe depression	Shrubs in meadows and moist places	Llama

CNS, Central nervous system.

*In most cases of poisoning from ingestion of poisonous plants, no specific antidote exists. Victims are treated symptomatically. The critical factor is to empty the digestive tract of the plant material with cathartics, parasympathomimetic stimulation, and enemas. Activated charcoal may be of value given orally.

Eye Injuries

An abrasion, laceration, or penetrating wound of the cornea is serious, especially in a field situation. Dust and other foreign bodies within the conjunctival sac require prompt removal to avoid more serious injury to the cornea. The management of eye problems in animals is the same as for humans, with the added difficulty of restraint for examination and therapy.

Lightning Injuries^[6] ^[9]

Lightning strike is a potential hazard in the wilderness (see [Chapter 3](#)). Animals with high head carriage, such as the horse and llama, are especially at risk, whether standing or recumbent. Animals may survive a lightning strike, but frequently a strike is lethal. Unless the strike is witnessed, it may be difficult to make a diagnosis, but signs include depression, blindness, nystagmus, paralysis of the hind limbs, and temporary unconsciousness. Linear singe marks are definitive, but lightning may kill an animal without producing burns. One llama was struck while recumbent in an open pasture, and the green grass beneath it had been singed. A single lightning strike may kill more than one animal, especially if a group has congregated under a tree for shelter. Lightning may kill so quickly that feed is still in the mouth of grazing animals.

During an electrical storm, animals should be taken to the safest environment, away from tall trees and exposed hills. Llamas may be encouraged to lie down in a small ravine, depression, or rock face, with the head

tied close to the ground. A picket-line stake may be used for the tie-down. An animal should not be tied to a tree, but a small bush may be safe. Horses are more difficult because they will not lie down unless specially trained to do so.

If an animal is struck and still alive, the degree of damage to the nervous system and other vital organs will manifest over time. If the strike is witnessed and the heart has stopped, cardiac massage may be performed if conditions are safe. With the animal in lateral recumbency, the forelimb is pulled as far cranially as possible, and the chest wall is compressed just caudal to the triceps muscle. Cardiac massage may be required for several minutes.

Snakebite^[5]

Venomous snakes are found in most wilderness areas of the world, except the Arctic and Antarctic. Leaders should know the species of snakes that may be encountered on the trek and should instruct all personnel on treating a bite in a human or animal. In the United States the venomous snakes most likely to be encountered are pit vipers,

especially rattlesnakes of *Crotalus* species. Other members of the North American pit viper group include the copperhead, *Agkistrodon contortrix*, and the water moccasin, *Agkistrodon piscivorus* (see [Chapter 38](#)).

Llamas and young horses are curious and may extend their nose to investigate a strange animal. Thus an animal may be bitten on the nose. Leg bites may occur in any animal.

Clinical Signs.

Venom injection results in pronounced swelling in the area of the bite in 1 to 3 hours. The most serious consequence of a nose bite is swelling that occludes the nostrils, making it difficult for horses and llamas to breathe. Dogs are not obligate nasal breathers, but the effects of a bite may be more severe in them than in larger animals. A rattlesnake bite on the nose is an emergency.

Treatment.

A 10-cm (4-inch) segment of 1-cm-diameter, flexible plastic tubing should be in the first-aid kit. The tube should be inserted into a nostril before any swelling occurs, preventing occlusion of the nostril and providing a passageway for air. A tube cannot be inserted after swelling has developed, when the only lifesaving procedure is a tracheostomy. The rescuer should *not* cut the skin and suck out the venom, since this is ineffective.

The only specific treatment for pit viper envenomation is administration of antivenin. Freeze-dried vials of antivenin may be carried and the same product is used for humans and animals. One to three vials should be administered intravenously when signs of envenomation have appeared.

Choke^[8] [9]

"Choke" in humans refers to lodging of food or other objects in the larynx or trachea, a life-threatening emergency. Choke in animals usually refers to lodging of food or other objects in the esophagus. The signs of choke may be alarming, but an animal will rarely die unless feed is regurgitated and inhaled into the lungs.

Etiology.

Choke is most often caused by overly rapid ingestion of pellets and grain. Animals should be accustomed to any supplemental feed used on the trek. Ingestion may be slowed by placing rock pebbles in the container used to feed the animal, causing it to separate the rocks from the feed. An animal rarely swallows a metallic or wooden object. Llamas and horses are too fastidious in their eating habits to consume such objects.

Clinical Signs.

Retching occurs as the animal attempts to dislodge the mass. Choked animals are able to breathe but are in obvious distress. Saliva may flow from the mouth, and the animal may cough up particles of the material (e.g., grain, pellets). A mass may be palpated on the left side of the neck if the obstruction is in the cervical area. Peristaltic waves may be observed moving up and down the left side of the neck. The mass may lodge anywhere along the esophagus but generally lies within the chest and is not visible externally.

Treatment.

Water may be offered, but feed should be withheld until the problem has corrected itself. If palpations along the lower neck reveals a bulge, gentle massage will determine if it can be moved. Moderate exercise may cause the object to move toward the stomach. In some cases, passage of a stomach tube and application of gentle pressure may push the mass into the stomach. Medication may be necessary to relax esophageal muscle spasm.

Drowning^[9]

Llamas, horses and dogs can swim, but circumstances may cause submersion in water and inhalation of water into the lungs. A heavy fleece is a serious detriment to a llama in water over its head. Floods may trap and drown animals.

The primary problem is to extricate the animal from its predicament, which may be extremely difficult with a large llama or a horse. It is necessary to act quickly (less than 5 minutes) to prevent death. If the animal is to revive, water must be drained from the lungs. The llama is placed on its right side with the body slanted downward to the neck and head so that water can flow out. Regurgitation is a risk in this position, but the need to remove the water from the lungs must take precedence, even though this is a

desperation maneuver at best. If immersion lasted for more than 2 to 3 minutes, the heart may have stopped, making cardiac massage necessary. The action must be continued until the animal responds or is declared dead. It is highly unlikely that resuscitation will be successful in an animal that has been under water for more than 5 minutes, regardless of the water temperature.

MANAGEMENT ISSUES

Wound Dressing and Bandaging

The principles of wound dressing for animals are basically the same as those for humans. Avoid placing cotton or a bandage directly on the wound. A gauze 4 × 4-inch compress or an absorbent hydrogel pad is the best material to place against the wound. A padded or absorbent layer is then placed to collect fluids. A surface or protective bandage is applied to hold the padding in place.

A variety of bandage materials is suitable. Coban or Vetrap (bandage tape) is the most effective bandage material because it is porous, sticks to itself, and is flexible, adjusting to uneven surfaces. Other products, such as Elastikon (elastic tape) or rolled gauze bandages, also are excellent. Duct tape is satisfactory, but care should be taken to avoid wrapping it too tightly, because the tape has no extensibility and may become a tourniquet.

Placement of a smooth bandage requires skill. Once the anchor roll is in place, firm but uniform pressure should be applied as the bandage unrolls. Joints require special attention. Bandaging should be done in a figure-8 pattern to provide uniform pressure over a variably shaped surface. Pressure is avoided over the point of the hock and the accessory carpal bone (back of the carpus).

The foot requires special consideration. Dress a foot wound appropriately, making certain that the space between the digits of dogs or llamas is padded with cotton. The easiest bandage to apply is a Vetrap (Coban) elastic bandage that conforms to the odd shape. If a severe foot wound occurs while trekking in the backcountry, additional protection may be necessary to allow the animal to continue on the journey. A sheet of pliable leather is used, and the dressed foot is placed in the sheet's center. The leather is gathered up around the pastern and held in place by duct tape or another bandage, forming a boot shape.

Another method of bandaging a foot uses a rolled gauze bandage. After dressing the foot, a wrap is made around the pastern, leaving a tail of gauze approximately 15 cm (6 inches) long. The tail is used as a fulcrum to change direction on the bandage as the digits are covered.

Cardiopulmonary Resuscitation^[8] ^[9]

It is unlikely that rescue breathing would be required for an animal while on trek, except

in a lightning strike or drowning. The procedure is different than employed in humans because mouth-to-mouth breathing cannot be performed on an adult llama or horse, although it could be performed in a dog by clamping the mouth and lips shut and breathing through the nostrils. A llama or horse should be placed in lateral recumbency, preferably on the right side. The rescuer stands at the animal's withers (top of the shoulder) and reaches across the body to grasp and lift the arch of the rib cage. This maneuver flattens the diaphragm and expands the chest, producing inspiration. This same area is not compressed to force expiration, since this will put pressure on the stomach and possibly cause regurgitation. Instead, the area over the heart is compressed just above the elbow and caudal to the muscles of the upper limb. The rate for the horse or llama is 10 to 15 breaths/min. Rescue breathing in the dog is performed by compressing the chest at the widest segment of the thorax at a rate of 20 to 30 breaths/min.

Cardiac massage may be performed by placing the llama or horse on its right side, if not already there. An assistant pulls the upper foreleg forward and presses the chest in the area vacated by pulling the leg forward. The rescuer kneels next to the bottom of the chest, positioning the heels of both hands against the chest approximately 15 cm above the sternum, with the fingers directed toward the spine. The person presses firmly with the arms held straight and releases quickly, repeating the movement every second. After 15 compressions, check for a pulse in the saphenous artery on the medial aspect of the stifle in a llama, or listen for the heart beat with a stethoscope. After 15 heart compressions, the rescuers administer five cycles of rescue breathing, as described previously. It is futile to continue cardiac massage if no oxygen is available to the heart or the general circulation. Massage must be continued until the heartbeat returns and the animal begins to breathe, or when signs indicate that the victim is dead (pupils dilated, no response to touching the cornea).

Small or round-chested dogs are placed on their back, with compressions over the sternum. For the type of dogs likely to be on a trek, cardiac massage is performed in lateral recumbency.^[1]

Disaster and Emergency Management^[6]

A wilderness trek may be engulfed by a natural disaster (see [Chapter 67](#)). Attitude may be the key to human survival in a disaster situation and is also important when dealing with animals. The best assurance of a positive attitude is advance planning and preparation. Although safety and protection of people take precedence, animals should be not neglected.

Ice Storm.

When rain freezes immediately on striking the ground or foliage, people and animals may have extreme difficulty walking. Animals may fall and injure themselves. In one

situation a late-spring snowstorm with freezing rain halted a group of horses on a small mountain peak. Frightened by the thunder and lightning, the horses, milled around as rain and snow accumulated within their shoes, producing horses on ice skates. Fortunately, no injuries occurred before the storm abated and the feet could be cleaned out.

Fire.

Fire is an ever-present risk in forests and shrubbed areas (see [Chapter 12](#)). Trek leaders should have a plan for evacuation to safety, as well as for dealing with the animals.

In brush and forest fires, wind is an important factor. Crown fires (flames racing through the tops of trees in a forest) are particularly troublesome. One should not try to outrun a fire burning up a slope. The heat generated by the fire rises and preheats the area above the fire, setting up ideal conditions for rapid spread. A hillside may seem to explode into flames because of the extensive preheating.

When llamas were caught in an advancing brush fire, they were herded into a bare ground area. In another situation, llamas were simply turned loose to fend for themselves. Owners reported that the animals adjusted quite well, without panic. When they could return, they found the animals were hungry and thirsty but with no evidence of smoke inhalation or eye damage. Llama fiber does not burn readily, but it does smolder, and some burn spots were noted in the fleece. At one ranch the only serious problem was burns on the footpads, presumably caused by animals stepping on hot coals. No one was able to observe how adult and young animals avoided the flames.

Flooding.

Animals may become involved in flood conditions when they are tethered near streams or rivers that are known to generate flash floods. Animals are at the same risk as the humans in the party. Dry stream beds in many desert areas are ideally suited for flash floods that may be generated miles away, so avoid dry stream beds for camping sites. Animals should not be tethered in such locations.

Trek leaders should be aware of dams along streams, especially earth-filled dams. Heavy storms may erode a dam or fill a reservoir beyond its capacity. A llama owner in Idaho watched as a wall of water filled a gorge more than 30 m (100 feet) deep and nearly engulfed his home, barns, llamas, and farm from a burst dam a few miles upstream. Horses, llamas, and dogs can swim but may not be able to cope with the currents generated during a flood.

DISORDERS OF HORSES, MULES, AND DONKEYS

Common trail disorders encountered in horses may be classified as traumatic, metabolic, or digestive tract upsets.

Laminitis (Founder)^{[2] [11] [13] [14]}

Etiology.

Trauma is the most likely cause of inflammation of the foot in the trek horse. Horses should have been trained in a terrain similar to that to be found on the trek. Even a trained horse, however, occasionally encounters an excessively rocky path that traumatizes its feet, especially if the rider fails to slow the pace when negotiating the trail. Leather or synthetic pads worn under the shoe may offer some protection, but new pads may be chewed off the foot by rocky trails after less than 80 km (50 miles).

Laminitis may be a sequel to severe digestive upset in a horse. Inflammation within the confines of an inflexible hoof causes malperfusion at the capillary level of the foot, which is accompanied by arteriovenous shunting.

Clinical Signs.

Laminitis usually develops on both forefeet, but rear feet may also be affected in severe cases. The horse shifts its center of gravity to the hind limbs to minimize pressure on the forefeet, standing with the hind limbs forward under the body and the forelimbs extended in front of the body. The feet are hot to palpation, and the digital artery pulse is pounding. The horse is reluctant to move.

Treatment.

Therapy is directed at reestablishing circulation in the foot. Proper circulation of blood within the hoof depends partially on the pumping action of the foot while walking. Mild exercise is an important aid in preventing damage to the laminae. The horse should be exercised slowly on soft ground for 10 to 15 minutes every hour for 12 to 24 hours, then exercise should be stopped. Even slow walking may be quite painful, and an analgesic (phenylbutazone, 2 to 4 g orally once daily) may be necessary. Corticosteroids are contraindicated.

Although soaking in cold water may give temporary relief to feet sore from laminitis, this practice is actually contraindicated in acute laminitis. Warm water soaks are

appropriate, since they dilate the vascular tree and enhance circulation. A low volar block inhibits vascular constriction within the foot. This is accomplished by palpating the pulsating artery on the posterolateral aspect of the fetlock ([Figure 45-6](#)). The nerve lies posterior to the artery. With a 20- to 22-gauge needle, 3 ml of 2% lidocaine is injected over each nerve. It may be necessary to repeat nerve blocks two or three times daily for several days.

1062

Figure 45-6 Diagram of the anatomy of the equine fetlock. *A*, Skin. *B*, Flexor tendons. *C*, Volar nerve. *D*, Palmar digital artery. *E*, Digital vein. *F*, Suspensory ligament. *G*, Sesamoid bone. *H*, Metacarpal bone (cannon).

Saddle, Cinch, and Rigging Sores^[3] ^[14]

Saddle sores are contusions, abrasions, or ulcerations of the skin and subcutis caused by friction or point pressure from the saddle, cinch, or rigging.

Etiology.

Improperly fitted or maintained tack is the primary cause of saddle sores. A saddle tree may fit a horse properly at the beginning of a training period but become unsatisfactory after the horse has trimmed down.

Poorly distributed pressure is the primary cause of saddle sores. Spot pressure causes local ischemia. If pressure is prolonged, the capillary bed may be damaged. When the pressure is released rapidly, blood rushes into the blanched site and extravasation may occur, causing swelling and pain.

If the lesion is rested and treated as inflamed tissue, complete healing may occur. If the saddle is reapplied, however, it overlies a lump that is subject to abrasion. The injury can extend through the dermis, resulting in severe ulceration. Cinch and rigging sores are usually caused by friction, leading to blister formation.

Clinical Signs.

Hot and tender swellings are the primary signs of acute saddle sores. The hair or epidermis may be rubbed off. General sensitivity over the back is usually caused by

muscle soreness. Evidence of previous sores includes white hairs in spots over the withers or saddle bed, scars with or without hairs, thickening of the dermis, and alopecia with or without swelling.

Treatment.

Prevention is better than treatment. Toughening the backs of trail horses is a major job of the trainer. Proper pads or blankets must be selected for each horse. On arrival at a rest area, the girth should be slowly loosened at intervals of 10 to 15 minutes to prevent rapid flow of blood into ischemic areas.

Once a sore has developed, the horse must be rested or the tack changed to eliminate pressure or friction on the lesion. Holes are often cut in pads to accommodate a saddle sore, but spot pressure at the ring edge may be as detrimental as the original cause of the saddle sore. Riders must keep tack cleaned and in good repair. When the saddle is removed, cold water poured over the back may minimize swelling.

Myopathy^[3] ^[11] ^[13] ^[14]

Exertional myopathies of horses range from simple muscle soreness, through the "tying-up" syndrome, to paralytic myoglobinuria (rhabdomyolysis, azoturia).

Etiology.

Muscle integrity and function depend on proper mobilization and use of energy. Conditioned muscles may function vigorously for extended periods, but if either energy parameter is accelerated to the extreme, mild to severe muscle necrosis may occur.

Clinical Signs.

Mild muscle soreness is characterized by alterations in gait that indicate muscle weakness. As severity increases, the gait becomes progressively altered until the horse is in obvious pain and reluctant to move. The horse has an anxious expression and may sweat excessively. Affected muscles are painful to palpation and may be swollen. Skin temperature over the muscle may be elevated. Muscle spasms may occur, but not consistently. Myoglobinuria is observed grossly in moderate to severe cases and should suggest stopping and resting or treating the horse.

Treatment.

Rest is paramount in all cases. A rider may have difficulty differentiating the pain associated with myopathy from that seen with colic. It is disastrous to force the severely myopathic horse to walk, as is done with a suspected case of colic. If there is doubt, the horse should not be exercised.

Horses in inaccessible locations should not be walked out until all possible recovery has

taken place. Horses with mild muscle soreness may improve if walked slowly, but rest from ride exertion is the primary recommended therapy.

Dehydration

Etiology.

Fluid and electrolyte imbalances play a major role in all metabolic problems that develop in the horse as a result of exertional stress. The degree of dehydration is directly related to the amount of fluid loss

1063

through evaporative cooling (sweat), which in turn is related to the amount and rate of work performed and to ambient temperatures and humidity.

The horse must have an adequate amount (10 to 15 gallons) of water each day during a trek. The more strenuous the activity, the more fluids are required. Mules and especially donkeys are adapted to cope with mild dehydration.

Clinical Signs.

Signs of mild dehydration (3% body weight loss) are low urine output, dry mouth, and mild loss of skin elasticity. Moderate dehydration (5% body weight loss) is characterized by marked loss of skin elasticity. The eyes become sunken. Blood pressure may fall as a result of decreased plasma volume, with weakness, fever, and a weak pulse. Sweating is not possible, even with elevated body temperature.

Marked dehydration (10% body weight loss) may involve circulatory failure from decreased plasma volume.

Treatment.

During 3 hours of hard work a 450-kg (990-pound) horse may lose as much as 45 L of fluid. If this degree of dehydration is not corrected quickly, death may result. The horse should be allowed to drink along the trail if water is available. Small amounts of cool (not cold) water should be offered. If the horse refuses to drink, gastric intubation may be indicated. Fluid is also absorbed from the colon; thus enemas (2000 to 5000 ml water) are effective in rehydration.

Heat stress usually accompanies dehydration, so cooling (e.g., shade, water bath) is important. Administration of intravenous (IV) fluids, if available, is routine therapy.

Exhausted Horse Syndrome^[2] ^[11] ^[13]

Exhausted horse syndrome (EHS) describes a complex metabolic disease occurring when horses are pushed beyond endurance limits. The syndrome has no precise characterization because the initiating mechanism may vary with the prevailing conditions. The development of EHS depends on the condition and training of the horse, the pace set by the rider, the terrain traversed, and climatic factors such as temperature, wind, and humidity.

Clinical Signs.

The severely affected horse is depressed and exhibits lethargic movements, holding its head low. The ears are expressionless. Facial grimacing creates an anxious expression, which may progress to a painful expression if colic or muscle spasms accompany the syndrome. The horse takes no interest in its surroundings. Anorexia is typical, and frequently the horse has no inclination to drink, even though dehydrated. The corneas appear glazed.

Body temperature is usually elevated and may reach 41° C (106° F). The horse does not cool properly. Usually, body temperature continues to rise. Temperature measured rectally may be inaccurate in the exhausted horse, since the anal sphincter loses tone and allows air to enter the rectum.

Cardiovascular and respiratory systems are greatly affected by endurance riding. Heart and respiratory rates are elevated. The degree depends on the prior condition of the horse, pace, length of action, and amount of work performed in climbing or walking on soft footing. Heart rates may reach 150 beats/min after a grueling climb. With 10 to 15 minutes of rest the heart rate of a conditioned horse should drop to below 60 beats/min, whereas tachycardia and tachypnea may persist in the exhausted horse, which may have a respiratory rate faster than the heart rate. Respiration is shallow and inefficient. Cardiopulmonary signs also include synchronous diaphragmatic flutter, arrhythmias, murmurs, and visible jugular pulses. Auscultation of the thorax may reveal moist rales and in extreme cases frank pulmonary edema.

Severe dehydration is the most consistent sign of EHS. Loss of skin elasticity, sunken eyeballs, dry mouth, and dry mucous membranes reflect a 7% to 10% loss of body weight, after loss of 30 to 40 L of fluid. Serious electrolyte and acid-base imbalances are associated with dehydration. Alkalosis is common.

Muscular manifestations of EHS include fatigue, trembling, spasm, stiffness, muscles painful to palpation, and rarely, tying-up. Tying-up is usually a distinct entity.

Horses suffering from EHS are prone to colic, which also may occur independently. When colic accompanies EHS, it is of the spasmodic type, with diminished or absent borborygmus.

Treatment.

Rest, rehydration, and electrolyte supplementation are the keys to recovery. If the horse is drinking and will take electrolytes in the water, the effect is almost as beneficial as the administration of IV fluids. Packaged electrolyte powders can be carried.

If the horse is hyperthermic, shows evidence of shock, and refuses to drink, more drastic steps must be taken. The horse may require 40 to 50 L of fluid. Besides IV fluid administration, gastric intubation may provide fluids orally. Enemas are also effective, since fluid is absorbed from the colon.

Synchronous Diaphragmatic Flutter^[3] ^[11] ^[13]

Synchronous diaphragmatic flutter (SDF) is a clinical sign observed in endurance horses while on long-distance rides and may be seen on an expedition. It is defined as a spasmodic contraction of the diaphragm

1064

synchronous with the heartbeat. Overexertion with excessive sweating produces mild to serious metabolic alterations that may be life threatening. The development of SDF on a trek indicates that the horse should not continue.

Unlike acute exertional stress, which is characterized by acidemia, SDF is associated with alkalemia. Electrolyte imbalances may also be involved. Hypocalcemia, hypokalemia, and alkalosis probably cause equine SDF.

Clinical Signs.

SDF may develop after 32 to 48 km (20 to 30 miles) of riding. There is no gender, age, or breed predilection. The primary sign is spasmodic contraction in the flank area. The "thump" is easily felt by light palpation in the flank area. Auscultating the heart while holding a hand over the dorsocaudal rib area reveals that diaphragmatic contraction is synchronous with the heartbeat. SDF may be the only clinical sign, or may be part of EHS.

The degree of thumping may vary from a barely perceptible quiver to a contraction that seems to rock the horse's body and is observable from a distance. The flutter may be continuous or intermittent, especially in degree.

Treatment.

Rest and rehydration are required.

Colic

Colic is the clinical manifestation of abdominal pain, usually the result of a gastrointestinal disorder. It may also arise from the urinary system or peritoneum. Types of colic are numerous because of the unique and complex anatomy of the equine digestive system.

Etiology.

Colic may be produced by gastric tympany, intestinal obstruction, or hyperspasticity. The most likely inciting causes on a trek are overeating of nonregular forages, ingestion of poisonous plants, or exhaustion. In one case a commercial packer took horses to graze in a meadow for a noon rest stop. Two hours later, at the start of the afternoon trek, two of the horses were colicky. In checking the meadow the packer saw many plants of death camas (*Zygadenus* species), some of which had been eaten. The colic was sufficiently severe to require a layover at the meadow for the rest of the day.

Clinical Signs.

Horses express colic by looking back at one side, stamping the feet, getting up and down, rolling, and pressing the head against trees or rocks. The pulse rate may exceed 100 beats/min with severe pain. The conjunctival membranes are congested and cyanotic.

Treatment.

Reports discuss only superficial emergency measures. Treatment depends on the anatomic location of the obstruction or spasm. Mild obstructions may be relieved by hydration and administration of a cathartic. Cold-water enemas may stimulate sluggish intestinal peristalsis and relieve impaction of the small (terminal) colon. Pain and spasms may be relieved by administration of flunixin meglumine (Banamine), 1 mg/kg intramuscularly twice a day. Walking the horse may prevent it from lying down and injuring itself by rolling.

DISORDERS OF PACK LLAMAS

Most of the medical problems of llamas have been considered under headings of disorders common to all animals. Llamas are hardy animals and unlikely to allow themselves to be pushed to exhaustion. If fatigued, they simply lie down and refuse to rise. They will not tolerate excessive loads. About 45 kg (100 pounds) is an appropriate load for a large, well-trained and conditioned llama.

Plant poisoning is more likely in llamas than in horses, but such incidents are rare. Rope burns from entanglement in tethers are less likely than in horses. The llama is less excitable, and if it becomes entangled, it usually lies quietly until help arrives.

North American venomous snakes pose minimal threat to large animals. Llamas are curious, however, and may be bitten on the nose while investigating the strange animal. Nose bites from rattlesnakes are especially hazardous to llamas because local swelling may occlude the nostrils. Llamas are primarily obligate nose breathers, so dyspnea and suffocation may ensue. Rattlesnake bites of the limbs cause edema and in severe cases, local tissue necrosis and ulceration. Many cases are diagnosed as nonspecific trauma unless the bite is observed. The signs of snakebite in llamas are essentially the same as for horses.^[5] ^[8]

Therapy for a nose bite may require tracheostomy and insertion of an improvised tube to allow breathing. Edema may persist for 2 to 3 days. If the bite is observed and progressive swelling noted, a small tube (1 cm diameter) can be inserted 15 cm (6 inches) into the ventral meatus of the nasal passage and sutured to the nares. Swelling occurs around the tube, but patency of the nasal passage is maintained.

DISORDERS OF DOGS

Exercise Stress

Sled dogs are usually conditioned for heavy work, but the inexperienced handler may push animals beyond their endurance. Dogs without adequate conditioning are frequently taken on other treks. Muscle soreness, fatigue,

1065

dehydration, and hyperthermia are common and are dealt with as for humans. Erosions of the footpads require special care. A sheet of soft leather out of which to fashion boots should be carried.

Porcupine Quills

When dogs are brought into porcupine country, the risk of an encounter is great. Some dogs fail to learn from experience and are repeatedly quilled. The dog must have physical contact with the porcupine for the introduction of quills. The muzzle and face are the usual sites of penetration, and a dog can be blinded by perforation of the eyeball.

The quills must be removed physically. A pair of pliers should be included in supplies and equipment. The process is painful and requires sedation (e.g., diazepam). The quill should not be broken because the retrograde barbs on the quill foster migration and abscess formation.

Grass Awns

Numerous species of grass awns ("foxtails") may become attached to the dog's coat or lodged in the external ear canal, nasal passage, conjunctival sac, or interdigital space. Dogs that travel when plants are mature and awns are easily dislodged from the seed head should be inspected frequently for awns in these sites.

Signs depend on the location of the foreign body. When it is within the ear canal, the dog paws at its ear and shakes its head. The head may be held tilted. Exudate may flow from the ear. Awns in the nostril cause sneezing and nasal exudate. Awns in the conjunctival sac cause lacrimation, photophobia, and corneal edema and ulceration.

The dog paws at the eye. Awn penetration between the digits and at other locations through the skin is more difficult to diagnose because the awn may be some distance from the fistula.

Awns must be removed physically. Sedation, topical anesthesia, or both may be necessary. Although topical ophthalmic anesthetics are desirable in the eye, lidocaine may be used in an emergency. A pair of small alligator forceps is most suitable for reaching into otherwise inaccessible places. An otoscope may be necessary to visualize awns in the nostril or ear canal. An antibiotic ointment should be instilled after removal of the awn.

Stinging Nettle Poisoning

Stinging nettle (*Urtica* species) is common along streams and lakes in wilderness areas. Humans vary in sensitivity when the plants accidentally contact exposed skin. Leaves and stems are covered by harsh hairs, some of which have a tiny ball tip that breaks off just before penetration. The specialized hairs are hollow. A base gland produces histamines and acetylcholine, which are injected into the victim.

Short-haired dogs that move through patches of stinging nettle are at risk of poisoning from the cumulative effect of thousands of minute injections of acetylcholine. Weakness, dyspnea, and muscle tremors are characteristic of the action of acetylcholine on peripheral nerves. Parasympathomimetic effects include salivation, diarrhea, tachycardia, and pupillary dilation. Atropine sulfate (0.04 mg/kg) subcutaneously is a specific treatment.

Harness Sores

Improperly fitted harnesses of sled dogs may produce the same frictional lesions that occur in horses or llamas.

ESCAPE OF SUPPORT ANIMAL

Support animals may escape from any type of restraint imposed and run away or simply wander off. More often, animals are tied with improper knots, or poor-quality snaps and halters break when pressure is applied. A trekker may tie an animal to a shrub, bush, or branch that can be easily pulled up or broken off. Animals that are frightened by predators or other animals may bolt and exert tremendous pressure on tethers, picket lines, stakes, or branches.

Hobbling is a common technique used to allow horses and mules to graze. Trek leaders must know the habits of individual animals when hobbled. One horse may accept having the front feet hobbled together and graze peacefully, taking only the short steps possible. Another horse may learn how to gallop with the front feet hobbled. Some horses must be hobbled with three restrained legs.

Even experienced trekkers (e.g., commercial packers) may become overconfident and accept an animal's willingness to stand quietly without wandering away. They may leave just a lead rope dragging on the ground (ground tie). The animal may become frightened or bored and wander off. One llama carrying a full pack wandered off and was missing for a month. Contrary to popular belief, not all llamas are social, so they may not return to a herd that is securely tethered. As with horses and dogs, llamas have homing instincts and may set off in the presumed direction.

If a breakaway is observed, members of the party should not further frighten the animal by rushing at it. It should be given a chance to settle down and return to the group. The handlers can move around the animal to block obvious escape routes but should not try to chase it. All these animals can run faster than a human.

1066

If the escapee has an animal "buddy" in the group or a favorite person, he or she can make an approach. A favorite treat in camp can be used to entice the animal back to the fold.

If an animal is discovered missing, the situation is assessed to determine the cause and direction taken. Generally, animals return toward the direction from which they have come. Frightened animals or those escaping at night may not adhere to any rule. A search for tracks can be made, but llamas may not leave much evidence, particularly in

rocky terrain.

Scanning the surroundings may reveal the animal. It may be in the vicinity of camp resting under a tree or in a clump of bushes. Unless tracks direct otherwise, the path back toward a trailhead should be searched first. Another animal, preferably a buddy of the escapee, should be taken on the search. Even though the animal is sighted, it may not be caught unless a second animal is there to bait it in. Using vantage points, searchers should consider where they might have gone under the circumstances. Lush meadows or other areas with desirable feed should be checked.

Fellow hikers and ultimately the Forest Service or other regulatory agencies should be alerted about the missing animal.

MEDICATION PROCEDURES

[Table 45-3](#) lists medications for animals and indications for their use; the [appendix](#) lists sources for these veterinary drugs. In the horse, intramuscular (IM) injections are given in the neck or rump. Subcutaneous (SC) injections are given by lifting a fold of skin just cranial to the scapula. IV injections are given in the jugular vein, which is easily distended along the jugular groove on the ventral aspect of the neck ([Figure 45-7](#)).

In the llama, IM injections are given in the relatively hairless area at the back of the upper rear leg, by standing against the body in front of the rear limb while facing the rear and reaching around the back of the animal to give the injection. SC injections are given in the relatively hairless area of the caudal abdomen, just in front of the rear limb. Since an inexperienced individual may have difficulty locating the jugular vein for IV administration in the llama, IM or SC routes are recommended.

In the dog, IM injections may be administered in the triceps muscles caudal to the shoulder or in the muscle masses on the upper rear limb. SC injections are made by lifting a fold of loose skin on the neck near the withers. IV administration is via the jugular or cephalic vein ([Figure 45-8](#)). For the latter, an assistant grasps the limb at the elbow to occlude the vein, which courses on the dorsal aspect of the forearm. The vein is more visible if the hair is wetted down with water.

Euthanasia

Euthanasia may become necessary in the event of injury or illness that cannot be corrected or when the animal cannot be removed to a location where remedial action can be taken. Horses, mules, donkeys, and llamas cannot be carried out of a wilderness area manually. Large animals can be airlifted out of the wilderness by helicopter, but obtaining such help may require great time and effort. Dogs may be placed in an improvised stretcher and carried out.

Indications for euthanasia include (1) compound and comminuted fractures of long bones, (2) falling or sliding into inaccessible places from which the animal is unable to extricate itself or trek participants are unable to aid the animal, (3) lacerations exposing abdominal or thoracic organs (e.g., wild animal attacks, tree branches rammed into the body), (4) head injuries resulting in persistent convulsions or coma, and (5) protracted colicky pain unrelieved by analgesics or mild catharsis, usually associated with a pulse rate greater than 100 beats/min, rolling, and congested conjunctival membranes.

The expedition may carry a bottle of euthanasia solution, which must be given intravenously or intraperitoneally (see [Table 45-3](#)). If firearms are carried, a properly

placed bullet to the head produces a fast and humane death. The shooter stands in front of the animal's head and draws an imaginary line from the medial canthus of each eye to the base of the opposite ear. The shot should be aimed where those lines cross and approximately perpendicular to the contour of the forehead ([Figure 45-9](#)). The tip of the barrel should be no more than 15 cm (6 inches) from the head. A heavy blow to the head at the same location is equally effective. The blow may be administered with the blunt edge of a single-bladed ax or hatchet. A large rock held in the hand may also be used. A less desirable but sometimes expedient method is to sever the jugular vein to allow exsanguination. This would probably be used on an animal that is already unconscious.

Some vital statistics for support animals are provided in [Table 45-1](#) . Equipment for support animals and the sources are listed in [Box 45-1](#) , [Table 45-4](#) , and the [appendix](#) .

Body Temperature

The rectal body temperature of an animal is assessed by inserting a thermometer lubricated with water or spittle through the anus with a slight twisting motion. Heavy-duty glass veterinary clinical thermometers are available, but regular human clinical thermometers are equally useful. In hot climates, clinical thermometers

must be kept in insulated containers; or high temperatures might render them useless.

Box 45-1. EQUIPMENT AND SUPPLIES FOR ANIMALS*

1. Sterile pack

Needle forceps

Thumb forceps

Scissors

Scalpel handle and blades

Hemostats (2)

2. Alligator forceps

3. Suture material (Vicryl), swaged needles, 4 packets, various sizes (0 to 4-0)

4. Gauze sponges, 4 x 4 inch (100)

5. Roll cotton, 1 pound

6. Vetrap bandages, 3 inch, 6 rolls

7. Syringes, plastic, 12 ml (6)

8. Needles, 22-18 gauge (20)

9. Tubing

Silastic, 1 cm outside diameter, 10 cm (4 inches) long, for endotracheal tube

Plastic flexible stomach tube, 1 cm inside diameter, 100 cm (40 inches) long

10. Funnel, plastic, to fit into stomach tube

11. Hose, garden, 20 cm (8 inches), to serve as speculum for passage of stomach tube

12. Hoof knife

13. Hammer

14. Pliers

15. Horseshoes and nails

16. Pliable sheet of leather

17. Heavy needle and thread

18. Otoscope

19. Stomach pump

*See [Table 45-4](#) for priorities with horses, llamas, and dogs.

TRANSPORTING ANIMALS^[8] ^[9]

Dogs

Dogs are easily transported in fiberglass carrying cages in common use by dog owners and for airline shipment. Appropriate opportunities for exercise and urination should be provided. Provision of food and water depends on the duration of the journey.

Horses

Horses may be transported in horse trailers or trucks. Each animal should have been trained to enter and leave the conveyance with ease. The conveyance should be covered to prevent insects and flying debris from striking animals in the face or eyes. Avoid exposure to exhaust fumes. Legs should be wrapped to support the lower limb tendons, joints, and ligaments.

Llamas

Llamas are often moved from one location to another and generally travel well. The majority lie down soon after the beginning of a journey and remain recumbent while moving; however, traveling is stressful for most lamoids whether or not they exhibit overt signs of stress. Llamas do not need to be tied within a truck or trailer, which may be hazardous. At least two fatalities have been associated with tied llamas.

Llamas are small and adaptable enough to be moved in many vehicles, including private vans, pickup trucks, livestock trucks, trailers, and commercial vans; insurance coverage should be checked. Llamas should be accustomed to the vehicle in which they are to travel.

Vehicles and trailers should be properly maintained, and exhaust fumes must not flow past the heads of the llamas.

Climatic conditions must be considered. More than one llama has died as a result of heat stress while being transported. Most trek animals will not be shipped by air, and most airlines refuse to carry live animals if daytime temperatures exceed 29.4° C (85° F) anywhere the plane lands. Caution is used when transporting in hot weather. Road conditions should be investigated, including any construction detours that may cause delays. Storms should be anticipated.

Some trailers have a small ramp leading up to the floor of the trailer for loading and

unloading. Others require that the animal step up to load. Llamas prefer to step rather than walk up a ramp. It is unwise to pull or push a llama into a step-up trailer. A leg may slip beneath the floor of the trailer and be fractured if the animal lunges forward. Appropriate training eliminates such problems.

Trailer flooring must be considered. Although llamas generally can walk on smooth surfaces, it is not appropriate to leave the metal or wood floor of a trailer bare. Rubber mats or indoor / outdoor carpeting are ideal because they provide footing and insulation from both heat and cold and are softer. Straw may provide insulation in cold weather but does not provide footing. It does absorb urine. It is unwise to use straw for bedding on long journeys, especially if no feed is supplied. Hungry or bored animals may eat the straw, and if unaccustomed to it, may develop digestive upsets. Sand may be used, but wood shavings or sawdust become embedded in the fiber coat and are difficult to remove.

Llamas may be trained to use different water containers, including a flowing stream or pool. If the animal is not used to a variety of water sources, a plastic or metal bucket can be used for a few days before beginning a trip. Animals may be reluctant to drink sufficient new-source water, which may be disastrous in hot weather. The odor and taste of new water may be disguised by pretraining the animal to drink water containing two drops of vanilla extract or oil of eucalyptus. New water can then be similarly treated.

Llamas may be unwilling to defecate or urinate in a strange environment and should be provided the opportunity to stand or exit the vehicle while stopping for a rest.

Recumbent Llama.

Moving a recumbent llama may be accomplished using the following technique:

1. Roll up a plastic or canvas tarp (longer than the length of the animal) on one side and place it next to the animal, which has been moved into the sternal position.
2. Do not roll the animal on its back onto the tarp; rolling may cause regurgitation and possibly inhalation pneumonia. Rather, partially roll the animal from lateral to sternal recumbency and push the roll under it.
3. Allow the animal to resume lateral recumbency so that the tarp may be unrolled beneath it.
4. Roll up both sides of the tarp to form a handhold for those who will lift and carry the animal.
5. Keep the head and forequarters higher than the rearquarters to avoid passive regurgitation.

For llamas it may be appropriate to rig a temporary sling inside a trailer or truck using a large bath towel or piece of canvas, as follows:

1. Cut four holes near the center, corresponding to the legs of the llama.
2. Gently lift a forelimb and insert the foot through one hole.
3. Repeat with the other forelimb, then repeat with the hind limbs.

4. Fasten a small rope to each corner by first folding the corner of the towel over a small rock.
-

1070

1071

5. Tie a slipknot around the cloth and the rock and pull it tight.
6. Tie the ropes to the side of the trailer or partition.

Figure 45-10 Rope sling for a llama. X, Halter tie; Y, Bowline.

Figure 45-11 Placement of a rope sling on a horse.

Figure 45-12 Commercial equine sling. (Courtesy University of California, Davis, Center for Equine Health.)

The llama's feet should remain on the floor of the trailer, and a person should ride beside the animal.

Field Evacuation of Injured Animals

Field evacuation of injured or seriously sick trek members by helicopter has become a

viable option for all but the most remote wilderness expeditions. Cost is not an important factor in evacuating humans but may have to be considered in animal evacuations.

Dogs may be taken into the cabin of a helicopter. Llamas and horses must be slung beneath the helicopter. A sling for a short journey of a llama may be fashioned with four rope loops, all brought together over the back of the llama ([Figure 45-10](#)).

A sling for a horse may be constructed from a rope. The diameter and length of the rope depend on the size of the animal; a 50-foot-long, ½-inch-wide nylon climbing rope is suitable to lift a 1000-pound horse. The technique follows:

1. Double the rope, then form a loose neck loop using a bowline knot.
2. Slip the loop over the head, and position the loop with the knot at the base of the chest.
3. Bring the running segments between the front legs and back through the corresponding side of the neck loop.
4. Cross the ropes over the back, then bring the ropes between the hind legs.
5. Be certain not to cross ropes underneath the animal. The ropes should pass on either side of the tail, up over the back and underneath all the ropes on the back.
6. Take all slack out of the ropes, and complete the sling by doubling the running ends back and tying with a halter tie.

Figure 45-13 Mule transport by helicopter. (Courtesy University of California, Davis, Center for Equine Health.)

An attempt should be made to place the lifting site over the approximate center of gravity of the animal (just behind the withers). Even if this is not done, however, the animal can still be lifted because each leg is in its own loop sling. The animal cannot slip out of the sling ([Figure 45-11](#)).

A more elaborate sling is available commercially* and has been used in numerous large animal rescue operations ([Figure 45-12](#) and [Figure 45-13](#)).

Chapter 46 - Seasonal Allergies

Naresh J. Patel
Robert K. Bush

Allergic rhinitis is the most common allergic disorder, occurring in 15% to 20% of the general population.^[47] Pollens, fungi, dust mites, and animals are the most commonly implicated allergens in allergic rhinitis. Pollens and fungi are primarily responsible for inducing symptoms in the outdoors. In temperate climates, individuals with allergic rhinitis often have worsening symptoms in the warmer months, correlating with pollination of various pollen-producing plants and increase fungi growth.

Although anaphylaxis is not as common as allergic rhinitis, it represents the most severe form of allergic reaction and can lead to serious outcomes or can be fatal if not treated promptly. For example, each year about 40 deaths in the United States are attributed to anaphylaxis resulting from a bee sting.^[3] Foods and drugs are the most common causes of anaphylaxis.

ALLERGIC RHINITIS

Allergic rhinitis is a chronic immunoglobulin E-mediated (IgE-mediated) inflammatory disease of the nasal mucosa. It is the most common atopic disorder, and for reasons not yet clear, its prevalence is increasing worldwide. The economic impact of allergic rhinitis is impressive; the estimated total annual cost in medications and physician visits is \$3.5 billion.^[52] The disease usually manifests in early childhood or adolescence and peaks in the second or third decade of life. The disease does not appear to favor any gender, ethnic group, or race. The most important risk factor for developing allergic rhinitis is a family history of atopy, especially with early onset of disease. The risk increases to 30% if one parent or sibling is atopic and 50% if both parents are affected.^[35] Conversely, lack of complete concordance for atopy in identical twins emphasizes the importance of environmental factors in disease development.^[5] Allergic rhinitis tends to cluster in families, as do other atopic conditions, such as asthma and atopic dermatitis.

Pathophysiology

Acute allergic reaction and late inflammatory events are important components in the pathogenesis of allergic rhinitis. Type I immediate hypersensitivity is responsible for most of the acute clinical manifestations of allergic rhinitis, and cells such as eosinophils, basophils, and T lymphocytes play important roles in late inflammatory events. Production of allergen-specific IgE (sensitization) antibodies forms the underlying basis of immediate hypersensitivity; atopy is defined as the genetic predisposition to develop allergen-specific IgE antibodies. The sensitization process requires a cooperative effort between CD4⁺ T lymphocytes and B lymphocytes (Figure 46-1 (Figure Not Available)). It begins with presentation of an allergen to CD4⁺ T lymphocytes by antigen-presenting cells (e.g., macrophages) in the context of a major histocompatibility complex. Cytokines released from CD4⁺ T lymphocytes as a result of this interaction cause differentiation of B lymphocytes into immunoglobulin-secreting plasma cells. This differentiation leads to isotype switching (production of specific antibody types) within the plasma cells. For example, IgE switching is promoted by release of cytokine interleukin-4 (IL-4) or interleukin-13 (IL-13) from T lymphocytes.^[12] Once allergen-specific IgE antibodies are produced, subsequent exposure and binding of the allergens to IgE molecules on the surface of mast cells results in cross-linking of the IgE molecules. Consequently, mast cells or basophils degranulate and release preformed and newly synthesized mediators. The prototype preformed mediator is histamine, and the newly synthesized mediators include those of the arachidonic acid pathway (leukotrienes, prostaglandins, and platelet-activating factor), neuropeptides (e.g., substance P), and cytokines (e.g., IL-4, IL-5).

The release of chemical mediators leads to various pathologic and clinical

consequences. Sneezing and itching are secondary to histamine stimulation of its receptors on sensory nerve endings, rhinorrhea results from increased vascular permeability produced by all the mediators, and leukotrienes and prostaglandins are believed to play major roles in nasal congestion.^[55] Our knowledge of the pathophysiology of allergic rhinitis has been greatly enhanced by nasal challenge studies.^[23] It is now known that the allergic reaction consists of an early phase characterized by mast cell or basophil degranulation, and a late phase, which occurs 4 to 6 hours after the early phase (Figure 46-1 (Figure Not Available)). The hallmark of late-phase reaction is an influx of inflammatory cells, such as eosinophils, basophils, and T lymphocytes.^[4] For example, basophils cause further histamine release and T lymphocytes release additional cytokines that enhance IgE production (via IL-4) and eosinophil activation (via IL-5). As a result of further inflammatory activity by these cells, there is recrudescence of symptoms many hours after the initial allergen exposure. Leukotrienes, prostaglandins, and cytokines released in the early-phase

1075

Figure 46-1 (Figure Not Available) Simplified schematic representation of the natural history of allergic rhinitis. During phase 1, the individual becomes sensitized to an allergen. During phase 2, clinical disease develops. The over-whelming majority of individuals have an early response upon reexposure to the allergen. The activation of mast cells and the release of mediators dominate the early response. After the early response, most individuals have cellular infiltration of the nasal mucosa causing late inflammatory events, including the spontaneous recurrence of release of mediators (late-phase reaction), hyperresponsiveness to irritants, and increased responsiveness to the allergen (priming). The circles indicate the heterogeneity of these late inflammatory events. Inflammation can resolve spontaneously, cause a complication, or lead to an irreversible form of chronic rhinitis. (From Naclerio R: *N Engl J Med* 325:860, 1991.)

reaction play an important role in recruiting the late-phase cellular milieu to the inflammatory site. Although inhaled corticosteroids block both the early- and the late-phase reactions, systemic glucocorticoids block only the late-phase reaction.

Allergens

Allergens are the etiologic agents of allergic rhinitis. Although many potential allergenic proteins exist, relatively few are clinically important and even fewer have been isolated and characterized. Allergens are low-molecular-weight proteins or glycoproteins capable of eliciting a Type I immediate hypersensitivity reaction (production of IgE antibodies). It is convenient to divide allergens into those that exist in the outdoor environment and those that exist in the indoor environment. In the outdoors, pollens of trees, grasses, and weeds and certain fungi (e.g., *Alternaria* and *Cladosporium* species) most commonly provoke allergic rhinitis symptoms. Pollen-sensitive individuals typically experience seasonal rhinitis in predictable time intervals from one season to the next. Although fungi are more ubiquitous in nature and do not have distinct seasons like pollens, both outdoor and indoor fungi thrive in moist environments. Therefore, in temperate climates, fungi counts start to rise in spring with a peak in mid- to late summer. Indoor allergens include fungi, animals, cockroaches, and dust mites. Unlike outdoor allergens, which typically produce seasonal symptoms, indoor allergens often

produce symptoms perennially; however, the symptoms are less drastic in nature, often making diagnosis more difficult.

Pollens.

Pollination in higher-order plants consists of the transfer of the male gametophyte to the female gametophyte. In this process, pollen grains serve as vectors for male gametophytes. Of the different types of pollen-producing plants, flowering plants (including trees, grasses, and weeds) are the most important from an allergic standpoint. Flowering plants may be divided into those that rely on animal vectors (e.g., insects) for pollination (termed *entemophilous*) and those that depend on the wind (termed *anemophilous*). In general, only anemophilous plants (including trees, grasses, and weeds) cause allergic symptoms.^[49] Pollens

TABLE 46-1 -- Selected Trees, Grasses, and Weeds of Allergenic Significance

REGION (STATES)	TREES	GRASSES	WEEDS
Northeast (ME, NH, VT, NY, PA, NJ, MA, RI, CT)	Birch	Orchard	Sheep sorrel

From Sicherer SH, Eggleston PA: Environmental allergens. In Lieberman P, Anderson JA, editors: Allergic diseases: diagnosis and treatment, Totowa, NJ, 1997, Humana.

Plants are listed in the order of bloom for each region. Grasses are listed by prevalence in each region.

of entomophilous plants do not achieve high airborne concentrations. In temperate climates, pollination of trees, grasses, and weeds occurs in predictable time intervals in a given region. It is important to know the relevant local botany and the respective pollination seasons ([Table 46-1](#) and [Figure 46-2](#)).

As shown in [Figure 46-2](#) , tree pollination marks the onset of allergy season in most parts of North America. It begins as early as mid-January in the Southwest to early April in the Northeast and terminates between early and late May. Trees of allergenic significance in various regions are listed in [Table 46-1](#) . Grass pollen,

1077

Figure 46-2 Pollen seasons by region in the continental United States. (From Sicherer SH, Eggleston PA: *Environmental allergens*. In Lieberman P, Anderson JA, editors: *Allergic diseases: diagnosis and treatment*, Totowa, NJ, 1997, Humana.)

with its worldwide distribution, is a significant source of allergen exposure and a major cause of allergic rhinitis in sensitive individuals. In frost-free areas of North America, grass pollen may be present year-round, whereas in temperate climates, grass pollination peaks between mid-May and mid-July. Important grass types are rye, timothy, Kentucky bluegrass, orchard, Johnson, and Bermuda. Unlike ragweed and tree pollen allergens, grass pollen allergens show extensive cross reactivity among different species, and allergic individuals are generally sensitive to many of these species. Weeds represent the final pollen of the season, with typical duration from mid-August through mid-October. Although a variety of weeds cause regionally significant allergies, ragweed is found in most parts of North America.

Fungi.

Numerous allergenic fungi are responsible for both seasonal and perennial symptoms.

The three most important classes of allergic fungi are Zygomycetes (e.g., *Rhizopus*, *Mucor*), Basidiomycetes (e.g., rust, smut, *Ganoderma*), and Ascomycetes (e.g., *Cladosporium*, *Penicillium*, *Aspergillus*, *Alternaria*, *Epicoccum*). Among the outdoor fungi, *Cladosporium* and *Alternaria* are the most abundant, causing significant symptoms in sensitive individuals. Although fungi can survive in various climates, they grow best in warm, humid environments. The peak fungal season in many areas is in middle to late summer and fall, with a marked reduction after the first frost in temperate climates. Fungi levels may rise in spring, when decaying vegetation is uncovered after the snow has melted. Common outdoor sources of fungal growth are leaves, moist debris, and soil; therefore outdoor activities, such as raking, farming, and mowing, significantly increase exposure.

Dust Mites.

Dust mites are microscopic arachnids that are close relatives of ticks and spiders. They feed on human epidermal scales and, like fungi, prefer a warm, humid environment. Dust mites are the most common indoor allergens and can cause significant perennial symptoms in sensitive individuals. Although there is no good correlation between exposure level and degree of rhinitis symptoms, a level of 10 µg/g of dust is considered

1078

a risk factor for the development of acute asthma symptoms.^[38] Common indoor sources of dust mite exposure include mattresses, pillows, blankets, upholstery, and furred toys. Dust mites may proliferate in sleeping bags stored in humid environments (e.g., damp basements).

Animals.

Animals, especially cats, can be highly allergenic and in sensitized individuals can cause significant rhinoconjunctivitis symptoms. Cats and dogs are the most common pets in the United States, with more than one third to one half of all homes housing at least one cat or dog.^[48] Birds, rabbits, hamsters, guinea pigs, rats, and mice are some other potentially allergenic pets. The major allergens of the cat and the dog are found in their saliva and sebaceous glands. The cat allergen can remain a potential source of allergy months after its removal because of its light, sticky qualities.

Outdoors, inhalation of the emanations of moths, locusts, beetles, and flies may cause allergic symptoms. Residents of the area around western Lake Erie may experience allergic symptoms caused by the mayfly.^[48] Finally the cockroach is a potential allergen frequently encountered in heavily infested, crowded, multifamily dwellings.

Functions of the Nose

The main functions of the nose—to warm, humidify, and filter air—are possible because of turbulent airflow resulting from increased surface area provided by the three

turbinates (superior, middle, and inferior) on each side. The nose's functions are mainly controlled by the underlying neurovascular system. The blood supply to the nose is via the ophthalmic (branch of the internal carotid) and internal maxillary (branch of the external carotid) arteries. Neural innervations include the sensory (via the trigeminal nerve, which is responsible for the sneezing reflex) and autonomic (parasympathetic and sympathetic) nervous systems. Nasal congestion is proportionally related to the amount of blood pooling in the cavernous sinusoids (located within the turbinates) and to the degree of mucosal edema. Sinusoid filling and emptying are controlled by the autonomic nervous system. Vasodilatory parasympathetic stimulation allows the sinusoid reservoir to fill via the opening and closing of the capillary and postcapillary venule sphincters, respectively. Conversely, sympathetic stimulation contracts the capillary sphincter and relaxes the postcapillary venule sphincter, allowing the reservoir to empty.

In most people, cyclical swelling and shrinking of the turbinates between the two sides is inherent. This nasal cycle, which is approximately 1 to 4 hours in length, results from alternating sympathetic discharge and is responsible for the sensation of alternating unilateral nasal blockage experienced by allergic rhinitis sufferers.^[20]

Another major function of the nose is olfaction. The olfactory area is located at the roof of the nasal cavity above the middle turbinate. Significant turbinate edema can lead to poor ventilation of this area and associated hyposmia, which is common among chronic rhinitis and sinusitis sufferers.

Clinical Evaluation

A good, careful history is crucial in the evaluation of allergic rhinitis and can often help determine whether the individual is allergic. In most cases allergy testing is used to confirm the underlying clinical suspicion. Allergic rhinitis can be divided into two main categories: seasonal (hay fever) and perennial (defined by nasal symptoms lasting more than 2 hours per day for more than 9 months of the year).^[35] Seasonal rhinitis usually indicates outdoor pollen sensitivity, most commonly caused by trees, grasses, weeds, and fungi. In addition to pollens and fungi, perennial rhinitis sufferers may be sensitive to indoor allergens, such as dust mites and animal dander.

Symptoms of allergic rhinitis can range from intermittently mild to incapacitating during peak pollen season. The hallmark of allergic rhinitis is temporal correlation of symptoms with allergen exposure.^[34] The most common symptoms of allergic rhinitis—sneezing, nasal congestion, rhinorrhea, and pruritus of the nose and eyes—are nonspecific. Itching and sneezing are the most distinctive complaints associated with allergic rhinitis,^[35] whereas congestion seems to be more prominent in perennial rhinitis than seasonal rhinitis. In some individuals, ocular symptoms predominate over nasal symptoms. Allergic rhinitis sufferers often experience the priming effect (an increase in sensitivity to allergens after repeated exposure) and hyperresponsiveness to nonallergenic environmental stimuli, such as tobacco smoke, strong odors, pollutants, and weather changes.^[10]

The timing of symptoms often helps in predicting the responsible pollens because

pollination occurs at predictable intervals. For example, in the Midwest, ragweed sufferers characteristically start experiencing symptoms in mid-August. However, the specific allergen can be difficult to surmise in individuals with perennial rhinitis because other more ubiquitous allergens, such as fungi, may play a role. Other conditions of the upper respiratory tract may mimic allergic rhinitis and must be considered. Complications of allergic rhinitis include sinusitis, asthma, sleep loss, work impairment in adults, and learning difficulties in children.

In addition to nonspecific symptoms, the signs noted on physical examination are not exclusive to allergic rhinitis. Classically the nasal mucosa is pale blue and edematous, but this color change is noted in only 60% of sufferers and many individuals have erythematous mucosa.^[14] In children the "allergic salute" (upward nasal rubbing) and "allergic shiners" (dark, puffy circles

under the eye) may be present. Other notable signs include septal deviation, polyps, and an obvious foreign body. If congestion is profound, use of a topical decongestant, such as oxymetazoline (Afrin), may improve visualization.

Allergy Testing

Although the clinical presentation of seasonal allergic rhinitis is usually sufficient to make the diagnosis, allergy testing is recommended for individuals with perennial symptoms. Testing pinpoints various allergens and can provide useful information regarding specific avoidance measures. Allergy testing must be performed if immunotherapy is being considered.

Differential Diagnosis

There is significant overlap of rhinitis symptoms and symptoms of other upper respiratory tract disorders ([Box 46-1](#)). Rhinitis can be acute or chronic, with the most common cause of acute rhinitis being a viral infection. Allergic rhinitis may be confused with viral rhinitis; however, unlike allergic rhinitis, symptoms of viral rhinitis do not persist longer than 2 weeks unless a superseding sinusitis develops. A foreign body or trauma also can cause acute rhinitis. Unilateral symptoms are the hallmark of foreign body obstruction.

Vasomotor (idiopathic) rhinitis

NARES (*nonallergic rhinitis with eosinophilia syndrome*) is characterized by (1) symptoms similar to allergic rhinitis, (2) eosinophilia noted on nasal smear, and (3) normal results of skin tests.^[24] Chronic sinusitis, which can occur as a complication of allergic rhinitis, commonly produces nasal symptoms, including postnasal drip, cough, and diminished senses of smell and taste. Unlike acute sinusitis, chronic sinusitis causes symptoms that are subtle and often require radiologic evaluation, preferably computed tomography. Systemic diseases, such as Wegener's granulomatosis, have been associated with chronic sinusitis. Rhinitis medicamentosa, which usually results from overuse of topical α -adrenergic vasoconstrictors (e.g., oxymetazoline), is associated with profound nasal congestion caused by rebound effects upon withdrawal of the decongestant, usually after 5 to 7 days. Other medications implicated in rhinitis medicamentosa are birth control pills and α -blocking antihypertensives.

Mechanical and anatomic abnormalities should always be sought on physical examination. Nasal polyps are bilateral, inflammatory, and often associated with chronic sinusitis and asthma. They appear pearly, smooth, and gray (like grapes). A foreign body, tumor, or septal deviation usually causes unilateral symptoms. Moreover, unilateral growth should always heighten suspicion for a foreign body or tumor. Most people have a certain degree of septal deviation; unless symptoms are severe or sinus drainage is compromised, no treatment is warranted.

Symptoms of gustatory rhinitis are caused by cholinergic discharge that occurs after such stimuli as eating, running, and exposure to cold air. Atrophic rhinitis is a rare condition that manifests in the elderly as thick, bilateral odorous discharge with little nasal congestion.^[19] Rhinitis of pregnancy should be considered in the pregnant woman with congestion, especially if there is no previous history of rhinitis. Although rare, a potentially dangerous cerebrospinal fluid leak must be considered in anyone with clear rhinorrhea and a history of central nervous system trauma. The diagnostic test is a nasal smear to detect glucose.

After all of the aforementioned conditions have been considered, many individuals are left with the diagnosis of vasomotor (idiopathic) rhinitis. These individuals typically have perennial symptoms that are often triggered by changes in weather, irritants (such as smoke or perfume), and spicy foods. Common symptoms are chronic congestion, postnasal drip, and cough. Skin tests reveal no allergies.

Treatment

Avoidance of the offending agent (or agents) is the backbone of the treatment plan for allergic rhinitis.

1080

However, even with rigorous avoidance measures, many individuals require pharmacologic intervention. The optimal treatment plan is individualized based on the context of the disease, symptom pattern, and other comorbid conditions. The ideal medication is efficacious, cost effective, and compliance friendly, causing minimal or no side effects. Furthermore, based on the pathophysiology of allergic rhinitis, the best therapeutic agent is one that effectively addresses both early-and late-phase reactions.^[50] Currently the main classes of medications available for treatment of allergic rhinitis are antihistamines, decongestants, topical or oral glucocorticoids, anticholinergics, and cromolyn. In addition, immunotherapy should be considered for a few selected individuals.

Avoidance.

Although it may be difficult to avoid pollen because of its widespread distribution, certain commonsensical measures can be taken to decrease exposure. Outdoor activities should be limited or completely avoided when pollen counts are at their peaks. Pollen counts typically peak in the late morning to mid-afternoon.^[60] Limiting such activities as leaf raking, lawn mowing, and farming can reduce exposure to outdoor fungi (e.g., *Alternaria* species). Because fungi thrive in moist, humid environments, important indoor control measures include dehumidification, proper ventilation, fungicide use in contaminated areas, and removal of sources of fungal growth.

Antihistamines and Decongestants.

Antihistamines have been used for 50 years and are considered by many to be the first line of therapy in the treatment of allergic rhinitis.^[40] They are most effective against seasonal rhinitis in which sneezing, itching, rhinorrhea, and watery eyes are the most prominent symptoms. However, only 33% to 50% of seasonal allergic rhinitis

TABLE 46-2 -- Nonsedating Antihistamines

MEDICATION	BRAND NAME	RECOMMENDED DOSE	HOW SUPPLIED	MINIMUM AGE (YEARS)
Loratadine	Claritin	10 mg PO qd	10-mg tablets; 5 mg/tsp syrup	6

	Claritin-D 12 Hour	5 mg PO bid	5 mg loratadine and 120 mg pseudoephedrine	12
	Claritin-D 24 Hour	10 mg PO qd	10 mg loratadine and 240 mg pseudoephedrine	12

Azelastine	Astelin	2 sprays in each nostril bid	137 µg/spray	12

PO, By mouth; *qd*, every day; *bid*, twice a day.

sufferers obtain complete relief with antihistamine therapy alone.^[7] Antihistamines have little or no effect on nasal congestion because of the minor role of histamine in the pathophysiology of congestion. For this reason, antihistamines are usually inadequate for treatment of perennial rhinitis, in which nasal congestion is often a predominant symptom.

Antihistamines act by occupying H₁ receptors on cells and thereby blocking histamine binding. In comparing first- and second-generation antihistamines, both are equally effective; however, second-generation antihistamines have gained tremendous popularity because their use is associated with a much lower incidence of sedation and fewer anticholinergic side effects. Commonly used first-generation antihistamines, most of which are available over the counter, are chlorpheniramine, diphenhydramine, brompheniramine, and clemastine. The duration of action of brompheniramine and diphenhydramine is 6 to 10 hours, whereas that of chlorpheniramine and hydroxyzine is 24 and 36 hours, respectively. All first- and second-generation antihistamines, with the exception of cetirizine and fexofenadine, are metabolized extensively in the liver via the cytochrome P₄₅₀ system. Simultaneous administration of other medications that compete for the cytochrome P₄₅₀ system and hepatic dysfunction may affect the metabolism of antihistamines and increase the risk of adverse effects.

Four nonsedating antihistamines are currently available (three are oral and one is intranasal) ([Table 46-2](#)). The recommended doses are given once or twice daily, depending on the medication. Cetirizine and loratadine are approved for use in children; cetirizine is recommended for children aged 2 years and older, and loratadine is for 6 those aged years and older. Azelastine (Astelin) is the only H₁ receptor antagonist available in a nasal spray; studies have shown that it is safe and

effective for relieving most allergic rhinitis symptoms, including nasal congestion.^[27] Although all antihistamines have relatively rapid onset of action and may be used as needed, they are most effective if taken before exposure (e.g., pollen season) and if used regularly.

In some individuals the addition of a decongestant to the antihistamine may be helpful. Decongestants act by stimulating α -adrenergic receptors and thereby reducing blood supply to the sinusoids. Most are short acting (4 to 6 hours) and available over the counter with or without antihistamines. Pseudoephedrine and phenylpropanolamine are the two most commonly used decongestants. Fexofenadine and loratadine (available in 12- and 24-hour preparations) also are available with a decongestant. Insomnia and irritability are the most common side effects of decongestants, although individual tolerance varies widely. Individuals with hypertension, bladder outlet problems, glaucoma, or cardiac arrhythmias should use decongestants cautiously or preferably avoid their use altogether. Topical decongestants (e.g., oxymetazoline) have a fast onset of action (within minutes) and are therefore provide rapid relief of symptoms. Because of the risk of rhinitis medicamentosa (as described previously), topical decongestant use is limited to 5 to 7 days. Thus these medications are inappropriate for long-term therapy.

Glucocorticoids.

Glucocorticoids represent the gold standard of treatment for allergic rhinitis. Numerous well-designed studies have shown that intranasal corticosteroids are superior to antihistamines and cromolyn sodium.^{[6] [8]} With the exception of ocular symptoms, nasal corticosteroids are effective in controlling all symptoms of allergic rhinitis. A glucocorticoid is often the first line of therapy for the patient with perennial rhinitis. Glucocorticoids control the rate of protein

TABLE 46-3 -- Topical Nasal Corticosteroids

MEDICATION	BRAND NAME	RECOMMENDED DOSE (EACH NOSTRIL)	MICROGRAMS PER SPRAY	PREPARATION

bd, Twice a day; *qd*, every day.

synthesis by either inducing or suppressing gene transcription within the cell.^[28] The inhibitory effect of all glucocorticoids on the late-phase reaction is well established, but studies have shown that intranasal corticosteroids, unlike their oral counterparts, also inhibit the early-phase reaction.^[2]

Several preparations of intranasal corticosteroids are currently available ([Table 46-3](#)). All are approximately equally effective; hence the criteria for selection depends on convenience, cost, and delivery system. Intranasal corticosteroids are given either once or twice a day in aqueous or dry powder form. Dry powder preparations are associated with a slightly greater risk of nasal irritation, burning, ulceration, and epistaxis. Because of slow onset of action, it may be 1 to 3 weeks after the initiation of therapy before the maximum benefits of inhaled corticosteroid use are achieved. For individuals with seasonal rhinitis, it is prudent to begin inhaled glucocorticoid therapy before pollen season begins. There is no role for regular use of oral glucocorticoids in the treatment of allergic rhinitis. However, a short course (7 to 10 days) of oral glucocorticoids may be appropriate when symptoms are severe (e.g., during the pollen season). In addition to providing quicker relief, oral glucocorticoids may facilitate improved delivery of intranasal corticosteroids to the nasal mucosa.

The most common side effects of intranasal corticosteroids are local irritation (reported in approximately 10% of patients) and bleeding (reported in approximately 2% of patients).^[33] The incidence of side effects is higher during dry winter months. Although rare, septal perforation has been reported in patients using intranasal corticosteroids.^[45] The physician must reevaluate each patient, performing a thorough nasal examination 2 to 4 weeks after initiating therapy. If significant septal ulceration and crust formation are

noted, therapy should be discontinued for a few days and nasal hygiene with saline spray should be instituted. Long-term studies have shown no evidence of mucosal atrophy associated with the use of intranasal corticosteroids.^[32]

There have been recent concerns about the effects of inhaled corticosteroids on growth in children. Studies have demonstrated that the use of intranasal corticosteroids in therapeutic doses suppresses serum and urinary cortisol levels.^[59] A study of 100 children (aged 6 to 9 years) receiving 168 µg of beclomethasone twice daily over 12 months showed statistically significant bone growth suppression at 1, 6, 8, and 12 months.^[39] The clinical significance of these findings remains to be determined because it may be that many children's height "catches up" in adolescent years. Based on such studies, the Food and Drug Administration has considered the use of class labeling with regard to growth suppression in children for inhaled and intranasal corticosteroids.

Other Medications.

Other classes of medication available for treatment of allergic rhinitis are antiasthmatics (i.e., cromolyn sodium) and topical anticholinergics. Although studies have shown the effectiveness of leukotriene antagonists, these medications currently are not approved for use in patients with allergic rhinitis.^[26] Although less potent than intranasal corticosteroids, cromolyn is very safe and effective therapy for allergic rhinitis. Its mechanism of action is not completely understood, but it is believed to inhibit mast cell degranulation. For optimal relief, it requires regular use and frequent dosing (three to four times daily). It is useful as a prophylactic treatment before known exposure (e.g., visiting a family with a cat) and in such situations may be used as needed. The only indication for the use of a topical anticholinergic in the patient with allergic rhinitis is rhinorrhea. A topical anticholinergic drug, such as ipratropium (Atrovent), can be used alone if rhinorrhea is the main symptom or in addition to intranasal corticosteroids and antihistamines if symptoms persist despite these therapies. An additional benefit of anticholinergic drugs is control of postnasal drip. The recommended dose of intranasal ipratropium is one to two sprays in each nostril two to four times a day. The main side effect of intranasal ipratropium is nasal dryness.

Immunotherapy.

Allergen immunotherapy is a form of immunomodulation in which a state of tolerance is achieved by injecting gradually increasing amounts of allergen extracts into a sensitized person. Although the precise mechanisms of immunotherapy are unknown, several immunologic changes have been observed, including induction of allergen-specific IgG "blocking antibodies," decreases in allergen-specific IgE, modulation of mast cell or basophil function, and increases in suppressor T cells (CD8⁺).^[17]

The efficacy of immunotherapy in patients with allergic rhinitis has been well documented in numerous studies.^{[13] [53]} Most individuals who receive immunotherapy for allergic rhinitis obtain a variable degree of relief, enabling better symptom control with less medication. Immunotherapy should be considered for individuals who do not respond to avoidance measures and medical therapy and for individuals who experience significant adverse effects as a result of conventional medical therapy. In

immunotherapy an initial series of weekly injections is administered, with escalating doses of allergen extracts, and is followed by monthly injections once specified maintenance doses are achieved (within 4 to 6 months). Although there are no data regarding the optimal duration of immunotherapy, the general recommendations are from 3 to 5 years.^[56]

The most common adverse reactions of immunotherapy are local and include erythema, edema, and pruritus at the site of injection. However, systemic reactions may include any or all of the following: urticaria, rhinitis, bronchospasm, abdominal cramping, and hypotension. Systemic reactions to immunotherapy occur in much higher proportion in individuals with poorly controlled asthma. Therefore immunotherapy generally is not recommended for asthmatics with a forced expiratory volume in 1 second (FEV₁) less than 70%. Because most systemic reactions occur within 20 to 30 minutes after injection, recipients should be observed in the physician's office during this time. Patients on immunotherapy should carry epinephrine (e.g., EpiPen, Ana-Kit) for self-injection at all times to treat a possible late-onset systemic reaction. With the exception of immunotherapy against anaphylaxis resulting from an insect sting, immunotherapy should not be initiated during pregnancy. Pregnant women on maintenance doses of immunotherapy can continue treatment.

ANAPHYLAXIS

Anaphylaxis is a systemic life-threatening allergic reaction resulting from IgE-mediated mast cell and basophil degranulation (Type I hypersensitivity). It is the most severe form of Type I hypersensitivity reaction, and clinical manifestations may occur in various end organs, including the skin, upper respiratory tract, lower respiratory tract, gastrointestinal tract, and cardiovascular system. An anaphylactoid reaction is non-IgE mediated but may be clinically indistinguishable from anaphylaxis ([Box 46-2](#)). Mechanisms of anaphylactoid reactions include direct release of mediators from mast cells and basophils (e.g., opiates, radiocontrast material), disturbances in arachidonic acid metabolism

1083

(e.g., nonsteroidal antiinflammatory drugs [NSAIDs]),^[15] and complement activation (e.g., transfusion reactions). The overall incidence of anaphylaxis is unknown. In a 1990 review of 20,064 persons admitted to a university hospital, there were nine cases of anaphylaxis (0.04%).^[1] Approximately 700 to 1800 persons in the United States die each year of anaphylaxis or anaphylactoid reactions.

Etiology

The various causes of anaphylaxis can be categorized into those that are IgE antibody mediated and those that are non-IgE antibody mediated ([Box 46-2](#)). In a study by the Mayo Clinic emergency department, food was the most commonly reported cause of IgE-mediated anaphylaxis.^[61] Consumption of eggs, cow's milk, peanuts (and other legumes, such as soybeans), tree nuts (e.g., hazelnuts, walnuts, cashews, almonds),^[44] fish (e.g., cod or whitefish), and shellfish (e.g., shrimp, lobster, crab)^[46] is responsible for most food-related anaphylactic reactions. In children, peanuts are probably the most frequent cause of food-induced anaphylaxis.^[43] Individuals may accidentally ingest the allergenic food when it is disguised in cooking preparations or hidden by misleading labeling or contamination during the preparation process.

Drugs, especially antibiotics, may cause an anaphylactic or an anaphylactoid reaction. Penicillin and its derivatives are most often implicated, with reactions occurring in between 1 and 5 of every 10,000 courses of treatment.^[22] Opiates and vancomycin cause drug reactions by directly degranulating mast cells and basophils, so prior sensitization is not required.

Aspirin and other NSAIDs can provoke allergic reactions that are either IgE or non-IgE mediated, depending on the presence or absence of underlying asthma or cutaneous diseases (e.g., chronic urticaria). In the presence of asthma and chronic urticaria, disturbance in arachidonic acid metabolism is the predominant mechanism. Aspirin and NSAIDs inhibit the cyclooxygenase pathway, leading to rapid synthesis of the lipoxygenase pathway products,^[29] especially leukotrienes, which are important mediators of inflammation.

Important outdoor-related causes of anaphylaxis are envenomation (e.g., a bee sting), contact with aquatic proteins, and antivenin therapy (e.g., for snakebite). In the Mayo study mentioned earlier, bee stings were the second most common (14%) cause of anaphylaxis after consumption of allergenic foods.^[61] The estimated incidence of insect sting anaphylaxis in the general population is 0.3% to 3%.^[41] Bee sting anaphylactic reactions are especially common in individuals younger than 20 years but are more likely to be fatal in the elderly. In general, children's reactions are milder (e.g., urticaria only) than are adults' reactions. Individuals who experience a sting-related anaphylactic reaction have a 50% to 60% risk for suffering anaphylaxis after subsequent insect stings.^[41] The offending insects vary depending on geographic location. In the United States, yellow jackets cause the most allergic reactions, whereas in Europe, honeybees and wasps caused nearly all insect sting-related reactions. Although rare, anaphylaxis can result from bites inflicted by some insects (e.g., the kissing bug [*Triatoma protracta*], the deer fly [*Chrysops discalis*])^[21] ^[58] and ticks.^[9]

Physical stimuli may provoke anaphylactoid reactions. In exercise-induced reactions, symptoms typically arise after 5 minutes of moderate to heavy exercise, resolving within 30 minutes to 4 hours after exercise cessation. About 50% of affected individuals are

atopic and most engage in regular vigorous exercise. A coinciding factor, such as the ingestion of an allergenic food (e.g., shellfish)^[31] or NSAID, may be necessary.^[37] Exercise or ingestion of a certain food or drug alone does not cause an allergic reaction. In a cholinergic anaphylactoid reaction, symptoms occur after exercise and after passive exposure to heat (e.g., hot showers, sweating, anxiety). In cold-induced anaphylactoid reactions, symptoms occur after exposure to low temperatures.

Recurrent anaphylaxis without identifiable cause is called *idiopathic anaphylaxis*. Although all the target organs of anaphylaxis may be affected, idiopathic anaphylaxis most commonly causes urticaria, angioedema, or both. Diagnosis is made by exclusion after all other possible identifiable causes have been

1084

eliminated. Individuals who suffer frequent episodes are less likely to undergo remission. Short-term treatment is the same as that for anaphylaxis resulting from other causes. Depending on the frequency of attacks, long-term treatment may require regular use of corticosteroids.

Complement activation plays a key role in anaphylactoid reactions resulting from the transfusion of blood products and immunoglobulins. Transfusion of an incompatible blood type can lead to cytotoxic anaphylactoid reactions if complement-fixing antibodies to formed elements of blood, such as red cells, white cells, and platelets, are present. In γ -globulin-related anaphylactoid reactions, immune complex aggregation occurs when antigen-antibody complexes activate complement.

Pathophysiology

Unlike the local pathologic and clinical manifestations of allergic rhinitis, the clinical consequences of Type I immediate hypersensitivity in anaphylaxis are systemic. Histamine is the most important mediator and is responsible for most clinical manifestations. Important effects of histamine include vasodilation, increased vascular permeability, smooth muscle contraction, stimulation of nerve endings, and glandular secretion. These effects lead to various clinical manifestations, including flushing, urticaria or angioedema, hypotension or shock, wheezing, abdominal cramps, and diarrhea. Arachidonic acid metabolites, such as leukotrienes, prostaglandins, thromboxane A₂, and platelet-activating factor, also are released from mast cells and basophils, causing airway smooth muscle contraction, increased vascular permeability, goblet and mucosal gland secretion, and peripheral vasodilation. Platelet-activating factor also contracts smooth muscle and enhances vascular permeability. A late-phase reaction may occur many hours after the initial event.

Clinical Features and Diagnosis

Clinical manifestations of anaphylaxis may occur in various end organs, including the skin (urticaria, angioedema, and flushing), upper respiratory tract (rhinitis, stridor, and

hoarseness), lower respiratory tract (wheezing, bronchospasm, and cough), gastrointestinal tract (abdominal pain, diarrhea, and vomiting), and cardiovascular system (tachycardia, hypotension, and shock). Urticaria and angioedema are by far the most common manifestations, occurring in 83% to 90% of individuals with anaphylaxis.^[25] ^[54] ^[57] The second most common manifestations are respiratory tract symptoms, followed by dizziness or syncope and gastrointestinal symptoms. Cardiovascular collapse with shock can occur rapidly, without any other antecedent symptoms.

Most anaphylactic reactions occur soon (within 5 minutes to 2 hours) after exposure to an inciting agent, but other patterns are possible. In bimodal anaphylaxis, symptoms begin within minutes of exposure; after transient clinical improvement the allergic reaction returns 1 to 8 hours later.^[51] Protracted anaphylaxis can begin suddenly or gradually, but the clinical manifestations are prolonged, sometimes requiring hours or even days of intense resuscitation. Generally the more rapid the onset, the more severe the episode.^[30] Fatalities usually result from airway obstruction, cardiovascular collapse, or both.

Treatment

Anaphylaxis is a medical emergency requiring prompt recognition and treatment. Treatment depends on the severity of the reaction and the organ system (or systems) involved. For mild anaphylactic or anaphylactoid reactions limited to the skin, antihistamines alone are effective. Individuals with cutaneous reactions should be monitored closely for signs of respiratory or cardiovascular compromise, and manifestations beyond the skin require more aggressive measures, such as administration of fluids, bronchodilators, and epinephrine.

Short-term management of anaphylaxis is detailed in [Box 46-3](#).^[50] Because most fatalities occur as a result of delayed treatment,^[16] the importance of prompt administration of epinephrine cannot be overemphasized. Intravenous epinephrine may be administered if the reaction is life threatening and if the patient does not respond to subcutaneous epinephrine. However, intravenous epinephrine should be used with caution in persons older than 35 years. Aerosolized aqueous epinephrine can prevent upper airway edema, but it is inadequate to abort systemic anaphylaxis.^[11] Use of over-the-counter epinephrine inhalation aerosol bronchodilators (e.g., Primatene Mist) generally is not recommended because of the lack of adrenergic specificity (i.e., it is non- β_2 selective) and the extremely short half-life. Even these agents should be used with caution, especially in individuals with a history of coronary artery disease and arrhythmias.

Repletion of intravascular volume is a mainstay of treatment for hypotension. A large volume of fluid may be necessary and should be given rapidly in either colloid or crystalloid form. Vasopressor drugs may be needed to treat hypotension if the response to subcutaneous epinephrine and fluids is inadequate. Dopamine is often the initial drug of choice. Norepinephrine, a potent vasopressor, can be used to treat severe hypotension that is unresponsive to epinephrine, dopamine, and fluids. Glucagon may

be necessary to treat refractory hypotension (e.g., patients on β -blocker medications)

1085

that is resistant to standard therapeutic regimens.^[62] Glucagon is the drug of choice for patients on β -blocker medications.^[18] Medical antishock trousers have been used successfully to treat refractory hypotension associated with anaphylaxis.^[36]

Box 46-3. TREATMENT OF ANAPHYLAXIS

GENERAL MEASURES

Place the individual in Trendelenburg's position.

Establish and maintain the airway. (If necessary, perform cricothyroidotomy.)

Administer oxygen as needed.

Place a venous tourniquet above the reaction site (e.g., insect sting) to decrease systemic absorption of the antigen.

Obtain intravenous access and infuse a volume expander (colloid-containing solution or normal saline) to achieve a systolic blood pressure of 90 mm Hg in an adult. Blood pressure may be briefly augmented by the application of military antishock trousers, which increases systemic vascular resistance.

EPINEPHRINE USE AND TREATMENT OF HYPOTENSION

Administer aqueous epinephrine, 1:1000, 0.3 to 0.5 ml (0.3 to 0.5 mg) subcutaneously or intramuscularly in the deltoid region. The epinephrine dose for children is 0.01 ml/kg. Repeat once or twice as necessary at 15 to 20 minute intervals to control the signs and symptoms.

If the reaction is life threatening and if the patient does not respond to subcutaneous epinephrine, administer epinephrine intravenously. Mix 0.1 ml (0.1 mg) of 1:1000 aqueous epinephrine in 10 ml of normal saline (final dilution, 1:100,000) and infuse over 10 minutes. If hypotension persists, a continuous epinephrine infusion may be started by adding 1 ml (1 mg) of 1:1000 epinephrine to 250 ml of normal saline, creating a concentration of 4 μ g/ml. Infuse this solution at a rate of 1 μ g/minute (15 minidrops/minute). The rate of infusion can be increased to 4 to 5 μ g/minute if the clinical response is inadequate. In children and infants the starting dose is 0.1 μ g/kg/minute, up to maximum of 1.5 μ g/kg/minute. Intravenous epinephrine should be used with caution in persons older than 35.

epinephrine infusion may be started by adding 4 ml (4 mg) of 1% (10 mg/ml) epinephrine to 250 ml of normal saline, creating a concentration of 4 µg/ml. Infuse this solution at a rate of 1 µg/minute (15 minidrops/minute). The rate of infusion can be increased to 4 to 5 µg/minute if the clinical response is inadequate. In children and infants the starting dose is 0.1 µg/kg/minute, up to maximum of 1.5 µg/kg/minute. Intravenous epinephrine should be used with caution in persons older than 35.

If epinephrine and fluids are ineffective, intravenous dopamine infusion should be initiated. Mix 400 mg of dopamine in 500 ml of D₅ W (800 µg/ml) and infuse at a rate of 2 to 20 µg/kg/minute. The rate should be titrated using the blood pressure. Norepinephrine, a potent vasopressor, can be used to treat severe hypotension that is unresponsive to the administration of epinephrine, fluids, and dopamine. Mix 4 mg of norepinephrine in 1000 ml of D₅ W (4 µg/ml) and infuse at a rate of 0.5 to 1 µg/kg/minute.

In a refractory case in which the individual is not responsive to epinephrine (especially the individual on a β-blocker medication), administer a glucagon bolus at a dose of 1 to 5 mg intravenously over 2 minutes. If necessary, a continuous infusion, 1 mg in 1000 ml of D₅ W (1 µg/ml), should be started at a rate of 5 to 15 µg/minute.

TREATMENT OF BRONCHOSPASM

Administer a β₂-agonist (albuterol, metaproterenol, pirbuterol, or terbutaline) via nebulization as required for bronchospasm that is not relieved by epinephrine.

Continuous nebulization may be required if bronchospasm persists.

ANTIHISTAMINES AND CORTICOSTEROIDS

Administer diphenhydramine 25 to 50 mg (1 mg/kg in children) intravenously over 3 minutes intramuscularly, or orally when the reaction is not severe. The addition of cimetidine 300 mg intravenously over 5 minutes may reverse refractory anaphylactic shock caused by the blockade of both H₁ and H₂ receptors. Transient hypotension, bradycardia, and arrhythmias have been reported after rapid intravenous administration of cimetidine.

Most authorities advocate the use of glucocorticoids to decrease the likelihood of a late-phase reaction. The standard therapy is either hydrocortisone 200 to 300 mg intravenously or prednisone 30 to 60 mg orally in milder cases.

For prominent wheezing, intermittent or continuous use (depending on severity) of an aerosolized β₂-agonist is recommended. Although antihistamines are only adjunctive therapy to epinephrine, they can relieve symptoms dramatically. Combining an H₁ antihistamine and an H₂ antihistamine may be more effective than administering either

alone.^[42] Most authorities recommend the use of glucocorticoids to decrease the likelihood of a late-phase reaction.

Because of possible recurrent symptoms, all individuals who suffer an anaphylactic or anaphylactoid reaction should be observed after the initial symptoms have subsided. For a mild to severe episode a period of observation between 2 and 24 hours is reasonable. Any individual with severe respiratory or cardiac compromise should be hospitalized. Persons at risk for anaphylaxis should carry a device allowing self-injection of epinephrine ([Table 46-4](#)) at all times and should wear a medical information bracelet or carry a medical information card. Finally, it is important to identify the precipitating agent for anaphylaxis so that preventive measures can be taken to reduce the risk of future reactions.

TABLE 46-4 -- Selected Self-Injecting Epinephrine-Containing Kits

BRAND NAME	COMPANY	DOSE (mg)	DOSES PER UNIT
Ana-Kit	Bayer-Miles	0.5	2
Ana-Guard	Bayer-Miles	0.5	2
Anahelp	Stallergenes	0.25	4
EpiPen	Dey Laboratories	0.3	1
EpiPen Jr.	Dey Laboratories	0.15	1
Fastjekt	Allergopharma	0.3	1

Chapter 47 - Plant-Induced Dermatitis

William L. Epstein
John H. Epstein

Advertent or inadvertent exposure to plants is a common cause of skin eruptions. Because the reactions are often acute, the victims frequently seek emergency care. This subject has been reviewed in detail.^[5] ^[28] This chapter considers plant dermatitis from the acute care perspective. Although most acute, itchy eruptions share clinical features, not every rash is poison ivy dermatitis. Plant dermatitis is discussed as irritation, allergy, phytophotodermatitis, and granulomas. Similarities, distinctions, and different plans for management are emphasized. Proper recognition and adequate early treatment often lead to a cure with no further recurrence, whereas failure to diagnose and less optimal management can result in chronic, disabling dermatosis.

IRRITATION

Primary irritation is the most frequent cutaneous response to vegetation. Most of these injuries are sufficiently mild to be ignored or self-treated. Many wild plants, such as brambles and berries, have sharp thorns that can inflict significant skin trauma. The typical appearance is of linear scratches or excoriations. The area can be swollen and red with a weeping or bloody crust. Fever and adenopathy are uncommon. Pruritus, when present, is mild.

Treatment consists mostly of cool soaks or compresses with soft gauze or soft linen with aluminum acetate solution diluted 1:20 for use. The lesions usually heal in a few days. Secondary infection relates to the environment and personal hygiene. Uncommonly, these wounds allow entry of microorganisms that cause systemic diseases, such as sporotrichosis. In addition to inflicting gross mechanical damage, many plants, weeds, and fruits have fine hairs (trichomes) and barbed hairs (glochids), which cause more subtle and annoying forms of irritation. The trichome-glochid response is acute development of wheals with itching and occasionally intense pain. Large blisters may form. Although this irritation appears to have mechanical origin, the reaction is produced by natural substances in the trichomes or glochids. Low-molecular-weight acids, glycosides, proteolytic enzymes, and crystals are among the major plant chemicals that cause primary skin irritation. These lesions can occur on skin or mucous membranes and are classified as nonimmunogenic urticaria. An example is itch powder, from dried cowhage (*Mucuna pruriens*), which contains a proteolytic enzyme and causes intense pruritus.^{[117] [118]} Other irritant enzymes include bromelin from pineapples, papain from papaya, and ficin from figs.

Many species of flowering plants, shrubs, and trees induce primary skin irritation, but most irritant species belong to the spurge family (Euphorbiaceae). Spurge is a huge and diverse family of over 7000 species, for practical purposes classified into five subfamilies and about 50 tribes,^[132] only three of which produce significant irritation in humans (Acalyphoteae, Crotonoideae, and Euphorbioideae) ([Figure 47-1](#)). Euphorbiaceae flourish primarily in tropical and subtropical climates. In rainforests, they may grow as tall trees, but usually they are found in arid areas as small trees and shrubs.^[134] In North America the varieties are limited and populate mainly southern Florida and the southwestern United States; varieties grow in Europe, where they are commonly called wolfsmilk. Honey made from these plants causes burning mouth irritation accentuated by drinking water. [Table 47-1](#) lists the more commonly recognized irritant plants of the spurge family. One of the most poisonous is the manchineel tree (*Hippomane mancinella*), or beach apple, which inhabits the Caribbean and at one time was the scourge of south Florida.^[81] Every part of the plant, including the fruit, contains a milky latex that is extremely irritating and causes burning, swelling, blisters, and even blindness when rubbed into the eyes. The most irritating ingredients are diterpene

esters similar to phorbol esters. [1]

Other well-known members of the spurge family are of the genus *Croton*, which contains up to 750 species distributed throughout the tropics. Croton oil is an extract of the seed of the croton plant (*Croton tiglium*). Croton oil was exported from the Caribbean and South America to the United States in the last century in large quantities to be used as a purgative and to treat warts, skin growths, and superficial fungal infections. When croton oil was purified, it was found to be a mixture of diterpenes called phorbol esters, which are well-known cocarcinogens^[13] and have been used extensively in recent years in cell biology and cell differentiation experiments. Phorbol esters appear to be the irritant chemicals in most members of the genus *Croton*. Most irritating euphorbs secrete a white, milky, or viscous latex composed of a mixture of polycyclic diterpenes or triterpenes and terpenoids, which can polymerize into rubber. These complex irritant terpenes may be cocarcinogens.^[58] Many are related to the phorbol esters. Poinsettia, a member of the genus *Euphorbia*, is considered by some to have relatively low irritant

1089

potential, whereas others have reported up to 10% irritant responses.^{[111] [132]}

Stinging hairs are found in many species of plants and produce injury by different mechanisms. The clinical presentation is usually an explosive onset of

TABLE 47-1 -- Some Common Irritant Plants in the Spurge Family (Euphorbiaceae)

SUBFAMILY	TRIBE/GENUS	COMMON NAMES	MECHANISMS OR IRRITANT CHEMICAL
Crotonoideae	<i>Croton</i>	Croton bush	Phorbol esters (croton oil)
	<i>Jatropha</i>	Coral plant	Thioglycoside (mustard oil)
	<i>Cnidoscolus</i>	Spurge nettle, tread softly	Stinging hairs
Euphorbioideae	<i>Hippomane</i>	Manchineel, beach apple	Diterpenes and alkaloid
	<i>Sapium</i>	Aurou-wood	Terpenes
	<i>Hura</i>	Sandbox tree	Ricinlike toxalbumin and triterpenes

	<i>Euphorbia</i>	Beach spurge, red spurge, milkweed, wolfs milk, asthma plant, candelabra cactus, caper spurge, snow-on-the-mountain, crown-of-thorns	Diterpenes and triterpenes; terpenoids
	<i>Poinsettia</i>	Poinsettia	Phorbol esters
	<i>Pedilanthus</i>	Slipper bush	Terpenes?
Acalyphoideae	<i>Tragia</i>	Nose-burn	Stinging hairs

painful urticaria, limited or extensive, that in some geographic regions can result in tissue necrosis. In the United States the genus *Tragia* of the spurge family is a prominent offender; more than 100 species are found, mainly in southern states. The stinging mechanism is

1090

complex and involves insertion into the skin of a long crystal that releases caustic chemicals. The exact nature of the injected material remains unclear,^[128] but it is considered to be a mixture of amines, possibly including histamine. Other plants with stinging hairs in the spurge family are found throughout the tropics in the genera *Cnidoscolus* and *Jatropha*. Their mechanism of stinging is similar to that of the stinging nettles, which are seen commonly in Europe and throughout North America. Plants of the genus *Urtica* produce injury when the tip of the nettle breaks off in the skin and syringelike action forces chemicals into the dermis. There is evidence that histamine and similar amines are responsible for this contact urticaria.^[89] ^[127]

Another family of irritant plants, Brassicaceae, contains the mustard seed plant radishes ([Figure 47-2](#)). Contact

Figure 47-2 White mustard plant, an irritant of the Brassicaceae family. (Courtesy Yves Sell, Institute of Botany, Louis Pasteur University, Strasbourg, France.)

with these odoriferous plants tends to cause blisters rather than hives. A third family of irritant plants is the buttercups (Ranunculaceae) ([Figure 47-3](#)). [Table 47-2](#) lists common plants in this family. The irritant chemical appears to be a glycoside, ranunculin, protoanemonin, or a dimer, anemonin.^[5] Many other families contain a few species of irritant plants (such as cereal grasses and dogwood leaves), which produce mechanical irritation.

The pathogenesis of primary irritation from plants has not been fully elucidated. In the case of nonimmunologic urticaria, release of histamine from mast cells with vasodilation and leakage of fluid appears to be an early direct chemical change leading to hives.^[21]^[115] The molecular events in mast cell degranulation are thought to be similar to those described for immunogenic urticaria, with certain discrete differences. Thus there is no evidence for a selective membrane receptor, such as the high-affinity immunoglobulin E (IgE) receptor that is now well characterized and required for immunologic degranulation of mast cells.^[115]^[122] Instead, current information suggests that a receptor-independent mode of action occurs for all nonimmunologic histamine liberators, acting directly on a pertussis toxin-sensitive G protein to initiate a signal through phospholipase C activation, which degranulates mast

cells of their histamine content.^[82] Furthermore, there does not seem to be a requirement for methylation of the membrane phospholipids. Rather, a high intracellular calcium accumulation must occur, and the reaction is rapidly terminated without delayed mediator release.^[107] Arachidonic acid metabolites are not formed in any amount.^[6]

It is currently believed that both irritation and contact sensitization are mediated by epidermal derived cytokines. Thus tumor necrosis factor- α (TNF- α), interferon- γ (IFN- γ), macrophage inflammatory protein-2 (MIP-2), and granulocyte-macrophage colony-stimulating factor (GM-CSF) are produced and secreted into the tissue in response to both allergens and irritants. However, a number of other proteins are released only by allergenic stimulation. This is a continuing area of investigation.^[105] ^[136]

Treatment

Treatment of primary irritant dermatoses is often unsatisfactory. The victim must be removed from exposure to irritant chemicals and treated conservatively with rest, medicated soaks, and compresses, such as aluminum acetate solution (1:20), dilute potassium permanganate solution (1:16,000 in water), acetic acid solution (1:100), or Dalibour solution (copper and zinc sulfate and camphor, supplied commercially as Dalidane). Antihistamines usually have minimal effect. The dermatitis heals in less than 5 days if no complications develop and if tissue damage is minimal. Corticosteroids are of no use in controlling primary irritation.

ALLERGY

As with conventional contact dermatitis, irritant reactions far outnumber allergic responses elicited by vegetation. However, distinguishing irritation from allergy is important clinically because treatment varies considerably according to diagnosis. Allergic responses are more likely to evoke a reaction severe enough that the victim seeks help. Plants cause all varieties of allergic reactions. Immediate hypersensitivity reactions with angioedema, urticaria, and anaphylaxis from ingestion of foods, especially nuts, are well recognized.^{[10] [77] [109]} (See [Chapter 36](#) for management of anaphylaxis.)

Contact urticaria, or hives from exposure to plants, is fairly common and increasingly recognized as a major cause of immunogenic contact urticaria.^[63] The victim has redness, itching, and swelling, which can develop as discrete wheals or widespread edema 1 to 2 hours after exposure. Usually, the eruption is linear or grouped at sites of contact, but extreme swelling and edema of an extremity can develop, depending on level of antigen exposure and the victim's degree of sensitivity, not unlike the range of responses in bee venom hypersensitivity. Thus an oral reaction may be minimal with simple burning and tingling, especially in the mouth, or massive, with edema of the lips, oral mucous membranes, and pharynx noted after eating fruit and vegetables. Because of chronic low-grade exposure, the eruption is a prominent occupational problem of field workers, packers, grocery workers, cooks, and bakers who handle raw fruits and vegetables.^[69] Long lists of offending agents have been published.^{[43] [63]} [Box 47-1](#) is a partial list of plants and plant products that cause immunogenic contact dermatitis.

The pathogenesis of immunogenic contact urticaria is a variation of immediate type I hypersensitivity. The central cytologic reactor in skin is the mast cell, which has high-affinity IgE receptors in its membrane. An IgE molecule binds to the receptor by its Fc portion, exposing the Fab segments as recognition sites. When a divalent protein antigen appropriately bridges two IgE molecules, a series of biochemical events transpires that leads to mast cell degranulation. The plasma membrane is perturbed. Several lipids are phosphorylated and G proteins are activated, which in turn activate phospholipase C to hydrolyze phosphatidylinositol 4,5-bisphosphate (PIP₂) and yield two messengers: diacylglycerol (DG) and inositol triphosphate (InsP₃).^[12] InsP₃ binds to its receptor on the endoplasmic reticulum, forming a calcium channel to release free calcium ions (Ca²⁺) into the cytosol.^{[3] [8] [51] [88]} Simultaneously, DG activates protein kinase C in the plasma membrane, opening calcium channels and allowing entrance of extracellular Ca²⁺, which further loads the cytosol with free Ca²⁺, an important "messenger" in the stimulus secretion process.^[67] G proteins interact with and release the nucleotide complexed to protein a-chains,^[124] some of which probably inhibit or

stimulate

1092

cyclic adenosine phosphate and its actions as a second messenger.^[12]

The result of the extensive alteration in intracellular milieu is activation of a serine proteinase and exocytosis of mast cell granule contents.^{[21] [115]} These come in three forms: preformed and rapidly released; preformed, bound to the granule matrix of heparin, and slowly released; and newly formed mediators. In addition, mast cells produce a variety of cytokines, including interleukins (ILs) IL-1, IL-3, IL-4, IL-5, and IL-6; granulocyte-macrophage colony-forming units; and TNF- α .^[123] These cytokines interact with cells and structures, such as endothelium in the skin, to amplify the various inflammatory responses.^{[21] [115] [123]} In acute urticaria, the rapidly released preformed mediators account for most of the signs and symptoms. These mediators include histamine, some chemotactic factors, and arylsulfatase. If the lesions persist or extend, other mediators, such as newly formed leukotrienes, heparin (or heparin fragments), cytokines, and a number of proteases, may be involved in the continuing tissue damage.

The sequence of inflammatory events leading to acute urticaria is most likely to occur in persons with an atopic background, especially those with pollen allergies.^[63] This is the same group of people, mainly women and especially health care workers, who have been found in recent years to be exquisitely sensitive to latex rubber gloves^{[14] [65] [119] [129]} and sensitive to proteins in the natural latex from rubber trees in Asia.^[83]

In the last decade, this has become an escalating problem. It now appears that there

are more than 200 polypeptides produced in natural latex rubber. Many of these are contact sensitizers, so that a single antigen is not likely to be identified for a given patient. The major problem is IgE-mediated immediate type hypersensitivity and the potential for anaphylaxis. In addition to these polypeptides appearing in natural rubber latex, many are also found in a large number of plants, particularly those consumed as food. These allergens are constantly being purified and characterized. One suggestion is that these cross-reacting allergens are "defense proteins" with a role to protect the plant from attack by pathogens.^[64] Whether this is true requires further investigation, but it is also possible that by plant engineering, these allergens may be genetically restricted from the foods we consume.

In addition to fruit and nuts, mustard in pizza has been implicated in anaphylaxis.^[93] In less severe cases, vesicular, eczematous rashes have been noted within hours of eating mustard or rapeseed, which is used widely in production of vegetable oils and margarine.^[75] Erythema multiforme-like eruptions are well recognized after contact with bracelets and ornamental necklaces made of exotic woods, such as *Dalbergia nigra*.^[37] Erythema multiforme has also been seen after exposure to more common plants, such as poison ivy, primula, and mugwort.^[37] It is theorized that multiforme lesions result from vasculitis caused by deposition of immune complexes in or around the blood vessels.

Diagnosis of immunogenic contact urticaria can be confirmed by simple tests. As a use test, application of the suspected plant product to the antecubital fossa twice a day for several days may reproduce the wheal response. Open and closed patch tests, with examination of test sites in 2 to 6 hours, can be useful, as can more conventional prick, scratch, or scratch-chamber tests, in which the results are read in 15 to 20 minutes.^[63] It is most important to determine whether urtication is immunologic or nonimmunologic in nature.^[43] ^[63] For complete evaluation an allergist obtains radioallergosorbent tests to quantify specific IgE in the patient's serum. More refined serologic tests include crossed radioimmuno-electrophoresis (CRIE) and CRIE inhibition.^[15]

Patients with contact urticaria visit the emergency department when an eruption is extensive or extreme, or if it is associated with stridor, wheezing, and collapse. Since mast cell degranulation is the central problem, and because epinephrine stimulates cyclic adenosine monophosphate formation that opposes degranulation, it is logical to use this drug. Other supportive treatments for anaphylactic shock may be required, such as albuterol, aminophylline, oxygen, or intravenous (IV) hydrocortisone. In less severe cases, antihistamines are valuable. Intramuscular (IM) or IV diphenhydramine (Benadryl) in an adult dose of 50 to 100 mg usually stops progression of wheal formation and can be followed by oral hydroxyzine (25 to 50 mg 3 times a day) or ciproheptadine (4 to 8 mg 4 times a day) for 2 to 5 days. Pure H₁-blockers, such as fexofenadine (60 mg 2 to 3 times a day), are also effective and do not depress the central nervous system, although the prescriber has to be aware of any unique adverse reactions. It is important to make certain the patient has not inadvertently hidden parts of the plant on the body, in clothing, or in a towel, blanket, or knapsack. Recrudescence of the urticarial response usually can be traced to continuing unknown contact with the offending agent.

Delayed-Contact Dermatitis

Delayed hypersensitivity or type IV allergy of the contact hypersensitivity variety occurs more frequently as a result of contact with plants than does type I contact urticaria. Sensitivity to poison ivy or poison oak is undoubtedly the single most common cause of allergic skin reactions in the United States and, along with contact allergy to sesquiterpene lactones ("compositae"), probably worldwide ([Figure 47-4](#)). When a distraught young person arrives in the emergency department with an acute, edematous, and erythematous skin eruption and a history of outdoor activity, this is probably a serious bout of poison ivy or poison

1093

Figure 47-4 Poison oak. (Courtesy Paul Auerbach.)

oak dermatitis. Approximately 50% of the U.S. adult population is clinically sensitive to poison ivy, poison oak, and poison sumac. If a sensitive individual brushes against the plant or comes in contact with the heavy, nonvolatile oil in the resin canals that contains the active allergenic principle urushiol, he or she will acquire poison ivy or poison oak dermatitis. In its natural state the oil is colorless or slightly yellow. Because the oil is virtually invisible, many people fail to understand how they acquired the rash. It is not a vapor because at 315.6° C (600° F) in a fire or oven, urushiol splatters like butter. In a camp or forest fire, it attaches to smoke particles and can be carried downwind. The oil also readily coats the fur of animals, which explains why persons often get the dermatitis from their outdoor pets. On exposure to air, however, the oil oxidizes, polymerizes, and turns black. This is a way to recognize the weeds, especially in autumn when the leaves fall off.

The amount of urushiol present in poison ivy and poison oak is roughly equal year-round, even when the plants are only sticks without leaves in the winter. As the leaves turn red and start to dry up in the fall, important nutrients, including urushiol, return to the stem and roots through the subepidermal resin canals.^[42] Thus the dead leaves that fall to the ground are virtually devoid of urushiol. The amount of purified urushiol required to elicit a reaction is 2 to 2.5 mg.^[35] Some people (about 35%) are considered subclinically sensitive because they have negative skin test reactions to 2.5 mg urushiol but react to higher concentrations, such as 5, 10, and 50 mg.^[25]^[35] Clinically this group is interesting because they invariably did not have poison ivy dermatitis as teenagers and often plucked the weeds with apparent impunity. However, usually in midlife after a bout of weed pulling, a rash spreads explosively. For unknown reasons, they have crossed the line into clinical sensitivity. If patch tested with dilutions of

urushiol, they are often exquisitely sensitive and do not appear to lose their reactivity. The flare-up may last for several weeks, probably because of prior contamination of the home and workplace with urushiol oil. Treatment must be aggressive and more prolonged than usual.

A smaller group (10% to 15%) does not react to the higher concentrations and cannot be sensitized by 1000 mg. This group was first detected and studied in passive transfer experiments in the 1950s.^[33] These individuals are considered to be naturally tolerant, but it remains unclear whether they achieved that state by early antigenic exposure or by genetic luck. They have no inherent resistance to contact sensitization with other chemicals^[34] and otherwise appear healthy. They may hold a clue to the molecular basis for immunologic tolerance.

The weeds are surprisingly fastidious. They do not grow in Alaska or Hawaii and do not survive well above 1220 m (4000 feet), in deserts, or in rainforests. They grow best along cool streams and lakes and luxuriate if it is also sunny and hot. In the California hills they grow like a forest, but in cooler, dry climates they remain isolated in small patches. Nevertheless, they are found in every state of the continental United States. The plants have different configurations in different regions, but generally, poison ivy grows east of the Rockies, poison oak grows west of the Rockies, and poison sumac grows best in the southeastern United States. Since avoidance is the best prevention, it is important to learn what the plant looks like in a given area ([Figure 47-5](#)). Once contaminated with the oil, an average person has 1 to 4 hours to wash it off to prevent dermatitis.

From a practical standpoint, only 10% to 15% of Americans (up to 40 million persons) can be categorized as exquisitely sensitive. Generally, these persons seek and need emergency medical care. They typically have had prior unpleasant experiences. Within 2 to 6 hours after exposure, swelling is accompanied by an erythematous, intensely pruritic, edematous, vesicular, and ultimately bullous eruption that can be associated with fever, malaise, and prostration. This true dermatologic emergency should be treated immediately and vigorously.

Extreme susceptibility tends to be familial; if one parent is supersensitive, children are likely to be as well. If both parents are sensitive, the chance of sensitive offspring is about 80%.^[131] The level of individual sensitivity is not determined by the severity of the initial bout of dermatitis. Although almost half of patients admit to a memorable bout of dermatitis as a teenager, no more than 25% to 35% of victims at age 30 to 40 were stricken within the previous year.^[25] If these subjects are patch tested with weak dilutions of urushiol, less than half react as might be expected from their histories. An individual's level of reactivity does not change appreciably if he or she is tested monthly over a year^[35] ; testing at less frequent intervals in very sensitive subjects

Figure 47-5 A, Poison ivy (*Toxicodendron radicans*). B, Poison oak (*Toxicodendron diversiloba*). C, Poison sumac (*Toxicodendron vernix*).

over 3 to 4 years has shown little or no change in the level of reactivity. Repeated mild to moderate bouts of dermatitis maintain the sensitive state, whereas a single severe bout may produce a prolonged period of anergy or refractoriness,^{[24] [25]} not unlike the clinical condition of "hardening" or unresponsiveness, well described in the industrial setting.^[114]

The urushiols in poison ivy, poison oak, and poison sumac differ only slightly in structure and biologically cross-react, so that a person sensitive to poison ivy may also react to poison oak and poison sumac ([Figure 47-6](#)). Plants, shrubs, and trees with cross-reacting catechols are found throughout the world, arising either indigenously or by transplantation.^{[27] [102]} The most common cross-reacting plants are mango, cashew nut shell, India marking nut, and Japanese lacquer. Increasing numbers of cross-reacting plants are reported from South America.^[53] A chemical curiosity is the cross-reaction with resorcinols from cashew nut shell oil.^[57] Similar cross-reacting resorcinol-containing plants have been observed in Australia^[76] and Hawaii. ^[61] Recently, it has been confirmed that philodendron plants contain a contact sensitizing resorcinol, but it only reacts in poison oak- or poison ivy-sensitized patients who have traveled to the mainland.^[62] Other studies have extended our information about the urushiol-like molecules that exists in many shrubs and small trees in South America, specifically Litre and Lithrea in Peru and Uruguay, respectively.^{[2] [70]}

IMMUNOLOGY OF POISON IVY/POISON OAK DERMATITIS

The immunologic mechanism for allergic contact dermatitis is generally conceded to be type IV cell-mediated delayed hypersensitivity.^[27A] However, in skin, keratinocytes are also part of the immune surveillance system. They respond quickly to every chemical insult, either irritant or allergenic, in antigen-dependent fashion, to produce a variety of cytokines. These function mainly to amplify future inflammatory responses.^[2B] ^[87A] Early on, they secrete TNF- α and intercellular adhesion molecule.^[1] Somewhat later, they release IL-1, IL-6, IL-8, and IL-10, and still later, macrophage chemotactic factor and other cytokines.^[2A] ^[43A] ^[43B] ^[87A] ^[99A] These may in turn release acute-phase reactants from mast cells and endothelial cells, as seen in irritant responses.^[2B] ^[87A] Current research is attempting to identify which keratinocyte cytokines specify the allergic reaction, as distinct from simply injury. Nevertheless, it is known that the catechol molecules of poison oak and poison ivy enter the skin and bind through nucleophilic attack at benzene ring positions 4, 5, or 6 to surface proteins on antigen-presenting cells (APCs), which are primarily Langerhans'

1095

Figure 47-6 General structure and composition of poison ivy urushiol.

cells in the epidermis. The molecules are then internalized and processed in the APCs, which leave the epidermis and travel to regional lymph nodes, where they present their processed antigen on the cell surface in context with a major histocompatibility complex (MHC) class I molecule to the T cell receptor complex on a CD8 T cell. To complete the sensitization signal, another surface protein (the B7 antigen) forms a co-stimulatory signal by binding to the CD28 ligand on the T cell. This then activates the T cell, which divides repeatedly to form a clone of urushiol-specific CD8 cells. These subsequently expand into clones of circulating activated T-effector and T-memory lymphocytes.^[54A] ^[70]

Upon a new challenge by urushiol, the CD8 lymphocytes elicit a cell-mediated cytotoxic immune response characterized by erythema, edema, and vesiculation resulting from

destruction of epidermal cells and activation of the dermal vasculature. Under this scenario, the clinical reaction is driven by the CD8 cytotoxic, effector T cells, and this can be modified by CD4 T cells that may be either Th-1 or, more likely, Th-2 in nature.^[54A] ^[70] In an individual patient, this determines the severity of dermatitis after exposure to the poisonous weeds. This logical formulation, however, does not completely explain acute poison oak or poison ivy dermatitis. An acute eruption tends to begin within hours of exposure and is primarily edematous. Some have emphasized the presence of basophils in acute poison oak and poison ivy lesions and have proposed a role for basophil mediators in the pathogenesis of an early-onset acute reaction.^[22] Certainly, the clinical presentation in these cases favors a late-phase

Figure 47-7 Generalized poison ivy dermatitis.

reaction^[65] and a mechanism possibly involving mast cell degranulation,^[58A] as well as other cytokine mediators. Also possible is a CD4 T cell mediated induction of IgE reactivity.^[55]

Treatment

Systemic corticosteroids are widely accepted as the first line of treatment, especially given early and in large, therapeutic doses. If the reaction is of less than 2 hours' duration, IV hydrocortisone or methylprednisolone can be curative. After a patient has suffered 4 to 6 hours with massive edema, erythema, and pruritus, IV therapy is highly effective, but it must be followed by more prolonged oral or IM administration of corticosteroids ([Figure 47-7](#)). Most patients in this category seek help after 8 to 16 hours of discomfort, at which point IV therapy is less effective. IM methylprednisolone sodium succinate (Solu-Medrol), 40 mg, combined with betamethasone sodium phosphate (Celestone), 8 to 12 mg, should give relief for 7 to 14 days. Adrenocorticotrophic hormone (ACTH) gel, 80 units IM with a repeat in 8 to 12 hours, often is curative. Prednisone, 100 to 120 mg divided in four equal doses daily for 2 days, may achieve the same salubrious effect. At the same time, patients are instructed to rest at home for 3 to 4 days. If a flare-up starts, another dose of ACTH gel or a repeat regimen of prednisone is prescribed. Subsequent exacerbations are usually caused by reexposure to urushiol that has contaminated the patient's local environment, so that the patient must be warned to thoroughly wash all clothing and other articles that might have been exposed during the initial contact.

If the dermatitis has been present for more than 24 hours, the aggressive regimen is less successful ([Figure 47-8](#)). Under these circumstances, many physicians prefer a more conservative approach. Oral prednisone, 80 to 100 mg/day for 3 to 4 days with a 10- to 14-day every-other-day taper, helps many patients, but the danger lies in a sudden flare-up at the end of therapy, which becomes poorly responsive to steroids. Whenever considering systemic corticosteroids for acute allergic contact dermatitis, the physician must be certain that the patient is otherwise healthy and without active infections, vascular accidents, endocrinopathies, or a familial history of glaucoma.

When the onset of dermatitis is delayed for several days and the eruption is mild or moderate, systemic therapy offers little benefit. In this situation of a mildly to moderately sensitive patient with delayed onset, there is very little the physician can do to alleviate the signs or symptoms. Most of these patients go to the drug store and look for over-the-counter (OTC) preparations. Usually they are disappointed. It takes 7 to 10 days to heal spontaneously; their most helpful option is an inexpensive agent, such as calamine lotion, that is comforting and helps form a crust. Plain water is helpful, as are soaks with bicarbonate of soda or vinegar in water. Regardless of the option chosen, time is required for healing. Antihistamines, aspirin, or nonsteroidal antiinflammatory

Figure 47-8 Acute poison oak dermatitis. **A**, Facial edema. **B**, Blisters. **C**, Penile edema. (Courtesy Axel Hoke.)

drugs are without effect. Results of systemic corticosteroids, even in large doses, are disappointing. Topical application of soothing aluminum acetate (1:20) soaks, calamine lotion, or tepid baths, with 1 cup Aveeno oatmeal or 2 cups linnet starch per tub, relieves pruritus and allows healing to occur uneventfully. Although field workers have mentioned that aloe vera latex empirically improves wound healing, a major study in contact dermatitis showed that it was ineffective.^[137] Topical lotions with anesthetics or antihistamines offer no additional benefit and may induce contact sensitization to the chemical additives. Allergic contact dermatitis is a self-healing disease that resolves over 10 to 14 days if iatrogenic influences are avoided. Secondary superficial infections may occur in children or during hospitalization. Cleanliness usually prevents this complication.

In the mildly to moderately sensitive person when the eruption is beginning (red and itchy but not yet blistered), potent, fluorinated steroids in a gel or optimized vehicle can prevent spread of the rash and speed healing. Many such preparations are available, such as fluocinonide 0.05% gel (Lidex) or clobetasol propionate gel 0.05% (Temovate). Since topical steroids are readily absorbed and can cause adrenal suppression, they

should be restricted to limited amounts (less than 15 g) for a brief period (2 to 3 days). Generally, the opportunity

1097

to use this approach does not occur in an emergency department, but it can be very effective in helping persons repeatedly exposed to poison ivy or poison oak in the course of their work.

As the dermatitis heals and scales after 10 to 14 days, the patient may note a resurgence of pruritus, which, untreated, can lead to a patch of subchronic lichenoid neurodermatitis ([Figure 47-9](#)). Judicious use of almost any steroid cream or ointment, such as triamcinolone acetonide 0.025%, desonide 0.025%, or hydrocortisone 1%, alleviates the symptoms.

The best approaches to prophylaxis come from an intimate understanding of the chemistry of urushiol and the biology of the weeds^[27] and resides mainly in recognition and avoidance. Where this is not possible, protective clothing that is either disposable or washable should be worn. Water rapidly inactivates urushiol, and organic solvents such as alcohol, gasoline, and acetone can extract it from contaminated surfaces. A commercially available solvent is Tecnu, sold OTC, but it is an inexpensive solvent sold at a high price. It should not be used for therapy. The best choice is rubbing (isopropyl) alcohol, which should be applied liberally for decontamination and followed by liberal use of water wash-off to avoid spreading the oil on the skin. Use of soap is a poor excuse for better solvents. The idea of using barrier preparations has become popular again, even though in the past such creams and ointments proved disappointing.^[91] The current favorite, an organoclay called Ivy-Block, was developed to protect forestry workers against these weeds during national firefighting escapades.^[30] This approach was confirmed in a multicenter study.^[71] The lotion can be obtained

Figure 47-9 Resurgence of pruritus leading to patch of subchronic lichenoid neurodermatitis.

readily from a pharmacist or by major marketers. Stokogard outdoor cream, composed of a linoleic ester dimer,^[92] was removed from the market for lack of U.S. Food and Drug Administration (FDA) approval but is still available in industrial supply houses that are not regulated. It also works, but when the cream is first applied, it has a foul smell, like dead fish, resulting from the release of the ester. This disappears in about 20 minutes and acts like butter to delay penetration of urushiol oil. Thus it must be washed off in 4

to 6 hours for protection.

Compositae Dermatitis

Although poison oak and poison ivy are the most common causes of allergic contact dermatitis in the United States, supremacy for this distinction worldwide is challenged by the enormous plant family Compositae. This family contains more than 20,000 species in 1000 genera and consists of many commonly recognized plants, vegetables, wildflowers, weeds, and commercially useful plants ([Figure 47-10](#)).^[113] A number of these plants and species are listed in [Box 47-2](#) . Fortunately, casual exposure is usually insufficient to induce contact sensitization, or the quality of outdoor life would be greatly compromised. Most Compositae dermatitis is reported as an occupational hazard by florists, horticulturists, forestry workers, food handlers, and similar workers. However, it occasionally affects home gardeners and recreational nature enthusiasts. In India the weed *Parthenium hysterophorus* (Congress grass, feverfew), which was incidentally imported from the U.S. with loads of grain, subsequently created an epidemic of Compositae dermatitis.^[69]

The eruption generally spares children and affects predominantly young and middle-aged men. The dermatitis involves the face, neck, arms, and exposed areas in airborne or photocontact patterns, so that both allergic dermatitis and photoallergic contact dermatitis have been suggested.^{[50] [99]} When the eruption presents as acute airborne dermatitis, the victim is often severely affected and likely to seek emergency care. The dermatitis can become subacute or chronic, as has been attributed to ragweed in the Midwest and to a variety of plants in Europe.^[19]

The underlying theme that links the Compositae species is the contact-sensitizing sesquiterpene lactones. More than 3000 of these 15-carbon ringed structures of complex organization with extensive ligand substitutions have been extracted from plant products. They have many important biologic properties, such as their use in antitumor, cytotoxic, anti-inflammatory, antimicrobial, and antiparasitic drugs. Only some of the structures are contact sensitizers. One problem with use of the term "Compositae dermatitis" is that cross-reacting allergens are found in plants and weeds of other plant families. Species of the Magnoliaceae, Lauraceae, and Liliaceae families have been implicated. Liliaceae is a very large family containing diverse, useful, and ornamental plants, such as aloe, asparagus, colchicum, hyacinth, and tulip. Certain species can be both irritating and sensitizing. "Hyacinth itch" is a primary irritant dermatitis probably caused by calcium oxalate crystals in the bulb scales, which may also contain an unknown sensitizer. "Tulip fingers" can be caused by irritation but usually result from contact sensitization to the sesquiterpene lactones tulipan A or tulipan B. In addition, at least three families of liverworts contain cross-reacting sesquiterpene lactones.^[113] Forestry workers sensitized to frullanolide in the liverwort genus *Frullania* show cross-contact reactivity to sesquiterpene lactones in plants of the families Compositae and Asteraceae.^[78]

Patterns of cross-reactivity vary extremely, so a simplistic approach is not acceptable.^[106] A sesquiterpene lactone mix has proved useful in diagnosing apparent airborne or generalized eczema.^[20] In a molecular analysis

Figure 47-11 The six skeletal backbones of sesquiterpene lactones. Note the methylene configuration on the lactone ring, which is responsible for contact sensitization and contributes to other biologic activities.

Figure 47-12 Wood dermatitis.

of the pattern of cross-reactivity in *Costus*-sensitized patients, sesquiterpene lactones with the lesser degree of oxygenated substituents close to the α -methylene- γ -butyrolactone ring gave the highest frequency of cross-reactivity.^[4] Furthermore, sesquiterpene lactones belonging to any one of the six skeletal classes ([Figure 47-11](#)) contain sensitizers that would not be expected to cross-react with those from a different class; this might explain some of the discrepancies in cross-reactivity patterns described in the literature.^[4] The emergency physician familiar with the Compositae family and sesquiterpene lactones may help sort out the correct offending agent in the unusual case of "poison ivy" dermatitis when that diagnosis does not clearly fit. This knowledge is critical in distinguishing between airborne and phototoxic allergic contact dermatitis.^{[50] [99]}

Toxic Woods

Toxic woods contain plant chemicals that produce allergic contact dermatitis ([Figure 47-12](#)). Most are exotic

TABLE 47-3 -- Some Trees that Cause Allergic Contact Dermatitis

COMMON NAME	BOTANICAL NAME
African blackwood	<i>Dalbergia latifolia</i>
Australian blackwood	<i>Acacia melanoxylon</i>
California redwood	<i>Sequoia sempervirens</i>
Cocobolo	<i>Dalbergia retusa</i>
Mansonia	<i>Mansonia altissima</i>
Pao ferro	<i>Machaerium scleroxylum</i>
Pine	<i>Pinus</i> (about 80 species in North America)
Rosewoods	<i>Dalbergia</i> species
Silky oak	<i>Grevillea robusta</i>

Spruce	<i>Picea</i> species
Teak	<i>Tectona grandis</i>
Western red cedar	<i>Thuja plicata</i>

tropical woods with great commercial value.^[47] They are crafted into a wide variety of common objects, such as furniture, musical instruments, boats, cabinets, walking sticks, jewelry, and art forms ([Table 47-3](#)).

The main problem with wood dermatitis occurs in an occupational setting with forestry workers, lumbar workers, carpenters, and craftspeople, but it can affect souvenir hunters or art aficionados. Chemical sensitizers in woods ^[46] are numerous and diverse. Many are quinones and can cause cross-sensitivity with primin found in some species of *Primula* (e.g., *P. obconica*).^[5] One of the best known is Brazilian rosewood (*Dalbergia nigra*), which has been nearly depleted by its wide decorative use. The sensitizing chemical is R-4-methoxydalbergione, a complex quinone. Because of the scarcity of rosewood in recent years, it has been replaced by pao ferro wood from South America. Unfortunately, pao ferro contains an even more potent sensitizer and may be the most hazardous timber in commercial use.^[47] Australian silky oak (*Grevillea robusta*) is grown as a shade tree but is also used for plywood furniture. Grevillol (5-*N*-tridecylresorcinol) is the sensitizer and may cross-react with urushiol.^[76] Pines contain several terpenes that are used commercially as crude balsams or purified colophony (rosin) and turpentine. All can cause allergic contact dermatitis. California redwood (*Sequoia sempervirens*) can induce allergic alveolitis and contact dermatitis.^[74] Along the Pacific coast, western red cedar (*Thuja plicata*) is a well-known cause of "cedar poisoning." It can elicit immediate hypersensitivity with allergic rhinitis, allergic alveolitis,^[121] and allergic contact dermatitis.^[47] The tree contains at least two quinones that act as contact sensitizers. One of these, β -thujaplicin, is reputed to be responsible for the trees' natural resistance to decay and is used in Japan to manufacture cosmetics.^[40]

There are many sensitizing plants whose allergenic chemicals have not yet been identified. Prenyl chain-substituted hydroquinones called phacelioids have been identified in the family Hydrophyllaceae, a woody shrub that grows wild in the Southwest.^[103] These plants produce allergic dermatitis in botanists and field workers. The phacelioids structurally resemble urushiol but do not show cross-reactivity. In humans the most potent sensitizer of the phacelioid group is geranyl hydroquinone.^[103] The creosote bush, *Larrea*, is responsible for an airborne weed dermatitis rash pattern, but whether the bush is a contact sensitizer or photosensitizer is uncertain.^[66] Although more than 100 chemicals have been isolated, the actual sensitizer remains unknown.^[66] English ivy, a common ground cover over much of the United States, can induce allergic contact dermatitis, usually in epidemics. Recently, the principal contact-sensitizing chemical has been identified as falcarinol.^[41] ^[48]

Treatment

Treatment for plant-induced allergic contact dermatitis is the same as described for poison ivy or poison oak dermatitis. The majority of eruptions from other plant sources would be considered mild to moderate and deserve conservative, not aggressive, therapy.

PHYTOPHOTODERMATITIS

Phytophotodermatitis is the term used for adverse reactions to plants. *Phytophotodermatitis* denotes adverse reactions to nonionizing rays from the sun induced by plants.^[59]

In general, two types of phytophotodermatitis occur. The reaction may be phototoxic or photoallergic.^[23] Phototoxic reactions are much more common than photoallergic responses. They occur in anyone if sufficient amounts of offending wavelengths arrive at the skin in the presence of enough of the photosensitizing molecules. The reaction is characterized by erythema with or without edema, followed by hyperpigmentation and desquamation.

Photoallergic reactions are generally uncommon. Like all allergies, they represent an acquired altered reactivity that depends on an antigen-antibody relationship or a cell-mediated delayed hypersensitivity response. Morphologically, they are characterized by an immediate wheal and flare or a delayed papular to eczematous eruption. In general, it requires less energy to induce a photoallergic reaction than a phototoxic response.

Sun-induced plant dermatitis reactions are not rare. They may be induced by internal ingestion or topical applications of plants or plant products. The former is quite rare because of the large amount of plant material that must be eaten to sensitize an individual. However, such events have been reported with the ingestion of relatively large amounts of psoralen contained in vegetables and prolonged exposure to intense UVA radiation (long-wave ultraviolet rays between 320 and 400 nm), as would occur in a suntan salon.^[68] Photoreactions to topical applications are common.

The major photoactive chemicals in plants are furocoumarins (psoralens), which are found in plant families such as Umbelliferae (e.g., celery, giant ragweed, parsnip, fennel, dill, wild carrot); Rutaceae (e.g., lime, citron, lemon, bergamot, gas plant, Persian lime); and Leguminosae (e.g., scurf-pea, bavchi) ([Table 47-4](#)) ([Figure 47-13](#)). Contact with the plant followed by exposure to UVA often leads to a phototoxic response.

The reaction is characterized by erythema with or without edema, followed by dense hyperpigmentation with unusual patterns and distribution. The lesions may be linear, irregular blotches, or confluent. All are confined to areas contacted by the plant and exposed to the sun or artificial irradiators, such as those used in UVA suntan salons ([Figure 47-14](#)).

Bullae may occur if the reaction is severe. A linear bullous eruption apparently induced by photosensitizers in "meadow grass" was described six decades ago as "dermatitis

bullosa striata pratensis."^[90]

Plant-induced photosensitization has caused industrial problems. For example, severe vesiculobullous eruptions involving sun-exposed areas were reported in a large number of field workers harvesting celery in Michigan in 1961.^[9] The cause of this response was contact with a psoralen compound elaborated by celery infected by pink rot (*Sclerotinia sclerotinorum*) and exposure to sunlight. Normally, noninfected celery contains some 5-methoxypsoralen (5-MOP). When it is infected with the fungus, the combination produces 8-methoxypsoralen (8-MOP) and trimethylpsoralen.^{[100] [101] [104] [112]} The infected celery also contains higher than normal concentrations of 5-MOP.

More recently, phytophotodermatitis developed in several grocery workers handling produce in a chain of supermarkets in 13 different states.^[7] This reaction apparently was induced by contact with a newly developed disease-resistant brand of celery. In at least one location, the eruption was related to handling the produce and subsequent tanning in a UVA suntan salon.^[17]

Another example of industrially induced phytophotodermatitis, noted in Florida, resulted from bartenders' squeezing Persian limes (*Citrus aurantifolia*) into cocktails.^[110] The rind contains a photosensitizing psoralen compound released by the squeezing.

Other persons at occupational risk are dairy workers (from plants eaten by cows), farmers, gardeners, and cannery workers who pack carrots, parsnips, figs, celery, or limes. Recently, a rare industrially related

photoeruption caused by topical contact with celery was reported in a chef.^[73] It should be noted that recreational exposures to limes and other plants can also induce phytophotodermatitis.^{[44] [133]}

Perfume-induced berloque dermatitis is a special form of phytophotodermatitis. It is characterized most notably by bizarre pigmentation with or without preceding erythema involving areas contacted by the perfume and exposed to the sun.^[39] The name "berloque" derives from the frequent pendant configuration of the hyperpigmentation.

^[108]

Oil of bergamot extracted from the rind of fresh bergamot oranges (*Citrus bergamia*) is a common ingredient in several commercial perfumes and colognes. This

TABLE 47-4 -- Common Plants Implicated in Causing Phytophotodermatitis

FAMILY	BOTANICAL NAME	COMMON NAME
Umbelliferae	<i>Anthriscus sylvestris</i>	Cow parsley, wild chervil

	<i>Apium graveolens</i>	Celery
	<i>Heracleum mantegazzianum</i>	
	<i>Heracleum maximum (H. dulce)</i>	Giant hogweed
	<i>Pastinaca sativa (P. urens)</i>	Parsnip (garden variety)
	<i>Heracleum laciniatum</i>	Tromsopalm
	<i>Angelica sylvestris</i>	
	<i>Heracleum spondylium</i>	Cow parsley
	<i>Heracleum giganteum</i>	Parsnip (wild parsnip)
	<i>Foeniculum vulgare</i>	Fennel
	<i>Anethum graveolens</i>	Dill
	<i>Peucedanum oreoselinum</i>	
	<i>Daucus carota</i>	Wild carrot, garden carrot
	<i>Peucedanum ostruthium</i>	Masterwort
	<i>Ammi majus</i>	
	<i>Angelica archangelica</i>	Angelica
Rutaceae	<i>Citrus aurantifolia</i>	Lime
	<i>Citrus medica (C. acida)</i>	Citron
	<i>Citrus sinensis</i>	
	<i>Citrus aurantium</i>	Bitter orange
	<i>Citrus limon</i>	Lemon
	<i>Citrus bergamia</i>	Bergamot
	<i>Dictamnus albus (D. fraxinella)</i>	Gas plant, burning bush
	<i>Ruta graveolens</i>	Common rue
	<i>Phebalium argenteum</i>	Persian lime (Tahitian)
Moraceae	<i>Ficus carica</i>	Fig
Compositae	<i>Achillea millefolium</i>	Milfoil, yarrow
	<i>Anthemis cotula</i>	Stinking mayweed
Ranunculaceae	<i>Ranunculus</i> spp.	Buttercup
Cruciferae	<i>Brassica</i> spp.	Mustard
Convolvulaceae	<i>Convolvulus arvensis</i>	Rindweed
Rosaceae	<i>Argrimonia eupatoria</i>	Agrimony

Chenopodiaceae	<i>Chenopodium</i> spp.	Goosefoot
Leguminosae	<i>Psoralea corylifolia</i>	Scurf-pea, bavchi
Hypericaceae	<i>Hypericum perforatum</i>	St. John's wort
Anacardiaceae	<i>Hypericum crispum</i>	Red quebracho
	<i>Schinopsis quebracho-colorado</i> (S. <i>lorentzii</i>)

oil contains a number of furocoumarins.^[72] The most potent photosensitizer appears to be bergapten, which is 5-MOP.^{[86] [96] [98]} Phytophotodermatitis follows contact with offending plants and subsequent exposure to UVA. Oral plant intake rarely induces photosensitization because a very large amount of plant must be ingested to attain high blood and skin levels of the photosensitizing furocoumarins, which are also readily metabolized to nonphotosensitizing molecules.

When photosensitizing furocoumarins are raised to an excited state (usually a triplet state) by exposure to UVA, they form photoaddition products with pyrimidine bases in the cellular deoxyribonucleic acid (DNA).^{[86] [87] [96] [97] [98]} The first reaction appears to be

1102

Figure 47-13 Plants that contribute to phototoxicity. **A**, Fig tree. **B**, Gas plant. (B Courtesy Yves Sell, Institute of Botany, Louis Pasteur University, Strasbourg, France.)

Figure 47-14 Phototoxic eczematous dermatitis caused by furocoumarins.

monoadduct formation to one strand of the DNA material, with some conversion to DNA interstrand cross-links by a second photon reaction. This is a type I reaction that does not require oxygen.

There is evidence that a type II reaction also occurs.^[94] This is a so-called photodynamic

reaction, which depends on the presence of oxygen. After UVA irradiation, the psoralen compound in the triplet state induces singlet oxygen, superoxide anions, and hydroxy radicals, which are responsible for cell membrane damage, erythema, and edema. The type I reaction results in nuclear and ribonucleic acid (RNA) damage. Keratinocytes, Langerhans' cells, melanocytes, mononuclear cells, fibrocytes, and endothelial cells can be involved in these phototoxic events.

Photoallergic reactions are rarely induced by psoralen compounds.^[58] Plant-induced photoallergic responses appear to relate to chemicals other than psoralens.^[56]^[79]

Dense hyperpigmentation is characteristic of the psoralen-induced photoreaction. This appears to be related to increased numbers of melanocytes, melanocytic hypertrophy, increased arborization of melanocytic dendrites, increased number of melanosomes, changed pattern of melanosomes, hyperplasia of the keratinocytes, and resultant increased transfer of melanosomes into keratinocytes.^[94]

A distressing eruption occurs in victims who present a clinical picture of airborne contact sensitivity but who actually have a phototoxic or even photoallergic component to the response.^[38]^[95] These victims demonstrate a mixture of acute and subacute dermatitis with pruritic, erythematous, edematous, scaly, and lichenified eruptions distributed over the face, back of the neck, and exposed regions of the extremities. Areas shielded by glasses, the nose, and the chin often are spared, so the dermatitis in its initial presentation is fairly distinctive. However, with severe reactions, the lesions often become disseminated to the trunk and elsewhere. Thus it is important to obtain a history of the original pattern of distribution. The dermatitis can be explosive and incapacitating. The key to good care is rapid recognition and prompt institution of therapy. Unfortunately, the correct diagnosis is often not made early and the skin disease progresses to a chronic, more slowly evolving generalized

1103

Figure 47-15 Persistent light eruptions that can eventuate from acute photoallergic contact dermatitis.

dermatitis with limited remissions and frequent exacerbations.

Although furocoumarins may cause the preceding type of reaction, they more often are responsible for acute reactions. More likely culprits include aromatic lichen compounds, such as usnic acid^[126] and atranorin,^[125] the Compositae oleoresins, and other sesquiterpene lactones, such as parthenin and ambrosin.^[38] Parthenin has been demonstrated during an epidemic of airborne contact, and presumably photocontact

dermatitis, after inadvertent importation of feverfew (*Parthenium hysterophorus*) into India.^[69] These cases unfortunately can eventuate as persistent light reactors^[16] ^[38] ^[52] ^[125] ^[126] and can even develop with granulomatous skin inflammation.^[124]

The pathophysiologic mechanisms behind some phytophotodermatitis remain unresolved. The phototoxic mechanisms of furocoumarin effects have been delineated,^[95] but how the aromatic lichen compounds and Compositae oleoresins effect these changes is unclear. Towers and associates^[130] reported phototoxic effects of polyacetylenes and thiophene, which are present in Compositae plants. α -Terthienyl from marigold (*Tagetes erecta*, a member of the Compositae family) has been shown to act as a nonphotodynamic photosensitizer in vitro and in vivo.^[54]

Rarely, cases are considered to be caused by photoallergy ([Figure 47-15](#)). It has been argued that because a relatively large number of photosensitive persons are also contact sensitive to sesquiterpene lactones, repeated exposure to these common allergens might predispose persons to become perennial and persistent light reactors.^[38]

This state of perennial or persistent light reactivity has become well recognized and is called chronic actinic dermatitis.^[18] It is characterized by a severe eczematous eruption involving primarily sun-exposed areas but spreading to covered sites at times. This eruption predominantly affects older men, a significant number of whom are contact allergic to Compositae oleoresins.^[38] A relationship between the contact allergy and the development of chronic actinic dermatitis has not been definitively demonstrated. However, Murphy et al^[84] recently reported a gardener who progressed from a state of proven contact allergy to Compositae resins to a state of proven photosensitivity. The patient had a chronic eczematous eruption of his hands and face for 12 months with positive patch tests to sesquiterpene lactone mix and negative phototests. Six months after the initial phototesting, he was retested and found to have a significant eczematous reaction to UVA radiation, as well as being contact sensitive to Compositae resins. The authors suggest that the initial contact allergy could enable formation of an endogenous photoallergen that would be responsible for a chronic photo-induced delayed-type hypersensitivity reaction.

Treatment

The management of phytophotodermatitis depends on a number of factors, including the extent and severity of the process; the identity, amount, and potency of the photosensitizer; and the nature of the photosensitive eruption.

The initial approach is to discontinue contact with the photosensitizing plant, avoid sun exposure, or both. The vast majority of these reactions are phototoxic. Thus the offending plant is usually identified from the history of contact with a known photosensitizing plant and the distribution and character of the eruption. If the contactants are not known photosensitizers, epidemiologic and photopatch testing procedures are needed to identify the offending plant. If the problem is photoallergic in nature, photopatch testing may also be needed.

The acute inflammatory aspects of the responses are treated with appropriate dermatologic measures. The intensity of treatment depends on the severity and the

extent of the dermatitis. Cool tap water wet dressings applied every 2 hours when awake for 2 to 3 days reduce inflammation and discomfort. Ice and ice water should be avoided. Topical fluorinated corticosteroids, such as fluocinonide 0.05% cream, ointment, or gel, may be useful. If the process is severe or extensive, systemic corticosteroids may be needed. Thus betamethasone suspension, 6 mg; methylprednisolone, 40 to 80 mg; or triamcinolone acetonide, 40 mg IM, are equally effective.

In general, a phototoxic event is self-limited and subsides within a week if further insult does not occur. Hyperpigmentation may persist for several months and frequently is unsightly. Topical application of 5% hydroquinone cream once or twice a day for several weeks may lighten the hyperpigmentation. Treatment of the chronic actinic dermatitis state has been most difficult. Complete elimination of light exposure temporarily ameliorates the photodermatosis. However, exacerbations generally occur with return to even minimal

1104

exposures. Photochemotherapy with 8-methoxypsoralen and UVA radiation has been helpful in a few cases.^[80] However, recent studies indicate that azathioprine, generally in daily doses of 100 mg for several months, is quite effective in inducing remissions.^[85] The appropriate laboratory evaluation must be performed periodically to detect azathioprine toxicity.

GRANULOMAS

Penetration and breakage of thorns, spines, and spicules in the skin can lead to foreign body granuloma.^[5] When a young person has an indurated and erythematous plaque or patch on the buttocks or an exposed part of the body and gives a history of having fallen in the desert from a horse, motorcycle, or all-terrain vehicle 7 to 10 days previously, the clinical diagnosis of cactus granuloma is not difficult. However, when an urban inhabitant arrives in the emergency room during or after recovery from a prolonged domestic bout of substance abuse with grouped erythematous papulopustules on the same exposed areas, the diagnosis may not be so apparent. Cacti abound throughout urbia and conurbia.

Cactus lesions generally evolve over a matter of days to weeks but can take years to appear.^[45] All lesions seem to be roughly the same age at the time of presentation. They do not develop explosively. Nevertheless, various infections must be considered, so a Gram-stained smear and microbiologic cultures are often indicated, although most lesions are aseptic. Plant-associated pathogens, such as *Mycobacterium* spp., should be considered. If the lesions are fairly firm and more papular than pustular, a biopsy should be performed. Sometimes a member of the party can provide the necessary botanical clue, but it is the essential observation that lesions are in groups or patches on extremities that leads to the suspicion that a victim might have fallen or been thrust inadvertently into a cactus. In Israel and other parts of the world, where edible cacti (prickly pears of the *Opuntia* spp.) are cultivated, a somewhat more acute papulopustular eruption is seen ([Figure 47-16](#)).^[116] ^[135] So-called sabra dermatitis is caused by implantation of detachable glochids of the cactus,^[127] which can be blown by wind onto the skin, or into the eyes to cause an annoying keratoconjunctivitis.^[134]

Although the basic histologic features are those of a foreign body granuloma, with periodic acid-Schiff-positive spicules detected in giant cells,^[26] lesions are clearly more inflammatory than simple foreign body reactions. The predominant cells are type 1 epithelioid cells with secretory rough endoplasmic reticulum and dense lysosomal bodies in the cytoplasm.^[31] ^[32] This implies that an element of hypersensitivity also exists. Although T lymphocytes and dendritic mononuclear

Figure 47-16 Beaver tail cactus (*Opuntia* species). (Courtesy Eric Lewis.)

cells are present in the area of chemically induced hypersensitivity granulomas, ^[29] it is not yet clear whether this type of granuloma requires an intact cell-mediated immune system to initiate granuloma formation. ^[29] ^[36] However, granulomas are fully formed in the presence of a cell-mediated immune response. ^[11] ^[26] ^[29] ^[32] ^[135]

Treatment

Acute care treatment of cactus-induced skin lesions must remain conservative because final diagnosis cannot be achieved without histologic interpretation. Systemic corticosteroids are effective in reducing inflammation and relieving discomfort. However, failure to recognize an active infection or an infectious granuloma could lead to aggravation by overzealous corticosteroid treatment. Topical corticosteroids offer little help. The victim should be treated with cool compresses of aluminum acetate and systemic medication for pain or discomfort until a diagnosis can be made and definitive treatment (surgical, supportive, or specific) is initiated. Surgical removal of solitary or small grouped granulomas is recommended where feasible. Incision and drainage may help expose the inciting agent. If the glochids are visible in the skin, removal with sterile splinter forceps in the reverse direction of penetration usually leads to rapid healing, but this procedure can be difficult and tedious. Removal of large spines may require localization using soft tissue radiographic techniques. Small spines in groups within the skin may be peeled off using water-soluble facial gel or rubber cement, taking care to avoid contact with sensitive mucous membranes. These procedures are gratifying when they work, but they often fail. The primary reason for failure is that the tiny barbs on the glochids point backward like barbed fishhooks and hold the dart into the skin. ^[120] At times, watchful waiting and supportive care are all that work, and the offending agent is extruded spontaneously. ^[120]

Chapter 48 - Toxic Plant Ingestions

Kimberlie A. Graeme
George Braitberg
Donald B. Kunkel †
Michele Adler

Plants have served as both poisons and medicines. Dioscorides listed several hundred plant species in his first *Materia Medica* in 78 BC. Galen, in second-century Rome, catalogued plants, including those containing opiates, ergotamines, and other alkaloids. Pharmacognosy was established as an independent discipline in nineteenth century Europe.^[114]

Toxic plants are ingested by curious children, by foragers mistaking poisonous plants for edible fare, by herbalists mistaking poisonous plants for nontoxic remedies, by pleasure seekers attempting to attain natural highs, and by suicidal patients attempting to harm themselves. Over 122,000 plant ingestions or exposures were reported to 65 poison control centers serving more than 257 million people in 1998.^[91] Plant exposures represented 5.5% of total toxic exposures reported in 1998 (fourth after cleaning substances, analgesics and cosmetics/personal care products). Approximately 7% of plant ingestions required treatment at a health care facility, with four deaths reported. More than 68% of all plant ingestions reported were in children under age 6 years.^[91]

GENERAL CONSIDERATIONS

Supportive care takes priority over identification of plants ingested, but the history should include time of ingestion, amount and part of plants ingested, initial symptoms, and time between ingestion and onset of symptoms. Method of preparation (e.g., drying, cooking, boiling), number of persons who ate the same plant, and symptoms are important considerations.

Airway, breathing, and circulation are assessed, then adequacy of hydration, end-organ perfusion, and urine output. Oral administration of activated charcoal (1 g/kg) aids gastrointestinal decontamination. Laboratory studies depend on clinical presentation and suspected plant exposure. Complications of poisoning include aspiration pneumonia, rhabdomyolysis, and deep venous thrombosis.

The differential diagnosis is initially kept broad so that other illnesses, such as infection and trauma, are not missed. Table 48-1 (Table Not Available) provides signs and symptoms of toxic plant ingestions.

PLANT TOXIN PRINCIPLES

The toxic principles underlying major poisonous plant ingestions can be organized by chemical structure of plant toxins and by primary organ systems involved in toxicity. This chapter discusses plant toxins by organ system and divides toxins into chemical groups: alkaloid, glycoside, resin, oxalate, and phytotoxin.

Alkaloids

Alkaloids are nitrogen-containing organic compounds that act as bases and form salts with acids. Plant alkaloids are soluble organic acid-alkaloid salts that contain nitrogen in a ring structure that is heterocyclic, aromatic, or both. Alkaloids are generally distributed throughout the plant, so all ingested parts are toxic. Further subdivision into chemical groups is based on ring structure ([Table 48-2](#)).

Glycosides

Sugars in the form of acetals are called glycosides. In glycosides, a glycosyl group replaces an alcohol or hydroxyl group. On hydrolysis, glycosides yield sugars, or glycones, and aglycone compounds. The aglycone moiety accounts for most of the toxicity, although the sugar may enhance solubility and absorption ([Figure 48-1](#)). The glycoside-producing plants include cardioactive, cyanogenic, saponin, anthraquinone, and coumarin glycoside compounds.

Resins

Resins are highly toxic compounds of diverse chemical and plant origin united by the physical characteristics of insolubility in water, absence of nitrogen, and solid or semisolid state on extraction at room temperature. Resins are usually mixed with other compounds, such as volatile or essential oils (oleoresins), gum (gum resins), and sugars (glycoresins).

Oxalates

Oxalates occur naturally in plants as soluble (sodium and potassium) or insoluble calcium oxalates or acid oxalates. Oxalates have corrosive effects and bind serum calcium, causing hypocalcemia.

Phytotoxins

Phytotoxins, or toxalbumins, are among the most toxic substances of plant origin. They are composed of large

†Deceased.

TABLE 48-1 -- Signs and Symptoms of Plant Intoxications

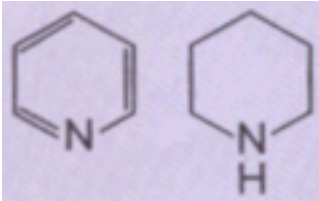

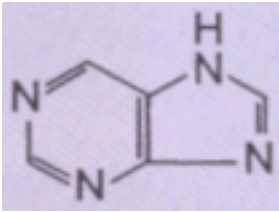

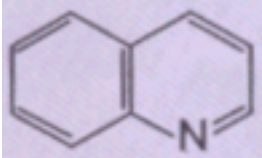

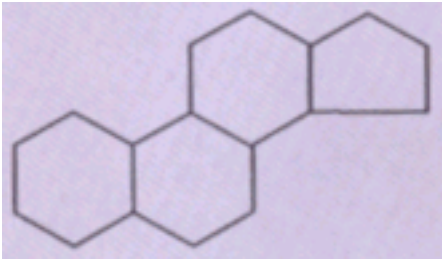

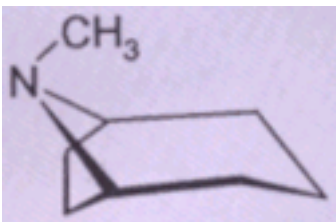

(Not Available)

Modified from Lampe KF, McCann MA: AMA handbook of poisonous and injurious plants, Chicago, 1985, American Medical Association.

1110

TABLE 48-2 -- Plant Alkaloids and Their Structures

ALKALOID TYPE	ALKALOID STRUCTURE	EXAMPLES
Indole		Ergonovine (ergots)
		Strychnine
		Physostigmine (calabar beans)
		Rauwolfia alkaloids (reserpine)
Isoquinoline		Opium alkaloids
		Emetine (ipecac)

Pyridine/piperidine		Nicotine (tobacco)
		Arecoline (betel nut)
		Lobeline (Indian tobacco)
Purine		Caffeine
		Theobromine (cacao)
Quinoline		Cinchona alkaloids (quinidine)
Steroid		Veratrum alkaloids (false hellebore)
		Aconite (monkshood)
Tropane		Atropine (belladonna)
		Hyoscyamine
		Hyoscine (scopolamine)

Figure 48-1 Hydrolysis of amygdalin, with its toxic aglycone group, yields hydrogen cyanide. The enzyme β -glucosidase, called emulsin, contained in plants can catalyze amygdalin hydrolysis.

Figure 48-2 Structure of ricin, a phytotoxin isolated from the castor bean plant, is similar in structure to biologic toxins, such as botulinum. This glycoprotein is composed of two peptide chains, designated *A* and *B*, connected by a disulfide bond.

protein molecules that resemble bacterial toxins in structure and in their ability to act as antigens ([Figure 48-2](#)).

ORGAN SYSTEM PRINCIPLES

Toxic effects of certain plants can be grouped into categories designated by major effects on the central nervous, cardiovascular, gastrointestinal, renal, endocrine-metabolic, and hematopoietic systems.

Central Nervous System

Anticholinergic Plants (Tropane Alkaloids).

Plants containing tropane alkaloids are often called belladonna

1111

Figure 48-3 Nicotinic and muscarinic receptors of the central nervous system, autonomic nervous system, and peripheral skeletal muscles. Anticholinergic toxins (e.g., tropane alkaloids) antagonize muscarinic receptors, causing confusion, agitation, abnormal movements, hallucinations, and coma centrally and mydriasis, anhidrosis, tachycardia, urinary retention, and ileus peripherally. Direct nicotinic agonists (e.g., arecoline, coniine, cytisine, lobeline, nicotine) stimulate nicotinic receptors; however, prolonged depolarization at the receptor causes eventual blockade of nicotinic receptors. *CNS*, Central nervous system; *ANS*, autonomic nervous system; *M*, muscarinic receptor; *N_N*, nicotinic receptor in nervous system; *N_M*, nicotinic receptor at skeletal muscle; *ACh*, acetylcholine; *NE*, norepinephrine; *Epi*, epinephrine.

alkaloids and include atropine, hyoscyamine (the levorotatory isomer of atropine), and hyoscine (scopolamine).^[121] Structures of the tropane alkaloids follow:

Tropane alkaloids are found in about 25 genera and 2000 species of plants. Plants causing human toxicity include *Atropa belladonna* (deadly nightshade), *Mandragora officinarum* (mandrake), *Hyoscyamus niger* (henbane), *Datura*, and *Brugmansia*.^{[61] [121]} The Solanaceae family includes *Solanum* and *Scopolia carniolica*, the source of scopolamine. *Solanum nigrum*, *H. niger*, *Cicuta minor*, *Datura stramonium*, and *Lactuca virosa* were used in the past to provide anesthetic solutions. Even today, poppy heads and mandrake roots are on the coat of arms of the Association of Anaesthetists.^[25]

ANTICHOLINERGIC SYNDROME.

Toxicity may ensue after ingesting or smoking plant parts.^{[28] [124]} The tropane alkaloids inhibit postsynaptic muscarinic receptors competitively, producing the classic anticholinergic syndrome ([Figure 48-3](#) and [Box 48-1](#)).^{[55] [61] [121]} A useful clinical sign of anticholinergic toxicity is dry axillae, without perspiration.^[122] Anticholinergic findings suggesting poisoning may be remembered using the following mnemonic^{[123] [129]} :

Hot as a hare (or hot as Hades),

Blind as a bat,

Dry as a bone,

Red as a beet,

Mad as a hatter.

JIMSONWEED.

Datura species are generally known as jimsonweed ([Figure 48-4](#)), and *Brugmansia* species are generally known as angel's trumpet.^{[59] [61]} Jimsonweed seeds contain the highest concentration of tropane alkaloids, the equivalent of 0.1 mg atropine per seed.^[129] As little as one-half teaspoonful of the seeds may cause death from cardiac and pulmonary arrest.^[139] Jimsonweed is thought to have derived its name from Jamestown, Virginia, where British troops were reportedly behaving bizarrely after consuming *Datura* in 1676. *Datura stramonium* has been reportedly used in Haitian zombification rituals.^{[28] [41] [59] [61] [139]} Jimsonweed has been used to treat asthma, heralding the current use of ipratropium bromide.

Reports of abuse of *Datura* and *Brugmansia* as hallucinogens have increased in the United States and Europe.^{[28] [61] [111]} Clusters of poisonings among adolescents are typical.^{[27] [61]} Tachycardia, dry mouth, agitation, nausea, vomiting, incoherence, disorientation, auditory

Figure 48-4 Jimsonweed (*Datura* spp.) is characterized by trumpetlike flowers (A) and thorny seedpods that contain numerous small kidney-shaped seeds (B). Nickel is shown for size comparison. (Courtesy Kimberlie Graeme, MD, and Steven Curry, MD.)

and visual hallucinations, mydriasis, decreased bowel sounds, slurred speech, urinary retention, and hypertension have been reported.^[28] Blurred vision and photophobia may be secondary to mydriasis. The associated pupillary dilation, or atropine mydriasis, is not reversed by application of 1% pilocarpine.^[135] Seizures, flaccid paralysis, and coma may ensue. Hyperthermia may occur, with the victim appearing flushed.

Dry skin (particularly dry axillae)

Urinary retention

Dry mucous membranes

Dry skin (particularly dry axillae)

Anticholinergic poisoning is often diagnosed by observing the victim attempting to communicate with imaginary friends, having mumbling speech, and demonstrating repetitive picking behavior.^[59] Symptoms generally begin 30 to 60 minutes after ingestion and continue for 24 to 48 hours, but they may begin within several minutes and persist for several days. Patients are generally amnesic of the events. Studies may show leukocytosis, mild transient elevation of liver enzymes, elevated creatine phosphokinase (CK) levels and other evidence of rhabdomyolysis, electrocardiogram (ECG) changes consistent with tachycardia and arrhythmias.^{[28] [61] [139]}

DEADLY NIGHTSHADE.

Ingestion of *A. belladonna* is less common than *Datura* and *Brugmansia* ingestion. All parts of deadly nightshade contain tropane alkaloids; each berry may contain up to 2 mg of atropine. A family of eight had varying acute exposures to *A. belladonna* after eating both raw and cooked berries in a pie. The most severely poisoned patient had anticholinergic symptoms, with hypertonia, hyperthermia, respiratory failure, and coma requiring mechanical ventilation. Urine drug screens detected only atropine, but not scopolamine, which is present in much smaller quantities.^[121]

In addition to poisonous or medicinal plants, a number of food staples, such as potato, tomato, eggplant,

1113

and chili pepper, belong to the Solanaceae family. Although atropine can be isolated from the green, unripened skins of these plants, toxicity seldom ensues.

TREATMENT.

Treatment of anticholinergic plant exposure consists primarily of decontamination and supportive care, including oral administration of activated charcoal, airway protection, intravenous (IV) fluids, and vasopressors for hypotension resistant to IV fluid. Hyperthermia should be assessed and treated if significant. Agitation can be treated with careful administration of benzodiazepines. Haloperidol and phenothiazines should not be used because these agents may enhance toxicity.^{[55] [121] [124]} Foley catheterization and nasogastric tube placement may be necessary if bladder distention and decreased gut motility develop, respectively.

Some recommend treating severe central anticholinergic syndrome with carefully titrated physostigmine, which is derived from the Calabar bean of *Physostigma*

venenosum. This cholinesterase inhibitor blocks acetylcholine degradation; the resultant accumulation of acetylcholine overcomes the competitive inhibition of atropinic agents, such as those found in jimsonweed. Rapid reversal of peripheral and central nervous system (CNS) effects ensues. However, bradycardia, asystole, ventricular arrhythmias, hypotension, bronchospasm, bronchorrhea, and seizures have been reported after rapid IV administration of physostigmine, limiting its routine use. Persons with cardiac conduction abnormalities are particularly susceptible to these cardiac complications.^[27]
^[55] ^[123] ^[132] ^[139]

Most cases of anticholinergic poisoning can be managed safely and effectively with supportive care alone.^[129] We recommend consultation with a toxicologist before using physostigmine. If physostigmine is used, the recipient should be on a cardiac monitor, with pulse oximetry and a physician at the bedside slowly administering graduated doses of the drug.^[21] Risk/benefit analysis must be assessed before administration.^[55] If the patient may have been exposed to tricyclic antidepressants, physostigmine should not be administered.^[123] ^[132]

Figure 48-5 Tree tobacco (*Nicotiana glauca*).

Nicotinic Plants (Pyridine-Piperidine Alkaloids).

The pyridine-piperidine group contains the major alkaloids nicotine, coniine, lobeline, arecoline, piperine, and isopelletierine. Structures of the pyridine/piperidine alkaloids follow:

Pyridine

Nicotine

Lobeline

Coniine

Nicotine alkaloids are found mainly in the Solanaceae family of plants. Other families containing nicotine alkaloids include Hippocastanaceae (horse chestnut) and

Asclepiadaceae (milkweed).

TOBACCO PLANTS.

Tobacco contains both nicotine and related alkaloids with similar pharmacologic properties, such as the alkaloid anabasine, which is found in *Nicotiana glauca* (wild tree tobacco; [Figure 48-5](#)). Anabasine, an isomer of nicotine, may account for much of the toxicity of *Nicotiana glauca* (wild tree tobacco).^[95] Other tobacco family members include *N. rustica*, *N. tabacum*, *N. trigonophylla* (desert tobacco; [Figure 48-6](#)), and *N. attenuata* (coyote tobacco). *N. tabacum* is the major source of commercial tobacco and contains between 0.5% and 9% nicotine. The kidneys excrete nicotine fairly rapidly after biotransformation in the liver and lungs. The half-life is 1 to 2 hours. The lethal dose of ingested nicotine is not well established. Two to 5 mg may cause nausea, and 40 to 60 mg may be lethal in humans. One to two cigarettes, ingested and absorbed, could be lethal to a child.

NICOTINIC SYNDROME.

Peripherally, acetylcholine is a neurotransmitter for autonomic and somatic motor fibers. Acetylcholine is stored in vesicles within the presynaptic neuron and is released by calcium-dependent exocytosis into the synapse. Acetylcholine binds to receptors at the synapse and is eventually degraded by acetylcholinesterase. Acetylcholine can bind to two receptor types, nicotinic and muscarinic. Nicotinic receptors are located on postganglionic autonomic neurons (N_N receptors) and at skeletal neuromuscular junctions (N_M receptors). Direct nicotinic agonists (e.g., arecoline, coniine, cytisine, lobeline, nicotine) prolong depolarization at these receptors and eventually cause blockade of nicotinic receptors. Clinical evidence of stimulation followed by blockade is apparent. Hypertension,

1114

Figure 48-6 *Nicotiana trigonophylla* (desert tobacco) and other *Nicotiana* spp. are characterized by narrow tubelike flowers. (Courtesy Kimberlie Graeme, MD, and Donald Kunkel, MD.)

tachycardia, vomiting and diarrhea, abdominal pain, salivation, bronchorrhea, muscle fasciculations and spasms, confusion, agitation, tremor and convulsions (stimulation) are followed by hypotension, bradyarrhythmias, paralysis, coma and respiratory failure (blockade)^{[26] [38] [88] [95]} ([Box 48-2](#) and [Figure 48-3](#)).

Green tobacco sickness is a mild form of nicotine poisoning seen in young field workers with dermal exposure to leaves of green tobacco in wet environments. Nicotine, a water-soluble alkaloid, is absorbed dermally. The syndrome is characterized by weakness, nausea, vomiting, abdominal cramps, headache, dizziness, difficulty breathing, and occasional fluctuations in blood pressure and heart rate. The urinary nicotine metabolite, cotinine, may be helpful diagnostically.^{[10] [88] [95]}

Lobeline, derived from the Indian tobacco plant, *Lobelia inflata*, is a high-affinity nicotinic ligand. It can cause nicotine-like effects (e.g., hypertension, hypotension, bradycardia) but is generally less toxic than nicotine.^[40]

POISON HEMLOCK.

Coniine and β -coniine, the principal alkaloids in *Conium maculatum* (poison hemlock), are pyridine derivatives similar to nicotine. The alkaloid is volatile and lost by drying or heating. *C. maculatum* ([Figure 48-7](#)) is also known as spotted hemlock, California or Nebraska fern, and carrot weed. It is often mistaken for an edible plant but has a mousy odor, an unpleasant bitter taste and burns the mouth and throat. The stem has purplish to reddish brown spots and is hollow. Its long taproot is solid and parsniplike. Although all plant parts are poisonous, the roots are especially toxic. Poisoning may also occur after eating birds that have consumed poison hemlock.

C. maculatum was used in ancient times for capital punishment and murder. Socrates was likely the victim of poison hemlock, suffering hypothermia, nausea, paralysis, and finally death by respiratory arrest. The primary action of the toxic alkaloids is activation then

Figure 48-7 Poison hemlock (*Conium maculatum*).

blockade of nicotinic acetylcholine receptors. Initially, stimulation causes sialorrhea, nausea, vomiting, diarrhea, abdominal cramping, and tachycardia, followed by dry mucosae, gastrointestinal (GI) hypotonia, diminished cardiac contraction, and bradycardia, as with nicotinic syndrome. Muscles rapidly swell and stiffen, with multifocal necrosis of myocytes and associated muscle pain. Muscle fasciculations and flaccid paralysis may be followed by rhabdomyolysis and acute tubular necrosis with renal failure. Elevated CK and liver function tests (LFTs) may be noted. Death is usually from respiratory failure.^{[45] [53] [55] [65] [116]}

BETEL NUT.

Areca catechu (areca palm) produces betel nut, a common masticatory drug in the Far East, Asia, India, and the South Pacific. An estimated 10% to 25% of the world's population chews "betel quid." It is generally chewed with lime (calcium hydroxide) wrapped in leaves of betel pepper (*Piper betel*), known as "quid," "punsupari," or "pan masala." Occasionally, tobacco is added. Quid is sucked in the lateral gingival pocket. *A. catechu* contains arecoline, a volatile cholinergic alkaloid, which is hydrolyzed to the alkaloid arecaidine. Both alkaloids are nicotinic and muscarinic. Betel pepper leaves contain betel oil, which contains psychoactive phenols and cadinene that possess cocainelike properties. Clinical effects resemble nicotinic syndrome and cholinergic toxicity, including CNS effects (dizziness, euphoria, subjective arousal, altered mental status,

Figure 48-8 Mescal bean bush (*Sophora secundiflora*) (A) is characterized by bean pods that contain burnt-red seeds (B). (Courtesy Kimberlie Graeme, MD.)

hallucinations, psychosis, convulsions), cardiac effects (tachycardia, hypertension, palpitations, arrhythmias, bradycardia, hypotension), pulmonary effects (bronchospasm, dyspnea), GI effects (salivation, vomiting, diarrhea), urogenic effects (urinary incontinence), and musculoskeletal effects (weakness and paralysis). Betel nut use is also associated with flushing, diaphoresis, warm sensations, red-stained oral mucosa and saliva, and dark brown-stained teeth.^{[33] [101] [107]}

QUINOLIZIDINE ALKALOIDS.

Cytisine is a quinolizidine alkaloid but is often classified with the pyridine and piperidine alkaloids. Cytisine stimulates nicotinic ganglions. Common toxic plants in this group include golden chain tree (*Laburnum anagyroides*), Kentucky coffee tree (*Gymnocladus dioica*), necklace pod sophora (*Sophora tomentosa*), and mescal bean bush (*Sophora secundiflora*) ([Figure 48-8](#)) (see Hallucinogenic Plants). Structures follow:

Quinolizidine

Cytisine

TREATMENT.

Treatment of nicotinic syndromes consists of supportive care with particular attention to airway protection and ventilation. Administration of activated charcoal is generally recommended. Benzodiazepines and barbiturates are given for seizures. Adequate urine output is maintained, with consideration of urine alkalinization. Treating initial excessive adrenergic stimulation with phentolamine is ill advised because this complicates the nicotinic blockade that follows. Symptomatic bradycardia can be treated with atropine and hypotension with IV fluids and inotropic agents (e.g., dopamine) if needed.^[88] With liver or renal failure, supportive treatment may be required for days.

Hallucinogenic Plants (Indoles, Phenylalkylamines).

About 90 of the 800,000 plant species are hallucinogenic. Numerous rituals and religious ceremonies have used these plants. Many psychoactive plants are indole derivatives, which are among the most potent psychoactive compounds in nature and have the following structure:

Indole nucleus

Chemical relationships exist among serotonin, psilocybin (*Psilocybe* spp.), and *D*-lysergic acid diethylamide (LSD). LSD is synthesized from ergonovine (or ergometrine), derived from *Claviceps purpurea*. Striking structural similarities exist between the most potent psychoactive plant compounds and biochemically important neurotransmitters, as follows:

ERGOT.

The ergot alkaloids, ergonovine and ergotamine, are indole derivatives found in the fungus *C. purpurea* that infects rye and other grains. In the Middle Ages, epidemics of

ergotism resulted from ergot-contaminated breads. Ergotism is a vasospastic condition with two forms, convulsive and gangrenous. Hallucinations can occur with both forms. In the ninth century a disease known as "St. Anthony's fire" was epidemic, consisting of burning limb pain and eventual loss of limb sensation, followed by gangrene and autoamputation of charcoal-black limbs. People migrated to St. Anthony's Order, a society of monks, and began to heal, largely because they received a diet free of ergot-contaminated grains. Neurologic ergotism manifests as diaphoresis, nausea, vomiting, formication, and convulsions. An outbreak of ergotism occurred in Ethiopia in 1977.^[23] ^[24] ^[65] ^[140]

Commercial grains are now inspected for the presence of ergot, and inadvertent poisoning is rare. Ergot derivatives are potent vasoconstrictors and oxytocic agents and are used medicinally for vascular headaches and for obstetric and gynecologic disorders.

MORNING GLORY.

The active component of the naturally occurring hallucinogen found in the seeds of morning glory (*Ipomoea violacea*) ([Figure 48-9](#)) is ergine, or (+)-lysergic acid amide, an indole derivative.^[59] About 300 seeds, or enough to fill a cupped hand, are equivalent to 200 to 300 mg of LSD, with similar systemic and hallucinatory effects. Ingestion of Hawaiian baby woodrose seeds (*Argyria nervosa*) presents similarly.^[56]

NUTMEG.

Myristica fragrans is used to make the spices nutmeg and mace. Mature rinds of the fruit split, revealing a bright-red fringed fleshy coating on the outside of its seed. The coating contains mace, and the seed contains nutmeg. Nutmeg contains myristicin, which has an indolelike structure and is metabolized to amphetamine-like compounds. Other alkylbenzene derivatives, such as safrole and elemicin, are also found in nutmeg. Nutmeg has been abused for its alleged hallucinogenic effects. A person who ingested one grated nutmeg (7 g)

Figure 48-9 Morning glory (*Ipomoea violacea*).

had weakness, loss of coordination, vertigo, fainting, nausea, and paresthesias but no hallucinations.^[127] ^[141]

CANNABIS.

Cannabis preparations are largely derived from the female *Cannabis sativa* plant. The primary psychoactive component is d-9-tetrahydrocannabinol (THC), which is most

concentrated in the flowering tops. Marijuana generally contains 0.5% to 5% THC; however, Sinsemilla and Netherwood varieties may contain up to 20% THC, and hashish and hashish oils have higher concentrations. Cannabinoids can be smoked or ingested. A typical marijuana cigarette contains 0.5 to 1.0 g of cannabis, and the THC delivered varies from 20% to 70%, with a bioavailability of 5% to 24%. As little as 2 mg of available THC produces effects in occasional users.^[66]

Cannabinoids bind to specific cannabinoid receptors in areas of the brain involved with cognition, memory reward, pain perception, and motor coordination. Cannabinoids act as neuromodulators in the release and action of neurotransmitters (e.g., acetylcholine, glutamate).^{[43] [66]} Endogenous ligands for these receptors are endocannabinoids. The first endocannabinoid identified is anandamide, after the Sanskrit word *ananda*, which means "bliss."

Desirable effects include mild mood-altering qualities, euphoria, alteration in perceptions, time distortion, and intensification of ordinary sensory experiences (e.g., gustatory, visual, and auditory sensations). Adverse effects include impairment of short-term memory and attention, impairment of motor skills and reaction times, and anxiety. Psychotic symptoms have been reported in persons vulnerable to psychosis. Clinically, tachycardia may occur within minutes of THC exposure and may last a few hours. Minor changes in blood pressure may also occur. No confirmed deaths have been reported from cannabis poisoning.^[66]

PEYOTE.

The hallucinogenic peyote cactus, *Lophophora williamsii* ([Figure 48-10](#)), contains alkaloids that are phenylethylamines or isoquinolines rather than indoles. Mescaline (3,4,5-trimethoxy- β -phenylethylamine), the

Figure 48-10 Peyote (*Lophophora williamsii*).

primary psychoactive component of peyote, is structurally similar to the neurotransmitters norepinephrine and epinephrine and to hallucinogenic amphetamines. Pharmacologically, however, mescaline is similar to hallucinogenic indoles. Mescaline may affect the action of norepinephrine and serotonin, evidenced clinically by sympathomimetic effects, followed by marked visual hallucinations. Mescaline produces a slight rise in blood pressure and heart rate, tachypnea, hyperreflexia, mydriasis, ataxia, perspiration, flushing, salivation, and urination. No deaths have been reported from peyote poisoning. Type B botulism was associated with consumption of a

ceremonial tea made from peyote that was stored in a jar by members of the Native American Church. Affected members had bilaterally symmetric, flaccid weakness in all extremities, dysphagia, nasal speech, and diplopia.^[4] ^[69]

MESCAL BEAN BUSH.

The mescal bean bush or Texas mountain laurel (*Sophora secundiflora*) of the pea family (Fabaceae) contains hallucinogenic dark-red beans (mescal beans; see [Figure 48-8](#)). The beans contain the toxic alkaloid cytisine, which causes nausea, convulsions, numbing sensations, hallucinations, unconsciousness, and death through respiratory failure. The beans may be boiled in water and the mixture consumed, producing a delirium or "visionary trance." The origin of mescalism in modern peyote religion is debated. Mescal beans are worn during some peyote ceremonies.^[4]

KHAT.

The evergreen khat tree, *Catha edulis*, grows in East Africa and Arabia. As early as 1237, khat was advocated in Arabic medical literature as a mood-elevating and hunger-suppressing agent. Khat leaves continue to be chewed for their stimulatory effects. Khat contains cathinone, cathine, and norephedrine. Cathinone (α-aminopropiophenone), a phenylalkylamine, is the major psychoactive constituent. Structurally, cathinone is similar to amphetamines, such as methcathinone synthesized from ephedrine. As with amphetamines, cathinone is an indirect sympathomimetic and induces the release of dopamine, serotonin, and norepinephrine.^[76] ^[146]

The structures of methcathinone and related drugs follow:

Cathinone is "diluted" in fresh plant material and must be extracted by masticating laboriously; this results in gradual absorption. As the leaf wilts, cathinone is converted to cathine, which has little activity. Because only fresh leaves produce the desired stimulatory effects, much khat use in the past was limited to countries where khat was produced (e.g., North Yemen, Ethiopia, Kenya); however, khat is now air-freighted to Europe and the United States. Freshly picked leaves are kept damp and often wrapped in banana leaves during transport.^[44]

Desirable effects of khat include increased energy and alertness, feelings of increased

endurance and self-esteem, and euphoria. Cathinone has both positive chronotropic and inotropic effects. Tachycardia, increased blood pressure, and mydriasis are seen. Adverse effects include hypomania, delusions, and paranoid psychosis. Khat is known to be habit-forming and has been classified as a "substance of abuse" by the World Health Organization. A person who developed abdominal pain was found to have immature *Fasciola hepatica* (flake infestation of the biliary tree), thought to be secondary to use of contaminated khat.^{[2] [44] [76] [78] [146]}

ANTICHOLINERGIC PLANTS.

Henbane (*Hyosyamus niger*), jimsonweed (*Datura stramonium*), and mandrake (*Mandragora officinarum*) contain tropane alkaloids and can produce hallucinations, as discussed earlier.

TREATMENT.

Treatment of patients exposed to hallucinogenic plants is generally supportive. First-line treatment for agitation is generally benzodiazepines.

Sedating Plants (Isoquinoline Alkaloids)

POPPY.

Papaver somniferum flowers are large and white with purple stain at the base of each petal. They yield opium, a complex of more than 20 alkaloids, including morphine, codeine, and papaverine. Morphine was the first plant alkaloid isolated, by pharmacist Friederich Wilhelm Adam Serturner in 1806.^[64] Seeds of *P. somniferum* are used in various foods and beverages, including bagels, muffins, pastries, curry sauce, rice, and teas. Ingestion of poppy seeds can result in detectable levels of morphine and codeine by urine drug screen testing; however, significant opiate-induced impairment is not apparent. Poppy dependence has been described.^{[15] [80] [96] [106] [138]}

Convulsant Plants (Indoles, Resins)

STRYCHNINE.

Strychnine, an indole found in seeds of the tree *Strychnos nux-vomica*, is a powerful CNS stimulant that competes with the inhibitory neurotransmitter glycine, producing an excitatory state with hyperreflexia, severe muscle spasm, and apparent convulsions. Children may be poisoned after accidental ingestion of rat poisons containing strychnine. Strychnine continues to be used as a suicidal and homicidal agent.^{[16] [112]} Treatment comprises decontamination and

support, including activated charcoal, benzodiazepines, barbiturates, and chemical paralysis, with endotracheal intubation and mechanical ventilation for severe toxicity. Rhabdomyolysis and acidosis may occur and require treatment.^[104] Occasionally, death ensues despite aggressive management.^[72]

WATER HEMLOCK.

Water hemlock (*Cicuta maculata*) and chinaberry (*Melia azedarach*) are two of the most toxic resin-containing plants. Chinaberry produces primarily GI symptoms (see below). The resin of *C. maculata*, an unsaturated aliphatic alcohol called cicutoxin, possesses convulsive properties and has the following structure:

Cicutoxin

Nine subspecies of *Cicuta* of the Umbelliferae family are poisonous ([Figure 48-11](#)). *C. virosa* is common European water hemlock, whereas *C. maculata* and *C. douglasii* are found in North America. *Oenanthe crocata*, or hemlock water dropwort, also contains cicutoxin and is found in Europe and North America. Common names for *Cicuta* species include cowbane, five-finger root, snake weed, wild carrot, dead man's fingers, death-of-man, poison parsnip, wild parsnip, beaver poison, children's bane, muskrat weed, spotted hemlock, spotted cowbane, musquash root, false parsley, fever root, mockeel root, wild dill, spotted parsley, and *carottee a moreau*. Roots have a parsnip- or carrot-like odor, and *Cicuta* is often mistaken for an edible plant. Mature roots have air-filled chambers and are found on the ends of hollow stems. All parts of the plant are toxic, but the roots contain the highest concentration of cicutoxin. Ingestion of as little as 2 to 3 cm of the

Figure 48-11 *Cicuta* species have characteristic flowering tops, typical of the Umbelliferae family (A), and roots with air-filled chambers at the end of hollow stems (B). (Courtesy Steven Curry, MD.)

root may be fatal to an adult. The plant is most toxic in the spring.^[29]^[55]^[131]

Early symptoms include muscarinic effects and are primarily GI, including abdominal pain, vomiting, and diarrhea; however, profuse perspiration, salivation, and respiratory

distress may be seen. Nicotinic effects are less prominent (see [Figure 48-3](#)). Tachycardia and hypertension or bradycardia and hypotension may be seen. Epileptiform seizure activity or spastic and tonic movements, including opisthotonus without electroencephalographic (EEG) seizure activity, may occur with severe poisoning. Pupils may be any size. Rhabdomyolysis and renal failure have been reported. Laboratory abnormalities include metabolic acidosis, elevated CK, and elevated liver transaminases (LFTs).^{[7] [29] [55] [99] [116] [131]}

A typical clinical presentation is illustrated by a 23-year-old man who was foraging for wild ginseng in the woods of midcoastal Maine. He found plants growing in a swampy area and took three bites from the root of one plant. Within 30 minutes, he vomited and began to convulse. Just over an hour after the ingestion, he was unresponsive, cyanotic, and tachycardic, with mydriasis and profuse salivation. Apnea, requiring endotracheal intubation, followed severe tonic-clonic seizures. Ventricular fibrillation occurred, and he died within 3 hours of ingesting the root later identified as *C. maculata*.^[29]

TREATMENT.

Treatment is symptomatic and supportive with particular attention to the airway. Activated charcoal is recommended, with benzodiazepines and barbiturates for seizure control. Adequate urine output maintenance and alkalinization of urine are initiated to treat rhabdomyolysis.^{[55] [131]}

Other Alkaloids.

Gelsemium sempervirens (Carolina or yellow jessamine) is a woody perennial evergreen vine with fragrant yellow flowers. It contains multiple indole

alkaloids, including gelsemine, gelseminine, and gelsemoidin. Gelsemine binds to acetylcholine receptors at the neuromuscular junction (peripheral nicotinic acetylcholine receptors) and, to a lesser extent, at muscarinic receptors. A toddler who ate the blossoms of *G. sempervirens* experienced neuromuscular blockade with ataxia, dysarthria, facial and extremity weakness, bilateral ptosis, and transient coma. The child recovered without sequelae.^[20]

Cardiovascular System ([Box 48-3](#))

Cardiotoxins that Inhibit Na⁺ -K⁺ ATPase (Cardiac Glycosides).

More than 200 naturally occurring cardiac glycosides have been identified. Plant cardiac glycosides are composed of a steroid backbone, an attached five-membered unsaturated lactone ring (six-membered for *Helleborus*), and either a carbohydrate or

sugar moiety in glycosidic linkage. The toxic aglycones are released by acid and enzymatic hydrolysis. The attached sugar moiety has no inherent cardiac action but may enhance solubility, absorption, and toxicity of the aglycone moiety. Cardiac glycosides bind to the membrane-bound enzyme, Na⁺-K⁺ ATPase, increasing intracellular Na⁺ and Ca²⁺ levels and automaticity ([Figure 48-12](#)). Cardiac glycosides are found in *Digitalis purpurea* (foxglove; [Figure 48-13](#)), *D. lanata*, *Nerium oleander* (common oleander; [Figure 48-14](#)), *Thevetia peruviana* (yellow oleander; [Figure 48-15](#)), *Convallaria majalis* (lily of the valley; [Figure 48-16](#)), *Urginea maritima* (squill or sea onion; [Figure 48-17](#)), *U. indica*, *Strophanthus gratus* (ouabain), *Asclepias* species (balloon cotton, red-headed cotton-bush milkweeds), *Calotropis procera* (king's crown), *Carissa spectabilis* (wintersweet), *C. acokanthera* (bushman's poison), *Cerebera manghas* (sea mango), *Plumeria rubra* (frangipani), *Cryptostegia grandifolia* (rubber vine), *Euonymus eruopaeus* (spindle tree), *Cheiranthus*, *Erysimum* (wallflower), and *Hellaborus niger* (henbane).^{[47] [49] [55] [63] [65] [87] [110] [137]}

FOXGLOVE.

Withering reported the medical use of extracts of *Digitalis purpurea* based on a recipe for treating "dropsy."^[110] *Digitalis purpurea* grows wild in parts of the United States and is cultivated as a garden ornamental plant. Recently, *D. lanata* was mistakenly substituted for plantain in herbal products, with resultant human cardiotoxicity.^[128] *D. lanata* contains lanatosides A, B, and C, which yield digoxin and digitoxin. *D. purpurea* contains only digitoxin, not digoxin. Digitoxin from *D. purpurea* is still used, although digoxin extracted from *D. lanata* is used more often. ^[19]

OLEANDER.

All parts of *Nerium oleander* and *Thevetia peruviana* are toxic, but the seeds contain more glycoside than other parts of the plant.^{[55] [87]} Yellow oleander (*T. peruviana*), a native plant of tropical America, grows abundantly in the United States. Seeds of yellow oleander are known as "lucky nuts." Popular in suicidal ingestions in Sri Lanka, yellow oleander contains the cardiac glycosides thevetin A and B, thevetoxin, neriifolin, peruvicide, ruvoside, and others. Of patients admitted with *T. peruviana* poisoning in Sri Lanka, 43% had arrhythmias, many requiring temporary pacing; 6% died shortly after admission.^[47] Common oleander (*N. oleander*), a native plant of the Mediterranean, grows abundantly in the United States. Common oleander contains the principal cardiac glycosides oleandrin and neriine, as well as folinerin and digitoxigenin.^{[19] [87] [110]} Severe toxicity has been reported after the consumption of unprocessed common oleander leaves and prepared teas.^{[60] [102]}

SQUILL.

Urginea maritima was used by ancient Egyptians and Romans as a diuretic, heart tonic, expectorant, emetic, and rat poison. Squill contains several cardiac

Figure 48-12 Cardiac glycosides bind to and inhibit the membrane-bound enzyme $\text{Na}^+ -\text{K}^+$ ATPase in cardiac myocytes (shown), baroreceptor cells, and skeletal muscle cells. Inhibition of $\text{Na}^+ -\text{K}^+$ ATPase in cardiac myocytes results in accumulation of intracellular Na^+ , which results in accumulation of Ca^{2+} within myocytes via $\text{Na}^+ -\text{Ca}^{2+}$ exchangers. The resultant increase in intracellular Ca^{2+} stimulates further release of Ca^{2+} from the sarcoplasmic reticulum. The increased intracellular Ca^{2+} interacts with troponin C of the actinmyosin complex to cause increased contractions, seen as increased automaticity (e.g., premature ventricular contractions on electrocardiograms). Inhibition of membrane-bound enzyme $\text{Na}^+ -\text{K}^+$ ATPase in baroreceptor cells and skeletal muscle cells contributes to increased vagal tone and hyperkalemia, respectively.

CLINICAL PRESENTATION.

The onset and duration of action is well known for certain glycoside preparations, such as digoxin, digitoxin, and ouabain, but may vary considerably after plant ingestions. For example, oleandrin exhibits protracted binding times to cardiac myocardial tissues.^[87] Generally, cardiac glycoside toxicity produces nausea, vomiting, visual changes (yellow and green colors, geometric shapes, scintillations), mental status changes (disorientation, lethargy, stupor, dysarthria, weakness, dizziness, seizures), cardiac disturbances (palpitations, bradycardia, atrioventricular block, extrasystoles, ventricular arrhythmias), hyperkalemia, and death. When death occurs, it is generally caused by cardiotoxicity. ECGs may reveal nonspecific ST-segment and T-wave changes, similar to digoxin-induced changes.^{[60] [128]} Serum digoxin levels (polyclonal digoxin immunoassays) may be elevated after exposure to plants containing cardiac glycosides, because antibody-based digoxin assays cross-react with various cardiac glycosides, nonquantitatively. Digoxin immunoassays predict only the presence of the glycoside, not the degree of toxicity.^{[63] [87] [137]}

TREATMENT.

Cardiac glycoside toxicity from plant ingestions have been successfully treated with activated charcoal to limit enterohepatic circulation, cardiac pacing, antiarrhythmic agents, and digoxin-specific Fab fragments (e.g., Digibind). Maintenance of fluid and electrolyte balance is important. Theoretically, administration of exogenous calcium could be harmful because of high intracellular calcium concentrations that might cause the heart to perform one final contraction without relaxation, a state termed "stone heart."^[83] Phenytoin and lidocaine have been used to treat arrhythmias. In theory, digoxin-specific Fab antibody

Figure 48-17 *Urginea* spp. (squill or sea onion) have broad leaves (A) and a red, underground bulb (B). (Courtesy Kimberlie Graeme, MD, and Donald Kunkel, MD.)

fragments could couple to circulating cardiac glycosides and limit binding of cardiac glycosides to Na⁺-K⁺ ATPase. The administration of digoxin-specific Fab to reverse cardiotoxicity from plant glycosides remains controversial.^{[34] [60] [87] [103] [113] [128]}

Cardiotoxins that Open Sodium Channels (Steroid Alkaloids, Resins).

Steroid alkaloids form principal toxic components of several common cardiotoxic plants:

monkshood (*Aconitum* spp.), American hellebore (*Veratrum viride*), and death camas (*Zigadenus* spp.). Aconite is found in *Aconitum* species, and veratrum alkaloids are found in *Veratrum viride* (false or American hellebore), *V. californicum* (skunk cabbage), *V. album* (white hellebore), *V. japonicum*, *Zigadenus paniculatus* (death camas), *Z. venenosus*, *Z. nuttallii*, and *Z. gramineus*.

ACONITE.

Recently, aconite poisonings have become more common secondary to the use of *Aconitum* species in herbal products, including *A. napellus* (monkshood; [Figure 48-18](#)), *A. carmichaeli* (chuanwa), *A. brachypodum*, *A. vulparia*, and *A. kusnexoffii* (caowu). *Delphinium* species (larkspur) demonstrate similar toxicity. All parts of these plants are toxic. *Aconitum* species contain diterpenoid-ester alkaloids, particularly aconitine, but

1122

Figure 48-18 Monkshood (*Aconitum* species).

also mesaconitine and hyaconitine. Boiling these plants in water hydrolyzes aconite alkaloids into less toxic benzoylaconine and aconine derivatives.^{[22] [31] [32] [55] [134]}

Aconite alkaloids activate sodium channels and affect excitable membranes of cardiac, neural, and muscle tissues. Enhancement of the transmembrane inward sodium current during the plateau phase of the action potential prolongs repolarization in cardiac myocytes and induces delayed and early afterdepolarizations. Delayed afterdepolarizations result in increased automaticity, such as premature ventricular beats. Early afterdepolarizations produce lengthening of the QT interval.

Symptoms begin within 3 minutes to 6 hours of ingestion and may persist for several days. Nonspecific GI symptoms (nausea, vomiting), salivation, diaphoresis, dyspnea, and restlessness are accompanied by cardiotoxicity and CNS toxicity. Cardiac effects are clinically similar to cardiac glycoside toxicity, with enhanced vagal tone, bradycardia, heart block, ectopic beats, supraventricular tachycardia, bundle branch block, junctional escape rhythms, ventricular tachycardia, bifascicular ventricular tachycardia, polymorphic ventricular tachycardia, torsades de pointes, ventricular fibrillation, asystole, and hypotension. Occasionally, death ensues, generally from ventricular arrhythmias, such as refractory ventricular fibrillation.^{[22] [31] [55] [134]}

Hyaconitine affects sodium channels of the nerve membrane more selectively than aconitine and is more potent than aconitine and mesaconitine in producing neuromuscular block.^[32] These neurotoxins produce conduction block and paralysis

through voltage-sensitive sodium channels in axons. Prolonged depolarization prevents repolarization of excitable membranes. [31] Visual impairment, dizziness, vertigo, ataxia, paresthesias (e.g., numbness of mouth and extremities), hyporeflexia, weakness, profound tetraplegia, coma, and convulsions may occur.

Elevated CK levels, without evidence of myocardial infarction, may occur. Hypokalemia, metabolic or respiratory acidosis, respiratory alkalosis, and renal and hepatic impairment may be noted. [22] [134]

VERATRUM ALKALOIDS.

Veratrum and *Zigadenus* species belong to the lily family. *Veratrum* species may be found in some sneezing powders and have been accidentally ingested when mistaken for *Gentiana lutea* and for *Phytolacca americana* (pokeweed). *Zigadenus* species have been accidentally ingested when mistaken for nontoxic wild onions. Veratrum alkaloids include protoveratrine, veratridine, and jervine, which are found within the entire plant, although the bulb and flower usually cause toxicity. These alkaloids are extremely toxic and rapidly increase the permeability of voltage-sensitive sodium channels in excitable cell membranes. This results in an initial depolarization and subsequent loss of membrane potential. Stimulation of vagal fibers may result in bradycardia and hypotension. [55] [71] [75] [109]

Symptoms generally occur within 30 minutes to 3 hours and resolve within 24 to 48 hours. Toxicity is characterized by diaphoresis, nausea, vomiting, diarrhea, abdominal pain, hypotension, bradycardia, and shock. Scotomata, paresthesias, fasciculations, muscle spasticity, hyperreflexia, vertigo, ataxia, syncope, respiratory depression, coma, seizures, and death may also occur. ECG findings may mimic cardiac glycoside toxicity, including repolarization abnormalities (e.g., abnormal T waves and ST segments), sinoatrial and atrioventricular blocks, and prolonged QT intervals.

TREATMENT.

Treatment of cardiotoxic steroid alkaloid poisoning is supportive and includes atropine, crystalloid fluids, and vasopressors. Victims may require mechanical ventilation and cardiopulmonary resuscitation. [134] Magnesium may suppress early afterdepolarizations and polymorphic ventricular tachycardia. [55]

GRAYANOTOXINS.

Resins called grayanotoxins are found in rhododendrons, mountain laurels, and azaleas. Grayanotoxins produce toxicity similar to the steroid alkaloids, veratrum and aconite, by binding to myocardial sodium channels and increasing their permeability. Poisoning may result from the ingestion of leaves, flowers, or nectar; however, grayanotoxin-contaminated honey is the most common source. [86] [147] The nectar of *Rhododendron* species contains the grayanotoxin O-acetyl-andromedol, or andromedotoxin, which is transferred to humans through consumption of honey produced by bees utilizing the nectar. [65] Poisonings still occur in the Turkish population

of Central Europe. Symptoms include salivation, emesis, hypotension, bradycardia, arrhythmias, circumoral and extremity paresthesias, incoordination, and muscular weakness.

Other Cardiotoxins

TAXANE ALKALOIDS.

Taxus species include *T. baccata* (English yew) and *T. brevifolia* (Western yew). The toxic alkaloids include taxine A, B, and C. All parts of *Taxus* plants are toxic except the pulp, or aril, which contains very little taxine. The seeds, which are surrounded by

1123

the aril, may be toxic if chewed sufficiently to allow absorption of taxine. Taxine B, believed to be the primary cardiotoxic alkaloid, inhibits both calcium and sodium transport across cell membranes.^{[85] [89] [142]}

Most *Taxus* exposures occur in children, are accidental, and are not associated with significant toxicity. However, serious toxicity and death have occurred after intentional ingestions of *Taxus* species.^[36] Although GI toxicity is most common, severe toxicity is characterized by arrhythmias.^{[85] [142]} Previously reported yew-induced arrhythmias are consistent with arrhythmias induced by blockade of voltage-gated sodium channels, being described as bradycardic rhythms with wide QRS complexes, despite normal electrolytes. Sodium channel blockade may be the primary cause of yew-induced arrhythmias. A patient who ingested yew plant, with severe cardiotoxicity and a wide QRS complex, responded favorably to administration of hypertonic sodium bicarbonate.^[97] Lidocaine administration and cardiac pacing have also been reported to be beneficial in the treatment of yew-induced cardiotoxicity. The antineoplastic drug paclitaxel (Taxol) is made from an alkaloid extracted from the bark of the Western yew.^[142] Taxol is also cardiotoxic.

PURINE ALKALOIDS.

The purine alkaloids caffeine and theobromine are found in various plants, but the derivative beverages and stimulants represent a toxic risk. Theobromine is especially toxic to dogs. Even cacao bean shells contain potentially toxic quantities of theobromine, and dogs that ingest large quantities of bean shells may suffer convulsions and death.

Oral and Gastrointestinal System

Gastrointestinal Irritants (Resins, Alkaloids) ([Box 48-4](#))

CHINABERRY TREES.

Melia azedarach plants ([Figure 48-19](#)) are found throughout the southern United States and Hawaii. Chinaberry trees, also known as China, Texas umbrella or white cedar trees, contain tetranortriterpens (resins), identified as meliatoxins A₁ , A₂ , B₁ , and B₂ , that are enterotoxic and neurotoxic. The exact mechanisms of these toxins have yet to be determined. Gastroenteritis can occur after ingestion of any part of the plant but typically occurs after the berries are ingested by children. Immature berries are green but turn yellow and wrinkle with age. After ingestion of as little as one berry, severe gastroenteritis and often bloody diarrhea ensue. Symptoms may be rapid or delayed for several hours after ingestion. Death has been reported in children after the ingestion of the African variety of chinaberry tree. ^[68] Treatment is supportive, with replacement of fluids and electrolytes and administration of activated charcoal. If hypotension ensues, it generally responds to IV fluids.

SOLANUM.

The *Solanum* species are the largest group of steroid alkaloid-containing plants and include *S. tuberosum* (potato), *S. gracile* (wild tomato), *S. carolinense* (horse nettle), *S. pseudocapsicum* (Jerusalem cherry), *S. dulcamara* (woody nightshade), *S. americanum* (black nightshade), and other nightshade plants. *Solanum* species are used medicinally in some countries. ^[39] ^[58] Solanine, a glycoalkaloid with a steroidlike moiety, is found throughout the plants but is most concentrated in unripe fruits. Solanine, which has been isolated from more than 1700 different *Solanum* species, generally produces gastroenteritis, but bradycardia, weakness, and CNS and respiratory depression may be seen. ^[27] Treatment is supportive, with replacement of fluids and electrolytes and administration of activated charcoal. If hypotension ensues, it generally responds to IV fluids. Atropine may be beneficial if bradycardia develops. Spontaneous recovery usually occurs in 1 to 3 days.

SAPONIN GLYCOSIDES (POKEWEED).

Saponin glycosides are found throughout the plant kingdom, contained within English ivy (*Hedera helix*), pokeweed (*Phytolacca americana*), tung tree (*Aleurites* spp.), ginseng (*Panax ginseng* or *quinquefolium*), and licorice (*Glycyrrhiza glabra*).^[55] Saponins may induce lysis of erythrocytes, causing hemolytic anemia. In addition, saponins are GI irritants that facilitate their own intestinal absorption. Most saponins are found in combination with other toxins, resulting in diverse clinical syndromes.

Phytolacca americana, or *P. decandra*, may be mistaken for horseradish, parsnips, or Jerusalem artichoke. Pokeweed is commonly known as Virginia poke, inkberry, pocan, pigeonberry, American cancer-root, garget, red ink, American nightshade, scoke, jalap, and redwood. *P. americana* has green leaves with red stalks. Berries are green when immature and turn deep purple with maturity. Pokeberries typically leave a purple stain. The root is the most toxic part of the plant. *P. americana* is ingested intentionally in pokeweed salad and poke-berry teas. When prepared for ingestion, leaves should be "parboiled," which entails boiling the leaves in water

1124

Figure 48-19 Chinaberry (*Melia azedarach*). (Courtesy Donald Kunkel, MD.)

that is discarded before boiling the leaves again and rinsing them with fresh water. Parboiling does not necessarily offer protection against toxicity.^[55]

The saponin glycosides, phytolaccatoxin and phytolaccagenin, account for the GI injury, which manifests as fulminant gastroenteritis with vomiting and diarrhea 2 to 4 hours after ingestion. Diarrhea may appear foamy from the sudsing effect of saponin glycosides. Hypotension may follow significant GI fluid losses. Severe ingestions may result in weakness, loss of consciousness, seizures, and respiratory depression.^[55]

P. americana also contains mitogenic, hemagglutinating, and antiviral proteins. Pokeweed mitogen may induce morphologic changes in lymphocytes and plasma cells. An increased number of circulating plasmablasts and proplasmacytes, eosinophilia, and thrombocytopenia can be seen after ingestion or handling of *P. americana* with broken skin. Pokeweed antiviral protein is a ribosome-inactivating protein being investigated for cancer treatment.^[74]

Treatment for acute ingestion includes administration of activated charcoal and fluid

replacement for dehydration secondary to GI losses. Airway support may be needed. Seizures should be treated with benzodiazepines. Hematologic changes generally resolve within weeks.^[55]

ANTHRAQUINONE GLYCOSIDES.

The aglycone moiety of this group is anthraquinone, which is known to have cathartic activity. Herbal teas that contain leaves, flowers, or bark of senna (*Cassia senna*), leaves of aloe (*Aloe barbadensis*), and bark of buckthorn (*Rhamnus frangula*) can cause severe diarrhea.^[1] Treatment is supportive, emphasizing adequate volume and electrolyte replacement.

Toxins that Inhibit Protein Synthesis (Phytotoxins)

PHYTOTOXINS (RICIN, ABRIN).

Phytotoxins are found in the families Fabaceae, including jequirity bean (*Abrus precatorius*), which contains abrin, and Euphorbiaceae, including the castor bean (*Ricinus communis*) ([Figure 48-20, A](#)), which contains ricin, and purging nut (*Jatropha curcas*), which contains curcin. Poisoning results from eating or chewing on the nut or seed. Fresh, immature castor beans are encased within a soft, thorny, red seedpod. With age the seeds and surrounding seedpod become brown; seeds develop hard shells that are difficult to penetrate ([Figure 48-20, B](#)).^[42]

Ricin, the phytotoxin found in castor beans, is a glycoprotein composed of two peptide chains, designated A and B, connected by a disulfide bond (see [Figure 48-2](#)). Chain B binds to the cell membrane, whereas chain A penetrates the cell by endocytosis and interferes with ribosomes and disrupts protein synthesis, leading to cell death. ^[3] ^[30] ^[42] ^[79] The oral lethal dose is estimated to be 1 mg/kg, theoretically as little as one bean in a child and eight to ten in an adult.^[145] Recently, a discrepancy between the serious toxicity of isolated ricin and the milder toxicity of ingested seeds of *Ricinus communis* has been recognized. A young adult consumed 10 to 15 seeds of *R. communis* and experienced severe crampy abdominal pain and vomiting 4 hours after ingestion, without GI bleeding or abdominal guarding. He received IV fluids, antiemetics, and charcoal. By the third day he had recovered completely. In contrast, a Bulgarian broadcaster who was injected with isolated ricin died from severe gastroenteritis and multiple organ failure.^[3] Ingested *R. communis* is much less toxic than parenteral ricin. The degree of mastication of castor beans may determine the degree of toxicity seen with oral ingestions. Fresh seeds are likely more toxic than aged seeds that are enveloped by a hard coat. Although deaths have been reported with ingestions of a couple of seeds, toxicity is unlikely if mature seeds are swallowed whole.

Similarly, deaths have been reported after ingestion of fresh jequirity beans (*Abrus precatorius*). Deaths occur 3 to 5 days after ingestion and are associated with cerebral edema and mucosal changes of the GI tract, including edema and hemorrhage of the Peyer's patches.^[42]

Clinically, mild symptoms involve diarrhea alone. More severe symptoms include persistent vomiting, diarrhea, and abdominal pain, with associated hypovolemia and hypokalemia.^[3] Hemorrhagic gastritis and bloody diarrhea may ensue. Dehydration may be associated with shock and hepatorenal dysfunction. Severely ill patients may present with hyperthermia, mental status changes, and seizures.^[42] Systemic effects may be delayed as inhibition of protein synthesis occurs. Terminally, elevated serum LFTs and CK levels may be seen, indicating hepatorenal failure.^{[30] [90] [145]}

TREATMENT.

Treatment is supportive, including fluid and electrolyte replacement and activated charcoal administration. Patients who remain asymptomatic for 4

1125

Figure 48-20 Castor bean plant (*Ricinus communis*) (A), which contains ricin, is characterized by broad, serrated leaves, with fresh beans encased within a soft, thorny, red seedpod. With age the seeds and surrounding seedpod become brown, and seeds develop hard shells that are difficult to penetrate (B). (Courtesy Kimberlie Graeme, MD, and Donald Kunkel, MD.)

to 6 hours after ingestion of seeds may be discharged, with instructions to return if symptoms develop. Before IV fluid resuscitation, mortality was as high as 8.1%; the rate has dropped to 0.4% since 1950.^{[3] [30]}

Toxins that Inhibit Cell Division (Amine Alkaloids)

COLCHICINE.

Colchicum autumnale, from the family Liliaceae, is commonly known as autumn crocus, wild saffron, meadow saffron, naked lady, naked boy, and son-before-the-father.^[73] It is found in Europe, America, and Asia. All parts of the plant contain colchicine, an amine alkaloid, but the highest concentrations are found in the underground bulb. Colchicine binds selectively and reversibly to microtubules, disrupting cell division, cell shape, mobility, and phagocytosis. Cells with the highest turnover, such as those of the GI mucosa and bone marrow, are affected most severely. Cell arrest in metaphase and abnormal nuclear morphology are seen at autopsy.^[73]

Acute poisoning may occur after a latent period of several hours. Initial GI effects are severe abdominal pain, nausea, vomiting, and diarrhea, which may result in volume depletion and shock. Muscular weakness and ascending paralysis cause respiratory

arrest, which may occur with a clear sensorium.^[54]

TREATMENT.

Treatment is symptomatic and supportive. Pulmonary function tests can be used to monitor respiratory function, assessing for fatigue and progressive ascending paralysis. Assisted ventilation is used as needed. Parenteral analgesics are given cautiously to relieve severe abdominal pain, since colchicine sensitizes patients to CNS depressants. Fluid and electrolyte replacement and occasionally blood component replacement may be necessary.^[73] Maintain adequate urine output and assess for infection.

Hepatotoxic Agents: Pyrrolizidine Alkaloids.

Plants containing pyrrolizidine alkaloids include *Senecio vulgaris* (groundsel), *S. longilobus* (gordolobo), *S. jacobaea* (tansy ragwort), *Symphytum officinale* (comfrey), *Gynura segetum*, *Ilex paraguanyensis* (mate), *Heliotropium*, *Crotalaria* (rattlebox), *Amsinckia intermedia* (fiddle neck or tar weed), *Baccharis pteronoides*, *Astragalus lentiginosus*, *Gnaphalium*, and *Adenotyles alliariae* (alpendost). These plants, especially when consumed as teas, are associated with hepatic veno-occlusive disease, hepatomegaly, cirrhosis, and Budd-Chiari syndrome. For example, *Senecio* and *Crotalaria*, which are used to make "bush tea" in Jamaica, have been associated with hepatotoxicity.^{[92] [114] [115] [117] [130]}

Pyrrolizidine alkaloids act as alkylating agents and may be activated in the liver by cytochrome P450 and mixed-function oxidase systems to reactive pyrrolic metabolites that alkylate proteins and deoxyribonucleic acid (DNA).^[98] Young victims seem more susceptible than adults. Ten milligrams of pyrrolizidine alkaloid are probably enough to produce acute or chronic veno-occlusive disease.^[8] Veno-occlusive liver disease is characterized by nonthrombotic occlusion of the central veins of hepatic lobules. Histologic liver findings include central vein dilation, sinusoidal congestion, centrilobular necrosis, and fibrosis. Clinical evidence of intrahepatic portal hypertension may include ascites, painful hepatomegaly, weight gain, and jaundice.^{[13] [114] [130]} Death may ensue. Treatment is supportive.

1126

Occasionally, laparoscopic liver biopsy and hepatic and portal decompression are helpful in diagnosis and treatment, respectively.^[92]

Oral Irritants (Glycosides, Oxalates)

DAPHNE.

Coumarin glycosides produce effects similar to those of irritant glycoalkaloids of the steroid-alkaloid group. The only plant of significance is daphne (*Daphne mezereum*),

with its fragrant succulent berries. The widely cultivated daphne represents a significant risk to curious children, in whom only a few ingested berries may be lethal.^[90] The fruits contain a coumarin glycoside and a diterpene that irritate mucous membranes, with swelling of the tongue and lips. Blisters will form if berries are rubbed on the skin. Severe gastroenteritis with GI bleeding may occur.^[49] In addition, progressive weakness, paralysis, seizures, and coma may develop. Treatment is supportive.

INSOLUBLE OXALATES.

Philodendron and *Dieffenbachia* species (Araceae family) plant exposures are frequently reported.^[84] These plants contain insoluble oxalates arranged in numerous needles of calcium oxalate (raphides) contained in specialized cells (idioblasts). When stimulated, as by mastication, idioblasts fire raphides that become embedded in exposed tissues, resulting in painful edema. These plants also contain trypsinlike proteases, histamine, and kininlike substances that may contribute to toxicity.^{[57] [105]}

Accidental ingestion of *Dieffenbachia* may result in painful edematous swelling, including angioedema. The victim may have dysphagia. *Dieffenbachia* is commonly known as dumbcane because of the victim's inability to speak after chewing the plant. Vesicle, bullae, or ulcer formation of the oral mucous membranes or oropharyngeal and esophageal erosions may be noted. Sudden death has been reported. Treatment is supportive, with special attention to maintaining a patent airway.^{[57] [93] [100] [105]}

Renal System

Soluble oxalates are found in rhubarb (*Rheum rhaponticum*) and sorrel (*Rumex*) plants. Soluble oxalates are rapidly absorbed through the GI tract. Generalized disturbance of monovalent and divalent cation metabolism occurs. Serum ionized calcium levels may drop rapidly. Weakness, tetany, hypotension, and seizures may develop. Acute renal failure may occur if calcium oxalate precipitates in urine and obstructs the renal tubules.^{[51] [81] [82] [119]} The structures of oxalates follow:

Sodium bicarbonate lavage should be avoided because of the risk of sodium oxalate formation. IV calcium gluconate is recommended for tetany, prolonged QT interval on ECG, or depressed serum ionized calcium. Urine output should be maintained to prevent deposition of calcium oxalate crystals in renal tubules.

Endocrine and Metabolic System

Plants that Induce Hypoglycemia: Ackee Fruit.

Blighia sapida, or ackee (akee) fruit, trees are indigenous to West Africa but are

prevalent in the West Indies, Central America, and southern Florida. Unripe ackee fruit has a closed aril that is toxic. Ripe ackee fruit, with a spontaneously opened aril, is nontoxic. Unripe ackee fruit contains hypoglycin A, or L(R,S)-2-amino-3-methylenecyclopropylpropionic acid, a water-soluble amino acid that is converted to methylenecyclopropylacetyl-coenzyme A in vivo. Both compounds are hypoglycemic agents^[94] ^[126]; the second is a suicide inhibitor of β -oxidation of fatty acids. Inhibition of fatty acid metabolism results in microvesicular steatosis of the liver, hyperammonemia, metabolic acidosis, and hypoglycemia. Laboratory and histopathologic findings are indistinguishable from Reye's syndrome.

Ackee fruit constitutes a traditional Jamaican breakfast and has been associated with Jamaican vomiting sickness. Ingestion of unripe ackee fruit produced an outbreak epidemic of fatal encephalopathy in West Africa, primarily affecting children ages 2 to 6 years, who experienced vomiting, hypotonia, convulsions, and coma. All children died within 48 hours of onset of vomiting. Necropsy revealed massive liver steatosis and severe hypoglycemia. Urine concentrations of dicarboxylic acids were elevated. Fatal ackee fruit poisoning is more common in children than in adults; adults are more likely to present with self-resolving cholestatic jaundice. ^[94]

TREATMENT.

Treatment is largely supportive and consists of securing an airway and administering activated charcoal and IV fluids. Before hypoglycemia was recognized, mortality rates of symptomatic unripe ackee fruit exposure approached 80%. Frequent glucose and electrolyte measurements with appropriate replacement are essential. Seizures are treated with benzodiazepines and barbiturates. Theoretically, riboflavin, glycine, and carnitine may be beneficial, although their efficacy is not established. Laboratory studies of hypoglycin poisoning in animals suggests that administration of riboflavin and glycine may be useful. Carnitine has been used for other toxins (e.g., valproate) that inhibit β -oxidation of fatty acids and may facilitate transport of fatty acids into mitochondria. ^[125] ^[126]

Corticoid Plants: Licorice.

Adverse effects with chronic ingestion of *Glycyrrhiza glabra* (natural licorice) result from altered steroid metabolism. *G. glabra* contains glycyrrhizic acid, which is converted to 18- β -glycyrrhetic acid within the GI tract. Both acids inhibit 11- β -hydroxysteroid dehydrogenase, an enzyme essential to the in vivo conversion of cortisol to cortisone. ^[18] ^[62] Excessive local cortisol binds to and activates mineralocorticoid receptors in the kidneys, producing a hypermineralocorticoid syndrome, characterized by water and sodium retention with potassium excretion. Signs and symptoms of chronic ingestion include hypertension, headache, edema, hypokalemia, metabolic alkalosis, paresthesias, weakness, paralysis, tetany, and muscle cramps. ^[48] ^[50] Myopathy with reversible myoglobinuria has been reported. ^[14] ^[46] Heart failure, arrhythmias (e.g.,

torsades de pointes), and cardiac arrest have been attributed to licorice root ingestion. [1]

TREATMENT.

Treatment consists of discontinuing exposure to licorice, maintaining good urine output, and alkalinizing urine of patients with rhabdomyolysis. Occasionally, potassium-sparing diuretics (e.g., triamterene, spironolactone) are useful. [18] Torsades de pointes may respond to magnesium or potassium infusion. [48]

Cyanogenic Plants: Glycosides.

Glycosides that yield hydrocyanic acid on hydrolysis are known as

Figure 48-21 Principal steps in hydrocyanic acid poisoning and detoxification. 1, Breakdown of cellular respiration resulting from the binding of cyanide to cytochrome oxidase. 2, Conversion of the ferrous (Fe^{2+}) form of hemoglobin to the ferric (Fe^{3+}) form (methemoglobin) by the use of nitrites. 3, Preferential binding of cyanide to methemoglobin, liberating cytochrome oxidase and restoring cellular respiration. 4, Providing exogenous thiosulfate to aid in formation of the less toxic thiocyanate via various sulfurtransferases, such as rhodanese. Thiocyanate is then excreted from the body. The reaction is slowly reversible via the enzyme thiocyanate oxidase, and rebound may occur.

cyanogenic glycosides (see [Figure 48-1](#)). Amygdalin (D -mandelonitrile- β - D -glucoside-6- β -glucoside), which is abundant in the Rosaceae family, is the cyanogenic compound found in these plants. [133] Seeds of *Malus* species (apples) and pits of *Prunus* species, including cherries, peaches, plums, and apricots (commercial source of laetrile), are rich in amygdalin. Black or wild cherries (*P. serotina*) are considered the most dangerous. Poisonings have resulted from milkshakes that include apricot kernels and from apricot kernels sold in health food stores as snacks. [1] [133] Deaths have been reported after ingestion of apricot, apple, cherry, and other fruit seeds. [90] [120] Linseeds (*Linum usitatissimum*) are also cyanogenic. [118] Chronic cyanide toxicity has been reported from ingestion of cassava (*Manihot esculenta*).

Cyanide combines with and inhibits many enzymes. It possesses great affinity for the ferric iron in cytochrome oxidase of the electron transport chain, accounting for most of its toxicity ([Figure 48-21](#)). By combining with cytochrome oxidase, cyanide prevents electron transport, thereby preventing adenosine triphosphate (ATP) production by oxidative phosphorylation. Metabolic acidosis ensues. Humans detoxify cyanide by transferring sulfane sulfur to cyanide to form thiocyanate. Numerous sulfur sources are likely acted on by various sulfurtransferases to form the sulfane sulfur needed to convert cyanide to thiocyanate. Administration of exogenous sulfane sulfur,

such as sodium thiosulfate, can greatly facilitate this detoxification.^[37]

Clinically, CNS changes (agitation, anxiety, excitement, weakness, numbness, hypotonia, coma, seizures), respiratory changes (hyperpnea, dyspnea, apnea), cardiovascular changes (tachycardia and hypertension followed by bradycardia and hypotension, heart block, ventricular arrhythmias, asystole), and metabolic changes (anion gap metabolic acidosis) are seen. Skin color may be pink or cyanotic, and the partial pressure of oxygen may be normal in cyanide poisoning. Arterial blood gases reveal metabolic acidosis. ECG may reveal T-on-R phenomenon due to progressive shortening of the ST segment. Multisystem organ failure and death may occur.^[37]

TREATMENT.

Patients with cyanide glycoside poisoning may respond to treatment with 100% oxygen and the cyanide antidote kit, which includes amyl nitrite, sodium nitrite (3% solution given intravenously based on hemoglobin and weight; generally 300 mg in a nonanemic adult), and sodium thiosulfate (12.5 g). Red blood cell or plasma cyanide levels can be determined; however, treatment should be initiated promptly, without confirmation of exposure, in patients with evidence of toxicity. Cyanide antidote kits are designed to induce methemoglobinemia through nitrite exposure. Cyanide binds preferentially to the ferric ion of methemoglobin rather than that of cytochrome oxidase in the electron transport chain. Forming methemoglobin limits inhibition of electron transport by cyanide and restores cellular respiration. Sodium thiosulfate in the cyanide kit provides exogenous sulfane sulfur groups that bind to cyanide and form thiocyanate. Although not available in the United States, hydroxocobalamin is used as antidotal therapy in some countries. Cyanide combines with hydroxocobalamin to form cyanocobalamin, which is excreted in the urine and bile.^[37] ^[133]

Chronic exposure to cyanogenic glycosides occurs with cassava consumption during droughts in areas where the bitter roots of cassava are a staple food, such as in Africa. Roots contain high concentrations of cyanogenic glucosides, specifically the cyanogenic glycoside linamarin, which produce an upper motor neuron disease known as Konzo or tropical spastic paraparesis. To remove cyanogens, roots should be soaked; however, when water is scarce, this soaking process is limited. Konzo outbreaks have been reported in populations exposed chronically to cassava that is not properly soaked.^[11] ^[12]

Hematopoietic System

Plants with Anticoagulant Properties: Lactone Glycosides.

Dipteryx odoratum and *Coumarouna* (or *Dipteryx*) *oppositifolia* (tonka bean) were among the first historically mentioned medical sources of coumarin. *Melilotus officinalis* (melilot), *Asperula odorata*, and *Galium odoratum* (woodruff) also contain significant quantities of coumarin. Occasionally, these coumarin-containing products are consumed

in teas.^[114] *Melilotus* (sweet clover) poisoning is caused by dicumarol, a fungal metabolite produced from substrates in sweet clover. Fungi dimerize coumarin to produce dicumarol. Dicumarol interferes with the synthesis of vitamin K-dependent coagulation factors, inducing coagulopathy. Generally, this has been problematic for livestock and not humans.^[108]

Plants that Induce Hemolysis: Fava.

Fava beans (*Vicia faba*) contain vicine and convicine, two metabolically inactive glycones that may be cleaved by β -glycosidase to produce divicine and isouramil. Divicine and isouramil may account for the hemolytic crisis seen in response to oxidative stress when individuals deficient in glucose-6-phosphate dehydrogenase ingest fava beans. Favism has been reported in infants who ingest breast milk from mothers who have recently ingested fava beans and in fetuses of mothers who ingest fava beans. Clinically, favism is characterized by hemoglobinuria, anemia, and jaundice.^[35] ^[70] Patients may present with complaints of malaise, weakness, lethargy, nausea, vomiting, headache, and lumbar or abdominal pain. Renal failure may ensue.^[67] Supportive care is the mainstay of treatment. Occasionally, transfusions and hemodialysis are needed.

OTHER TOXINS

Oils

Irritant oils, including various mustards (*Brassica* spp.), horseradish (*Amoracia lapathifolia*), and protoanemonin from the buttercup family (Ranunculaceae), induce gastroenteritis. Essential oils, often found in combination with resins (oleoresins), are extracted commercially for use as rubefacients, salves, and liniments. Essential oils include wintergreen, eucalyptus, wormwood, and pennyroyal oils.

Wintergreen.

Methyl salicylate is the methyl ester of salicylic acid, derived from *Gaultheria procumbens* (wintergreen). Widely used as an antirheumatic agent in the nineteenth century, it fell into disfavor because of its extreme side effects and the availability of more effective acetylsalicylic acid.^[46] Poisoning now occurs most often in children, who are attracted to the color, smell, and flavor of wintergreen oil. Poisoning is identical to salicylism, including CNS excitation, hyperventilation, hyperthermia, and metabolic acidosis.

1129

Structures of salicylic acid and methyl salicylate follow:

Salicylic acid

Methyl salicylate

Eucalyptus.

1,8-Cineole is the toxic component of eucalyptus oil, derived from leaves of *Eucalyptus globulus*. Ingestion of eucalyptus oil is associated with CNS depression (hyporeflexia, coma, respiratory depression), GI upset (vomiting, diarrhea, abdominal pain), and respiratory effects (bronchospasm, pneumonitis). Hypotension and death may occur.^[6]

[136] [144]

Wormwood.

Wormwood oil, from the plants *Artemisia absinthium* and *A. pontica*, was used in the liqueur absinthe, which was eventually banned because of its neurotoxicity. Wormwood oil contains α - and β -thujone and causes vomiting, vertigo, delirium, convulsions, coma, respiratory arrest, and death.^[17]

Pennyroyal.

Pulegone, a monoterpene, is the primary toxin of pennyroyal oil, which is derived from *Hedeoma pulegioides* or *Mentha pulegium*. Pennyroyal oil also contains several other monoterpenes. Pulegone is oxidized by hepatic cytochrome P450 enzymes to form the toxic metabolite menthofuran and other toxins. Menthofuran induces much of the hepatic and pulmonary damage. Reactive oxidative metabolites of pulegone and menthofuran bind to target cell proteins and induce cellular damage. *M. pulegium* use has caused death in women using it as an over-the-counter abortifacient and death in infants given mint teas made with *Mentha pulegium*. Hepatic and neurologic injury are generally seen. Hepatic failure followed by shock, multiple organ failure, and death may occur after ingestion. Neurologic manifestations include dizziness, obtundation, hallucinations, seizures, and cerebral edema. Laboratory studies may reveal elevated liver transaminases, coagulopathies, and metabolic acidosis. Liver histology at autopsy reveals centrilobular hepatic necrosis or confluent hepatocellular necrosis.^{[5] [9]} Treatment includes oral administration of activated charcoal and fluid and electrolyte replacement as needed. *N*-Acetylcysteine has been used for treatment because the hepatotoxicity is similar to acetaminophen-induced hepatotoxicity and is associated with glutathione depletion.^{[5] [9]}

Elements and Nitrates

Many plants absorb or accumulate metallic compounds (selenium, molybdenum, arsenic, lead, cadmium), nitrites, and nitrates. They are generally of little importance in humans but constitute a danger to grazing livestock. However, numerous cases of methemoglobinemia in infants ingesting vegetables high in nitrate content have been reported. Vegetables cited include spinach, beets, cabbage, and carrots grown in high-nitrate soils. Nitrates are converted to nitrites in the infant gut.^[77]

IN MEMORIAM

This chapter is dedicated to our dear friend and mentor, Donald B. Kunkel, MD (1939–2000). Don fostered our interest in plant toxicology, and his knowledge and teachings were invaluable to the writing of this chapter.

Kimberlie A. Graeme, MD

We are saddened by the death of Don Kunkel, who was incredibly energetic and a

constant mentor. His accomplishments in toxicology and the science of medicine were appreciated greatly by all who had the good fortune to know him. He made us want to be better people.

Paul Auerbach, MD

ACKNOWLEDGEMENT

We thank Edward C. Geehr for his contributions to previous editions of this chapter.

APPENDIX: Plants: Toxic Principles and Therapeutics

COMMON NAME	GENUS	SPECIES	POISONOUS PRINCIPLE
Ackee (Akee)	<i>Blighia</i>	<i>sapida</i>	Hypoglycin
Anemone	<i>Anemone</i>	spp.	Protoanemonin
Angel's trumpet	<i>Datura</i>	<i>sauveolens</i>	Atropine, hyoscyamine, hyoscyne
Apple of Peru	<i>Nicandra</i>	<i>physalodes</i>	Unknown
Apple seeds	<i>Malus</i>	spp.	Cyanogenic glycosides
Apricot pits	<i>Prunus</i>	spp.	Cyanogenic glycosides
Arnica	<i>Arnica</i>	<i>montana fulgens</i>	Unknown
Autumn crocus	<i>Colchicum</i>	<i>autumnale</i>	Colchicine
Azalea	(See <i>Rhododendron</i>)		
Balsam pear	<i>Mamordica</i>	<i>balsimia</i>	Saponic glycoside
Baneberry	<i>Actaea</i>	spp.	Protoanemonin, unknown glycosides
Beech	<i>Fagus</i>	spp.	Saponic glycoside
Belladonna	(See deadly nightshade)		
Bellyache bush	<i>Jatropha</i>	<i>gossypiifolia</i>	Curcin

Betel nut	<i>Areca</i>	<i>catechu</i>	Arecoline, arecaine
Bird of paradise	<i>Poinciana</i>	<i>gillesii</i>	Unknown
Black cherry	<i>Prunus</i>	<i>serotina</i>	Cyanogenic glycoside
Black locust	Robinia	<i>pseudoacacia</i>	Robin, robitin (glycoside)
Black nightshade	<i>Solanum</i>	<i>nigrum</i>	Solanine
Black snake root	(See death camas)		
Bleeding heart	(See dicentra)		
Bloodroot	<i>Sanguinaria</i>	<i>canadensis</i>	Sanguinarine
Blister bush	<i>Phebolium</i>	<i>anceps</i>	Unknown
Blue cohosh	<i>Caulophyllum</i>	<i>thalactroides</i>	Unknown
Boxwood	<i>Buxus</i>	<i>sempervirens</i>	Buxine, volatile oil
Brazilian pepper, also: pink or red peppercorn, Florida holly	<i>Schinus</i> flowers	<i>terebinthifolius</i>	Unknown
Broom, also: Scotch broom	<i>Cytisus</i>	<i>scoparius</i>	Cytisine
Buckeye	<i>Aesculus</i>	spp.	Aesculin
Buckthorn	<i>Rhamnus</i>	<i>cathartica</i> , <i>frangula</i>	Anthraquinones

Burning bush	<i>Euonymus</i>	spp.	Unknown
Bushman's poison	<i>Acokanthera</i>	spp.	Oubain, G-strophanthin, acokantherin
Buttercup	<i>Ranunculus</i>	spp.	Protoanemonin
Caladium	<i>Caladium</i>	spp.	Oxalates
Candle nut (see lumbang nut)			
Caper spurge	<i>Euphorbia</i>	<i>lathyris</i>	Unknown alkaloid
Carolina jessamine, also: yellow jessamine	<i>Gelsemium</i>	<i>sempervirens</i>	Gelsemine, sempervirine
Cassava, also: manioc, tapioca	<i>Manihot</i>	<i>esculenta</i>	Cyanogenic glycoside
Castor bean	<i>Ricinis</i>	<i>communis</i>	Ricin
Catnip	<i>Nepeta</i>	<i>cataria</i>	Acetic, butyric and valeric acids, nepetalic acid, limonene
Chalice vine	<i>Solandra</i>	<i>nitida</i>	(see trumpet flower)
Cherry	<i>Prunus</i>	spp.	Cyanogenic glycoside
Chinaberry tree	<i>Melia</i>	<i>azederach</i>	Unknown resin
Christmas rose	<i>Helleborus</i>	<i>niger</i>	Hellebrin, helleborin, helleborein
Clematis	<i>Clematis</i>	spp.	Steroid alkaloids
Coca	<i>Erythoxylon</i>	<i>coca</i>	Ecogonine
Coontie	<i>Zamia</i>	<i>floridana</i>	Unknown alkaloid
Coral plant	<i>Jatropha</i>	<i>multifida</i>	Curcin

Corn cockle	<i>Agrostemma</i>	<i>githago</i>	Githagenin, sapogenin
Cotoneaster	<i>Cotoneaster</i>	spp.	Unknown
Coyotillo	<i>Karwinskia</i>	<i>humboldtiana</i>	Unknown
Crepe jasmine	<i>Ervatamia</i>	<i>coronaria</i>	Unknown
Crownflower	<i>Calotropis</i>	<i>gigantea</i>	Unknown
Crown of thorns	<i>Euphorbia</i>	spp.	Unknown alkaloid
Cup of gold	<i>Solandra</i>	<i>cuttata</i>	Solanine-like alkaloids
Cycads	(See coontie)		
Cypress spurge	<i>Euphorbia</i>	<i>cyparissias</i>	Unknown alkaloids
Daffodil	<i>Narcissus</i>	spp.	Lycorine
Daphne	<i>Daphne</i>	<i>mezereum</i>	Dihydroxy-coumarin, diterpene mezerein
Day jessamine	<i>Cestrum</i>	<i>diurnum</i>	Tropane alkaloids
Deadly nightshade	<i>Atropa</i>	<i>belladonna</i>	Atropine
Death camas, also: black snakeroot	<i>Zigadenus</i>	spp.	Zygacine, zygadenine
Delphinium	<i>Delphinium</i>	spp.	Delphinine, ajacine
Desert potato	<i>Jatropha</i>	<i>macrorhiza</i>	Phytotoxin
Devil's trumpet, also: hairy thorn apple	<i>Datura</i>	<i>metel</i>	Atropine, hyoscyamine, hyoscyne
Dicentra, also: bleeding heart, Dutchman's breeches	<i>Dicentra</i>	spp.	Protopine, apomorphine, protoberberine

Dieffenbachia, also: dumbcane	<i>Dieffenbachia</i>	spp.	Oxalate, asparagine
Dogbane, also: Indian hemp	<i>Apocynum</i>	<i>cannabinum</i>	Cymarin
Duranta	(See sky flower)		
Elderberry	<i>Sambucus</i>	spp.	Unknown alkaloids
Elephant ear	<i>Colocasia</i>	<i>antiquorum</i>	Oxalates
English bean	(See fava bean)		
English ivy	<i>Hedera</i>	<i>helix</i>	Hederogenin
False hellebore, also: Indian poke	<i>Veratrum</i>	spp.	Veratrin
False sago palm	<i>Cycas</i>	<i>circinalis</i>	Alkaloids
Fava bean	<i>Vicia</i>	<i>faba</i>	Hemolytic anemia in glucose-6-phosphate deficiency
Finger cherry	<i>Rhodomyrtus</i>	<i>macrocarpa</i>	Saponin
Fool's parsley	<i>Aethusa</i>	<i>cynapium</i>	Unknown
Four o'clock	<i>Mirabilis</i>	<i>jalapa</i>	Unknown
Foxglove	<i>Digitalis</i>	<i>purpurea</i>	Digitoxin, gitaloxin, gitoxin
Ginseng	<i>Panax</i>	<i>quinque-folium</i>	Saponin glycosides
Glory lily	<i>Gloriosa</i>	<i>superba</i>	Colchicine-like alkaloids
Golden chain, also: golden rain	<i>Labrunum</i>	<i>anagyroides</i>	Cytisine
Golden seal	<i>Hydrastis</i>	<i>canadensis</i>	Steroid alkaloids

Ground cherry	<i>Physalis</i>	spp.	Unknown
Hill gooseberry	<i>Rhodomyrtus</i>	<i>tomentosa</i>	None—N.A. nontoxic (<i>Rhodomyrtus</i> spp.)
Holly	<i>Ilex</i>	spp.	Ilicin
Horse bean (see fava bean)			
Horse chestnut	<i>Aesculus</i>	spp.	Aesculin
Horse nettle, also: wild tomato	<i>Solanum</i>	<i>carolinense</i>	Solanine
Horseradish	<i>Amoracia</i>	<i>rusticana</i>	Mustard oil

Chapter 49 - Mushroom Toxicity

Sandra Schneider
Mark Donnelly

*"Had nature any outcast face? Could she a son condemn? Had nature an
Iscaiot That mushroom—it is him."
Emily Dickinson*

Mushrooms are often considered the vermin of the vegetable world, likened to snakes, slugs, and worms. Some are regarded as mystical and others as delicacies. The location of tasty morels is passed from generation to generation, closely guarded from strangers. Each autumn and spring, foragers scour the woods for known delicacies, and new ones untried. Some mushroom foragers search for "little brown mushrooms," not for their taste, but to evoke hallucinations.

Eating unidentified or misidentified species can be dangerous. Each year there are 10,000 to 15,000 cases of mushroom toxicity in the United States. ^[48] In up to 95% of these cases, the mushroom was incorrectly identified. ^[78] More than 40,000 species of fungi are currently described, with new ones added each year. Only a few species are toxic.

The fungi kingdom contains molds, smuts, rusts, mildews, yeast, and mushrooms, which are different from plants because they lack chlorophyll. "Toadstool" is often used to describe toxic mushrooms; this chapter differentiates toxic mushrooms by their toxins and scientific names.

The body of a fungus is a dense network of branching filaments or hyphae. The mushroom is the fruiting body of the fungus containing the spores. The hyphae and mycelia generally occur in an underground network supporting the visible mushroom. Mushrooms often grow in large rings radiating from a central network of mycelia. In the past these "fairy rings" were thought to have mystical influence. Fungi are largely saprophytic, involved with decomposition of rotting materials, usually wood. They can also be parasitic or symbiotic, living on viable materials with or without beneficial effect

to the host.

As a mushroom emerges from the ground, it is covered with a membrane or veil ([Figure 49-1](#)). As the mushroom grows, the membrane breaks, leaving residual marks on the cap of the mushroom known as "warts." These warts may remain firmly attached to the mushroom, or only residual spots may remain, depending on the species of mushroom and environmental conditions. The emerging cap takes on a shape consistent with the specific species, ranging from cylindrical to convex to funnel shaped.

Gills, located under the caps, contain the spore-producing bodies. Some gills are covered with a second membrane or partial veil, later pulling away to form an annulus or ring midway down the stalk of the mushroom. Gills may be attached firmly to the stalk, even running down the stalk, or only to the cap itself (free gills) ([Figure 49-2](#)). The attachment of the gills is an important aid to identification of some poisonous mushrooms, such as *Amanita phalloides* ([Figure 49-3](#)).

The stalk (stipe) begins at the cap and ends either underground or in a cup (vulva). A cup or vulva at or just below ground level often is seen with a poisonous species. The stalk is generally located in the middle of the cap and may or may not be tapered. The stalks of many poisonous species enlarge below the cap, ending in a bulb. The stalk may have a ringed membrane as evidence that the partial veil formerly protected the gills. Spores are produced by sporeforming bodies on the gills and are expelled into the air after they mature.

Spores vary in size, color, and shape but are usually unicellular. They average 5 to 10 μm in diameter. Spores are useful in identifying mushroom species. They can be obtained by cutting the stalk of a fresh specimen close to the gills, then laying the cap gill-side down on white paper for a few hours at room temperature. The initial color seen after removal of the gills is used for identification. With drying the color may fade or change. Additional information about spores can be acquired by staining with Melzer's reagent (a solution of iodine and chloral hydrate). Spores that stain blue are called *amyloid*, indicating the presence of starch. This technique may be particularly useful in spore identification from gastric aspirates. The spores of *Amanita* species are amyloid. Thin-layer chromatography of spores is a more accurate aid to identification.

Mushrooms contain approximately 90% water and 3% proteins and other nitrogen-containing compounds. The remainder is largely carbohydrate, fat, and a few vitamins. Nutritionally unimpressive, mushrooms are consumed in great quantities, primarily for their taste and texture. Wild mushrooms have the additional allure of being free. Of the many varieties of wild mushrooms, few are deadly or cause serious pathophysiologic derangement.

Figure 49-2 Mushroom gill types.

1143

Figure 49-3 Death cap (*Amanita phalloides*).

Figure 49-4 Shiitake mushroom.

Many immigrants fail to realize that the nontoxic mushrooms from their native lands have toxic look-alikes in America. This has been particularly true of Southeast Asian immigrants, who are attracted to the large *Amanita* species. Entire families have been poisoned, with many fatalities. The Russian roulette played by mushroom foragers is statistically safe. Some self-proclaimed experts are simply lucky; occasionally, they are not.

NONTOXIC MUSHROOMS

The most common commercially available mushroom in the United States is *Agaricus bisporus*. It is cultivated in abandoned mine shafts and caves. This small white mushroom with dark gills is often picked before the gills are fully exposed. Although the mushroom is considered nontoxic, hypersensitivity reactions and gastrointestinal (GI) symptoms have been reported. Researchers have tried to link carcinogenesis to *A. bisporus*.^[78]^[97] Although tumors of the bone (osteomas, osteosarcomas) and stomach (papillomas, carcinomas) develop in mice fed large amounts of uncooked mushrooms, no direct link exists between human ingestions and cancer.^[96]

Figure 49-5 *Cantharellus cibarius*.

A. bisporus can also be found in the wild. *Agaricus* species may be confused with the deadly *Amanita* species, as well as some *Agaricus* species that cause GI irritation.

Nontoxic mushrooms may carry environmental toxins, such as heavy metals and pesticides. Mushrooms with high lead concentrations have been gathered near highways.^[35] High mercury concentrations are found in mushrooms from industrial sites.^[18]^[35] Human toxicity has not been reported.

Mushrooms may cause allergic reactions. Acute anaphylaxis from mushroom ingestion is rare, despite the presence of haptens capable of inciting an allergic response.^[56] More often, symptoms develop from inhalation of spores.^[72] Victims may present with anaphylaxis or more often with chronic hypersensitivity pneumonitis. Hypersensitivity reactions are described in workers exposed to cultivation of *A. bisporus* (the most popular commercially grown mushroom in America)^[63] and shiitake (*Lentinus edodes*), the popular Japanese mushroom ([Figure 49-4](#)).^[85] Asthma symptoms developed in nearly 10% of shiitake-exposed workers. In one study, all workers had positive skin and inhalation challenge tests.^[91] Spore counts correlate with asthma symptoms.

GI symptoms after ingestion of mushrooms may not be caused by toxins. Bacterial food poisoning may occur in foods that coincidentally contain mushrooms. Small bowel obstruction occurred in a person who consumed 500 g of the edible mushroom *Cantharellus cibarius* (chanterelle) ([Figure 49-5](#)).^[36] This was largely a result of poor

mastication, since entire mushrooms were recovered from the victim's intestines.

Most wild mushrooms are nontoxic, and many are delicious. Morels (*Morchella esculenta*, *M. deliciosa*) are highly prized delicacies. Chanterelles (*C. cibarius*) and several species of *Boletus* are particularly tasty. The chicken mushroom (*Laetiporus sulphureus*) often replaces chicken in Chinese dishes ([Figure 49-6](#)).

1144

Figure 49-6 *Laetiporus sulphureus*.

GASTROINTESTINAL TOXINS

Most toxic mushrooms fall into the group of GI irritants. This large, heterogenous group of mushrooms causes GI distress—nausea, vomiting, and diarrhea—beginning 1 to 2 hours after ingestion and resolving in 6 to 12 hours. Even *A. bisporus*, the common cultivated mushroom, may cause brief gastroenteritis in some individuals.^[92]

Causative Mushrooms

A large number of unrelated mushrooms cause GI symptoms with varying host response ([Box 49-1](#)). *Chlorophyllum molybdites*, also known as *Lepiota morgani*, is the most frequently reported toxic mushroom

1145

ingested in America (Figure 49-9 (Figure Not Available)).^{[14] [99]} Most persons who ingest *C. molybdites* confuse it with *A. bisporus*, which it closely resembles. The common name for *C. molybdites*, green-spored parasol, describes the characteristics of this summer mushroom. The whitish cap is large, 10 to 40 cm (4 to 16 inches), initially smooth and round, and becomes convex with maturity. Tan or brown warts may be present. The gills are free from the stalk, initially white to yellow, and become green with maturity. The stalk is 5 to 25 cm long, smooth, and white. The ring is generally brown on the underside. Spores are green. The mushroom is common in most of eastern and southern North America and in California. In southern California it is a common lawn mushroom.

Figure 49-8 *Scleroderma*.

Another common mushroom causing GI symptoms is the jack-o'-lantern (Figure 49-10 (Figure Not Available)). The botanical classification is not completely settled. Most often it is referred to as *Omphalotus illudens*, *O. olearius*, or *O. olivascens*. It is a bright orange-yellow mushroom with sharp-edged gills and often grows in clusters at the base of stumps or on buried roots of deciduous trees. The cap is 4 to 16 cm in diameter on a stalk that is 4 to 20 cm long. Gills are olive to orange, with white to yellow spores. The mushroom shows characteristic luminescence lasting 40 to 50 hours after collection. Members of this family are found in both eastern and western North America, generally in autumn and early spring. They may be mistaken for the edible species *Cantharellus cibarius*. Some European reports have documented hepatic impairment and muscarinic effect after ingestion. ^[64] ^[65] It is not clear whether the mushroom and its toxins are the same on both sides of the Atlantic. ^[3]

Figure 49-9 (Figure Not Available) *Chlorophyllum molybdites*, gastrointestinal irritant. (From Phillips R: *Mushrooms of North America*, Boston, 1991, Little, Brown.)

Figure 49-10 (Figure Not Available) *Omphalotus olearius* (jack-o'-lantern mushroom), gastrointestinal irritant. (From Phillips R: *Mushrooms of North America*, Boston, 1991, Little, Brown.)

Although the genus *Amanita* is most famous for its deadly member *A. phalloides*, the genus also contains tasty nontoxic mushrooms (*A. caesarea*, *A. calyptрата*, *A. velosa*). Several *Amanita* species cause GI symptoms indistinguishable from those caused by jack-o'-lantern mushrooms or *Chlorophyllum molybdites*. *A. brunnescens* and *A. flavorubescens* are frequently listed as containing GI toxins, although they are occasionally listed as edible. These mushrooms resemble *A. rubescens* ("the blusher") ([Figure 49-11](#)). Both have broad yellowish to brown caps (3 to 15 cm) with loosely attached warts. The stalks are 3 to 18 cm long, enlarging toward the base with a

superior ring. *A. brunnescens* stains reddish brown when bruised. As with their edible cousins, these mushrooms are found in summer or fall associated with hardwoods or conifers.

Several members of the genus *Agaricus*, particularly *A. alboluteus*, *A. silvaticus*, and *A. xanthodermus*, can cause GI symptoms. They resemble the cultivated mushrooms in grocery stores and are found in meadows and lawns in the summer and autumn. [Table 49-1](#) lists the look-alike toxic and nontoxic mushrooms in this group.

Figure 49-11 *Amanita rubescens*.

Toxins

A variety of toxins have been extracted from these mushrooms, although the structures are poorly described. Most are protein based and heat labile, although toxicity may not be completely eliminated with cooking. In some cases the toxin may be destroyed by heating, parboiling, or even preserving in salt. Host response to a toxin varies; some persons can eat such mushrooms without harm, whereas others become quite ill. Some mushrooms also contain hemolysins and toxins that cause hemorrhage and hepatitis in

animals.^[57] ^[95] Human hemolysis has not been reported.^[57]

Clinical Presentation

Within 1 to 2 hours of ingestion of these mushrooms, nausea, vomiting, intestinal cramping, and diarrhea develop. Stools are usually watery and occasionally bloody with fecal leukocytes. Chills, headaches, and myalgias may occur. Symptoms remit spontaneously in 6 to 12 hours. Most victims require only electrolytes and fluid replacement. The few serious cases reported in the literature have been associated with severe dehydration. In a review of 106 cases, all victims responded well to electrolyte replacement and occasional antiemetic or antidiarrheal medications.^[19] Admitted patients were discharged in an average of 2 days.

Persons whose symptoms are delayed (beginning 4 hours or more after ingestion) probably have ingested a more toxic mushroom possibly *Amanita*, *Galerina*, *Lepiota*, or *Gyromitra*. These persons have severe GI distress and may develop hepatic failure. Most mushroom fatalities occur from ingestion of these mushrooms.

Recent reports of ingestion of jack-o'-lantern mushrooms describe mildly elevated liver transaminases.^[101] Cases of metabolic acidosis and dehydration, and even death are attributed to *Chlorophyllum molybdites*.^[14] ^[94]

1147

Treatment

Treatment is largely supportive and does not depend on the type of mushroom ingested. Intravenous (IV) fluid and electrolyte replacement may be required. In a severe case an antiemetic such as prochlorperazine, 5 mg IV or 10 mg intramuscularly (IM), may prevent further emesis. Antidiarrheals are generally withheld unless diarrhea is prolonged or severe. Activated charcoal (1 g/kg) can be given orally or through a nasogastric tube, although no evidence shows that it decreases toxicity.

Care should be taken not to dismiss early GI symptoms when several types of unknown mushrooms have been ingested. Individuals may ingest both GI-irritant mushrooms *and* mushrooms containing serious toxins. Persons with prolonged gastroenteritis from unidentified mushrooms should be observed for delayed hepatic damage. Special efforts should be made to identify the ingested mushrooms.

DISULFIRAM-LIKE TOXINS

A fascinating toxicity is caused by some members of the *Coprinus* genus, known as "inky caps" ([Figure 49-12](#)). Individuals who ingest these mushrooms and subsequently ingest alcohol have symptoms similar to those of an alcohol-disulfiram (Antabuse) reaction.

Causative Mushrooms

Several members of the *Coprinus* genus may contain disulfiram-like toxins ([Box 49-2](#)), but symptoms are most common with *C. atramentarius*. The mushroom has a 2- to 8-cm cylindrical cap on a thin 4- to 5-cm stalk. The cap is white, occasionally orange or yellow at the top. The mature cap often develops cracks, which turn up at its margins. The cap blackens as it matures and then liquefies ("inky cap"). A ring may be present low on the stalk. Spores are black. *C. atramentarius* grows throughout North America in clusters of three or more in grass or wood debris. It often appears overnight after a rain. Several members of the *Coprinus* genus are edible, including *C. comatus* ("shaggy mane"). All members of this genus are edible if no alcohol is ingested for the next 72 hours.

OR REPORTED TO CAUSE
ALCOHOL-DISULFIRAM REACTION**

Clitocybe clavipes

Coprinus atramentarius

Coprinus comatus

Coprinus insignis

Coprinus micaceus

Toxin

Mushrooms causing a disulfiram reaction contain the toxin coprine, isolated from the mushroom *C. atramentarius* in 1975. [45] Coprine is distinct from disulfiram and is most likely a derivative of glutamine. It probably is not present in the raw mushroom but rather is a hydrolyte created during cooking. [59]

Coprine (or its derivative L-aminocyclopropranol) inhibits acetaldehyde dehydrogenase, similar to the action of disulfiram. Acetaldehyde accumulates, leading to β -adrenergic stimulation and the typical vasomotor response of flushing, diaphoresis, headache, tachycardia, nausea, and vomiting. Some authors believe that coprine is a relatively poor inhibitor of acetaldehyde dehydrogenase and suggest that symptoms result from altered neurotransmitter levels. [74]

Clinical Presentation

A history of wild mushroom ingestion within days before symptoms is rarely offered. Ingestion of the mushroom imparts sensitivity to alcohol, which begins 2 to 6 hours after ingestion and may last up to 72 hours. Within 15 to 30 minutes of subsequent alcohol ingestion the victim experiences severe headache, flushing, and tachycardia. Hyperventilation, shortness of breath, and palpitations may occur. Chest pain and orthostatic hypotension occur in more severe cases. Symptoms can be confused with an allergic reaction or acute myocardial infarction. Symptoms resolve spontaneously within 3 to 6 hours.

Figure 49-12 *Coprinus mushroom*.

Treatment

Supportive and symptomatic treatments are suggested. Baseline laboratory tests (blood urea nitrogen [BUN], creatinine, electrolytes, glucose) should be drawn. Urine output should be monitored. IV fluids should be given to keep urine output at 50 ml/hr (in children 1 ml/kg/hr). Activated charcoal is not beneficial. Charcoal does not adsorb alcohol; coprine has already been absorbed by the time the reaction occurs. Hypotension generally responds to IV fluid administration. Severe hypotension

refractory to fluid replacement should be treated with norepinephrine (initially 4 to 8 $\mu\text{g}/\text{min}$; 1 to 2 $\mu\text{g}/\text{min}$ in children and increased as necessary) rather than an indirect vasopressor, since norepinephrine stores are depleted in a true disulfiram reaction. Propranolol (0.5 to 3 mg IV; 0.01 to 0.02 mg/kg IV up to 1 mg in children) has been suggested for the treatment of supraventricular tachycardia. Propranolol may be repeated as needed after 5 to 10 minutes.

NEUROLOGIC TOXINS

Muscarine

Muscarine was first isolated from the mushroom *Amanita muscaria* more than 150 years ago. A classic muscarinic reaction includes salivation, lacrimation, urination, diaphoresis, GI upset, and emesis (SLUDGE syndrome). Buddhist adepts may have used *A. muscaria* to achieve enlightenment.^[42]

Causative Mushrooms.

Amanita muscaria has a cap 5 to 30 cm in diameter that is scarlet red with white warts ([Figure 49-13](#)). The stalk tapers upward and is white, often hollow, and grows 15 to 20 cm in length. It has a prominent cup and vulva and numerous rings. Gills are free and white, as are spores. The mushrooms grow in eastern North America and throughout much of the western United States, often near *Boletus edulis*. They grow under hardwoods and conifers from spring to autumn.

Figure 49-13 *Amanita muscaria*.

Potentially toxic amounts of muscarine are found in some members of the *Inocybe* and *Clitocybe* families ([Table 49-2](#) and [Box 49-3](#)). The *Inocybe* family contains small brown mushrooms with conical caps up to 6 cm in diameter (Figure 49-14 (Figure Not Available)). Stalks are 2 to 10 cm long, covered with fine, brown to white hairs. Gills are brown and notched; spores are brown. They are found typically under hardwoods and conifers in the summer and fall. All members of this family are considered poisonous.

Figure 49-14 (Figure Not Available) *Inocybe cookei*, which contains muscarinic toxins. (From Phillips R: *Mushrooms of North America, Boston, 1991, Little, Brown.*)

1149

In contrast, many members of the *Clitocybe* family are edible. *Clitocybe* mushrooms are whitish tan to gray mushrooms with caps 15 to 33 mm long on hairless stalks 1 to 5 cm long. Gills are decurrent (run down the stalk), and spores are white. They are usually single specimens (not clustered) found on lawns in summer and fall.

Many *Inocybe* and *Clitocybe* mushrooms contain larger concentrations of muscarine than does *A. muscaria*.^[13] Other toxins (e.g., ibotenic acid) are present in *A. muscaria*, and contribute to its toxicity.

Toxin.

Muscarine is a quaternary trimethyl ammonium salt of 2-methyl-3-oxy-5-(amino)tetrahydrofuran. Muscarine stimulates postganglionic cholinergic receptors (muscarinic receptors), mimicking the action of acetylcholine. Muscarine stimulation of the GI tract leads to increased secretory activity, contraction amplitude, and peristalsis. Stimulation of the urinary tract leads to bladder contraction and increased peristalsis of the ureters. Stimulation of secretory tissue leads to salivation and lacrimation. Bronchoconstriction, flushing, and diaphoresis result from additional stimulation of bronchial and vascular tissues. Cardiac effects include reflex tachycardia, or more often bradycardia, and decreased atrioventricular conduction. Central nervous system (CNS) effects include headache, ataxia, and visual disturbances. The sensorium is generally not affected (except in ingestion of *A. muscaria*, which contains other CNS toxins).

Clinical Presentation.

Symptoms develop within 15 to 30 minutes after ingestion of muscarine-containing mushrooms. Typical symptoms include salivation, urination, lacrimation, diarrhea, diaphoresis, abdominal pain, nausea, and emesis. Bradycardia, bronchospasm, and constricted pupils are also noted. Copious bronchial secretions may cause respiratory failure requiring mechanical ventilation.

Symptoms remit spontaneously in 6 to 24 hours. In Europe, some deaths are reported from *Inocybe patouillardii*.^[59] Although this mushroom is rarely eaten, ingestion carries a mortality rate of 6% to 12%, particularly among persons with preexisting pulmonary or cardiac disease. Most deaths occur within the first 12 hours as a result of respiratory

failure or cardiovascular collapse.

Treatment.

Many victims require supportive care with oxygen, suctioning, and IV fluid replacement. Activated charcoal and cathartics are rarely given because of the prominent emesis and diarrhea. Atropine is a muscarine antagonist but should be used only to control secretions or profound bradycardia. It should not be given prophylactically because it may worsen the CNS effects induced by *A. muscaria*. Atropine (0.01 mg/kg IV for children, 1 mg IV for adults) can be repeated as needed until secretions are manageable. Symptoms resolve spontaneously within 24 hours.

Isoxazole Reactions

The isoxazole derivatives ibotenic acid and muscimol produce CNS symptoms, including excitement and alteration in visual perception.

Causative Mushrooms.

Several mushrooms contain ibotenic acid ([Table 49-3](#) and [Box 49-4](#)). *Amanita muscaria* is described previously. *Amanita pantherina* is 5 to 15 cm long with a cap 5 to 15 cm in diameter (Figure 49-15 (Figure Not Available)). The cap is generally white to pink in the young specimen but becomes reddish brown or brown, often darker at the rim, with maturity. Fragments of the universal veil form warts on the cap but may be washed

off by rain. The stalk has a distinct ring, with a vulva and cup at the bottom. When the flesh is cut or injured (e.g., by insect larvae), it develops a pinkish tinge. Gills are free and produce white spores. The raw mushroom has little smell and tastes very much like a raw potato. It grows from June to November in woodlands throughout North America.

OR SUSPECTED TO CONTAIN
IBOTENIC ACID, MUSCIMOL, AND
RELATED COMPOUNDS**

Amanita cokeri

Amanita gemmata

Amanita muscaria

Amanita pantherina

Panaeolus campanulatus

Tricholoma muscarium

Toxin.

Ibotenic acid is found in the bright-red cap of *A. muscaria* and undergoes decarboxylation during drying to form muscimol, the more toxic of the compounds. The potency of the cap remains high for up to 7 years despite drying.^[58] *A. muscaria* contains 0.17% to 1% isoxazole derivatives, whereas *A. pantherina* contains only 0.02% to 0.53%^[44] and tends to lose potency with storage. Muscimol is a γ -aminobutyric acid (GABA) receptor agonist.^[48] Muscimol increases CNS serotonin levels and decreases catecholamine levels. Ibotenic acid is a neurotransmitter agonist.

Clinical Presentation.

Ingestion of 10 mg of *A. muscaria* produces mild intoxication, dizziness, and ataxia. Ingestion of 15 mg leads to pronounced ataxia and visual disturbances.^[44] ^[69] Delirium or manic behavior may develop after large ingestions. Physical activity is accelerated with inability to judge size. Visual hallucinations, seizures, and muscle twitching are common.^[8] Some victims complain of residual headache.

Symptoms begin within 30 minutes of ingestion and generally last 2 hours. Rare fatalities have been reported. Some victims had ataxia and paralysis of ocular convergence.^[37] In rare cases, symptoms last as long as 48 hours, depending on the dosage and individual host effect. In animals, short-acting hypnotics are potentiated by muscimol.^[44] Phenobarbital or diazepam administered to treat *A. muscaria* ingestion may lead to unexpected apnea, flaccid paralysis, or both.

Treatment.

Treatment consists of supportive care. Emesis caused by the toxin is unusual. Gastric emptying and charcoal administration are difficult to initiate because of the CNS disturbances and have no proven effectiveness. Appropriate sedation with IV phenobarbital (30 mg hourly, 0.5 mg/kg in children) or IV diazepam (5 mg every 10 to 15 minutes in adults as needed, 0.1 to 0.3 mg/kg in children) is often necessary but requires caution. Airway support and ventilatory assistance should be immediately available. Atropine may worsen the CNS symptoms associated with isoxazole derivatives and therefore should be withheld unless the muscarinic effects are serious.

Hallucinogenic Mushrooms

Perhaps the most sought after mushrooms are "magic mushrooms," which are available in the wild and as spores available through mail-order catalogs. These mushrooms have been used for centuries because of their hallucinogenic effects. Small stone mushroom icons believed to be 3500 years old were found in Meso-American ruins.^[59] Recently, honey laced with *Psilocybe cubensis* was confiscated at the Dutch-German border. Honey with *Psilocybe* can be purchased at Dutch coffee shops.^[9]

Causative Mushrooms.

The most common hallucinogenic mushrooms are members of the *Psilocybe* family ([Table 49-4](#) and [Box 49-5](#)). This family includes more than 100 species, not all of which cause hallucinations ([Figure 49-16](#)). These are "little brown mushrooms" (LBMs). The cap is 0.5 to 4 cm in diameter (depending on the species), is usually smooth, and becomes sticky or slippery when wet. The stalk is slender and 4 to 15 cm long. Gills are gray to purple gray; spores are dark, nearly black. The flesh of these mushrooms turns blue or greenish when bruised or cut. The mushrooms are often mistaken for more poisonous species (e.g., *Galerina*, *Inocybe*). These mushrooms also resemble *Agaricus bisporus*. Regular grocery store mushrooms laced with lysergic acid diethylamide (LSD) or other hallucinogens are sold on the street as *Psilocybe*. Hallucinogenic mushrooms grow in a variety of habitats and are found throughout the world.

Other mushrooms, including members of the *Panaeolus* and *Gymnopilus* genera, may contain psilocybin. *Panaeolus* mushrooms are also LBMs about the same size as *Psilocybe*. Gills are dark gray or black with black spores. They also grow on dung throughout the tropics and subtropics of North America. Unlike *Psilocybe*, their caps do not become sticky or slippery when wet. The hallucinogenic effect and quantity of toxin vary among *Panaeolus* species.

Some *Gymnopilus* species (e.g., *G. aeruginosus*) contain hallucinogens. These medium-sized mushrooms (cap, 5 to 15 cm; stalk, 5 to 12 cm) are variable in color (green, yellow, salmon, red) with yellowish gills and rusty spores. They grow on stumps or sawdust in the Pacific Northwest.

Visual hallucinations and ataxia were reported in a person ingesting *Laetiporus sulphureus*, previously thought to be harmless. ^[4] It is not clear whether this mushroom contained hallucinogenic material or the individual ingested an additional mushroom as well.

Toxin.

Psilocybin and its somewhat unstable metabolite psilocin are indole compounds derived from tryptamine. These two toxins were first isolated by Albert Hofmann, ^[46] known as the father of LSD. Chemically the toxins resemble 5-hydroxytryptamine and LSD and have similar effects. They maintain their potency in dried specimens.

| *Coprinus* spp.

Figure 49-16 *Psilocybe caerulipes*.

Psilocybin, as well as LSD, inhibits the firing rate of serotonin-dependent neurons, particularly at the presynaptic receptors. It induces a strange euphoria, hallucinations, and a loss of time sensation. Many of these symptoms are similar to those seen with LSD. Some species contain phenylethylamine, which may be responsible for tachycardia and other adverse reactions.^[6] In human volunteer studies, peak plasma levels were reached at 105 minutes.^[43]

Clinical Presentation.

Ingestion of 5 mg of psilocybin (10 mg of fresh *P. cubensis*) causes moderate euphoria. Ingestion of 10 mg leads to hallucinations and a loss of time sensation. Heightened imagination occurs within 15 to 30 minutes of ingestion. Hallucinations may last for 4 to 6 hours. Serious side effects are rarely seen, but fever and seizures have been reported in children.^[68] Up to 50% of victims have tachycardia and hypertension.^[77] A case resulting in myocardial infarction has been reported.^[10] Flashbacks have been reported in some victims for up to 4 months after ingestion.^[7]

Treatment.

Initially the victim should be placed in a quiet, supportive environment. Gastric emptying and activated charcoal administration are often impossible and may only enhance the hallucinations, but should be considered in victims with very large ingestions who are brought for treatment early. Sedation can be accomplished when necessary with a benzodiazepine (diazepam, 0.1 mg/kg IV in children, 5 mg IV in adults, repeated every 5 minutes as needed), phenobarbital (0.5 mg/kg IV in children, 30 to 60 mg IV in adults, repeated every 10 minutes as needed), chlorpromazine (50 to 100 mg IM), or haloperidol (5 mg IM). Seizures can be controlled with diazepam in the doses just listed. Hyperpyrexia, seen primarily in

PROTOPLASMIC POISONS

Gyromitra Toxin

False morels (*Gyromitra esculenta*) were once thought to be edible. Even today they are collected, sold fresh, canned, and exported ("morchels") in eastern and central Europe.^[71] Since 1793 they have been suspected of causing toxicity and since World War II have been known to cause hepatic failure, neurologic symptoms, and death.^[41] Symptoms appear 4 to 50 hours (usually 5 to 12 hours) after ingestion, with timing similar to that of *Amanita phalloides* poisoning. Since *Gyromitra* grows primarily in the spring and *A. phalloides* in the fall, however, the identity of the two mushrooms is rarely confused.

Causative Mushrooms.

Gyromitra esculenta is approximately 5 to 16 cm in height with a reddish brown to dark-brown, irregularly shaped cap (Figure 49-17 (Figure Not Available)). The cap's surface is curved and folded, resembling a brain. The stalk is often as thick as the cap. The insides of the cap and stalk are hollow. This mushroom grows in the spring near pines and in sandy soil throughout North America. It is particularly common in Germany, Poland, and other eastern European countries. Mature species, particularly those with cap decay, may have increased

Figure 49-17 (Figure Not Available) *Gyromitra esculenta*, which contains the hepatotoxin gyromitrin. (From Phillips R: *Mushrooms of North America*, Boston, 1991, Little, Brown.)

toxicity. These mushrooms may be mistaken for morels, which are considered among the most delicious wild mushrooms ([Table 49-5](#)).

Other members of the *Gyromitra* family contain gyromitrins. None of these mushrooms has been reported to cause toxicity in humans.

Toxin.

Gyromitrin (*N*-methyl-*N*-formylhydrazine) was first isolated in 1967.^[61] This substance is moderately volatile and heat sensitive. Cooking thoroughly and discarding the cooking liquid may decrease or eliminate the toxin. Symptoms have occurred despite proper cooking.^[38]

Once gyromitrin enters the stomach, hydrolysis yields *N*-methyl-*N*-formylhydrazine

(MFH), which forms *N*-methylhydrazine or monomethylhydrazine (MH),^[72] a component of rocket fuel. Workers in rocket fuel plants exposed to volatile MH develop CNS toxicity and nephrotoxicity.^[54] ^[93] MH is a competitive inhibitor of pyridoxal phosphate, which interferes with enzyme systems requiring pyridoxine as a cofactor, including decarboxylases, deaminases, and transaminases.^[5] As a result, levels of GABA fall, interfering with neurotransmission.^[55] This may lead to altered mental status, seizures, or both. This widely accepted theory has been questioned, since MH may cause seizures without a change in brain GABA levels.^[67]

MFH and MH undergo oxidation in the liver to two highly reactive intermediates: a free methyl radical and an unstable diazonium compound.^[71] These substances appear to produce local hepatic necrosis by blocking the activity of cytochrome P₄₅₀ systems, glutathione, and other hepatic biomolecules.

Gyromitrin causes tumors in a variety of animals.^[98] There are significant concerns about long-term toxicity associated with repeated consumption of *G. esculenta*. Gyromitrin has been included in the list of naturally occurring carcinogens.^[51]

Each kilogram of fresh *G. esculenta* contains 3 to 100 mg of gyromitrin. Fresh mushrooms contain 50 to 300 mg of MH/kg and dried mushrooms up to 400 mg/kg.^[62] The human median lethal dose (LD₅₀) is suspected to be 20 to 50 mg/kg for adults and 10 to 30 mg/kg for children, or 0.4 to 1 kg of fresh mushrooms for an adult (average 30 mushrooms) and 0.2 to 0.6 kg for a child.^[71]

TABLE 49-5 -- Look-Alike of Mushroom Containing Gyromitrin

TOXIC SPECIES	EDIBLE SPECIES
<i>Gyromitra esculenta</i>	<i>Morchella esculenta</i>

Clinical Presentation.

Symptoms are generally delayed for 4 to 50 (average 5 to 12) hours after ingestion. Initial symptoms include nausea, vomiting, and severe diarrhea. Some victims may have dizziness, weakness, muscle cramps, and loss of muscle coordination. In a severe ingestion, delirium, seizures, and coma are present. Hepatic failure develops over several days after ingestion, although hepatic damage is generally mild. Hypoglycemia, hypovolemia, severe hepatic failure, and death may occur.

Symptoms from gyromitrin toxin, as with other mushroom toxins, depend on amount consumed, toxin concentration, nature of the mushrooms, and other factors. The variability of symptoms after ingestion of *Gyromitra* mushrooms is much greater than with other mushroom species. Some individuals can consume large quantities of

Gyromitra with few or no symptoms. A second meal by the same person may lead to severe toxicity. Repeated consumption may increase the risk of a severe reaction.^[15]

Several drugs, including isoniazid, hydralazine, and probably MH,^[16] are metabolized through acetylation of a hydrazine or amino group by the liver. Individuals vary greatly in the rapidity of acetylation. Two major human groups are termed fast and slow acetylators, with slow acetylation being an autosomal recessive trait. Slow acetylators in general have greater and more prolonged toxicity after ingestion of these drugs. Similar variation in fast and slow acetylators is seen when *Gyromitra* mushrooms are ingested.

Treatment.

Symptoms develop several hours after *Gyromitra* ingestion. Activated charcoal (1 g/kg orally or via gastric tube) is often given but, as with gastric emptying, is of little value. Pyridoxine has been useful in victims with neurologic disorders from MH toxicity and is of theoretic benefit in victims of gyromitrin toxicity. High-dose pyridoxine therapy may cause peripheral neuropathies.^[4] Persons who ingest *Gyromitra* mushrooms and develop significant neurologic symptoms should receive pyridoxine (25 mg/kg, up to 20 kg/day, orally).^{[54] [108]} No evidence indicates that pyridoxine alters the course of hepatic disease.

Baseline measurements of alanine and aspartate transaminases (ALT, AST), prothrombin time (PT), partial thromboplastin time (PTT), BUN, creatinine, complete blood cell count (CBC), platelet count, glucose, and electrolytes should be performed. ALT/AST, PT, PTT, BUN, and creatinine should be monitored at least daily for 3 to 4 days for the development of hepatic failure. Rapid deterioration of liver function (ALT/AST levels of greater than 2000 IU, PTT > 50 secs) indicates immediate transfer to a tertiary center with transplant capability. Persons with significant hepatic failure may require monitoring of blood glucose every 2 to 4 hours and supplemental glucose administration for symptomatic hypoglycemia.

No specific antidote or treatment is available for fulminant hepatic failure. The appropriate timing or necessity of liver transplantation is uncertain. In persons with fulminant hepatic failure from infectious causes, prolonged PT (unresponsive to fresh-frozen plasma) and development of hepatorenal syndrome, grade II hepatic encephalopathy, hypoglycemia, and uncorrectable metabolic acidosis are used as signs that transplantation is needed on an emergent basis. Persons with fulminant hepatic failure from toxic ingestion, elevated bilirubin level, and young age are important indicators of a poor prognosis.^{[32] [75]} Mortality from gyromitrin poisoning is reported to be 15% to 35%.^{[33] [76]}

Renal Toxicity

Although originally thought to be an edible mushroom, *Cortinarius orellanus* was associated with 81 cases of renal toxicity in the 1950s.^[40] This led to isolation of the toxin orellanine, which is found in the mushrooms *C. orellanus*, *C. speciosissimus*, and

C. gentilis. Most cases occur in Europe and Japan.

Causative Mushroom.

C. orellanus has a small, brown to brownish red, smooth cap 30 to 80 cm in diameter. The stalk is somewhat yellow, often darker toward the soil. Gills are orange to rust with rust-colored spores. It grows in deciduous woods, most often in sandy soil underneath oaks and birches. It is ubiquitous throughout Europe. Other *Cortinarius* species are found in the United States and may be toxic ([Box 49-6](#)).

Toxin.

The two toxins isolated from *C. orellanus*, orellanine and orelline, are structurally related to paraquat and diquat. Their mechanism of action remains a mystery. These are heat-stable compounds, unaffected by cooking. The toxin appears to cause intense interstitial nephritis with early fibrosis.^[47]

Amanita smithiana, which contains the nephrotoxins norleucine (aminohexadrenoic acid) and chlorocrotylglycine,

1154

grows in the Pacific Northwest and may be mistaken for pine mushrooms.^[104] *Amanita proxima* is found in France and also causes renal failure.^[17]

Cortinarius venenosus

Clinical Presentation.

Persons who ingest *C. orellanus* are generally asymptomatic for 2 to 20 days. After this latent period, acute renal failure develops. Some persons develop neurologic changes, including paresthesias, taste impairment, and cognitive disorders.

Symptoms vary greatly. One case report described 26 soldiers who ate soup made of *C. orellanus* in nearly identical quantities.^[11] Acute renal failure developed in 12 on or about day 11. Eight soldiers later recovered normal renal function, whereas four required long-term dialysis or kidney transplantation. The other 14 soldiers showed no rise in BUN or creatinine levels but developed leukocyturia and hematuria that persisted for more than 1 month. Renal failure reportedly occurs in 30% to 46% of persons who ingest these mushrooms and become ill. Renal function returns in 46% to 66% of victims.

Renal biopsy in patients with orellanine-induced renal failure shows tubule lesions with epithelial necrosis and disruption of the tubular basement membrane. These biopsy changes may persist for up to 3 months.^[11]

Treatment.

In most persons who ingest renally toxic mushrooms, unexplained acute renal failure develops many days later. If a person presents early after eating orellanine-containing mushrooms, gastric emptying and activated charcoal administration (1 g/kg orally or via gastric tube) might prevent some absorption, decreasing the resultant toxicity. Early presentation, however, is rare.

Once acute renal failure develops, baseline and repeated monitoring of BUN, creatinine, electrolytes, CBC, differential, and urinalysis should be performed to monitor renal function. Urine output should be monitored, and if it decreases, fluid administration should be used to achieve optimal hydration. Serum potassium, calcium, and magnesium should be monitored closely. If renal failure progresses, the victim should be transferred to a facility for hemodialysis and possible renal transplantation. Renal function may return to normal after months of dialysis dependency. Steroids seem to have no effect on the course of the disease, but they may have been given too late.

Amatoxin

The mushrooms that contain amatoxins are responsible for 90% to 95% of fatalities caused by mushrooms ([Table 49-6](#) and [Box 49-7](#)). *A. phalloides* is most common in central and eastern Europe; immigrants to the U.S. may have carried mushroom spores in wood products

Causative Mushrooms.

The common names of *A. phalloides* (see [Figure 49-3](#)) and its relatives *A. verna* and *A. virosa* are death cap, death angel, and destroying angel, reflecting their association with fatal outcome. *A. phalloides* has a white to greenish cap 4 to 16 cm in diameter, often with remnants of the veil (warts). The stalk is generally thick, 5 to 18 cm long, with a large bulb at the base, often with a vulva or cup. A thin ring is usually present on the stalk. Gills are generally free and white to green in color; spores are white. The mushrooms grow under deciduous trees in the autumn.

A. virosa is more common in the United States (Figure 49-18 (Figure Not Available)). It resembles *A. phalloides*, but the cap is more yellow or white. *A. verna* is characteristically white. All grow in deciduous woods. Even mushroom experts have been tempted by the large white mushroom, which is tasty. The fatality rate, however, is

35% in adults and 50% in children.

Some *Lepiota* mushrooms, including *L. castanea* and *L. jasserandii*, contain high concentrations of amatoxin. Human toxicity has been reported.

Mushrooms that contain amatoxin may have a positive Meixner test. This test was first described by Wieland in 1949^[107] and popularized by Meixner.^[70] A drop of liquid is expressed from a fresh mushroom onto print-free (ligand-free) newspaper and allowed to dry. A drop of concentrated (10 to 12 N) hydrochloric acid is added. A blue color develops within 1 to 2 minutes in the presence of amatoxins. Control tests on newspaper without mushroom juice and paper containing

1155

Figure 49-18 (Figure Not Available) *Amanita virosa*, which causes delayed hepatotoxicity. (From Phillips R: *Mushrooms of North America, Boston, 1991, Little, Brown.*)

ligand should be conducted. False-positive results are common and can be elicited from excessive drying temperatures (greater than 63° C [145° F]) or exposure to sunlight. False-positive tests also occur from mushrooms containing psilocybin, terpenes, and bufotenin. Nearly 20% of gilled mushrooms that did not contain amatoxins tested positive in one study,^[90] placing the usefulness of this technique in doubt. Thinlayer chromatography (TLC) more accurately identifies the presence of amatoxin and can be done on mushroom liquid, human serum, or urine.^[81] Radioimmunoassay (RIA) of serum or urine can detect amatoxins in the body.

Toxin.

The mushroom *A. phalloides* contains two groups of toxins: amatoxins and phallotoxins. Each group contains several toxins. There are now eight identified amatoxins: α -amanitin, β -amanitin, γ -amanitin, ϵ -amanitin, amanin, amaninamide, amanullinic acid, and amanullin.^[103] ^[105] Of these, α -amanitin is thought to be primarily responsible for human disease. α -Amanitin injected into animals produces hepatic toxicity characteristic of human ingestion of *A. phalloides*. Phallotoxins include phalloidin, phalloin, phallisin, phallacidin, phallacin, phallisacin, and prophalloin.^[103] Phalloidin is the primary phallotoxin. Phallotoxins bind to F-actin, disrupting plasma membranes and causing massive efflux of calcium and potassium. Phallotoxins cause death in animals within 2 hours but are not believed to play a role in human toxicity.^[34] Humans may not even absorb these toxins, which may be responsible for local gastric irritation. *A. virosa* contains amatoxins and virotoxins. Virotoxins resemble phallotoxins biochemically, and also bind F-actin and cause death within a few hours. Six different virotoxins have been isolated, but none is thought to play a role in human *Amanita* hepatotoxicity.^[105]

After ingestion, amatoxins are absorbed from the gut and actively transported into the liver through transport systems shared by bile acids and xenobiotics.^[106] α -Amanitin is rapidly cleared from plasma.^[52] Amatoxins are not protein bound. They bind to

ribonucleic acid (RNA) polymerase II and inhibit the formation of messenger RNA (mRNA).^[60] This in turn inhibits transcription as the reservoir of RNA is depleted.^[25] Amatoxins are excreted into the bile, where they are reabsorbed and once again transported into the liver.^[12] Interruption of this enterohepatic circulation may be an important therapeutic tool.

Within the liver, a-amanitin may undergo some metabolism through the cytochrome P₄₅₀ system. Animal studies suggest that a more toxic metabolite is produced through this metabolism.^[87] ^[89] Nuclear fragmentation and condensation of chromosomal material have been observed within 15 hours of injection.^[24] Glycogen is rapidly depleted, and fatty degeneration occurs within the liver parenchymal cells.^[20] Mitochondria become swollen, and microvesicles appear throughout the cytoplasm.^[76] Direct renal toxicity may occur, but renal failure (10% of cases) is more likely to be caused by hepatorenal syndrome.

Clinical Presentation.

Persons who ingest *A. phalloides* feel well for 4 to 16 hours. Severe nausea, vomiting, abdominal cramps, and diarrhea follow this characteristic latent period. Early complications include fluid and electrolyte imbalance (hypoglycemia, hypokalemia, elevated BUN). Persons in whom symptoms develop earlier (4 to 10 hours) are more likely to experience severe hepatotoxicity. Over the next 12 to 24 hours the victim's GI symptoms abate. The second latent period is followed by hepatic failure, which develops 48 to 72 hours after ingestion in most victims. Hepatic failure may be of varying severity; it is frequently worse in children and depends minimally on the amount of mushroom ingested.

Children have greater toxicity and higher mortality, perhaps because of the relative quantity of mushrooms ingested or the varying metabolism in young children (differing levels of P₄₅₀-metabolizing enzymes). Previous experiments showed that concurrent ethanol with *A. phalloides* ingestion (whole mushroom lyophilized) decreased hepatotoxicity.^[30] Therefore decreased toxicity in adults could result from ingestion of ethanol with an *Amanita* mushroom dinner. More recently, however, ethanol failed to alter hepatotoxicity in an animal model poisoned with a-amanitin, which raises doubts about this explanation for increased toxicity in children.^[86]

In addition to hepatic failure, endocrinopathies may develop, with hypocalcemia, decreased thyroid function, and elevated insulin levels in the presence of hypoglycemia.^[53] Hypocalcemia may be caused in part by loss of calcium through diarrhea or may be a direct effect

on osteoclasts. Renal failure may contribute to hypocalcemia. The thyroid abnormalities probably result from decreased hormone synthesis caused by overwhelming illness and

blocked peripheral conversion of thyroxine (T_4) to triiodothyronine (T_3).

Thyroid-stimulating hormone (TSH) depression may result from decreased synthesis caused by the inhibition of RNA polymerase II by amatoxin. Hypothyroidism has not been clinically significant. Hypoglycemia is probably the result of several processes, including impaired hepatic gluconeogenesis, increased insulin release from the initial hyperglycemia, or tissue destruction of the pancreas.^[53] Bone marrow toxicity with decreased neutrophils, lymphocytes, and platelets has been noted.^[84] Disseminated intravascular coagulation and coagulopathies secondary to hepatic dysfunction are common.^[84] Pancreatitis occurs in up to 50% of patients.^[28] Hypophosphatemia is particularly common in children, for unknown reasons. Myopathy has been associated with *Amanita* toxicity.^[39]

Hepatic biopsy shows diffuse and severe steatosis with periportal inflammation and necrosis. Extremely high levels of hepatic enzymes are seen. ALT/AST level is not helpful in predicting the victim's prognosis. A precipitous drop may occur just before death.

Treatment.

Attempts to treat *A. phalloides* poisoning have ranged from scientific to purely empiric. Noting that rabbits were able to eat the *A. phalloides* mushroom with impunity, clinicians fed ground raw rabbit to victims of *Amanita* poisoning, without success.^[100] Hemodialysis was long recommended but has been shown to be ineffective, since the toxin is rapidly cleared. Amatoxin is taken up in liver cells within 5 hours after IV administration.^[22] In a retrospective study of 205 cases of amatoxin ingestion,^[32] hemodialysis worsened the prognosis, and charcoal hemoperfusion did not improve outcome. Plasmapheresis appears to be ineffective for similar reasons.^[80]

Amatoxins are enterohepatically circulated. Attempts have been made to divert the enterohepatic circulation. Although animal studies showed some benefit with this treatment,^[23] it is not recommended. Multidose activated charcoal (1 g/kg orally or via gastric tube, 15 to 20 g every 4 to 8 hours with a cathartic given every second or third dose if no diarrhea) may adsorb the amatoxins and interrupt the enterohepatically circulated drug.

Antigen-binding fragment (Fab) monoclonal antibodies against amatoxin were developed by immunizing rats and fusing their spleen cells to mouse myeloma cells. The amatoxin-specific clones were selected and their immunoglobulin separated into Fab fragments. When this Fab antibody was used in α -amanitin-poisoned mice, renal toxicity was 50 times greater. All animals died of renal failure but had no hepatic damage.^[21] The Fab-amatoxin compound may have dissociated in the kidney, leading to severe local damage.

Thioctic acid is used throughout Europe as a treatment for *A. phalloides* poisoning. Although its exact mechanism is unknown, it may act as a free-radical scavenger or interfere with the hepatic transport of toxin. In animal studies, thioctic acid has been ineffective against α -amanitin or extracts of the mushroom.^[2] In a large retrospective study, thioctic was more frequently associated with a fatal outcome in humans.^[32] Its use

is not recommended.

Silymarin is the active component of the milk thistle *Silybum marianum*. A water-soluble preparation (silibinin) is effective against amatoxin in both animals and humans. Silibinin also may interrupt the enterohepatic circulation or act as a free-radical scavenger. Patients treated with silibinin were more likely to survive in one study.^[50] In a retrospective study, silibinin was associated with increased survival.^[32] IV silibinin is not available in the United States, but an oral form may be found in health food stores.

High-dose penicillin decreased toxicity in an animal study evaluating hemodialysis with penicillin used prophylactically.^[31] The control group (penicillin alone) showed a decrease in toxicity. Other animal studies have indicated penicillin's effectiveness in reducing hepatotoxicity.^[27]^[88] In humans, penicillin has been very effective.^[32] Other antibiotics, including rifampin and cephalosporins, have been shown to protect against amatoxin poisoning.^[26]^[73] Penicillin's exact mechanism of action is unclear. Sterilization of the intestines may lead to decreased GABA production, which may diminish ensuing cerebral encephalopathy. Penicillin may share a common transport system with amatoxin, which interferes with uptake.^[29] Regardless of the mechanism, large doses of IV benzylpenicillin (300,000 to 1 million units/kg/day) are recommended. This dose may be associated with seizures.

French physicians have used hyperbaric oxygen as a treatment for *Amanita* toxicity.^[57] Hyperbaric oxygen may facilitate hepatic regeneration and lessen toxicity. It is most often used with high-dose penicillin.

Animal data suggest other therapies. High-dose cimetidine (4 to 10 g/day IV in adults) appears to inhibit formation of more toxic metabolites by blocking the cytochrome P₄₅₀ system.^[87] Cimetidine has not been given in children for *Amanita* ingestion. Other drugs under investigation in animals include vitamin C,^[102] zinc, and thiol compounds.^[29]

Gastric aspirate or emesis can be sent for spore analysis if mushroom specimens are not available for identification. Persons with documented or suspected amatoxin ingestion should receive activated charcoal (1 g/kg orally or via gastric tube followed by 15 to 20 g every 4 to 8 hours). Repeated administration may bind

drug that is enterohepatically circulated. Cathartics are generally not necessary, since diarrhea is prominent. IV normal saline or Ringer's lactate is needed to replace GI fluid losses. Electrolyte losses (particularly potassium) may be great. BUN, creatinine, CBC with differential, platelet count, electrolytes, glucose, calcium, phosphorus, magnesium, urinalysis, PT, PTT, fibrinogen, amylase, protein, and albumin should be initially measured and repeated at least daily to monitor liver and renal function. Hyperglycemia is common on the first day, but insulin is generally not required. Hypoglycemia occurs after 24 hours and may be significant, requiring concentrated IV glucose. Bedside determinations of glucose should be performed at least every 6 hours. Tests of liver

function, including ALT, AST, alkaline phosphatase, PT, and PTT, should be repeated at least daily and more often if findings become abnormal. Levels rapidly rising or greater than 2000 IU for ALT/AST and 50 seconds for PTT should signal severe toxicity and the need for referral to a transplant center.

To confirm the diagnosis of amatoxin ingestion, a serum RIA is ordered for amatoxins. Urine can also be studied. The nearest laboratory performing this RIA is usually known to the regional poison information center.

Specific treatment should begin as soon as diagnosis is suspected, either by symptoms or confirmed by the fresh specimen or spores. Benzylpenicillin (penicillin G), 300,000 to 1 million U/kg/day, should be given IV in divided doses. Silibinin, if available, can be given intravenously, 20 to 40 mg/kg/day in divided doses. Hyperbaric oxygen treatments (dives to 2 atm for 30 minutes once or twice a day) can be tried. Cimetidine (4 to 10 g IV for adults for 2 days) is experimental but has few side effects.

Once liver failure begins, hypoglycemia becomes more likely. Supplemental glucose should be readily available. Dietary protein should be limited and thiamine and multivitamin supplementation given. Oral lactulose, 30 to 45 ml every 6 to 8 hours, may reduce hepatic encephalopathy. Clotting studies should be performed several times a day and vitamin K or fresh-frozen plasma (or both) used to correct abnormalities.

If hepatic failure progresses, liver transplantation may be required. The timing is highly controversial, and criteria for transplant in other forms of fulminant hepatic failure are often applied to this setting. Factors associated with poor prognosis in acetaminophen-induced hepatic damage include metabolic acidosis, elevated PT and elevated serum creatinine.^[75] In viral hepatitis and other drug reactions, however, factors such as bilirubin, victim's age, and duration of jaundice before clinical encephalopathy are important.^[65] In the few pertinent studies of *A. phalloides* ingestion, poor outcome was related to age less than 10 years, a short latent period, and the severity of coagulopathy.^[32] The largest study suggests that a person with ALT or AST level greater than 2000 IU, grade II hepatic encephalopathy, or PT greater than 50 seconds is at serious risk for death and should be considered for emergency liver transplantation.^[19] Persons who met these criteria have survived.^[64]^[82] A recent report suggests that increased reparative enzymes correlate with hepatic recovery.^[49] Because hepatic failure develops rapidly, victims with significant hepatic dysfunction must be transferred early to a transplantation site. Patients undergoing liver transplantation for fulminant hepatic failure (not caused by *A. phalloides*) have a 62% survival rate. Recently a temporary liver transplant sustained a child while her liver recovered.^[83]

Persons who survive acute hepatic failure without needing hepatic transplant may have persistent elevation in liver transaminases. In one study of 14 persons with severe hepatotoxicity, eight had elevated AST/ALT without normalization over a 1-year follow-up.^[19] All had biopsy evidence of chronic active hepatitis, with positive anti-smooth muscle antibody and cryoglobulins. It is not known whether these persons will have an increased risk of hepatoma or develop more serious complications of chronic active hepatitis.^[79] Amatoxin ingestion during pregnancy does not appear to have serious

consequences to the fetus provided the mother remains healthy.

APPROACH TO THE VICTIM OF MUSHROOM POISONING

Four types of individuals develop mushroom toxicity: foragers, children, those seeking hallucinogenic "highs," and rarely, victims of attempted homicide. Most victims seek medical care after symptoms develop. Caregivers who observe small children chewing on lawn mushrooms should call the nearest poison center. Children who have ingested an entire lawn mushroom or more should receive ipecac and be observed for symptoms at home. Follow-up calls should be made to ensure that emesis has occurred and at 1, 4, and 24 hours to assess symptoms.

Persons with agitation, altered perceptions, or frank hallucinations temporally related to mushroom ingestion are probably intoxicated with isoxazole or hallucinogenic mushrooms. Whether the mushrooms are picked accidentally or ingested intentionally, the treatment and clinical course are identical.

Persons who develop muscarinic symptoms (salivation, urination, diaphoresis, GI upset, emesis) present a classic picture that is rarely confused with any other presentation. Some drugs (e.g., bethanechol) may cause similar symptoms when taken in overdose. Victims of mushroom poisoning generally remain

1158

mentally clear and should be able to relate an appropriate history.

Victims with GI symptoms can be divided into those with early and those with delayed presentations. Those with early (within 2 hours) GI symptoms generally have a benign course, *except* for persons with a mixed ingestion. Most guidebooks for mushroom hunters recommend eating only one variety of mushroom at a time, but more daring or foolish individuals mix multiple mushrooms and eat them frequently over a day. This makes diagnosis based on time of symptom onset difficult. Early onset of GI symptoms may mask more significant delayed symptoms. In these cases, identification of ingested mushrooms becomes essential to planning therapy.

Accurate botanical identification of the mushroom can be difficult. Only 800 of the 3000 species found in Europe can be identified without a microscope. ^[100] When multiple mushrooms are eaten together, the residual specimens may not be those causing toxicity. Cooking and refrigeration alter identifying features. Fresh mushroom specimens should be transported in a paper bag rather than a plastic container to limit the effects of humidity. Finally, precise identification of even a good specimen can be difficult and

should be done by an expert. Mycologists can be contacted through a poison center, university, museum, or commercial mushroom grower.

In difficult cases, spores can be obtained from emesis or gastric emptying procedures. Specimens should be refrigerated while awaiting analysis. More specific diagnosis can be made through TLC or RIA techniques. Botanical identification may not match the victim's symptoms. The victim should be treated according to time of symptom onset and current condition when examined.

Victims with early-onset GI symptoms require supportive care with fluid and electrolyte replacement. For those with delayed GI symptoms or mixed ingestions of amatoxin or gyromitrin mushrooms, treatment should begin as soon as possible. These mushrooms generally can be differentiated by the description or by the season (spring for *Gyromitra*, autumn for *Amanita*).

Persons who have disulfiram-like reactions to alcohol should be questioned about prior mushroom ingestion. This situation is rarely diagnosed correctly, because symptoms are thought to result from panic attacks, alcohol intoxication, or even an allergic reaction. Persons rarely relate their symptoms to the dinner of mushrooms eaten days earlier.

Any person with unexplained acute renal failure should be questioned about prior wild mushroom ingestion. Although *Cortinarius orellanus* is more common in Europe and Japan, it is found with increasing frequency in the United States. Because of the long delay before the onset of renal failure (1 to 2 weeks), the history of mushroom ingestion may be missed.

Chapter 50 - Ethnobotany: Plant-Derived Medical Therapy

Kevin Jon Davison

The history of ethnobotany begins before the advent of written records. In all ancient civilizations, plants served as important elements of food, shelter, dyes, ornamentation, religious rituals, and medicines. The term *ethnobotany* refers to an individual culture's use of specific plants. The medicinal use of the plant kingdom has been termed *herbalism*, *plant medicine*, *natural-based medicine*, and *phytomedicine* in its current application. The word "herb" is broadly defined as a nonwoody plant that dies down to the ground after flowering. The most commonly used interpretation, however, is any plant used for medicinal therapy, nutritional value, food seasoning, or dyeing another substance.

The precise medicinal discovery of the uses of plants by humans remains conjectural. Many scenarios probably occurred. Perhaps, in a prehistoric jungle of South America, a pool of water containing fallen plant material leached out some of the precious medicinal constituents of leaves, flowers, stems, and bark. Tannins, glycosides, sugars, and alkaloids from the bark were infused into the waters. Because of burning fever and severe dehydration, an extremely ill native drank from the pool, and his fever miraculously disappeared. The pond became known for its magical healing powers. If the water held bark from the cinchona tree, the native may have serendipitously discovered quinine.

Archeologic evidence shows that prehistoric humans used plants extensively to treat physical ailments. Instinct and trial and error led to the realization that, for example, cinchona bark controlled intermittent fevers, animals fed on ergotized grain aborted their fetuses, and latex from the opium poppy could be eaten to alleviate pain. Innumerable medicinal plant traditions that remain intact to the present originated as far back as 2700 BC. Ethnobotanically, the use of plant-based medicines represented much more than a culture's individual efforts to survive. Analyzing the methods and degrees of use of indigenous medicines reveals much about cultural philosophy, ingenuity, and sophistication. The Chinese developed an extensive and elaborate system for

prescribing, classifying, and processing herbs, which dates back to the third millennium BC. The formulas identified the specific effect of each herb and interactions with other herbs. Less tolerable herbs were blended with those that would counteract undesirable effects. Formulas were custom blended, taking into account a victim's constitution and the stage of the disease. Some of the ancient knowledge from these writings is being used in many contemporary herbal preparations commercially sold as "patent" (readily available in pill form) medicines.

Many native tribes of New Guinea, Indonesia, and the Amazon use single-herb formulations as they did thousands of years ago to treat nearly all their medical conditions. In the West, written records dating to the Sumerians accurately describe the medicinal uses of specific plants.^[101] In the same period of about 3000 years ago, the first Asian written record, the *Ben Tsao Gan Mu*, was compiled by the Chinese. It listed more than 360 medicinal plants and their classification, uses, contraindications, and methods of action as perceived at that time. Roman and Greek herbal remedies were described in the writings of Hippocrates and later in those of Galen, providing a pattern for the development of the Western medical tradition. Hippocrates was an advocate for using a few simple plant preparations along with fresh air, rest, and proper diet to help the body's own "life force" eliminate problems. Conversely, Galen promoted the use of direct intervention to correct the imbalances that cause disease, employing large doses of complicated "drug" mixtures that included animal, plant, and mineral ingredients.^[114]

The earliest European compendium that listed the uses and properties of medicinal plants, *De Materia Medica*, was written by the Greek physician Dioscorides in the first century AD. He described about 600 plants, and his work remained the authoritative herbal medicinal resource into the seventeenth century.^[41]

Herbalism was practiced in many different ways during and after the Middle Ages. There were learned traditional herbalists and lay practitioners, as well as wandering herbalists who professed pagan animism or Christian superstitions that often were more influential in healing than the herbs' properties. Little was added to the knowledge of herbalism during this period. After the Middle Ages and invention of the printing press in the 1400s, hundreds of herbal publications were compiled. Most early works were available only in Latin or Greek; it was not until the fifteenth through seventeenth centuries that the great age of herbalism was appreciated in English.^[101]

Tides changed in European herbalism when a Swiss pharmacist-physician named Theophrastus Bombastis von Hohenheim, better known as Paracelsus (1490–1541), introduced a new dimension. He advocated chemistry and chemical processing and used mineral salts, acids, and other preparations in medicinal therapies. This was a

departure from the plant-based medicinal methods of the past. During the latter seventeenth century, the predominance of plant medicines slowly eroded. In 1806, Freidrich Sertuner, a small-town German pharmacist, became known for his efforts to

isolate organic acids from plants in an attempt to find the active ingredient in opium. He discovered organic alkaloids, which became known as the first set of active plant constituents.^[149] Because of their physiologic activity, the search for plant alkaloids continued into the twentieth century.

Discoveries quickly followed. The bronchodilator and antitussive ephedrine, from the herb *Ephedra sinica*, was often used in Chinese medicinal formulas for bronchial asthma. The discovery of morphine led to creation of all the narcotic analgesics. The bark of cinchona was found to contain quinine in 1819, which led to development of antimalarial drugs.

The traditional herbal extract from rhubarb (*Rheum* species) has several active compounds. These compounds mediate many of the pharmacologic effects, such as its purgative action (from sennosides); antibacterial, antifungal, and antitumor activities (from anthraquinones); antiinflammatory and analgesic activities; and improvements of lipid metabolism (from stilbenes). Treatment of leukemias from an extract of Madagascar periwinkle (*Catharanthus roseus*), known as vincristine, has been highly effective.^[42]

Discoveries in the nineteenth and twentieth centuries included atropine (from belladonna leaves, *Atropa belladonna*) in 1831, cocaine (from coca leaves, *Erythoxylum coca*) in 1860, ergotamine (from *Claviceps purpurea*) in 1918, and tubocurarine in 1935.^[114]

European settlers brought herbal knowledge and their medicinal methods to the Americas. Because of the abundance and wide use of plants on the new continents, they also learned much from the indigenous peoples. The colonists found that conditions afflicting them, such as malaria and scurvy, were treated effectively with herbs by the Native Americans.^[115] In the 1700s, herbal medicine continued to have popular applications in lay circles but also was investigated by the new medical establishment. Although the creation of a small elite group of learned professionals was thought to violate the political and constitutional concepts of the early American democratic movement, the practice of medicine was carried over from England and Scotland during prerevolutionary days. Before a professional medical class was established, most illness in America was treated within the family or extended family network.

Many concepts were modified in the colonies between 1765, when the first medical school opened, and 1850, when more than 42 schools of medicine had been recognized. The inquiry into *Digitalis purpurea* (foxglove) by William Withering exemplified the change in perspective from anecdotal folk medicine to a critical examination for specific uses of botanicals from a biochemical point of view. During the early 1800s the trend was to look at the efficacy of botanicals and their intrinsic value from a more scientific perspective.

Several developments delayed the appreciation of herbalism by physicians in the colonies. For instance, Samuel Thomson promoted a system of herbal medicine by proselytizing about his patented method of herbal prescribing, which used many Native American herbs. A central theme in his approach was the advocacy of self-prescribing

based on the philosophies and herbal prescriptions found in his book *New Guide to Health*. The right to sell "family franchises" for use of the Thomsonian method of healing was the basis of a widespread lay movement between 1822 and Thomson's death in 1843. Thomson adamantly believed that no professional medical class should exist and that democratic medicine was best practiced by lay persons within a Thomsonian "family unit."^[39] Although his methods were considered crude and unscientific, he had over 3 million faithful followers in 1839. Founded on ignorance, prejudice, and dogma, the Thomsonian school did little to help physicians accept European and American herbal medicines. European physicians in the Thomsonian movement wished to separate themselves from the lay practitioners by creating requirements and standards for the practice of Thomsonian medicine. Thomson was adamantly against this, but a decade after his death the Thomsonian physicians formed the Eclectic School of Medicine, which attempted to unite "professional physicians," Thomsonianism, and traditional herbal medicine. The establishment of several Eclectic medical schools was a step toward validating herbal medicine, but it failed to bring herbalism into the mainstream medical establishment. The founding of the American Medical Association and the Flexner Report on medical education in 1910 thoroughly established the modern pharmaceutical industry in the medical education system.^[39]

Because of the availability of pure, active constituents from plant drugs and the synthetic drugs that began to appear on the market toward the end of the nineteenth century, the prescribing habits of physicians began to change. The sensibility and predictability of administering exact doses were appealing. For example, the pure alkaloid of quinine could be prescribed for malaria rather than a foul-tasting extract of cinchona bark containing variable percentages of quinine and other alkaloids with different physiologic properties.

Many "crude drugs" were standardized for therapeutic activity. Digitalis, which still retains its status in the *United States Pharmacopeia (USP)*, is one example. Of the 200 plant drugs officially listed in the USP in 1936, about 19% are still official today.^[149] An estimated 25% of all prescriptions dispensed in community pharmacies between 1959 and 1980 contained ingredients extracted from higher plants. For a significant number of synthetic drugs, natural drug products continue to serve as either models or starting points for synthesis.

EVOLUTION OF PHYTOPHARMACEUTICALS

The drive toward patenting and ownership in the pharmaceutical industry has been a strong incentive to research and develop plant-based products. Because a plant cannot be patented, however, little U.S. effort has gone into developing herbal medicines during the last century. Active principles of botanicals are investigated for their biologic activity, although in many cases the active constituent is less effective than the whole crude extract of a herb.^[114]

One problem in the development of the botanical pharmaceutical industry in the United States has been quality control. In addition, lack of standardization plagues plant-based products. Quality control and standardization of crude plant extracts for herbal medicines were virtually nonexistent until recently,^[114] or we might be using more botanical medicines for common ailments. In Europe and Asia, where pharmaceutical firms have been producing standardized *phytopharmaceuticals* (plant-based standardized extracts) for decades, research and development have demonstrated economic and medical sense. Europeans use phytopharmaceuticals as part of their "mainstream" medical practice. In hospitals they are used primarily as adjuvant therapies. More than 70% of general practitioners in Germany prescribe phytopharmaceuticals, and the public health insurance system pays for most of these prescriptions. The total annual market for phytopharmaceuticals in Germany alone is \$1.7 billion. Beginning in 1993 the licensing procedure for German physicians required a knowledge of phytotherapy.^[130]

Production and evaluation of botanical medicines have improved significantly in the past six decades. In crude plant evaluation, modern laboratory analysis can determine the percentage of active principles, as well as solubility, specific gravity, melting point, optical rotation, and water content. Scientists detect resins, alkaloids, flavonoids, enzymes, essential oils, fats, carbohydrates, and protein content. They can precisely assay using liquid, high-pressure liquid, paper, and thin-layer chromatographies; spectrophotometry; atomic absorption;

Figure 50-1 A, *Calendula officinalis*. B, *Calendula* drying and dried in a jar.
(Courtesy Cascade Anderson Geller.)

and magnetic resonance imaging. These methods improve the predictability and

therapeutic effectiveness of standardized crude botanical medicines, which are then evaluated for their efficacy in animal studies to determine pharmacologic potency, activity, and toxicity. U.S. and European companies have set strict quality control guidelines to ensure optimum yields of pharmacoactive principles and acceptable levels of impurities, bacterial counts, pesticides, residual solvents, and heavy metals.

Specific cultivation and harvesting techniques affect the therapeutic value of a given herb, which is related to the amount of active constituents in a specific medicinal plant. Methods of packaging, storage, and transport can dramatically affect the stability of active compounds. Both extracts and concentrates are obtained by adding appropriate solvents to raw herbs, which removes the active constituents. The most common method is infusion. As a tea bag is steeped in hot water to make a cup of tea, the water acts as a solvent. If the water were slowly evaporated, the concentrate would contain the active constituents.

Pure ethanol is an effective solvent often used to concentrate active herbal constituents. Immersing a high-quality bulk or raw herb in pure ethanol for hours or days, depending on the herb and the part used, then pressing it out, yields an herbal tincture. The alcoholic tincture is remixed with water to yield a 20% alcohol tincture. In another method, a 20% alcohol mixture is the solvent. Fluid extracts are made by distilling off some of the alcohol with vacuum distillation to avoid elevating the temperature, which may affect some of the active constituents. Another concentration process, solid extraction, yields a solid or semisolid product that can then be powdered or granulated for administration.

Once an extract is produced, qualitative and quantitative analyses can be performed to assist in standardization. The percentage of known active constituents is assayed, to obtain predictable clinical results.

An herbal infusion is generally a better source of active compounds than an air-dried or sun-dried powdered herb ([Figure 50-1](#)), but it may not be as strong in

action as concentrates such as tinctures, solid extracts, and fluid extracts. Potency of an extract can be defined by (1) percentage of active constituents or (2) concentration. Herbalists express concentration as an equivalency; a four-to-one extract is equivalent to or derived from four parts of the crude herb to yield one part extract. This is usually written as "4:1 solid extract." Longer shelf life, greater effectiveness, and higher concentration of active constituents make a more standardized (better) product than does the raw powdered herb; however, efficacy is difficult to compare.

An example of a product that is standardized to the percentage concentration of pharmacoactive glycosides is the extract of *Gingko biloba*, marketed in Europe under the trade names Tanakan, Rokan, and Tebonin. It is typically standardized as 24% flavonoid glycoside. *G. biloba* extract has been shown to prevent metabolic and

neuronal disturbances of cerebral ischemia and hypoxia in experimental models.^[86] ^[96]

Quality control is addressed for many herbal products when the known clinical effectiveness can be attributed to a specific active constituent. Improved analytic methods and use of high-quality herbs (high in active principles) helps ensure standardization. In Europe the dosage is expressed in milligrams of active constituents, which favors consistency. The main difference between this method and chemical isolation or synthesis is that the extracts still contain all the synergistic cofactors that enhance the function of the active ingredient. This important aspect of herbal medicine is lost once the active constituent is removed from the whole plant.

HERBAL PREPARATIONS FOR CLINICAL AND WILDERNESS USE

Botanical preparations are readily applicable in acute prescribing for travelers and wilderness enthusiasts. Throughout the ages, botanicals have been useful adjunctive therapeutic agents. Knowing how and what preparations from the natural pharmacopeia can be used provides a sense of integration with the natural environment. Indigenous peoples who have depended on the botanical world throughout their existence hold a vast amount of untapped knowledge. Wilderness enthusiasts should help engender and preserve this understanding of the natural world and help save natural habitats. Further investigation into the plant kingdom for useful medicinal agents will aid in these efforts.

Herbal medicines can be prepared by decoction or infusion of bulk or raw herbs or by the use of extracts, concentrates, and tinctures.

Infusions are prepared like a standard tea. The soft parts of plants, flowers, stems, and leaves—are placed in a warmed pot. Boiling water is poured over the herb, and the pot is covered to prevent beneficial essential oils from evaporating. The mixture infuses for about 10 minutes, then is strained. The supernatant can be used immediately or refrigerated in an airtight container for as long as 2 days. A standard adult dose of an herbal preparation would be 1 ounce (28 g) of dried herb to 1 pint (or 500 ml) of water, or a teaspoon per cup. The amount is doubled if the herb is fresh.

Generally, it is best to take infusions hot by the cupful three times daily for a chronic problem and up to every hour or two during an acute illness. To make infusions palatable, many herbalists have added licorice, aniseed, or honey. The hard or woody parts of plants, such as bark, seeds, roots, rhizomes, and nuts, have tough cell walls that must be broken down by great heat before they can impart their constituents to water. The herbs can be broken into small pieces by chopping, crushing, or hammering.

Traditionally, a decoction was prepared in an earthen crock reserved especially for making herbal preparations. In the past, herbalists believed that some of the quality of the medicine was affected by the type of vessel or container in which the brew was prepared. Contemporary practitioners generally recommend the use of stainless steel, ceramic, or enamel and specifically discourage the use of aluminum or other alloyed metal pots. The herb is placed in an appropriate container and covered with cold water. The mixture is brought to a boil, covered, and simmered for 10 to 45 minutes, depending on the type and part of the herb being used. A decoction can be strained, flavored, or sweetened like an infusion, and it is consumed while hot.

Modern practitioners use the most efficient and predictable forms of specific herbal medicines. Concentrates in capsule form are most effective and easiest to administer.

The standard herbal concentrate found in the marketplace is in the ratio of 4:1. Ease of administration and dosage and the predictable clinical effects have made this the industry standard. Herbal tinctures are extracted into a specific percentage of alcohol and can be mixed easily to make formulas tailored to personal conditions. A combination may be many times more effective than a single herb. Formula prescribing is an art. Classic formulas for common ailments have been cataloged since the first herbal compendiums were recorded centuries ago. For the purposes of this chapter, however, single herbs and their specific uses, identification, and preparation are detailed.

HOMEOPATHIC USE OF BOTANICALS

Medical pioneer Samuel Hahnemann developed a radically different system of medicine nearly 200 years ago. Homeopathy is derived from the Greek words *homoios*, which means "similar," and *pathos*, which means "disease" or "suffering." The "law of similars" states that a substance that causes a set of symptoms in pharmacologic dosages can create a cure for similar symptoms (even if the etiologic agent is different) if that substance

1165

is given in a homeopathic dilution. Most homeopathic remedies are prepared from plant, mineral, and animal products. In homeopathic medicine, there is a perfectly matched *similimum* (the most effective medicine) if the predominant symptoms of a disease or illness match the symptoms produced when the substance is taken in large doses in a healthy individual. For example, the herb *Atropa belladonna*, which contains atropine, is poisonous. In excessive doses the herb causes death; in moderate doses it creates hot, feverish states; and in tiny (homeopathic) doses it can effectively treat certain types of fevers, viral syndromes, and inflammatory states.

A homeopathic dilution is created by taking a prepared tincture (mother tincture) of a botanical or an extract from nonplant sources and diluting it in a sequential or serial method. The difference in a homeopathic dilution is in its methodology. A homeopathic medicine must be succussed (shaken or agitated) mechanically or manually a prescribed number of times between each serial dilution to be effective. The succussion method originally discovered by Hahnemann is said to "dynamize" the medicine. The succussion method may affect the water molecules, creating a "memory" that the water molecules store in a lattice formation. This is similar to the storage of information on a magnetic disk or tape, except the signature resonance pattern is created from the interaction of the original tincture within the water's lattice structure. The dilution can range from a 1x potency, which is a decimal dilution of a given ingredient (one part mother tincture per nine parts solute), to a 1c (one part mother tincture to 99 parts solute), to an extremely dilute 200c (one part mother tincture per 99 solute, serially diluted 200 times). A high-potency dilution (serially diluted more than 30 times in the x potencies and more than 12 times in c potencies) would be taken much less frequently than a low-potency dilution.

To make a 30x homeopathic preparation of *Arnica montana*, one drop of the plant tincture is added to nine drops of pure water, and the mixture is succussed 50 to 100 times. Next, one drop from that solution would be added to nine drops of pure water and

again succussed 50 to 100 times. This is repeated 30 times to yield the desired 30x homeopathic remedy. The number refers to the number of succusions and the letter to the ratio of the mother tincture to pure water.

The mechanisms by which homeopathy works have yet to be elucidated, even though it has been practiced effectively for several hundred years. In 1900 an estimated 15% of U.S. physicians were prescribing homeopathic remedies.^[105] Recent studies have shown effective results in clinical trials using homeopathic medicines.^{[28] [80] [91]} Mechanisms of action for many common pharmaceuticals also remain unknown. Many theories in medicine are still based largely on empiric observations rather than theoretic understanding.

One herbal folk remedy for bruises, sprains, strains, and rheumatism in European and native American medicine was topical application of the plant *Arnica montana* (leopard's bane). Consistent with the homeopathic principle, the toxic effects of the whole-plant extract of *Arnica* produce the same set of symptoms it is intended to cure when administered internally in a homeopathic dosage or if the tincture or oil is applied topically to the affected area.

Arnica is contained in herbal and homeopathic dosages in numerous ointments, salves, and poultices for the treatment of trauma resulting from localized sprains, strains, or contusions. Controlled studies in Germany have shown that effective products for sprains from athletic activity use an ointment that contains homeopathic *Arnica*.^[158]

TOPICAL APPLICATION

The earliest method of plant administration was topical application. Although many plants contain generalized moisture-enhancing properties, some were found to be particularly effective in ameliorating specific acute conditions when applied topically. Two methods are used to apply remedies to the skin. The *endermatic method* applies medicine on the skin without friction, as when applying a compress to the dermis and epidermis after an abrasion or laceration. The *epidermatic method* uses friction and is most effective with botanical oils, liniments, ointments, and medicated warm and cold friction rubs, primarily for subdermal contusions and trauma to effect circulatory changes.^[51]

Topical application of medicinal plants is useful for many conditions, including abrasions, lacerations, burns, insect bites, infections, rashes, and dermatoses. Other applications include contusions, varicosities, joint pain, inflammation, and musculotendinous aches, strains, and sprains.

Topical herbal remedies are applied with a poultice, compress, fomentation, or ointment. Probably the most common, the poultice is used to apply a remedy to a skin area with moist heat. A poultice is prepared by bruising or crushing the medicinal parts of the plant to a pulpy mass, then applying this to the affected area and covering it all with a moist heat source. If dried plants are used (or fresh plants if necessary), the materials are moistened by mixing with a hot, soft, adhesive substance such as moist flour or corn meal. A good way to apply a poultice is to spread the paste or pulp on a wet and hot cloth, which is wrapped around the affected area to help retain moisture and heat. The cloth is moistened with hot water as necessary. With irritant plants, as in a mustard "plaster," the paste is kept between two pieces of cloth to prevent direct contact with the skin. After the poultice is removed, the area is washed well with water to remove any residue. A poultice can be used to soothe, to irritate, or to draw impurities

from the affected area, depending on which plants are applied.

A *fomentation* is a hot cloth soaked with an herbal infusion or decoction. Fomentations are generally less active than poultices. A cold compress is used for conditions that require an antiinflammatory cure. A cold, infusion- or decoction-soaked cloth is applied to an area and then removed when the body's circulation has warmed the cloth to body temperature. The botanicals' active principles determine what actions the external applications will impart. For example, a poultice with an astringent herb such as

Hammamelis (witch hazel) has an entirely different effect than one made with a strong vasodilator and rubefacient, such as *Capsicum* (cayenne pepper).

Ointments are another method of topical administration. Most ointments are made in a base of petroleum jelly, stable vegetable oils, beeswax, or a combination of these. The extract from the desired botanical is suspended within the base to create a stable solid product. Topical botanical products have the same function as topical pharmaceutical ointments and are used to treat lacerations, abrasions, infections, and insect bites. Other uses for botanical topicals include hemostatic, antiinflammatory, antihistamine, rubefacient, analgesic, emollient, and circulatory stimulant actions. As with pharmaceutical topical agents, herbal poultices, compresses, and ointments deliver their active compounds transdermally.

The first uses of most medicinal plants were probably topical. In contemporary herbology, many of these plants are also used internally. Whole plants containing more than one ingredient with biologic activity generally invoke synergistic action of several components to produce the therapeutic action. Thus most botanicals have multiple applications for therapeutic purposes. Herbalists and homeopaths treat trauma of the skin, muscles, tendons, ligaments, and joint tissue with a topical agent in ointment or poultice form and give the same medicine internally in minute (homeopathic) doses to enhance the activity, as with concurrent use of *Arnica* ointment and homeopathic *Arnica*.

The major precaution in medical botany is to identify toxicity. Some of the most effective topical agents can be toxic if ingested. Most of these plants found in the wild could not be taken in sufficient doses to be fatal before causing gastrointestinal (GI) upset. A tincture, herbal concentrate, or powdered version of the plant, however, could have deadly potential.

USE OF HERBAL MEDICINE IN THE WILDERNESS

Travelers in the wilderness can choose preprocessed herbal preparations or naturally available plants in the immediate vicinity. A surprisingly large number of minor medical conditions encountered in an outdoor setting can be treated with plants in that location. North American recreational areas are home to medicinal plants that have been used by Native Americans for centuries. Recreationists in desert, alpine, and river environments can find medicinal plants in abundance. Nearly all the vegetation encountered during an alpine trek in North America has some medicinal property. Many plants in tropical and subtropical regions have medicinal properties.

Considerations for using herbal products in the wilderness are availability, ease of application, incidence of side effects, toxicity, spectrum of applicability, affordability, and effectiveness.

Availability and Application

If a condition can be improved by application of a local botanical growing in the immediate vicinity, the pharmacy is immediately available. Plants may be in season, plentiful, and easily harvested. Finding the appropriate plants can be challenging, however, depending on the location, season, the traveler's familiarity with botanicals, and the type of medical condition. During the popular mild seasons and at elevations conducive to plant growth in the continental United States, the chances of finding common plants are good. If not, standardized commercial preparations of these herbs can be carried. These are packaged for long storage life, sanitary and convenient application, and standardization of active ingredients.

Hundreds of plants can be applied topically for a variety of conditions. Most of the readily available plants, even if properly identified, require some form of processing for the active constituents to be used fully. Furthermore, expertise in the field requires years of training by a knowledgeable botanist and herbalist. It also requires knowledge of plant seasonal variation, ecologic niches, and precise plant identification. However, a non-botanist-herbalist can gain a basic understanding of a few plant medicines that have a wide spectrum of applicability and a broad range of geographic distribution.

Side Effects and Toxicity

The American Association of Poison Control Centers annually reports plant ingestion as a significant category of accidental poisoning. In 1997, 5.6% of U.S. poisonings came from plants and mushrooms. Of the substances that were involved in pediatric

poisonings, plants were responsible for 7.4% of exposures.

Side effects or toxic reactions from botanicals are rarely experienced. In those covered in this chapter, toxicity is not a major consideration. Anything can be toxic when used excessively or indiscriminately. Many toxic plants produce GI distress, vomiting, or diarrhea before any severe neurologic or cardiorespiratory derangement. Often, toxic side effects are caused by one substance in a plant. When isolated, minute amounts of an

alkaloid may be potentially dangerous, but when ingested in a form modified by other constituents the altered drug effect allows tolerance of larger amounts of the toxic substance or substances.

As with any medication, medicinal plants should be applied appropriately, and dosages for internal use should not exceed recommendations. Pregnancy and nursing may pose contraindications. Dosages for almost any herb can be found in numerous references.^[114] Felter^[51] stated that "as a rule, doses usually administered are far in excess of necessity and it is better to err on the side of insufficient dosage and trust to nature, than to overdose to the present or future harm or danger of the patient." In general, for the self-harvested herbs presented in this chapter, the dry, crushed, herbal adult dosage should be 1 teaspoon per pint of water; when the fresh herb is used, the amount should be twice that. Although no absolute law exists in administering medicines to children, Cowling's rule takes the child's age at the next birthday and divides by 24 to determine what fraction of the adult dose should be given.^[51]

Spectrum of Applicability

Most herbal medicines that have been catalogued and used historically are specifically indicated for one condition, although additional therapeutic effects have been noted over time. All the botanicals covered here have multiple uses. Comfrey (*Symphytum officinale*) may be used as a topical antiinflammatory agent; it also has principles that are effective for GI conditions when taken internally.^[101] Aloe vera gel is an excellent topical agent for abrasions and burns; taken internally, the latex portion serves as an effective laxative.^[101] *Calendula officianalis* has antimicrobial properties that make it an effective topical dressing for mild infectious conditions, whereas internally it has antipyretic effects.^[101]

Affordability

If the herbalist collects plants and processes them personally, the cost is minimal. The purchase price of botanicals depends on the rarity and origin. Some exotic and rare botanicals from Asia and the Amazon rainforest demand a high price on the world market. *Panax ginseng* has long been regarded by Asian peoples as a prized herbal tonic and can cost hundreds of dollars per root, depending on the size, origin, and age.

Panax quinquefolius, or American ginseng, can cost as much as \$52 per pound, and was valued at \$62 million as a cash crop in 1992.^[15] Many exotic herbal and animal-derived medicines from China have prices as high as those of precious metals.

Most of the herbs produced in the continental United States used for common ailments average 20 to 30 cents per dose (equivalent to 1 teaspoon of herbal tincture). Prices are not yet standardized. Quality control for production and supply and demand seem to dictate the cost of the mass-marketed herbal products. The best way to obtain a standardized product with a good quality/price ratio is to acquire the product from a botanical company that has been in business for at least 10 years and sells only to licensed health care practitioners.

NORTH AMERICAN PLANT MEDICINES

Ephedra (*Ephedra viridis*)

Description and Habitat.

Common names for *Ephedra* include Brigham Young weed, desert herb, Mormon tea, squaw tea, and teamsters' tea.

Ephedra species are shrubs with erect strawlike branches found in desert or arid regions throughout the world and in the southwestern deserts of the United States ([Figure 50-2](#)). The Chinese *Ephedra* called Ma Huang, *Ephedra sinica*, is found throughout Asia; *E. distacha* is found throughout Europe; *E. trifurca* or *E. viridis* (desert tea), *E. nevadensis* (Mormon tea), and *E. americana* (American *Ephedra*) are found in North America; and *E. gerardiana* (Pakistani *Ephedra*) is found in Pakistan and India. The 2- to 7-foot shrubs grow on dry, rocky, or sandy soils. The broomlike shrub has many jointed green stems with two or three small scalelike leaves that grow at the joint of stems and branches.

Pharmacology.

Ephedra is generally utilized for its alkaloid content, which tends to be ephedrine, pseudoephedrine, and norpseudoephedrine. The various species vary significantly in both alkaloid type and content. In *E. sinica* the total alkaloid content can be from 3.3% to 20%, with 40% to 90% being ephedrine and the remainder pseudoephedrine.^[46] The North American varieties, such as Mormon tea (*E. nevadensis*), are reported to contain no ephedrine.

Ephedra's pharmacology centers on the actions of ephedrine. Ephedrine and pseudoephedrine are used widely in prescription and over-the-counter drugs to treat asthma, hay fever, and rhinitis.^[58]

Figure 50-2 *Ephedra viridis*. (Courtesy Cascade Anderson Geller.)

1168

The central nervous system (CNS) effects of ephedrine are similar to those of epinephrine but are much milder and longer in duration of action. The cardiovascular effects are increased blood pressure, cardiac output, and heart rate. In addition, ephedrine increases brain, heart, and muscle blood flow while decreasing renal and intestinal circulation.^[58] Relaxation of bronchial, airway, and uterine smooth muscles also occurs.^[58]

Pseudoephedrine has weaker CNS and cardiovascular system actions but has bronchial smooth muscle relaxation effects. Because of fewer side effects, it is used more often than ephedrine for asthma.^[58] Pseudoephedrine also demonstrates significant antiinflammatory activity.^[70] ^[87] Per 100 g, the dry leaf of *Ephedra* is reported to contain 5 g protein, 5810 mg calcium, and 500 mg potassium.^[46]

Native and European Medicinal Uses.

Ephedra has been used extensively in the West and in Asia for upper respiratory conditions such as asthma, bronchitis, and hay fever. It has also been used to treat edema, arthritis, fever, hypotension, and urticaria.^[34] It is said to be valuable as a diuretic, febrifuge, and tonic.^[101]

The Navajo Indians used the dried, crushed, long leaf of *Ephedra* to apply to syphilitic sores, and the Hopi Indians drank a tea from the branches and twigs of a related species for the same condition.^[152] Other tribes used the ground and roasted root for making bread.^[46]

Mormon tea is a folk remedy for colds, gonorrhoea, headache, nephritis, and syphilis.^[46] Mexicans mix the leaves with tobacco and smoke them for headaches.^[46]

Modern Clinical and Wilderness Applications.

Ephedra has proved to be an effective bronchodilator for treating mild to moderate asthma and hay fever. The common preparations include other herbs that have antitussive and expectorant effects, such as licorice (*Glycyrrhiza glabra*) and grindelia

(*Grindelia camporium*).

Ephedrine promotes weight loss.^[114] Appetite suppression plays a role, but an increase in metabolic rate of adipose tissue is the main mechanism.^[7] The weight reduction effects can be enhanced by up to 60% with the addition of methylxanthine.^[47]

Clinically, standardized *Ephedra* preparations are used because of the predictable alkaloid content. *E. sinica* extracts are available with a standardized 10% ephedrine alkaloid content. The dosage of a 10% alkaloid content extract is 125 to 250 mg three times a day.

In the wilderness, specifically the desert, the raw herb Mormon tea from *E. nevadensis* or *E. viridis* can be useful for hay fever, mild asthma, bronchitis, or an upper respiratory infection (URI). These species contain minimal amounts of ephedrine and principally contain pseudoephedrine; thus they can be used without some of the unpleasant side effects of the Asian species. They can also be used for mild fevers associated with influenza or URI.

The shrubs are typically found growing on dry, rocky, or sandy slopes. The leaves can be picked fresh or sun-dried for 6 to 8 hours and can be prepared as a steeped tea or an infusion. Generally, the dose should be the equivalent volume of 1 tablespoon of dried, crushed stems per 4 ounces of water, steeped for 10 minutes. The patient should not exceed a dosage given six times per day. Once harvested, the leaves can be kept for an indefinite period for later use if stored in an airtight container.

Toxicity.

According to Duke,^[46] an infusion of *Ephedra* produced a "prompt and extensive contraction of uterine muscle when applied to smooth muscle strips of virgin guinea pig uteri." *Ephedra* may also elevate blood pressure. Frequent use may result in nervousness and restlessness. It should be used with caution if the patient has hypertension, heart disease, thyrotoxicism, diabetes, or benign prostatic hypertrophy. Ephedrine should not be used with antihypertensive or antidepressant medications.

Goldenseal (*Hydrastis canadensis*)

Description and Habitat.

Hydrastis has a perennial root or rhizome, which is tortuous, knotty, and creeping. The internal color is bright yellow, with numerous long fibers. The stem is erect, simple, herbaceous, and rounded, from 15 to 30 cm (6 to 12 inches) in height, becoming purplish and bearing two unequal terminal leaves. The leaves are alternately palmate with three to five lobes, hairy, dark green, and cordate at the base. The flowers, which are evident in early spring, are solitary, terminal, small, and white or rose colored.

The plant is a native of eastern North America and cultivated in Oregon and

Washington. The parts used are the dried rhizome and roots.

Pharmacology.

The alkaloids derived from *Hydrastis* are hydrastine (1.5% to 4%), berberine (0.5% to 6%), berberastine (2% to 3%), canadine, hydrastinine, and related compounds. Other constituents include meconin, chlorogenic acid, phytosterins, and resins.^[114]

Native and European Medicinal Uses and Folklore.

Native Americans used *Hydrastis* extensively as an herbal medicine and clothing dye. The Cherokee Indians used the roots as a wash for local inflammations and as a decoction for general debility, for dyspepsia, and to improve appetite. The Iroquois Indians used a decoction of the root for whooping cough, diarrhea, liver trouble, fever, sour stomach, flatulence, pneumonia, and heart trouble.^[109]

Early European uses date back to 1793; in the *Collections for an Essay Towards a Materia Medica of the United States*, Benjamin Smith Barton noted that *Hydrastis* was useful as an eyewash for conjunctival inflammation and as a bitter tonic. In the pharmacy of the nineteenth

century (1830), goldenseal was listed among the official remedies in the first revision of the New York edition of the *USP*. It was listed in the *USP* until 1926 and recognized in the *National Formulary* until 1955.^[71]

Modern Clinical and Wilderness Applications.

Goldenseal is among the top sellers in the American herbal medicine market. It is used as an antiseptic, hemostatic, diuretic, laxative, tonic, and antiinflammatory for inflammation of the mucous membranes. It has also been recommended for hemorrhoids, nasal congestion, sore mouth and gums, conjunctivitis, external wounds, sores, acne, and ringworm.^[98]

Modern research into the active ingredients berberine and hydrastine has shown why some of the folk applications are effective. The most widely studied component is berberine. This isoquinoline alkaloid has demonstrated antibiotic, immunostimulatory, anticonvulsant, sedative, febrifugal, hypotensive, uterotonic, choleric, and carminative activities (promoting the elimination of intestinal gas).^[114] Berberine has broad-spectrum antibiotic activity. The antimicrobial activity has been demonstrated on protozoa, fungi, and bacteria, both in vitro and in vivo. Antimicrobial action has been noted against *Staphylococcus*, *Streptococcus*, *Chlamydia*, *Corynebacterium diphtheriae*, *Escherichia coli*, *Salmonella typhi*, *Vibrio cholerae*, *Pseudomonas*, *Shigella dysenteriae*, *Entamoeba histolytica*, *Trichomonas vaginalis*, *Neisseria gonorrhoeae* and *N. meningitidis*,

Treponema pallidum, *Giardia lamblia*, *Leishmania donovani*, and *Candida albicans*.^[114]
Berberine inhibits the adherence of bacteria to host cells.^[140]

Active ingredients in the crude botanical may be responsible for the wide-spectrum effectiveness of *Hydrastis*. The antifungal properties, for example, prevent the overgrowth of *Candida* that frequently occurs with the use of other antibiotic therapies.

Other studies have shown the immunostimulatory activity of berberine-containing plants. Berberine increases blood flow through the spleen; improved circulation may augment the immune function of this lymphoid organ.^[125] Berberine also activates macrophages.^[91] Historically, berberine-containing plants have been used as febrifuges, and in rat studies they have an antipyretic effect three times as potent as that of aspirin.^[114]

Plants such as goldenseal are very effective in treating acute GI infections. In several clinical studies, berberine has successfully treated acute diarrhea caused by *E. coli*, *Shigella dysenteriae*, *Salmonella*, *Klebsiella*, *Giardia*, and *Vibrio cholerae*.^{*} Berberine-containing plants, in addition to their antimicrobial properties, influence the enterotoxins produced by offending pathogens.^{[24] [141] [142]}

GI illness is a major concern of the traveler to areas where sanitation is questionable. Both waterborne and food-borne bacterial and protozoal infections are concerns for persons in wilderness and Third World environments. Some experts recommend using a berberine-containing botanical source prophylactically at least 1 week before a visit to questionable areas and for 1 week after return.^[114]

Various eye complaints involving the conjunctivae and surrounding mucous membranes have been effectively treated with forms of berberine extract. Recent studies point to the effectiveness of berberine in treating the infection caused by *Chlamydia trachomatis*. Clinical trials found that a 2% berberine solution compared favorably to sulfacetamide. Although the symptoms resolved more slowly with the berberine extract, the rate of relapse was much lower in the berberine-treated group.^{[9] [110]}

A standardized form of *Hydrastis canadensis* is beneficial for generalized digestive disorders (acute dysentery, gastritis) and infective, congestive, and inflammatory states of the mucous membranes (sinusitis, pharyngitis, stomatitis). A typical dose depends on the source and method of the extract. For the previous conditions, the following three-times-a-day dosage is recommended: dried root or as infusion, 2 to 4 g; tincture (1:5), 6 to 12 ml (1.5 to 3 teaspoons); or solid extract (4:1 or 10% alkaloid content), 250 to 500 mg. *Hydrastis* can also be used as a wash or rinse for conjunctivitis, sinusitis, and pharyngitis. Eye drops, nasal lavage, and gargle are applied in a 5% preparation of a 1:5 tincture, or 1 to 2 teaspoons of powdered herb to 8 ounces water to create an infusion for application to inflamed mucous membranes. This can be repeated three times a day.

Toxicity.

Berberine and berberine-containing plants are generally nontoxic. In recommended doses, berberine-containing plants have not been shown to be toxic in clinical trials. The median lethal dose (LD₅₀) of berberine sulfate in mice is approximately 25 mg/kg, and in dogs, intravenous (IV) doses up to 45 mg/kg do not produce lethal or gross toxic effects.^[125] *Hydrastis* should not be used during pregnancy, and long-term ingestion may interfere with the metabolism of B vitamins.

Arnica (*Arnica montana*)

Description and Habitat.

Arnica is a perennial plant generally found in mountainous areas of Canada, the northern United States, and Europe. The plant reaches a height of 30 to 60 cm (1 to 2 feet) and generally contains from one to nine large daisylike flowerheads, which bloom during summer months ([Figure 50-3](#)).

Pharmacology.

The flower is used both internally and externally for medicinal effects. The rootstock is used to make commercial preparations for tinctures and oils that are applied topically. The active principles of the plant drug are flavonoids, volatile oils, and plant pigments (carotenoids).^[153] Specific constituents include arnicine,

*References ^[11] ^[37] ^[45] ^[66] ^[85] ^[126] ^[131]

1170

Figure 50-3 *Arnica latifolia*.

formic acid, thymohydroquinone, lobelamine, and lobeline (piperidine alkaloid).^[28]

Native and European Medicinal Use and Folklore.

The Catawa Indians administered the tea of *Arnica* roots to treat back pain. In Europe the flowerheads have been used since the sixteenth century as an application for bruises and strains.^[151] European *Arnica* was included in the *USP* from the early 1800s

until 1960 and was recognized for its effects on the healing of bruises and sprains.

Specific instructions given in the *American Dispensory* in 1922 listed *Arnica* as effective for "muscular soreness and pain from strain or overexertion; advanced stage of disease, with marked enfeeblement, weak circulation, and impaired spinal innervation; ... tensive backache, as if bruised or strained; [and] ... headache with tensive, bruised feeling and pain on movement."^[51] *Arnica* in tincture (concentrated) form has been a popular but not necessarily safe medicine to treat inflammatory swellings and to relieve the soreness of myalgia and the effects of bruises and contusions. Doses above the therapeutic range cause vagal inhibition when ingested and may cause toxicity if the concentrated tincture is applied topically. Therefore the most common use has been fomentation of the flowers for topical applications in treatment of strains and sprains.

Modern Clinical and Wilderness Applications.

Contemporary use of *Arnica montana* is generally limited to topical commercially prepared ointments and salves, in conjunction with internal homeopathic (low-dose) use for the same indications. Although its alkaloid (arnicine) and volatile oil (thymohydroquinone) are both relatively toxic, the actions of these constituents are extremely useful in resolving contusions and soft tissue injury. Most ointments are found to contain a 1x homeopathic dilution of *Arnica* tincture, which is about 4% by volume. Oral dosage is given in homeopathic potencies of 6x to 200c, depending on the severity of the condition.

Figure 50-4 Garlic blossom (*Allium* species). (Courtesy Cascade Anderson Geller.)

For application in the wilderness, most naturopathic first-aid kits include both the ointment and the oral homeopathic forms of *Arnica*. For direct use of the plant in treating minor sprains and strains, 2 teaspoons of the dried flower tops can be steeped in 1 cup of water for 10 minutes, and the infusion can be applied in a cold compress to the affected area. This should be repeated each 2 hours in addition to standard first-aid procedures. The infusion lasts a day if refrigerated and a few hours if not; therefore it is best to use a fresh infusion whenever possible. In addition, if available, the oral homeopathic preparation (30x to 200c) should be taken three times daily until the swelling is reduced significantly. A topical ointment can be applied every 2 to 3 hours for this condition in place of the compress.

According to Weiss,^[152] *Arnica* is safe and effective for topical contusions and for stimulating granulation and epithelialization. A tablespoon of tincture is added to 500 ml of water, and the gauze compress is then placed on the wound. This stimulates local

circulation and acts on the peripheral vasculature. After granulation has occurred, ointments may be applied.

Toxicity.

Arnica tincture or infusion can be toxic if the concentration is too high. Undiluted tincture should not be used internally or in compress form over an open wound. Vagus nerve inhibition is the primary toxic effect; GI irritation is also noted. Toxic reactions include gastric burning; nausea; vomiting; headache; decreased temperature; dyspnea; cardiovascular collapse; convulsions; motor, sensory, and vagal paralysis; and death.^[28]

Garlic (*Allium sativum*)

Description and Habitat.

Garlic is a member of the lily family. It is a perennial plant cultivated worldwide ([Figure 50-4](#)). The garlic bulb is composed of individual cloves enclosed in a white skin. The medicinal herb is found in the bulb and is used either fresh or dehydrated. Garlic oil, which also has medicinal value, is obtained

1171

by steamed distillation of the crushed fresh bulbs.^[98]

Pharmacology.

The medicinal compounds in garlic generally contain sulfur and have been the subject of most research on garlic. Two primary compounds are an odorless chemical called alliin and the enzyme allinase, which begins a cascade of chemical reactions when the garlic clove is cut, crushed, or bruised. Alliin is converted to allicin, which is responsible for the characteristic odor of garlic. Allicin is strongly antibacterial and considered to be the major source of the antimicrobial effects of garlic. Diallyl sulfide, disulfide, and trisulfide are yielded from the breakdown of allicin. Heat speeds up the reaction, so cooked garlic and steamed distilled garlic oil contain little or no allicin. Within garlic, about 0.1% to 0.36% of the volatile oil is composed of sulfur-containing compounds (e.g., allicin, diallyl sulfide, diallyl trisulfide). These volatile oils are considered to be responsible for most of the pharmacologic properties of garlic. Other constituents of garlic include s-methyl-L-cysteine sulfoxide, protein (16.8% dry weight basis), a high concentration of trace minerals (particularly selenium and germanium), vitamins, glucosinolates, and enzymes, which are composed of allinase, peroxidase, and myrosinase.^[114] ^[122]

Native and European Medicinal Use and Folklore.

Throughout history, garlic has played an important part in medicinal herbology. Clay

garlic bulbs dating back to 3750 BC were found in Egypt. Preserved garlic bulbs were discovered in the tomb of Tutankhamen. An entire basket of these bulbs from the tomb of Kha at Thebes is in the Turin Museum. The Greek historian Herodotus recorded that an enormous amount of money was spent on garlic for the builders of the great pyramids. One of the earliest Sanskrit manuscripts, *The Bower Manuscript*, devotes its entire first section to garlic, describing its legendary origins. It says that garlic keeps in order the three fluids and can cure thinness, weakness of digestion, lassitude, coughs, inflammation of the skin, piles, glandular swellings in the abdomen and enlargement of the spleen, indigestion, constipation, excessive urination, worms, wind in the body (rheumatism), leprosy, epilepsy, and paralysis.

Within the traditional medical circles of Greece and Rome, medieval Europe, and the Far East, similar claims may be found. Galen, Dioscorides, and Aristotle extolled garlic as an excellent medicine. Hippocrates recommended garlic as a diuretic; to regulate digestion; to treat bowel pains, inflammations, and infections; and to regulate menstruation. Early Chinese and European herbalists used garlic for heating and drying and therefore to prevent and cure diseases arising from cold, poisons, excesses of diet and drink, and sluggish metabolism.

Pasteur noted garlic's antibiotic properties in 1858. Albert Schweitzer used garlic in Africa to treat amebic dysentery. Garlic was also used as an antiseptic to prevent gangrene during both world wars.

Modern Clinical and Wilderness Applications.

The pharmacologic effects of garlic are based on its activity as a hypoglycemic and hypolipemic regulating agent,⁴ anticoagulant,⁵ antihypertensive,^{[103] [124]} antimicrobial,⁶ detoxifier of heavy metals,^[2] and immune system modulator.^[82]

Animal and human studies have substantiated that garlic lowers serum cholesterol and triglyceride levels and increases the amount of high-density lipoproteins. Dietary atherosclerosis was significantly reduced in rabbits fed garlic consistently for weeks; also, extract of garlic and onions was more effective than clofibrate against hyperlipidemia and subsequent lipid deposition within the aorta.^[23] After 4 months of feeding the rabbits a high-cholesterol diet, the average lipid content in the aorta of the control animals rose from 5.95 to 13.75 mg/100 g dry weight. Animals taking clofibrate for 4 months had 7.95 mg and garlic-fed animals 6.23 mg/100 g dry weight of lipid content in the aorta.^[23] Other studies of experimental atherosclerosis in rabbits support these findings.^{[76] [88]} Decreased atheromatous lesions seem to be a consistent finding in rabbits fed high-cholesterol diets supplemented with garlic.

Of various sulfur-containing amino acids isolated from garlic, s-methylcysteine and s-allylcysteine exert the greatest antilipidemic effects.^[74] Components of garlic can combine with the sulfhydryl group, the functional part of coenzyme A that is necessary for the biosynthesis of fatty acids, cholesterol, triglycerides, and phospholipids. The lipid-lowering effect may best be attributed to inactivation of the sulfhydryl group.^[8] Both in vitro and in vivo tests show reduced conversion of acetate into cholesterol by liver tissues.^[35] Since the sulfhydryl groups are involved at all levels of metabolic activity, the

impact of garlic could be more extensive. Studies suggest that garlic may lower blood pressure by acting similar to prostaglandin E₁, which decreases peripheral vascular resistance.^[118]

As a nutritional supplement, garlic is composed of magnesium, iron, copper, zinc, selenium, calcium, potassium chloride, germanium, sulfur compounds, amino acids, and vitamins A, B₁, and C. Garlic increases the body's capacity to assimilate thiamine by enhancing its absorption. Thiamine is a key part of the co-carboxylase enzyme system, which has beneficial effects on liver cells; this may explain why garlic offers prophylaxis against liver and gallbladder damage. In one study, garlic was shown to protect hepatocytes in tissue

*References ^[6] ^[8] ^[12] ^[17] ^[18] ^[20] ^[21] ^[26] ^[35] ^[36] ^[65] ^[74] ^[75] ^[78] ^[79] ^[80] ^[83] ^[84] ^[88] ^[89] ^[116] .

†References ^[5] ^[16] ^[19] ^[24] ^[25] ^[57] ^[77] ^[102] ^[119] ^[127] ^[137] .

1172

culture from the damage of carbon tetrachloride.^[118]

Antioxidant activity has been attributed to garlic and garlic derivatives. The free radical scavenger action of garlic may be explained by its germanium, glutathione, selenium, and zinc content. The last three are key components of the antioxidant enzyme superoxide dismutase and glutathione peroxidase. Animal studies show that feeding garlic oil enhanced physical endurance in normal rats and also reduced the decrease in physical endurance induced by isoproterenol, a synthetic catecholamine that induces necrosis of the myocardium.^[129]

Garlic inhibits platelet aggregation in animals; similar effects can be demonstrated in vitro and in vivo in humans.^[43] ^[137] An antiplatelet extract of garlic, ajoene, was found to potentiate the antithrombotic effect of antiinflammatory drugs. Under fasting conditions inhibition of platelet aggregation by garlic or its extracts is dose related.^[138]

The garlic effect may be linked to inhibition of thromboxane synthesis or to altered properties of the plasma membrane. Methyl (2-propenyl) trisulfide, another component of garlic, is 10 times more potent as an inhibitor of platelet aggregation than is diallyl disulfide or trisulfide.^[5] Thrombocyte aggregation inhibition is enhanced by two other compounds, 2-vinyl-1,3-dithiene and allyl-1,5-hexidienyl-trisulfide.^[14]

Garlic and its juice or oil also enhance fibrinolysis.^[22] In a double-blind placebo-controlled trial, cycloalliin, a component of garlic, was given to volunteers and patients after myocardial infarction and significantly increased fibrinolysis 1 ½ hours later.^[49] Chutani and Bordia^[38] observed that the increase took place 6 ½ to 12 hours after garlic intake. Daily garlic ingestion for 1 month generated a 72% to 85% increase in fibrinolysis in patients with ischemic heart disease.^[124]

The pharmacologic versatility of garlic is best reflected by its antiviral, antifungal, antiprotozoan, antiparasitic, and antibacterial activities.² Laymen are credited with being the first to describe the scientific basis for the medicinal use of garlic extract.^[155] Huddleson et al^[72] and Cavallito et al^[33] demonstrated in 1944 that garlic juice and allicin inhibited the growth of *Staphylococcus*, *Streptococcus*, *Bacillus*, *Brucella*, and *Vibrio* species at low concentrations. Recent studies using serial dilutions and filter paper disk techniques have shown that fresh garlic, powdered garlic, and vacuum-dried preparations were effective antibiotic agents against many bacteria, including *Staphylococcus aureus*, α - and β -hemolytic *Streptococcus*, *E. coli*, *Proteus vulgaris*, *Salmonella enteritidis*, *Citrobacter*, and *Klebsiella pneumoniae*.^[114] These studies compared the antimicrobial effects of antibiotics, including penicillin, streptomycin, chloramphenicol, erythromycin, and tetracycline, with those of garlic. Besides confirming garlic's well-known antibacterial effects, studies demonstrated its effectiveness in inhibiting the growth of some antibiotic-resistant bacteria.^{[1] [48] [132]}

Garlic has also demonstrated significant antifungal activity against a wide range of fungi.² From a wilderness perspective, inhibition of fungi that can affect the skin (*Microsporum*, *Trichophyton*, *Epidermophyton*, and *Candida albicans*) can be significant. Garlic juice applied topically is an effective alternative in treating fungal skin diseases.^[3] Garlic compares well with nystatin, gentian violet, and six other reputed antifungal agents to treat *C. albicans*.^{[1] [111] [121] [128]}

Garlic has long been associated with prophylaxis against influenza virus. In vivo studies with mice revealed that garlic administration protected mice against intranasal inoculation with influenza viruses and enhanced reproduction of neutralizing antibodies after vaccine administration.^[115] In vitro studies have shown that garlic has antiviral activity against influenza B virus and herpes hominis virus type I.^[145] Preliminary studies have revealed significant enhancement of natural killer (NK) cell activity in humans administered raw or cold, aged whole-clove garlic preparations daily for 3 weeks.^[82] The antiviral activity of garlic in humans may be secondary to the direct toxic effect on viruses and enhanced NK cell activity that destroys virus-infected cells.

Wilderness Medical Applications.

The use of garlic in the outdoor setting can be extensive. Its use as a food should be encouraged despite its odor, particularly in people with elevated cholesterol levels, heart disease, hypertension, diabetes, asthma, fungal infections, respiratory infections, and GI disorders (intestinal parasites, dysentery). A macerated garlic poultice and garlic slices serve as topical agents for fungal infections, ulcerated wounds, pyoderma, and other skin infections. The poultice can be used directly on the dermatologic problem and as a suppository can be used to treat vaginitis, particularly infections caused by *C. albicans*. For this application, one to two fresh chopped cloves can be made into a poultice. This should be kept on the affected site for several hours and changed at least once every 6 hours with a fresh preparation. If the garlic causes epidermal irritation, its use is discontinued.

Prophylactic use during the flu season can reduce the incidence of infection. Within the

first 48 hours of onset of a flu or URI, one or two cloves can be consumed with a carbohydrate source to prevent stomach irritation. Alternatively, two or three oil of garlic capsules can be taken. For persons concerned about the social segregating aspect, extracts that preserve the allicin content but remain odorless can be used.

1173

Toxicity.

For the vast majority of individuals, garlic is nontoxic at usual dosages. However, some people develop allergic contact dermatitis or irritation of the digestive tract. Apparently, they are unable to detoxify allicin and other sulfur-containing components. Prolonged consumption of large amounts of raw garlic by rats results in anemia, weight loss, and failure to grow. [\[117\]](#)

Ginger (*Zingiber officinale*)

Description and Habitat.

Ginger is an upright perennial herb with tuberous rhizomes, from which grows an aerial stem to 1.5 m (5 feet) in height. It is native to southern Asia, although it is cultivated in the tropics. Extracts and dried ginger are produced from dried unpeeled ginger; peeled ginger loses much of its essential oil content. [\[148\]](#)

Pharmacology.

Ginger is composed of a rich variety of nutrients and enzymes. The general composition is starch (50%); protein (9%); lipid (6% to 8%) composed of phosphatidic acid; lecithin; free fatty acids; triglycerides; protease (up to 2.26%); volatile oils (1% to 4%), the principal components of which are three sesquiterpenes (bisabolene, zingiberene, zingiberol); vitamins, especially niacin and vitamin A; and resins. [\[148\]](#)

Native and European Medicinal Use.

Zingiber officinale is native to southern Asia and tropical Africa. Therefore it did not have a role in the early herbal preparations of European and Native American herbal medicine.

Modern Clinical and Wilderness Applications.

Clinical use of ginger for antiinflammatory action, cholesterol-lowering effects, and relief of dizziness and motion sickness is noted in herbal texts.^{*} A choleric effect (the promotion of bile flow to the gallbladder and small intestine) and the conversion of

cholesterol into bile acids are enhanced by ginger ingestion and may be responsible for its overall cholesterol-lowering effect.

An early eclectic medical text listed ginger as local stimulant, sialogogue, diaphoretic, and carminative.^[51] Powdered ginger in a large quantity of cold water taken before sleep frequently "breaks up" a severe cold, and a hot infusion of ginger tea is a popular remedy for similar use to mitigate the pains of dysmenorrhea.^[51] Ginger may relieve painful spasmodic contractions of the stomach and intestine. The antiinflammatory action of ginger is thought to be caused by potent inhibition of inflammatory compounds, such as prostaglandins and thromboxanes.^[90] Ginger is also known to contain strong plant proteases such as bromelain, ficaine, and papain, which may explain some of its antiinflammatory action.^[148]

Ginger has been used historically for major GI complaints. It is generally regarded as an excellent carminative (promotes the elimination of intestinal gas) and intestinal spasmolytic.^[114] One of the most noted uses of ginger in contemporary herbal medicine that applies to wilderness medicine is its action on the symptoms of motion sickness and seasickness.^{[62] [63] [113]} Ginger is also a significant antiemetic. It has long been used in the treatment of nausea and vomiting associated with pregnancy. The efficacy of ginger has been confirmed in hyperemesis gravidarum, a severe form of nausea and vomiting during pregnancy. Ginger root powder at a dose of 250 mg four times a day brought a significant reduction in both the severity of nausea and the number of attacks of vomiting during pregnancy.^[52] To treat motion sickness and vertigo, two 500-mg capsules of powdered ginger root are eaten 20 to 30 minutes before the precipitating event. The same dose is used for the nausea of pregnancy during the acute attack. The raw ginger root can be grated using 1 teaspoon in 4 ounces of water, steeped for 10 minutes, and taken every 30 minutes until the symptoms of motion sickness abate.

Toxicity.

There appears to be no toxicity associated with ginger root ingestion.

Comfrey (*Symphytum officinale*)

Description and Habitat.

Comfrey is a perennial herb with a stout spreading root that is essentially divisible for propagation. Comfrey grows about 1 m (3 feet) high and has coarse, bristly, oblong, lanceolate leaves. The tubular flower can be purplish, blue, white, red, or yellow ([Figure 50-5](#)). About 25 *Symphytum* species are described; they are indigenous to countries around the Mediterranean Sea and in northern Asia. Comfrey is typically found in moist meadows and other wet places in the United States and Europe.

Pharmacology.

The chemical constituents of *Symphytum officinale* roots include carbohydrate, predominantly sucrose; the amino acids serine and asparagine; the phenolic acids

chlorogenic acid, caffeic acid, and

Figure 50-5 Comfrey (*Symphytum officinale*). (Courtesy Cascade Anderson Geller.)

*References [\[51\]](#) [\[52\]](#) [\[62\]](#) [\[63\]](#) [\[64\]](#) [\[90\]](#) [\[113\]](#) [\[134\]](#) [\[138\]](#) [\[139\]](#) [\[148\]](#) .

1174

p-coumaric acid; the alkaloids choline and allantoin; and the pyrrolizidine alkaloids viridiflorine, echinatine, heliosupine, symphytine, echimidine, and lasiocarpine.^[150] The most concentrated (0.88% to 1.71%) alkaloid, allantoin, is generally credited with comfrey's beneficial effects.

Native and European Medicinal Uses and Folklore.

In Europe, comfrey is a common perennial grown in the garden for animal fodder. Russian comfrey is often promoted as a medicinal herb for use as a tonic. Comfrey is also cultivated in Japan as a green vegetable and tonic and has been used in American herbal medicine for hundreds of years.^[95]

Comfrey has long been known as an external agent for the rehabilitation of musculoskeletal and orthopedic injuries. Its former name, "bone knit," derives from the external use of poultices of leaves and roots, which were believed to help heal burns, sprains, swellings, and bruises. Comfrey has been claimed to heal gastric ulcers and hemorrhoids, suppress bleeding, and relieve bronchial congestion and inflammation.^[13] The healing action of a poultice derived from the roots and leaves is probably related to the presence of allantoin, an agent that promotes cell proliferation. The underground parts contain 0.6% to 1.3% allantoin and 4% to 6.5% tannin.^[30] ^[107] Comfrey extracts applied topically have been reported to heal wounds and bones in about half of the normal time. In herbology a general rule is that if anything is broken, use comfrey.^[156] Herbalists have also found that the allantoin concentration from a fluid extract of comfrey can increase the rate of wound healing of lacerations sufficiently to avoid the use of sutures.^[154]

In European folklore, comfrey was regarded as an herb having unsurpassed ability to heal any injured or broken tissue. The mucilage (gelatinous mucopolysaccharide) of the comfrey root was named "the great cell proliferator," helping new flesh and bones to grow. Comfrey was one of the main herbs found in any poultice or fomentation. European herbalists considered comfrey exceptional for coughs and soothing inflamed tissues. Comfrey is effective for treating upper respiratory inflammation and has been used successfully to treat hemorrhagic conditions of the lungs.

Modern Clinical and Wilderness Applications.

Comfrey lotions and salves containing 0.5% to 2.5% allantoin have been used for sprains, strains, and contusions. In the 1980s, comfrey became controversial because of potential hepatotoxicity. Members of the family Boraginaceae (*Heliotropium*, *Symphytum*) contain a variety of related pyrrolizidine alkaloids reported to cause hepatotoxicity in animals. Although no hepatotoxic episodes from the ingestion of comfrey have been reported in humans, the potential exists, so caution is advised when using comfrey for internal consumption.^[95] Topical use of comfrey products as yet poses no concern for toxicity.

As a topical agent after acute trauma for musculoskeletal injuries, strains and sprains, or contusions, comfrey is an exceptional medicine.^[31] A prepared gel of comfrey with a standardized allantoin concentration should be carried during travel or camping expeditions in the wilderness.

The raw herb can be used if the person is in the plant's environment. The herb is readily identifiable, although it should not be confused with foxglove (*Digitalis purpurea*) and should be used with caution when taken internally in its raw state. For use in a poultice or compress, the leaves may be picked damp, macerated, and applied topically for up to 24 hours.

Toxicity.

Comfrey is not recommended for routine internal ingestion. Animal studies indicate that hepatic damage is an eventual outcome if the herb is consumed over a long period.

Aloe (Aloe vera)

Description and Habitat.

The aloe is a perennial plant native to South and East Africa and is also cultivated in the West Indies and other tropical and temperate areas. The leaves, which emerge from a central rosette produced by a central fibrous root, are 30 to 60 cm (1 to 2 feet) long, narrow, fleshy, and light green with spiny teeth on the margins ([Figure 50-6](#)). Aloe is easily cultivated as a houseplant and can be grown in a sunny warm spot with good drainage.

The genus *Aloe* comprises more than 300 species, which are members of the Liliaceae (lily) family. *Aloe* species are perennial succulents native to Africa. They are not cacti and should not be confused with American aloe, the century plant.

Pharmacology.

Two important products are derived from aloe: a gel and a latex. Aloe gel is a clear

gelatinous material extracted from the mucilaginous cells found in the inner tissue of the leaf. The gel is obtained by crushing the leaves and repeated straining to remove

Figure 50-6 *Aloe claviflora*. (Courtesy Cascade Anderson Geller.)

1175

cellular debris. The result is a clear gel, which is the product most frequently used in the health food and cosmetic industries. It is generally devoid of anthraquinone glycosides. A variety of compounds have been identified in the aloe species, including polysaccharides, tannins, organic acids, enzymes, vitamins, minerals, saponins, and steroids.^[95]

The bitter yellow latex of aloe contains cathartic anthraquinone glycosides, mostly barbaloin, as the active principles. The concentrations of the glycosides vary with the type of aloe, ranging from 4% to 25% of aloe in concentration. The water-soluble fraction of aloe is called aloin and is a mixture of active glycosides. Cathartics have been derived from extracts of the latex and can create strong purgative effects by stimulating the large intestine.

Native and European Medicinal Uses and Folklore.

Fresh *Aloe vera* gel is well known for its domestic medicinal values.^[59] ^[97] ^[112] ^[120] Aloe has been dubbed the burn plant, first-aid plant, and medicine plant. When fresh, the gel relieves thermal burns and sunburns and promotes wound healing. It also has moisturizing and emollient properties. Because of these effects, aloe is widely used as a home remedy.

Aloin and other anthraquinone derivatives of aloe are extensively used as active ingredients in laxative preparations. Aloin is also used as an antiobesity preparation.^[98] Aloe or aloin extracts are also used in sunscreens and other cosmetic preparations and in drugs for moisturizing, emollient, or wound-healing purposes.

In folk medicine, aloe is used for condylomas, warts, abnormal skin growths, and cancers of the lip, anus, breast, larynx, liver, nose, stomach, and uterus.^[46] Other folklore suggests that parts of the plants be chewed to purify the blood. The pulp is said to possess wound-healing hormonal activities and "biogenic stimulators" and is used for intestinal ailments, sore throat, and ulcers. In India it is used to treat piles and rectal fissures. Slukari hunters in Africa's Congo basin rubbed their bodies with the gel to eliminate the human scent, making them less likely to disturb prey. During epidemics of

influenza, Lesotho natives take a public bath in an infusion of *Aloe latifolia*.^[46]

Modern Clinical and Wilderness Application.

Although numerous claims have been made for aloe gel, its most common lay use is in the treatment of minor burns and skin irritations. In 1935 a report described the use of aloe in the treatment of radiation-induced dermatitis.^[40] This study followed a 5-week course of topical applications of either the whole leaf or leaf macerated into gel, resulting in complete wound healing after 4 months. In 1937, studies used a calamine and lanolin-based aloe preparation to treat skin irritations resulting from burns, pruritus vulvae, and poison ivy. The results suggested that aloe stimulated tissue granulation and accelerated wound healing.^[95]

Barnes^[10] evaluated the effect of 5% aloe ointment on sandpaper-abraded fingertips and found that the wound-healing rate was two to three times that of control subjects, as measured by decreased electrical potential of the wound. Other studies measured tensile strength of the healed surgical wounds of mice. Healing occurred within 9 days, an improvement over the control mice.^[60]

Studies of antibacterial activity of aloe extracts have been attempted several times, yielding mixed results. In 1963, studies of the antibacterial effect of macerated *Aloe vera* gel found no activity against *S. aureus* and *E. coli*.^[54] Other studies have determined that *Aloe chinensis* is effective against *S. aureus*, *E. coli*, and *Mycobacterium tuberculosis*, although *Aloe vera* showed no inhibitory effect.^[61] The latex possesses in vitro activity against several pathogenic strains of bacteria, although the whole leaf minus the latex from the leaf epidermis and mesophyll of aloe showed no activity.^[99] Two commercial preparations of aloe gel were found to exert antimicrobial activity against gram-negative and gram-positive bacteria and *C. albicans* when used in concentrations greater than 90%.^[67]

The moisturizing effect of aloe may be beneficial in the treatment of burns. The healing process may be related to mucopolysaccharides along with sulfur derivatives and nitrogen compounds in the gel, but this has not been well substantiated.^[94] In attempts to document the antiinflammatory effects of aloe, a 1976 study found that *Aloe vera* had bradykinase activity in vitro, but this was not confirmed in vivo.^[56]

Evidence for the internal use of aloe has been limited to studies involving mucous membrane tissue repair. Corneal ulcers treated with aloe extracts had more healing, less cellular reaction, and fewer signs of irritation than did control groups.^[95] Topical application of *Aloe vera* gel after periodontal flap surgery reduced postoperative pain more than the saline control, and swelling of the treated tissue was less marked than with the control.^[69]

Because of easy recognition and administration, use of the aloe plant in the wilderness environment is practical. The wild plant can yield an excellent preparation for dermal abrasions, cuts, and superficial wounds. A leaf cut from the base of a healthy plant can be conveniently carried. This allows the gel to remain intact, protected by the outer skin of the leaf. It can be squeezed from the inside through the cut portion directly onto

superficial wounds with or without a gauze dressing. A standardized preparation of *Aloe vera* may be used as an antibacterial agent and an emollient for superficial wounds or dermatitis.

1176

In the event of constipation, the mixture of aloe gel and latex can be scraped or squeezed from the leaf cortex and ingested, 1 tablespoon three times daily, or until a mild laxative effect is noted. A gel and latex mixture produces less cathartic effect than only latex. Because of the bitterness of the gel and the latex, it should be taken with food or a flavored beverage.

Toxicity.

Because of its cathartic effects, oral aloe is not advised if gripping pain is associated with constipation. Aloe taken orally is contraindicated in pregnancy. Otherwise it has no reported toxicity.

Plantain (*Plantago major*)

Description and Habitat.

The common broadleaf plantain is a familiar perennial "weed" that may be found along roadsides and in meadowlands. Plantain belongs to the order Plantaginaceae, which contains more than 200 species, 25 or 30 of which have a domestic use. The plant is a small weed with a rosette of ribbed leaves and small projecting seed stalks. Its seeds, known as psyllium seeds in North America, resemble those of another species, *Plantago psyllium*. The leaves contain 84% water, 2.5% protein, 0.2% fat, and 14% carbohydrate, trace amounts of calcium, phosphorus, iron, sodium, and potassium, as well as β -carotene, riboflavin, niacin, and ascorbic acid. Biochemically identified compounds include allantoin, adenine, baicalein, baicalin, benzoic acid, chlorogenic acid, choline, cinnamic acid, ferulic acid, L-fructose, fumaric acid, gentisic acid, D-glucose, *P*-hydroxybenzoic acid, indicain, lignoceric acid, neochlorogenic acid, oleanolic acid, plantagonine, planteose, saccharose, salicylic acid, scutellarein, sitosterol, sorbitol, stachyose, syringic acid, tyrosol, ursolic acid, vanillic acid, and D-xylose. ^[46]

Native and European Medicinal Uses and Folklore.

Historically, plantain has been used for stings, bites, and irritations from venomous insects and reptiles. The folk medicine of the eastern United States suggests using crushed plantain leaves to stop the itching of poison ivy. It has also been reported to help relieve toothache. Ancient herbalists maintained that plantain had refrigerant (imparts a cooling sensation to the mucosa and allays thirst), diuretic, and astringent properties. When the leaves are applied to a bleeding surface wound, hemorrhage

lessens. In the highlands of Scotland, plantain is still called *slan-lus*, or plant of healing.

In the United States, plantain has been known as snake weed, from the belief that it is effective for bites from venomous creatures. Felter^[51] noted that "the crushed leaves were very effective for the distressing symptoms caused by puncture by the horny appendages of larvae of Lepidoptera and the irritation produced by certain caterpillars, as well as the stings of insects and bites of spiders." In native American folklore, the plant was known as "white man's foot," in reference to its trait of growing in the settlements of white men. The Shoshoni Indians heated the leaves and applied them in a wet dressing for wounds.^[153]

Modern Clinical and Wilderness Applications.

Plantain is readily available in the recreational areas of North America. This plant is extremely useful for various superficial wounds, abrasions, stings, and bites of mildly venomous insects. The constituents in the crushed leaves have an antihistaminic effect, and anesthetic quality. In the event of a tooth fracture, a compress or poultice of ½ teaspoon of fresh leaves may be used on the exposed nerve root of a tooth. The seeds of the plantago plant are useful for spastic colon, an effect that appears to be related to their mucilaginous properties. Psyllium seeds, known on the Asian continent as flea seed husk, are often used as a bulk laxative. The seeds are collected from the stalk, and 1 teaspoon of fresh seeds in 4 ounces of water is taken twice a day for mild constipation. Water should be ingested throughout the day to alleviate the condition and assist the laxative effect.

Because of its astringent effects, an infusion of the leaves is recommended to treat diarrhea. The preparer pours 1 pint of boiling water on 1 ounce of the herb and leaves it in a warm place for 20 minutes. After, straining and cooling, ½ cup is ingested three or four times a day.

Toxicity.

No known toxicities are attributed to *Plantago*.

Chamomile (*Matricaria chamomilla*)

Description and Habitat.

Chamomile is a low-growing perennial with a hairy prostrate branching stem. It blooms late in July through September and is found growing throughout North America and Europe. Chamomile is derived from the Greek *chamos* (ground) and *melos* (apple), which refer to the plant's low growth and the applelike scent of its fresh blooms.^[135] The flower head is about 2.5 cm (1 inch) in diameter, has a conical receptacle, and is covered by yellow disk flowers surrounded by 10 or 20 white down-curving ray flowers.

Pharmacology.

The most important chemicals associated with chamomile are the volatile oils containing tiglic acid esters, chamazulene, farnesene, and α -bisabolol oxide. These volatile oils are destroyed if the herb is boiled.^[136]

Native and European Medicinal Uses and Folklore.

A distinction should be made between German and Roman chamomile, which have been used interchangeably for centuries. The German chamomile is preferred on the European continent, whereas the Roman chamomile has been used widely in Great Britain. In

1177

the United States, German chamomile is by far the more widely consumed of the two species.^[104]

German chamomile has a long tradition as a folk or domestic remedy. Its uses include external compresses or fomentations for gout, sciatica, inflammations, lumbago, rheumatism, and skin ailments. Infusions, decoctions, and tinctures have long been used internally to treat colic, convulsions, croup, diarrhea, fever, indigestion, insomnia, teething, toothaches, and bleeding or swollen gums. Historically, Roman chamomile was used similarly.^[46]^[98] Chamomile is also a folk cancer remedy.

Modern Clinical and Wilderness Applications.

The biochemical constituent of chamomile is chamazulene. It is found in both species of chamomile and is reported to have antihistaminic properties.^[50] Both histamine release and inhibition of histamine discharge have been considered mechanisms for the potential antiallergic action of chamazulene.

In Germany, chamomile products include tinctures, extracts, teas, and salves, widely used as antiinflammatory, antibacterial, antispasmodic, and sedative agents.^[104] Studies have shown that both chamazulene and α -bisabolol have antiinflammatory activity. Chamazulene may constitute as much as 5% of the essential oil. Other studies have shown that α -bisabolol has a protective effect against peptic ulcer, as well as antibacterial and antifungal effects. α -Bisabolol has also reduced fever and shortened the healing time of skin burns in laboratory animals.^[44] Most commercial European chamomile preparations have been standardized with regard to the chamazulene and α -bisabolol content.^[149]

According to Rudolph Weiss,^[152] one action of chamomile is to reduce gastric motility and secretions, which would alleviate colic and painful spasm. About 20 flavones and

flavonols, such as apigenin, are found in the aqueous portion of the distillation process. These are three times as effective at spasmolytic activity as the opium alkaloid papaverine. Chamomile also has a significant calming effect and has been traditionally applied as a mild sedative.

Chamomile is a good botanical to have on hand when traveling or camping. For infants experiencing restlessness and discomfort from teething, one third of the adult dosage may provide relief. For the treatment of conditions that may arise from excessive nervous tension (intestinal gas, colic, peptic ulcers), 2 teaspoons (or one standard teabag) of the flower tops can be added to a cup of boiling water and infused for 5 to 10 minutes; 2 to 3 cups may be taken in 30 minutes for acute intestinal colic.

Echinacea (*Echinacea angustifolia*)

Description and habitat.

Echinacea is a perennial herb native to the midwestern region of North America, from Saskatchewan to Texas. The plant produces a characteristic large pale-purple flower and thick hairy leaves and grows 60 to 90 cm (24 to 36 inches) high. The dried root is typically used for medicinal purposes.

Pharmacology.

The compounds currently identified from *Echinacea* species are inulin, glucose, fructose, betaine, echinacin, echinacoside, trihydroxyphenyl proprionic acid, and nonspecific resins.

Native and European Medicinal Uses.

This medicinal herb came to the attention of American herbalists in the late 1800s. *Echinacea* was originally used by the Indian tribes of Nebraska and the Sioux for the treatment of snakebite and as an antiseptic and analgesic. Eclectic practitioners used it externally for the same purposes but used it internally to treat "bad blood," or any condition that manifested signs of local or systemic infection, whether bacterial or viral.

Modern Clinical and Wilderness Applications.

Echinacea is probably the most common botanical used and known by the public, especially in relation to its immunomodulating effects. Many have found that echinacea can reduce symptoms and derail the onset of URIs and minor influenza episodes.

Echinacea is also a good systemic adjunct to the treatment of any contusion or laceration. The polysaccharide component echinacin can maintain the structure and integrity of the collagen matrix in connective tissue and ground substance and can accelerate wound healing experimentally.^[114] Echinacin also has a cortisone-like effect, with intermediate stabilization of inflammation reactions. Inulin, a major component of

Echinacea, is a powerful activator of the immune system's alternative complement pathway. It may increase host defense mechanisms for the neutralization of viruses, destruction of bacteria, and increased action of white blood cells (lymphocytes, neutrophils, monocytes, eosinophils) within areas of infection. Extracts of the root have been shown to possess interferon-like properties. As an immune stimulant early in infection, and for posttrauma rehabilitation, dosages are taken orally three times a day: tincture (1:5), 30 to 60 drops, or solid extract (dry powdered extract 6:1), 250 to 500 mg.

Calendula (*Calendula officinalis*)

Description and Habitat.

Calendula is found throughout Asia, North America, and Europe and is in the daisy and dandelion family. It is most often known as the marigold. The flower is generally used for the production of the tincture.

Pharmacology.

Calendula's chemical constituents include flavonoids, carotenes, saponin, resin, and volatile oil. The volatile oil content is responsible for a localized increase in blood circulation and diaphoresis. The resin

1178

content is responsible for the antimicrobial and antiinflammatory action of the topical application.

Native and European Medicinal Uses.

Native Americans apparently did not use calendula extensively, and the early European literature only mentions its medicinal role. Calendula, however, is one of the best topical applications for the treatment and prevention of infection and skin irritation. Early American surgeons highly regarded its ability to treat and prevent postsurgical infections.

Modern Clinical and Wilderness Applications.

A fluid/water extraction or oil infusion (prepared as a tincture but using vegetable oil instead of alcohol) of *Calendula* should be used in the initial treatment of lacerations, abrasions, and scalds; immediately after any required debridement and cleaning of a wound; and for generalized inflammation of the mucous membranes. It has shown its usefulness in dermatitis and vaginal, sinus, ophthalmic, and middle and external ear infections over the decades. The application of calendula ointments, tinctures, or fluid extracts depends on the wound. The succus (fluid extract) of the flower should be

applied for irrigation of wounds and in ophthalmic uses.

NATURAL PRODUCTS FIRST-AID KIT

A natural products first-aid kit should contain a variety of products that are easy to obtain and replace and that have a wide spectrum of use, including herbs ([Box 50-1](#)), homeopathic preparations, and vitamin and enzyme supplements ([Table 50-1](#)).

Homeopathic Medicines

Homeopathy can be an excellent source of relief and treatment for emergencies and general first-aid situations. Homeopathic preparations include powders, tablets, tinctures, lotions, ointments, creams, and sprays. The advantages of homeopathy are the ease of administration, lack of toxicity, rapid action, and small volume of material. The disadvantages are the degree of understanding and competence required to become an effective prescriber and the lack of readily available sources of each medicine at most North American pharmacies.

**Box 50-1. HERBAL MEDICINES
RECOMMENDED FOR FIRST-AID KIT**

Aloe gel and powder capsules
Arnica ointment
Calendula gel, ointment and tincture
Chamomile tincture
Comfrey gel or ointment
Echinacea tincture or freeze-dried powder capsules
Ephedra freeze-dried powder capsules
Goldenseal tincture or ointment
Hypericum ointment or tincture
Plantain tincture
Witch hazel fluid extract or tincture

A kit made exclusively of homeopathic medicines can cover most first-aid emergency situations. For the acute, straightforward injury or malady without a complex presentation, the correct similimum and rapid amelioration of symptoms are not difficult to achieve. This section discusses a few indications for the use of homeopathic medicines and the preparation most often used. Unless otherwise noted, a 6x to 12x potency in lactose pellet form should be given every 15 to 30 minutes immediately after the injury until noticeable improvement occurs. If no effect is noted after the first two doses, one must reconsider the medicine selection.

A personal experience exemplifies the relief that can be obtained from an acute injury with the appropriate homeopathic medicine. I was bitten on the lip by a small centipede while sleeping. I instantly experienced swelling and intense burning pain. Local application of ice provided no relief. I chose the homeopathic medicine *Apis mellifica* in a 6c potency because the wound was shiny and felt hot and swelling was increasing. After sublingual ingestion of two pellets I waited 1 to 2 minutes, still in excruciating pain with no change in symptoms. My next selection was *Cantharis* in a 6c potency, since a key symptom for this remedy is extreme red and hot burning pain of the face. Less than 30 seconds after administration the pain was almost undetectable. Total relief was obtained within a few minutes after being bitten. For comparison, I have had no

homeopathic kit available after other centipede bites, and the pain generally lasted for hours and the residual swelling for days. Reactions from different centipedes can cause different sensations and symptoms, however, so *Cantharis* may not work for all bites.

Proper selection of the similimum or indicated homeopathic medicine requires the ability to note the subtle differences in the way the victim responds to an apparently similar traumatic or toxicologic influence.

An appropriate homeopathic field guide that lists the specific indications and differentiation for each of the homeopathic remedies should accompany any first-aid kit. Unlike with Western pharmaceutical medications, it is essential to understand the specific homeopathic indications (similimum) for each of the remedies on hand. Without this, the chance of obtaining a successful outcome using homeopathics is small.

Practitioners and the homeopathic industry have realized the difficulty of single remedy prescribing, which involves understanding and memorizing the indications

TABLE 50-1 -- Physiologic Responses from Phytoph

PLANT MEDICINES	ANALGESICS	ANTIBIOTICS	ANTIFUNGALS	ANTIINFLAMMATORIES
<i>Aconitum napellus</i>				
<i>Apis mellifica</i>				Homeopathic topical, internal
<i>Arnica montana</i>	Homeopathic internal			Homeopathic topical, internal
	Botanical topical

Comfrey				Botanical topical

Echinacea	Botanical internal, topical	Botanical internal, topical	Botanical internal, topical	Botanical internal
Ephedra				
Goldenseal		Botanical internal, topical	Botanical internal, topical	Botanical topical
Hypericum				
Peppermint				
Plantain				
<i>Rhus toxicodendron</i>				Homeopathic topical, internal
Witch hazel				

for every homeopathic medicine. Therefore medicines have been developed that combine individual preparations to cover a large number of symptoms and symptom characteristics that typically accompany most ailments. These medicines, known as complex or combination homeopathic preparations, can be very helpful for the new user.

Single Preparations and Indications

ACONITE.

Tincture of the whole plant with root is derived when monkshood or wolfsbane (*Aconitum napellus*) begins to flower. Aconite is indicated for acute states of emotional disturbance, including anxiety and intense fear or pain. This is one of the key remedies that should be administered after an acute injury that has dazed, shocked, or frightened the victim. Persons who are fearful or restless, cannot tolerate being touched, and have pain followed by numbness and tingling sensations are most responsive to aconite. Those with sudden onset of fever, nausea, and vomiting and who exhibit symptoms of fear, restlessness, and anxiety may also benefit.

APIS.

The original tincture is manufactured from the whole honeybee and from dilutions of the venom (*Apis mellifica*). *Apis* is used for insect stings, particularly from bees and related insects, when the wound is swollen, shiny, and hot to the touch. Treatable symptoms from other conditions are histamine reactions (resulting in facial flushing, puffiness or swelling around the mouth, face, and eyes) sunburn, hives, burns, and early stages of abscesses and frostbite. If symptoms include a stinging, burning, or swelling quality and subside by applying cold rather than heat, *Apis* is the indicated remedy.

ARNICA.

The tincture comes from the whole fresh plant, flowers, and dried roots of leopard's bane or Fallkraut (*Arnica montana*). *Arnica* is indicated for blunt traumatic wounds (resulting in both deep and superficial hematomas), contusions, swelling, and localized tenderness. This is also effective for sore muscles, as well as sprains, fractures, dislocations, and internal bleeding. I recommend taking a 6x to 30x potency every 15 minutes to 3 hours for the first few days for a severe injury. The more severe the injury, the more frequently the dosage is taken for the first day. As the symptom severity decreases, the medicine is taken less often. *Arnica* can be helpful in decreasing severity and recovery time.

ARSENICUM.

Derived from arsenic trioxide, arsenicum is used for skin rashes (which feel warm but are relieved by hot applications), hay fever, asthma (especially when accompanied by notable anxiety), diarrhea, vomiting, and gastroenteritis (especially from food-borne microbes).

HYPERICUM.

The tincture comes from the whole fresh plant and flowers of St John's wort (*Hypericum perforatum*). Indications include any pain that affects the peripheral or central nervous system and exhibits shooting pains that travel in a dermatomal pattern (e.g., sciatica). Wounds that affect the nerve endings, such as injuries to the fingers, toes, or teeth, are improved by *Hypericum*. Pain from dental surgery, toothaches, injuries to the coccyx, and first- and second-degree dermal burns are other indications.

LEDUM.

Ledum is made from the leaves and stems of the whole fresh plant of wild rosemary (*Ledum palustre*). Homeopathic indications include puncture wounds from small, sharp objects (e.g., nails, needles) and some mosquito bites when the injured area feels cold, swollen, and numb and pain is relieved by cold application.

RHUS.

This homeopathic preparation comes from the leaves and stems of the whole fresh plant of poison ivy (*Rhus toxicodendron*). This is the remedy of choice for the urticaria caused by poison ivy exposure and is also helpful for some cases of poison oak. Other skin rashes that are red, weeping, blistered, and swollen with itching can be treated with *Rhus*. It is also effective for the treatment of connective tissue irritations with swelling, stiffness, and tightness. *Rhus* is often used for overuse injuries (e.g., fasciitis, tendinitis) and some forms of arthritis, especially when the injured area feels better with warm applications and movement.

Combination Preparations for Acute Sprains and Strains.

Homeopathic companies have created combination remedies for the general public that can be used without the need for in-depth understanding of homeopathic prescribing. These remedies are designed to cover a broad range of symptoms associated with acute ailments and trauma-induced medical conditions.

Traumeel (Heel Biotherapeutics, Albuquerque, NM) is a combination homeopathic formula that is effective in the treatment of trauma and inflammatory changes affecting skin, connective tissue, and muscle. The preparation comes in liquid, tablet, and ointment form. Traumeel includes remedies indicated for traumatic injuries (sprains, strains, contusions) and the resulting pain, swelling, and ecchymoses. Many German studies have demonstrated its effectiveness.^[27] Traumeel may be the primary homeopathic medicine chosen for the first-aid kit because of its wide range of application and multiple delivery system.

Herbal Combination Formulas

Acute Gastroenteritis.

In the tradition of Chinese herbal medicine, many formulas have been developed over the centuries to treat acute ailments. Many of these

formulas were kept secret from the general populace and reserved for the nobility and ruling class. As the field of Chinese herbology developed and became more accessible to the general populace, some of the secret formulas have been mass produced into convenient pill form known as patent medicines. Many of these are extremely useful for acute conditions.

Pill Curing (Kang Ning Wan, "Healthy Quiet Pill"), botanically called Coix Formula, consists of 16 herbal medicines that are collectively effective for relieving the disturbances caused by motion sickness, food poisoning, overeating, excessive alcohol consumption (nausea, headache, vomiting) difficulty passing stool or loose stools, and

GI cramping and pain. Coix Formula is currently produced in a convenient globule form (Metagenics, San Clemente, Calif). One or two capsules of globules are swallowed with warm water every hour until symptoms improve. Relief should occur within 4 hours of administration.

Acute Hemorrhagic Conditions.

The product Yunnan Bai Yao ("Yunnan White Medicine"), produced in the western Chinese province of Yunnan, has been used for centuries as a first-line approach to trauma that results in internal or external bleeding. It is prescribed in China for excessive menstrual cramps and bleeding, bleeding ulcers, trauma-induced swelling, bleeding wounds, and allergic reactions to insect bites. It comes in powder (4-g bottles) and capsule (packets of 20) form and contains one red pellet that is to be ingested only for serious bleeding conditions. Dosage is 1 to 2 capsules four times per day. The powder can be applied externally after the wound has been properly cleaned. This product is exclusively produced in China from a proprietary formula and can be obtained from most Chinese herbal pharmacies.

Nutritional Supplements

For immune system support, antiinflammatory action, and pain relief, many natural products in the nutritional supplement category have proved to be effective agents.

Bromelain.

Bromelain is a naturally occurring proteolytic enzyme found in pineapple that is used to reduce pain and swelling after sprains and strains of soft tissues. Ingested on an empty stomach, the complex proteases in bromelain are absorbed intact and have significant antiedema, antiinflammatory, and coagulation-inhibiting effects. Bromelain shows fibrinolytic activity and acts to inhibit fibrinogen synthesis, decreasing kininogen and bradykinins.^[100] For treatment of injuries and postsurgical recovery, 125 to 400 mg is ingested three times daily at 30 minutes before or 90 minutes after a meal. Bromelain is nontoxic even at high doses and is generally prepared as 100-mg tablets.

Papain.

As with bromelain, papain is a naturally occurring plant enzyme (papaya fruit) that exhibits proteolytic activity. Papain is generally used externally to neutralize bee, ant, or wasp venom. Papain is available as commercial meat tenderizer (e.g., Adolph's) or in tablet form. After removal of the stinger, a thick paste is prepared from water and tenderizer or from five or six crushed tablets and applied to the area as soon as possible.

Vitamin C.

Ascorbic acid has both wound-healing and antiinflammatory effects. Vitamin C is required for hydroxylation of proline and subsequently for the synthesis of strong

collagen. Studies have shown that the stress associated with injury and wound healing results in an increased need for vitamin C.^[106] For acute trauma and acute upper respiratory allergy, vitamin C in larger dosages (2 to 5 g/day in divided doses) can greatly reduce anaphylactic reactions and recovery time.^[68] Therefore, for any traumatic event, high-dose vitamin C should be administered as part of the treatment.

APPENDIX

Companies

Nature's Apothecary
997 Dixon Rd
Boulder, CO 80302
800-999-7422

Small herbal kits include Dental Poultice Pac for toothaches and abscesses, Clear Eyes Eyewash Kit (including Eyebright *Euphrasia* extract), and reformulated Home Herbal Medicine Kit.

Boiron
1208 Amosland Rd
PO Box 54
Norwood, PA 19074
800-258-8823

Natural Home Health Care LeKit contains 36 single-remedy medicines in distinctive blue tubes, including the commercial flu remedy *Oscillococcinum*. The home kit also contains four external remedies: tinctures of *Calendula* and *Hypericum* and ointments of *Arnica* and *Calendula*. Travel LeKit is a more compact collection of single remedies (22 multidose and 16 unit-dose tubes) plus the flu remedy.

Dolisos America
3014 Rigel Ave
Las Vegas, NV 89102
702-871-7153, 800-365-4767

Single Remedy Family Kit contains 48 single remedies, a Flu-Solution remedy, *Calendula* ointment and tincture, and *Arnica* cream. The 48 combination Energy Medicine Kit includes remedies for bruises, insect bites, and poison ivy.

Biological Homeopathic Industries (BHI)
11600 Cochiti S.E.
Albuquerque, NM 87123

800-621-7644

BHI is the U.S. distributor of the German line of complex homeopathic remedies manufactured by Heel.

Part 8 - Food and Water

1186

Chapter 51 - Field Water Disinfection

Howard D. Backer

Waterborne disease is a risk for international travelers who visit countries that have poor hygiene and inadequate sanitation and for wilderness users relying on surface water in any country, including the United States. Natural water may be contaminated with organic or inorganic material from land erosion, dissolution of minerals, decay of organic vegetation, biologic organisms that reside in soil and water, industrial chemical pollutants, and microorganisms from animal or human biologic wastes.^[38]^[67] Fecal pollution with enteric pathogens is the primary reason for disinfecting drinking water. However, chemical contamination of groundwater is increasing at an alarming rate in the United States and worldwide from industrial, agricultural, and individual sources. Of the 1700 million square miles of water on earth, less than 0.5% is potable.^[221] According to the National Water Quality Inventory Report by the U.S. Environmental Protection Agency (EPA), as of 1994, about 40% of the nation's surveyed rivers, lakes, and estuaries are too polluted for basic uses such as fishing and swimming. Natural organic and inorganic material may not cause illness but can impart unpleasant turbidity, color, and taste to the water. Appearance, odor, and taste are not reliable to estimate water safety.

ETIOLOGY

Infectious agents in contaminated drinking water with the potential for waterborne transmission include bacteria, viruses, protozoa, and parasites ([Box 51-1](#)). The number of pathogenic microorganisms capable of waterborne transmission is more than 100 and similar to that of potential etiologic agents of travelers' diarrhea. Separating the contribution of waterborne transmission of these pathogens from food-borne and person-to-person transmission is impossible. The latter two are probably more common.

The source of fecal contamination in water may be either human or animal. Some bacterial pathogens (*Shigella*, *Salmonella typhosa*) occur exclusively in human feces, whereas others (*Yersinia*, *Campylobacter*, nontyphoidal *Salmonella*) may be present in wild or domestic animals. The enteric viruses seem to occur exclusively in human feces. No enteric viruses excreted by animals have been shown to be pathogenic to humans.^[162] The major source of these enteric pathogens is fecal contamination from infected human residents. *Legionella pneumophila* and *Vibrio cholerae* exist as natural organisms in water. However, the mode of transmission of *Legionella* is inhalation of aerosolized water.^[194] No evidence exists of human immunodeficiency virus (HIV) transmitted via a waterborne route, and no epidemiologic evidence exists of casual transmission by fomites or by any environmentally mediated mode.^[168]

Viruses

Hepatitis A virus (HAV), Norwalk virus, and rotavirus are the main viruses of concern for potable water supplies; the last two are responsible for about 77% of acute waterborne gastroenteritis.^[221] In addition to HAV, waterborne transmission of hepatitis E is suspected in outbreaks among travelers from Asia.^[26] ^[100] During 1993 and 1994 an explosive waterborne epidemic of hepatitis E virus occurred in Islamabad, Pakistan, with about 4000 cases of acute icteric hepatitis.^[185] Many other viruses are capable and suspected of waterborne transmission, and more than 100 different virus types are known to be excreted in human feces.^[72] ^[175] The most frequent waterborne illness (acute infectious nonbacterial gastroenteritis of unknown etiology) in the United States may be caused by undetected viruses.^[43] ^[119] ^[189]

Protozoa

Six protozoa cause enteric disease and may be passed via waterborne transmission: *Giardia lamblia*, *Cryptosporidium parvum*, *Entamoeba histolytica*, *Cyclospora cayetanensis*, *Isospora belli*, and the microsporidia.^[118] The first two are the most important for wilderness travelers. *Cryptosporidium* is a recently recognized enteric pathogen.^[27] Many aspects of the epidemiology and transmission appear similar to

Giardia; large waterborne outbreaks of *Cryptosporidium* have been documented.^{[25] [49]}
^[78] Waterborne transmission of *E. histolytica* is common in developing countries. *Cyclospora* has been epidemiologically linked to waterborne transmission in the United States and in Nepal, but the reservoir and host range are not known. Unlike *Giardia* and *Cryptosporidium*, *Cyclospora* is not infectious when passed in feces and requires up to two weeks in the laboratory to sporulate.^[187] Surface water is a common environmental source for microsporidia, however, the route of infection is unknown. *Naegleria fowleri* is a waterborne protozoan that enters the body through the nasal epithelium during swimming in contaminated surface water and causes meningoencephalitis.

Data from Drinking Water Health Effects Task Force, US Environmental Protection Agency: Health effects of drinking water treatment technologies, Chelsea, Mich, 1989, Lewis; and Gelreich EE: Microbiological quality of source waters for water supply. In McFeters GA, editor: Drinking water microbiology, New York, 1990, Springer-Verlag.

Parasitic Organisms

Parasitic organisms other than *Giardia* and *E. histolytica* are seldom considered in discussions of disinfection. Infectious eggs or larvae of many helminths are found in sewage, even in the United States.^[164] ^[184] The frequency of infection by waterborne transmission is unknown, since food and environmental contamination or skin penetration is more prevalent.^[228]

The most obvious risk is from nematodes with no intermediate hosts that are infectious immediately or soon after eggs are passed in stool. *Ascaris lumbricoides* (roundworm) is transmitted by ingestion of the eggs in contaminated food or drink. In endemic areas, 85% of the population is infected; this leads to daily global environmental contamination by 9×10^{14} eggs.^[228] *Ancylostoma duodenale* (hookworm) usually infects as larvae penetrate the skin of the foot, but it also may be acquired by mouth. Oral entry of the larvae causes pulmonary (Wakana) disease. *Necator americanus* does not appear to be infectious via the oral route.

Taenia solium (pork tapeworm) is infectious to humans in cyst or egg form. Eggs passed in stool are ingested in food or water and develop into tissue cysts, often in the brain, resulting in cysticercosis.

Echinococcus granulosus (dog tapeworm) can use humans as intermediate hosts. Eggs from the feces of an infected dog or other carnivore are ingested in food and water. Hydatid disease generates cysts in the liver, peritoneum, and other sites.

Fasciola hepatica (liver fluke of herbivores and humans) is normally acquired by ingestion of encysted metacercariae on water plants or free organisms in water.

Cercariae of schistosomiasis, which live in fresh water and normally enter through skin, can enter through the oral mucosa. The cercariae are killed by stomach acid.

Dracunculus medinensis (Guinea tapeworm) is a tissue nematode of humans and causes the only such disease transmitted exclusively through drinking water.^[218] *Dracunculus* larvae are released in water from subcutaneous worms on the legs of infected bathers or water-gatherers. Larvae are ingested by a tiny crustacean (*Cyclops* species), which acts as the intermediate host and releases infectious larvae when ingested by humans.

Bacterial Spores

Bacterial spores can cause serious wound and gut infections but are not likely to be waterborne enteric pathogens. *Clostridium* is ubiquitous in soil, lake sediment, tropical water sources, and the stool of animals and humans.^{[79] [183]} *C. botulinum* and *C. perfringens* type A food poisoning are not waterborne because they require germination of spores in food by inadequate cooking, then production of an enterotoxin, which is ingested. *C. perfringens* type C causes enteritis necroticans,

1188

probably through in vivo production of an enterotoxin, and thus has the potential for waterborne transmission in the tropics. However, the epidemiology of these infections, as in infant botulism, is related to food-borne sources in the United States.

Chemical Hazards

Chemical hazards are also becoming an alarming source of pollution in surface water. In the United States, chemical contamination is routinely responsible for about 30% of waterborne gastroenteritis where an etiology can be identified.^{[30] [31]} Most common sources include lead that leaches into water lines, as well as copper, nitrate, fluoride, and a variety of other chemicals. Industrialization proceeds worldwide without adequate environmental protection. A vast array of toxins are sold with little concept of safe use and no means of safe disposal. Inorganic chemicals in drinking water include common salts, heavy metals, asbestos, fluorides, nitrates, radionuclides, and some heavy metals (arsenic, copper, iron, lead, selenium). Natural organic chemicals predominate from soil runoff, forest canopy aquatic biota, and human and animal wastes. Synthetic organic matter includes pesticides, herbicides, and chemicals from industrial or human activities.^[53] Major underground aquifers are becoming contaminated. Streams and rivers in rural areas are contaminated by individual carelessness, leaching landfills, and agricultural runoff. Atmospheric spread has resulted in pesticides being found in remote wilderness lakes and in the well-publicized acid rain. Numerous pesticides have been found in runoff and rivers in agricultural areas of the Midwest.^[125] Wilderness users may soon need to ensure removal of chemical, as well as microbiologic, contaminants.

RISK EVALUATION

Risk of waterborne illness depends on the number of organisms consumed, which is determined by the volume of water, concentration of organisms, and treatment system efficiency.^[42]^[89] Additional factors include virulence of the organism and defenses of the host. Infection and illness are not synonymous; the overall likelihood of illness from multiple studies for all three categories of microorganisms (bacterial, viral, protozoan) is 50% to 60%. Death is unlikely except with specific organisms (e.g., *Escherichia coli* O157:H7, *Vibrio cholerae*), hepatitis E in pregnant women, and *Cryptosporidium* with underlying malnutrition. Total immunity does not develop for most enteric pathogens and reinfection may occur.^[89]

Waterborne outbreaks do not give a complete picture of the potential for waterborne illness. Most outbreaks of waterborne disease are not identified because not enough people become ill, providing an insensitive mechanism for detecting water contamination. When an outbreak is identified, it is very difficult to prove

TABLE 51-1 -- Estimated Infectious Dose of Enteric Organisms

ORGANISM	INFECTIOUS DOSE
<i>Salmonella</i>	10 ⁵
<i>Shigella</i>	10 ²
<i>Vibrio</i>	10 ³
Enteric viruses	1–10
<i>Giardia</i>	10–100
<i>Cryptosporidium</i>	10–100 (?)

conclusively that the source was waterborne. The supply may have been only transiently contaminated; water samples from the time of exposure are seldom available; some organisms are difficult to detect; and almost everyone has some exposure to water.^[204]

The data on concentration of microorganisms in surface water show widely varying values, but the testing is insufficient for risk assessment and dose-response models. Instead, infectious dose data and statistical techniques have been used to devise models for determining risk ([Table 51-1](#)).^[89] These cannot be applied unless the microbial content of water is known. Few water sites are monitored. The excretion and loading of microbial contaminants are dynamic and change over time. Pathogenic

microorganisms clearly exist in most raw source waters, especially in surface waters. ^[53]

Most microbiologic testing is done on community water intake sources and sewage treatment effluent. Less information is available for more remote water sources. ^[42] ^[175] ^[227] Protozoan cysts can be found even in pristine water, but their levels are a small fraction of the number in polluted water. ^[177]

Recreational Contact

Inadvertent ingestion during recreational water contact is a risk for swimmers and white-water boaters. The microorganisms that cause infection require only a small dose. Recreational water activities have resulted in giardiasis, cryptosporidiosis, typhoid fever, salmonellosis, shigellosis, viral gastroenteritis, and hepatitis A, as well as in wound infections, septicemia, and aspiration pneumonia due to *Legionella*. ^[43] From 1993 to 1994, 36 outbreaks of gastroenteritis (excluding hot tub dermatitis) from recreational water were reported. Sixteen outbreaks were caused by *Cryptosporidium*, four by *Giardia*, six by *E. coli* O157:H7, three by *Shigella sonnei*, and one by Norwalk virus. ^[31] Six isolated cases of primary amebic meningoencephalitis (*Naegleria fowleri*) were reported, with 100% fatality.

Underdeveloped Countries

In tropical areas and developing countries, water has a complex relationship with spread of disease. [Table 51-2](#)

TABLE 51-2 -- Water and Spread of Disease

TYPE	MECHANISM	EXAMPLES	PREVENTION
Waterborne	Fecal contamination of drinking water by infectious organisms	Typhoid fever, cholera, campylobacteriosis, giardiasis, hepatitis A	Sanitation and disinfection of water
Water washed	Person-to-person fecal-oral spread via direct contact, food, or water (all these are also waterborne)	Shigellosis, amebiasis, ascariasis, eye and skin infections	Handwashing and personal hygiene
Water based	Organism or agent that lives in water	Schistosomiasis, dracunculosis, parasitic worms	Prevention of exposure from bathing
Water related	Spread by insects that breed in water or collecting water	Malaria, sleeping sickness, yellow fever, dengue	Insect protection and piped water

Modified from Bradley DJ: Health aspects of water supplies in tropical countries. In Feachem R et al, editors: Water, wastes and health in hot climates, New York, 1977, Wiley.

presents a useful classification, and Steiner et al^[195] proposed adding the category "water carried" for infections resulting from accidental ingestion in recreational water. Worldwide, 1.5 billion rural people and 200 million urban people in the world lack safe drinking water and adequate sanitation. An estimated 80% of the world's diseases are linked to inadequate water supply and sanitation. Between 10 and 25 million people die each year (28,000 to 68,000 persons each day) from diseases caused by contaminated water and unsanitary conditions. In undeveloped countries, these illnesses account for 1 billion cases of diarrhea every year and 95% of deaths in children under 5 years of age.^[79] ^[218] Of the four diseases that may cause the most morbidity and death in underdeveloped parts of the world—cholera, hepatitis, malaria, and typhoid—malaria is the only one that is not waterborne.^[89]

The sanitary situation in many undeveloped countries is illustrated by current statistics from Peru evaluated during a recent cholera epidemic. Only 73% of the urban population have access to a water distribution system and only 50% to sanitation services. In rural areas, only 23% have access to a water supply and 6% to a sanitation system. In urban areas over the past 5 years the quality of water has deteriorated because of the lack of water treatment chemicals, laboratories for monitoring, and operators to control the processes. Institutional barriers impede improvements for adequate water and sanitation systems.^[44] The statistics for Egypt are only slightly better.

In certain tropical countries the influence of high-density population, rampant pollution, and absence of sanitation systems means that available raw water is virtually wastewater.^[35] Contamination of tap water must be assumed because of antiquated and inadequately monitored disposal, disinfection, and distribution systems. Water from springs and wells and even commercial bottled water may be contaminated with pathogenic microorganisms.

Waterborne pathogens account for most outbreaks of infectious diarrhea acquired in U.S. wilderness and recreation areas ([Box 51-2](#)). From 1920 to 1980, 178 waterborne outbreaks caused by use of contaminated, untreated surface water or groundwater were reported in systems serving parks, campgrounds, and recreation areas.^[43] Between 1970 and 1990, gastroenteritis of undefined etiology accounted for most cases overall, while *Giardia* caused the most cases of defined etiology.^[43] ^[81] A distinct seasonal variation is seen, with the majority of cases from recreational areas occurring during summer months.^[43] This is probably a result of both

1190

increased contamination and number of persons at risk. Between 1993 to 1996, *Giardia* continued to be one of the most common waterborne infections, but *Cryptosporidium* epidemics were being identified with increasing frequency in both public and surface water supplies.^[78] ^[174] An outbreak of *Cryptosporidium* in a public water supply in Milwaukee affected more than 400,000 people.^[115] A surface water outbreak occurred at Lake Mead. During this period, bacteria linked to water ingestion included *Salmonella*, *Campylobacter*, *Shigella sonnei*, *Plesiomonas shigelloides*, and another emerging pathogen, *E. coli* O157:H7.^[30] ^[31] Enteric bacteria are still associated with 12% of waterborne outbreaks in the United States.^[177]

Viruses

Testing in the United States, Europe, and developing countries shows consistent, sometimes astounding, degrees of viral contamination of drinking and surface water.* Even remote surface lakes and streams tested in California showed disturbing levels of viral contamination.^[72] Widespread enteric viral contamination was found at multiple sites in a popular recreation canyon in Arizona. Viruses included poliovirus, echovirus, coxsackievirus, rotavirus, and other unidentifiable viruses, and exceeded the recommended state level for recreational water use in several areas. Virus levels correlated with human activity but not with excess levels of standard coliform indicators.^[175] All surface water supplies in the United States and Canada contain naturally occurring human enteroviruses.^[221] The infectious dose of enteric viruses is only a few infectious units in the most susceptible people.^[119] ^[217] ^[227]

Protozoa

New methods to detect *Giardia* cysts in surface water have found widespread contamination^[91] ^[169] ^[193] ([Table 51-3](#)). Cysts have been found as frequently in pristine water and protected sources as in unprotected waters.^[82] ^[176] Repeated sampling of "negative" sources invariably produced positive results.

A zoonosis with *Giardia* is known, but with at least three different species, the extent of cross-species infection is not clear.^[12] ^[225] Many of the species apparently capable of passing *Giardia* cysts to humans, including dogs, cattle, ungulates (deer), and beaver,

are present in wilderness areas. Forty percent of beaver in Colorado were infected and shedding 1×10^8 cysts per animal per day. All 386 muskrats found were infected. Up to 20% of cattle examined were infected.^[82] Beaver have been implicated in multiple municipal outbreaks of giardiasis. Samples from Rocky Mountain National Park^[106] ^[128] and the California Sierra Nevada^[193] ^[197] show a direct correlation between numbers of cysts and levels of human use or beaver habitation. In Yukon, Canada, 13 of 61 scat samples from various wild animals yielded *Giardia* cysts.^[170]

Ten *G. lamblia* cysts may result in infection, although the infections in this widely quoted study were asymptomatic.^[165] Even with a low infectious dose, the environmental cyst recovery data indicate that the risk of ingesting an infectious dose of *Giardia* cysts is small.^[230] ^[231] However, the likely model that poses a risk to campers is pulse contamination—a brief period of high cyst concentration from fecal contamination. Beaver stool and human stool may contain 1×10^6 cysts/g. Stream contamination from a beaver has been calculated to reach 245 cysts/gallon.^[91] In this instance, small amounts of water may cause infection, similar to an outbreak among lap swimmers from inadvertent water ingestion in a fecally contaminated pool.^[152]

Cryptosporidium oocysts are found widespread in surface water, and the cyst is durable in the environment. A large zoonosis is evident. Environmental occurrence appears ubiquitous.^[173] ^[174] *Cryptosporidium* is now found more frequently than *Giardia* in surface water, but in smaller numbers.

Persistence of Enteric Pathogens

Once environmental contamination has occurred, a natural inactivation or die-off begins. However, enteric pathogens can retain viability for long periods ([Table 51-4](#)).^[53] ^[177] Factors promoting survival of microorganisms are pH near neutral (between 6 and 8) and cold temperatures, which explain the risk of transmission in mountain regions. In temperate and warm water, survival is measured in days, with densities of infectious agents decreasing by 90% every 60 minutes. However, tropical water differs from temperate in nutrients, creating a microbiologically rich environment. Coliform bacteria can survive several months in natural tropical river water and may even proliferate. Survival of other bacteria is also much longer (about 200 hours in tropical compared with 30 hours in temperate water). *E. coli* and *Vibrio cholerae* may occur naturally in tropical waters and are capable of surviving indefinitely.^[44] ^[79] ^[148]

Most enteric organisms, including *Shigella*, resist freezing.^[52] *Salmonella typhosa* (*typhi*) can survive for up to 5 months in frozen debris and ice.^[221] HAV survives 6 months at below-freezing temperatures.^[203] *Cryptosporidium* may be able to survive a week or more in home freezers.^[195]

Natural Purification Mechanisms

It is widely believed that streams purify themselves and that certain water sources are reliably safe for drinking. These concepts have some truth but do not preclude the need

for disinfection to ensure water quality.

<i>Shigella</i>	Temperate stream	Half-life 22 hours	[186]
	Freeze/thaw	Yes	[54]
Enteric pathogens	Freeze/thaw	Yes	[52]
<i>Salmonella typhosa</i>	Ice/frozen debris	5 months	[221]
Viruses	Cold	17–130 days	[182] [227]
Enteric viruses	15°–25° C water	6–10 days	[177]
	4° C water	30 days	[177]
Hepatitis A virus	Cold	1 year	[16] [203]
	Fresh, sea, wastewater	12 weeks	[16]
	< 0° C	6 months	[203]
<i>Giardia</i>	Cold	2–3 months	[15] [51]
	15° C lake, river	10–28 days	[51]
<i>Entamoeba histolytica</i>	Cold	3 months	[34]

Microsporidia	4° C	> 1 year	[118]
<i>Cryptosporidium</i>	Cold	12 months	[48]
<i>Ascaris</i> eggs	Wet or dry	6–9 years	[228]
Hookworm larvae	Wet sand	122 days	[228]

Surface water is subject to frequent, dramatic changes in microbial quality as a result of activities on a watershed. Storm water causes deterioration of source water quality by increasing suspended solids, organic materials, and microorganisms. Some of these contaminants are carried by rain from the atmosphere, but most come from ground runoff. In water sources downstream from towns or villages, storms may overload sewage facilities and cause them to discharge directly into the receiving water. However, rainwater can also flush streams clean by dilution and by washing microbe-laden bottom sediments downstream.^{[67] [79]}

Every stream, lake, or groundwater aquifer has limited capacity to assimilate waste effluents and storm water runoff entering the drainage basin. Self-purification is a complex process that involves settling of microorganisms after clumping or adherence to particles, sunlight providing ultraviolet destruction, natural die-off, predators eating bacteria, and dilution. Environmental factors include water volume and temperature, hydrologic effects, acid soil contact, and solar radiation. The process is time dependent and less active during wet periods and winter conditions. Hours needed in flow time downstream to achieve a 90% bacterial kill by natural self-purification vary with pollution inflow and rate of water flow. They have been measured at approximately 50 hours in the Tennessee River in summer, 47 hours in the Ohio River in summer, and 32 hours in the Sacramento River.^[67]

Storage in reservoirs or lakes also improves microbiologic quality, with sedimentation as the primary process. A 100- to 1000-fold increase in fecal coliform bacteria can be found in bottom sediments compared with overlying water. This removal must be considered temporary, influenced by recirculation of organisms trapped in bottom sediments.^{[51] [66]} In optimal conditions, 10 days of reservoir storage can result in 75% to 99% removal of coliform bacteria and 30 days can produce safe drinking water. Generally, 80% to 90% of bacteria and viruses are removed by storage, depending on inflow and outflow, temperature, and no further contamination. Cysts, with a larger size and greater weight, should settle even faster than bacteria and viruses.^[3]

Groundwater is generally cleaner than surface water because of the filtration action of overlying sediments, but wells and aquifers can be polluted from surface runoff. Spring water is generally of higher quality than surface water, provided that the true source is not surface water channeling underground from a short distance above the spring.

Drawing conclusions from the preceding factors is difficult. The major factor governing

the amount of microbe pollution in surface water is human and animal activity in the watershed. The settling effect of lakes may make them safer than streams, but care should be taken not to disturb bottom sediments when obtaining water.

Benefits of Water Treatment

Methods for treating water are found in Sanskrit medical lore, and pictures of apparatus to purify water appear on Egyptian walls from the fifteenth century BC. Boiling and filtration through porous vessels, sand, and gravel have been known for thousands of years. The Greeks and Romans also understood the importance of pure water.^[127] Safe and efficient treatment of drinking water was one of the major public health advances of the twentieth century.^[195] As the percentage of the U.S. urban population served by water treatment utilities increased after 1900, the annual death rate from typhoid decreased. Drinking water treatment processes provide enormous benefits with minimal risk. Without disinfection and filtration, waterborne disease would spread rapidly in most public water systems served by surface water.^[43] ^[53] Disinfection alters the incidence of certain enteric diseases but does not eliminate diseases. In underdeveloped countries, improving water quality decreases incidence of diarrhea and improves health status.^[7]
^[90]

Standards

Because coliforms originate primarily in the intestinal tracts of warm-blooded animals, including humans, they are used as indicators of possible fecal contamination.^[79] Although compelling reasons exist for testing other organisms before determining the safety of drinking water, cost and relative difficulty in testing for viruses and protozoa are major obstacles to expanding routine water testing. Coliforms remain the worldwide standard indicator organism. Only recently have U.S. regulations stated that testing must be done for specific organisms, mainly *Cryptosporidium*. In the future, molecular probes should make this process much easier.^[127]

The basic federal law pertaining to drinking water is the 1974 Safe Drinking Water Act, which was expanded and strengthened by amendments in 1977, 1986, and 1996.^[127] The U.S. Public Health Service recommendations for potable water specify a mean of one coliform organism/100 ml of water, or 10 organisms/L. Absolute limits are three coliform bacteria/50 ml, four/100 ml, and 13/500 ml.^[214] In 1989 the standards for detection of fecal coliform bacteria in drinking water were relaxed slightly in recognition that coliform bacteria occur in large numbers in many water distribution systems that have no problem with waterborne disease.^[212] Generally the goal is to achieve a 3- to 5-log reduction in the level of microorganisms. Treatment must reduce *Giardia* by 99.9% (3 log) and enteric viruses by at least 99.99% (4 log).^[161] All standards acknowledge the impracticality of trying to eliminate all microorganisms from drinking water; they allow a small risk of enteric infection.^[189] Risk models are used to predict levels of illness and desired levels of reduction. For example, EPA guidelines suggest *Giardia* cyst removal

with the goal of ensuring high probability that consumer risk is no more than one infection per 10,000 people per year.^[162] The concept of risk is important for wilderness travelers as well, since it is impossible to know the risk of drinking the water in advance and not practical to eliminate all risk with treatment.

Definitions

Disinfection, the desired result of field water treatment, means the removal or destruction of harmful microorganisms. Technically, it refers only to chemical means such as halogens, but the term can be applied to heat and filtration. *Pasteurization* is similar to disinfection but specifically refers to the use of heat, usually at temperatures below 100° C (212° F) to kill most pathogenic organisms. Disinfection and pasteurization should not be confused with *sterilization*, which is the destruction or removal of all life forms.^[107] The goal of disinfection is to achieve *potable water*, indicating only that a water source, on average over a period of time, contains a "minimal microbial hazard," so that the statistical likelihood of illness is acceptable. Water sterilization is not necessary, since not all organisms are enteric human pathogens.^[84] *Purification* is the removal of organic or inorganic chemicals and particulate matter to remove offensive color, taste, and odor. It is frequently used interchangeably with disinfection, but purification may not remove or kill enough microorganisms to ensure microbiologic safety.^[218]

HEAT

Heat is the oldest means of water disinfection. It is used worldwide by residents, travelers, and campers to provide safe drinking water. In countries with normally safe drinking water, it is often recommended as backup in emergencies or when water systems have become contaminated by floods or a lapse in water treatment plant efficacy. Fuel availability is the most important limitation to using heat. One kilogram of wood is required to boil 1 L of water.^[35] For wilderness travelers without access to wood, liquid fuel is heavy.

Heat inactivation of microorganisms is exponential and follows first-order kinetics. Time plotted against temperature yields a straight line when plotted on a logarithmic scale.^[96] Thus the thermal death point is reached in shorter time at higher temperatures, whereas lower temperatures are effective with a longer contact time. Pasteurization uses this principle to kill enteric food pathogens and spoiling organisms at temperatures between 60° and 70° C (140° and 158° F), well below boiling.^[64] Therefore the minimum critical temperature is well below the boiling point at any terrestrial elevation.

Microorganisms have varying sensitivity to heat; however, all common enteric pathogens are readily inactivated by heat ([Table 51-5](#)). Bacterial spores (e.g., *Clostridium* species) are the most resistant; some can survive 100° C (212° F) for long periods but, as discussed, are not likely to be waterborne enteric pathogens.

Protozoal cysts, including *Giardia* and *Entamoeba histolytica*, are the most susceptible to heat. *Cryptosporidium* is also inactivated at these lower pasteurization levels.

Parasitic eggs, larvae, and cercariae are all susceptible to heat. For most helminth eggs and larvae, which are more resistant than cercariae and *Cyclops*, the critical lethal temperature is 50° to 55° C (122° to 131° F).^[184]

Common bacterial enteric pathogens (*E. coli*, *Salmonella*, *Shigella*) are killed by standard pasteurization temperatures of 55° C (131° F) for 30 minutes or 65° C (149° F) for less than 1 minute.^[64] ^[137] Recent studies confirmed safety of water contaminated with *V. cholerae* and *E. coli* after 10 minutes at 60° to 62° C (140° to 143.6° F) or after boiling water for 30 seconds.^[76] ^[166]

Viruses are more closely related to vegetative bacteria than to spore-bearing organisms^[96] and are generally inactivated at 56° to 60° C (132.8° to 140° F) in less than 20 to 40 minutes.^[2] ^[149] ^[199] Inactivation at higher temperatures is similar to that of vegetative bacteria. Death occurs in less than 1 minute above 70° C (158° F). This has been confirmed in milk products, despite some degree of thermal protection from

particles.^[198]

Given its environmental stability and clinical virulence, hepatitis A virus is a special concern. It should respond to heat as do other enteric viruses, but data indicate that it has greater thermal resistance. Widely varying data probably result from different models for virus infectivity and destruction and from the use of various test media.

Boiling Time

The old recommendation for treating water is to boil for 10 minutes and add 1 minute for every 1000 feet (305 m) in elevation. However, available data indicate this is not necessary for disinfection. Evidence indicates that enteric pathogens are killed within seconds by boiling water and rapidly at temperatures above 60° C (140° F). In the wilderness the time required to heat water from 55° C (131° F) to boiling temperature works toward disinfection. Therefore any water brought to a boil should be adequately disinfected. An extra margin of safety can be added by boiling for 1 minute or by keeping the water covered and allowing it to cool slowly after boiling. Although the boiling point decreases with increasing altitude, this is not significant compared with the time required for thermal death at these temperatures ([Table 51-6](#)). The boiling time required is important when fuel is limited. In recognition of the difference between pasteurizing water for drinking purposes and sterilizing for surgical purposes, many other sources now agree with this recommendation to bring water to a boil. Because of scant data for hepatitis A the Centers for Disease Control and Prevention (CDC) and EPA still recommend boiling for 1 minute to add a margin of safety.^[28] Some sources still

TABLE 51-5 -- Heat Inactivation of Microorganisms

ORGANISM	LETHAL TEMPERATURE (° C)/TIME	REFERENCES
<i>Giardia</i>	55 for 5 min	[94]
	100 immediately	[15]
	50 for 10 min (95% inactivation)	[143]
	60 for 10 min (98% inactivation)	
	70 for 10 min (100% inactivation)	
	55	[6]
<i>Entamoeba histolytica</i>	Similar to <i>Giardia</i>	
Nematode cysts, helminth eggs, larvae, cercariae	50–55	[184]

	55 warmed over 20 min	
	64.2 within 2 min	[59]
	72 heated up over 1 min	
<i>Escherichia coli</i>	55 for 30 min	[64]
	60–62 for 10 min	[76]
	50 for 10 min ineffective	[137]
	60 for 5 min	
	70 for 1 min	
<i>Salmonella, Shigella</i>	65 for < 1 min	
<i>Vibrio cholerae</i>	60–62 for 10 min	[166]
	100 for 30 sec	
<i>E. coli, Salmonella, Shigella, Campylobacter</i>		
	60 for 3 min (3-log reduction)	[8]
	65 for 3 min (all but a few <i>Campylobacter</i>)	
	75 for 3 min (100% kill)	
Viruses	55–60 within 20–40 min	[2]
	70 for < 1 min	
Hepatitis A	98 for 1 min	[105]
	85 for 1 min	[203]
	61 for 10 min (50% disintegrated)	
	60 for 19 min (in shellfish)	[150]
Hepatitis E	60 for 30 min	[203]
Bacterial spores	>100	[2]

TABLE 51-6 -- Boiling Temperatures at Various Altitudes

ALTITUDE [ft (m)]	BOILING POINT (° C)
5000 (1524)	95
10,000 (3048)	90
14,000 (4267)	86
19,000 (5791)	81

suggest 3 minutes of boiling time at high altitude to give a wide margin of safety. [32] [66] [87] [174]

Hot Tap Water

Although attaining boiling temperature is not necessary, it is the only easily recognizable end point without using a thermometer. Other markers, such as early bubble formation, do not occur at a consistent temperature. When no other means are available, the use of hot tap water may prevent travelers' diarrhea in developing countries. Newman^[137] ^[138] cultured samples from the hot water tap of 17 hotels in west Africa and in 15 found no coliforms, one yielded a single colony and another two colonies. Water temperature ranged from 57° to 69° C (131° to 140° F). As a rule of thumb, water too hot to touch fell within the pasteurization range. Bandres et al^[8] also measured hot tap water temperature in 14 hotels in four different countries outside the United States. Most temperatures were 55° to 60° C (131° to 140° F), but one was 44° C (111.2° F), only one was 65° C (149° F), and several were 52° C (125.6° F). The authors concluded that hot water from taps would not be safe to drink. Groh et al^[76] showed that tolerance to touch is too variable to be reliable, since some people found 55° C too hot to touch. If water has been sitting in a tank near 60° C for a prolonged period, enteric pathogens will be significantly reduced, likely to potable levels. Neumann's suggestion is reasonable if no other method of water treatment is available.

Solar Heat

Pasteurization has been successfully achieved using solar heating. A solar cooker constructed from a foil-lined

N/S, Not specified.

cardboard box with a glass window in the lid can be used for disinfecting large amounts of water by pasteurization. Bottom temperatures of 65° C have been obtained for at least 1 hour in up to three 3.7-L jugs. Exposure to full sunshine in Kenya destroyed *E. coli* in 2-L clear plastic bottles within 7 hours if the maximum temperature reached 55° C. Inactivation in this situation was a combination of thermal and ultraviolet irradiation.^[97]
^[120] This could be a low-cost method for improving water quality, especially in refugee camps and disaster areas.

PHYSICAL REMOVAL

Filtration

Filters have the advantages of being simple and requiring no holding time. They do not add any unpleasant taste and may improve taste and appearance of water. However, they add space and weight to baggage. All filters eventually clog from suspended particulate matter (present even in clear streams), requiring cleaning or replacement of the filter. A crack or eroded channel allows passage of unfiltered water.

Filtration is both a physical and a chemical process, so many variables influence filter efficiency. The characteristics of the filter media and the water, as well as flow rate, determine the interactions. Filtration can reduce turbidity, bacteria, algae, viruses, color, oxidized iron, manganese, and radioactive particles.^[47]

The size of a microorganism is the primary determinant of its susceptibility to filtration ([Table 51-7](#) and [Figure 51-1](#)). Filters are rated by their ability to retain particles of a certain size, which is described by two terms. *Absolute* rating means that 100% of a certain size of particle is retained. *Nominal* rating indicates that more than 90% of a given particle size will be retained. Filter efficiency is generally determined with hard particles (beads of known diameter), but microorganisms are soft and compressible under pressure.

A membrane with pore size of 0.2 μm can remove enteric bacteria. *Giardia* and *E. histolytica* cysts are easily

filtered, requiring a maximum filter size of 5 μm . *Cryptosporidium* cysts are somewhat smaller than *Giardia* and more flexible; 57% are able to pass through a 3 μm membrane filter, so a filter with 1- to 2- μm pores is recommended.^[174] Helminth eggs and larvae, which are much larger, can be removed by a 20- μm filter. *Cyclops* that transmits dracunculosis can be removed by passage through a fine cloth.^[184]

Filters are constructed with various designs and materials, and many filters are designed for field use. Surface, membrane, and mesh filters are very thin with a single layer of fairly precise pores, whose size should be equal to or less than the smallest dimension of the organism. These filters provide little volume for holding contaminants and thus clog rapidly, but can be cleaned easily by washing and brushing without

destroying the filter. Maze or depth filters depend on a long, irregular labyrinth to trap the organism, so they may have a larger pore or passage size. Contaminants adhere to the walls of the passageway or are trapped in the numerous dead-end tunnels. Granular media, such as sand or charcoal, diatomaceous earth, or ceramic filters function as maze filters. A depth filter has a large holding capacity for particles and lasts longer before clogging but may be difficult to clean effectively, since many particles are trapped deep in the filter. Flow can be partially restored to a clogged filter by back flushing or surface cleaning, which removes the larger particles trapped near the surface. For ceramic filters, surface cleaning is highly effective but destroys some of the filter medium. As a filter clogs, it requires increasing pressure to drive the water through, which can force microorganisms through the filter.

Portable filters can readily remove protozoan cysts and bacteria but may not remove viruses, which are another order of magnitude smaller than bacteria. Only the semipermeable membranes in reverse-osmosis filters are inherently capable of removing viruses. However, adsorption and aggregation reduce viruses using other mechanical filters. Virus particles may adhere to the walls of diatomite (ceramic) or charcoal filters by electrostatic chemical attraction.^[58] ^[71] ^[163] Viruses in heavily polluted water often aggregate in large clumps and become adsorbed to particles or enmeshed in colloidal materials, making them amenable to filtration. ^[53] ^[159] Thus turbidity (cloudiness from contaminants) may help remove pathogens with filtration while it inhibits halogens. In one study, however, only 10% of total virus particles detected were recovered on 3- to 5- μm pore prefilters, suggesting that most were *not* associated with the suspended sediment. ^[141] Furthermore, adsorbed viral particles can be subsequently dislodged and eluted from a filter.^[158] ^[206] Some filters now can remove 99% to 99.9% of viruses, but the fourth log required by water treatment units remains a challenge. Recently, the First Need filter (General Ecology, Exton, Pa.) was able to meet the EPA standards for water purifiers, including 4-log removal of viruses. It is not clear how this filter succeeded when others have failed^[71] (see [Appendix](#)). In general, however, mechanical filters should not be considered adequate for complete removal of viruses, except with special equipment.^[219] Additional treatment with heat or halogens before or after filtration guarantees effective virus removal. ^[163] New designs and materials may overcome this limitation of microfiltration.

For domestic use and in pristine protected watersheds where pollution and viral contamination are minimal and the main concerns are bacteria and cysts, filtration can be used as the only means of disinfection. For foreign travel and for surface water with heavy levels of fecal or sewage contamination, however, most filters should not be used as the sole means of disinfection.^[58] One rational use of filtration is to clear the water of sediment and organic debris, allowing lower doses of halogens with more predictable residual levels.^[134] Filters are also useful as a first step to remove parasitic and *Cryptosporidium* organisms that have high resistance to halogens.

Filtration using simple, available products is of interest for use in developing countries and in emergency situations. Sand filtration is still used widely in municipal plants. A column of fine sand 60 to 75 cm deep that permits no more than 200 L/m²/hr is capable of removing turbidity and greater than 99% of organisms.^[161] Rice hull ash filters are moderately effective. The United Nations International Children's Emergency Fund has devised a filter containing crushed charcoal sandwiched between two layers of fine sand

that can filter 40 L/day and requires cleaning only once a year, but it has not been well tested.^[35]

Reverse Osmosis.

A reverse-osmosis filter uses high pressure (100 to 800 psi) to force water through a semipermeable membrane that filters out dissolved ions, molecules, and solids.^[53] This process can desalinate water, as well as remove microbiologic contamination. If pressure or degradation causes breakdown of the membrane, treatment effectiveness is lost. Even *Giardia* cyst passage has been shown to occur in a compromised reverse-osmosis unit.^[45]

Small hand-pump reverse-osmosis units have been developed. Their high price and slow output currently prohibit large-scale use by wilderness travelers, but they are important survival items for ocean travelers. Battery-operated units are often used on boats. The U.S. Department of Defense uses large-scale mobile reverse-osmosis units for water purification units because these are capable of producing potable water from fresh, brackish, or salt water, as well as from water contaminated by nuclear, biologic, or chemical agents. Moreover, these are considered the most fuel-efficient mobile

units, producing the highest quality water from the greatest variety of raw water qualities. The units use pretreatment, filtration, and desalination, then disinfection for storage.^[219]

Granular Activated Carbon (GAC).

Granular charcoal has been used as an adsorbent for water purification since biblical times.^[108] It is still in use for water treatment and for medical detoxification. When activated, charcoal's regular array of carbon bonds is disrupted, yielding free valences that are highly reactive and adsorb dissolved chemicals.^[68] ^[178] GAC is the best means to remove organic and inorganic chemicals from water (including disinfection byproducts) and to improve odor and taste.^[53] ^[134] Thus it is widely used in municipal disinfection plants and in home undersink devices. GAC is also a common component of field units as a filter and water purifier. GAC can be compressed into block form that acts both as a depth filter and adsorbent charcoal. The block carbon is more effective than granular because the passages are smaller, forcing closer contact with the carbon.

Many, but not all, viral particles and bacteria adhere to GAC, ^[134] and some cysts are trapped in the matrix. ^[113] However, using a bed of GAC to filter particles and microorganisms results in more rapid saturation of binding sites and clogs the bed. An alternative means of disinfection should always be used. GAC does not kill microorganisms, so it does not disinfect. In fact, bacteria colonize beds of GAC and slough off into the effluent water. Bacteria attached to charcoal are resistant to chlorination because the chlorine is adsorbed by the GAC.^[53] ^[108] ^[134] This bacterial

contamination has not been found to be harmful because the usual heterophilic bacteria are not enteric pathogens. Enteric pathogens have been shown to survive on GAC, but if an active biofilm exists, the pathogens are rapidly displaced by heterophilic bacteria and fail to become established. Therefore nonpathogenic bacterial colonization is encouraged in municipal plants. ^[163]

Eventually the binding sites on the carbon particles become saturated and no longer adsorb; some molecules are released as others preferentially bind. ^[134] Unfortunately, no reliable means are available to determine precisely when saturation is reached. Filters using charcoal in compressed block form as the filter element may clog before the charcoal is fully adsorbed. Presence of unpleasant taste or color in the water can be the first sign that the charcoal is spent. To test the charcoal, filter iodinated water or water tinted with food coloring. With regular use the lifetime of GAC is probably measured in months; it is substantially longer with infrequent use. GAC can be "recharged," but this is not practical for small-quantity use. Ingested particles of charcoal are harmless.

GAC can be used before or after disinfection. Before disinfection, GAC removes many organic impurities that result in bad odor and taste and that are precursors to trihalomethane formation. GAC is best used after chemical disinfection to make water more palatable by completely removing the halogen ^[134] ^[221] and other chemical impurities. With increasing industrial and agricultural contamination of distant groundwater, final treatment of drinking water with GAC may become a necessity for wilderness users. GAC also removes radioactive contamination.

Silver Impregnation.

Silver impregnation of filters neither prevents microbial contamination of the filter nor sustains its action as a bactericide in the effluent water. ^[11] Although silver has slow antibacterial effect on coliform organisms, filter cartridges impregnated with silver typically become colonized with heterotrophic bacteria, which increase the total bacterial count in the effluent water but have not been linked to increased illness. ^[11] ^[58] ^[68] ^[163] In GAC filters designed to operate in line with chlorinated tap water, silver merely exerts selective pressure on the kinds of bacteria that will colonize the filter. Colonization of filters with pathogenic coliforms has not been demonstrated, but protective effect cannot be attributed to silver impregnation. ^[58] ^[163]

Commercial Devices Using Mechanical Filtration.

Portable water treatment products are the third highest intended purchase of outdoor equipment after backpacks and tents. ^[95] Some are designed as purely mechanical filters, whereas others combine filtration with GAC. Filters that contain iodine resins are considered in the discussion on halogens (see [Appendix](#)).

Environmental Protection Agency Registration.

Until recently, no testing criteria were mandated for EPA registration. The EPA does not endorse, test, or approve mechanical filters; it merely assigns registration numbers. ^[39]

However, registration requirements distinguish between two types of filters: those that use mechanical means only and those that use a chemical, designated as a pesticide. Standards were developed to act as a framework for testing and evaluation of water purifiers for EPA registration, as a testing guide to manufacturers, to assist in research and development of new units, and as a guide to consumers.^[212] To be called a "microbiologic water purifier," the unit must remove, kill, or inactivate all types of disease-causing microorganisms from the water, including bacteria, viruses, and protozoan cysts, so as to render the processed water safe for drinking. An exception for limited claims may be allowed for units removing specific organisms to serve a definable environmental need, for example, removal of *Giardia* only.

The EPA standards include performance-based microbiologic reduction requirements, chemical health

limits for substances that may be discharged, and stability requirements for chemical(s) sufficient for the shelf life of the device. The unit should signal the end of effective lifetime (e.g., by terminating discharge of treated water) or give simple instructions for servicing or replacing within measurable volume, throughput, or time frame. There are currently no national guidelines for the removal of chemicals by portable filters.

Challenge water seeded with specific amounts of microorganisms is pumped through the filters at given intervals during the claimed volume capacity of the filter. Between the bacteriologic challenges, different test waters without organisms are passed through the unit. Water conditions are specified to include average and worst-case conditions, which are 5° C with high levels of pollution, turbidity, and alkaline pH. Testing must be done with bacteria (*Klebsiella*), viruses (poliovirus and rotavirus), and protozoa (*Cryptosporidium* has replaced *Giardia*). A 3-log reduction is required for cysts, 4-log reduction for viruses, and 5- to 6-log reduction for bacteria. Testing is done or contracted by the manufacturer; the EPA neither tests nor specifies laboratories.

Filter Testing.

Current registration of mechanical filters requires only that the product make reasonable claims and that the location of the manufacturer be listed; no disinfection studies are required.^[24] However, many companies now use the standards as their testing guidelines. For mechanical filters the standards should be applied only for those microorganisms against which claims are made, such as protozoa and bacteria, excluding viruses. Despite criticisms of the methodology and inconsistencies and loopholes in the reporting process, the EPA standards are currently the best means to compare filters.

The ceramic filters (especially Katadyn) have been tested most extensively and generally perform well.^{[58] [143] [206]} Results may not apply to all ceramic filters because efficacy depends on the characteristics of the ceramic, water quality, product

engineering, and prior extent of filter use. Comparative testing of different filters is in progress. Available data are from testing organized by one filter manufacturer, so the results are not generally accepted, despite nearly all filters performing well ([Table 51-8](#)).

Turbidity and Clarification

River, lake, or pond water is often cloudy and unappealing. Turbidity (cloudiness) is an optical measurement of light scattering as it passes through water. Visibility in water with turbidity of 10 nephelometric turbidity units (NTU) is about 30 inches and with 25 NTU is 10 inches. Turbidity is caused by suspended organic and inorganic matter, such as clay, silt, plankton, and other microscopic organisms. High turbidity is often associated with unpleasant odors and tastes, most often caused by organic compounds and metallic hydroxides with a much smaller particle size.^[38] ^[109] Clayorganic complexes may also carry pesticides or heavy metals. Bacteria, as well as viruses, may be adsorbed to particulate matter or be embedded in it, and in highly contaminated water, microorganisms tend to aggregate and clump. In one study, 17% of turbidity particles contained attached microbes, averaging 10 to 100 bacteria per particle.^[109] Organisms in the center of these conglomerates are afforded some protection from disinfectants. Even the flocculate produced by a chlorination-flocculation tablet may harbor viable organisms.^[155] Thus, removing particulate matter also decreases the number of microorganisms and halogen demand.^[98] ^[134]

Removal of turbidity and particulates may be important in preventing chemical or infectious illness. Even if turbidity is caused by benign inorganic particles, such as clay, removal is desirable for improving esthetic quality of the water. Filtration can remove larger particles, but cloudy water can rapidly clog a filter. Sedimentation and coagulation-flocculation are other clarification techniques routinely used in municipal disinfection plants that can be easily applied in the wilderness for pretreatment of cloudy water, which is then disinfected by filtration or halogenation. Coagulation-flocculation and filtration are also used to remove *Giardia* and *Cryptosporidium* cysts that are more resistant to chlorine. Early experiments with water heavily contaminated with feces containing hepatitis A virus demonstrated that filtration and sedimentation alone did not prevent infection but reduced the severity of the illness. Water pretreated with coagulation, settling, and filtration was subsequently disinfected with 0.4 ppm of residual chlorine, whereas water chlorinated to 1 mg/L without pretreatment remained infectious.^[135] ^[136]

Sedimentation.

Sedimentation is the separation of suspended particles large enough to settle rapidly by gravity, such as sand and silt. The time required depends on the size of the particle. Generally, 1 hour is adequate if the water is allowed to sit without agitation. After sediment has formed on the bottom of the container, the clear water is decanted or filtered from the top. Microorganisms, especially protozoal cysts, eventually settle, but this takes longer and the organisms are easily disturbed during pouring or filtering. In one test in Tanzania, 4 days were required for sedimentation to improve microbiologic

quality of the water.^[35] Sedimentation should not be considered a means of disinfection.

Coagulation-Flocculation.

Smaller suspended particles and chemical complexes too small to settle by gravity are called *colloids*. Most of these can be removed by coagulation-flocculation, a technique that has been used to remove unpleasant color, smell, and taste in water since 2000 BC.

Coagulation is achieved with addition of an appropriate chemical that alters the physical state of dissolved

TABLE 51-8 -- Performance Evaluations of Portable Filters

REFERENCE	CHALLENGE	FILTERS TESTED	RESULTS			CONCLUSIONS/COMMENTS
			BACTERIA	PROTOZOA	VIRUS	
[157]	Challenged Katadyn filter with 10 ⁸ <i>B. subtilis</i> spores, 10 ⁶ <i>Naegleria</i> cysts, 10 ⁵ <i>Giardia</i> cysts using EPA test waters 1 and 3 (clear and cloudy) at 20° and 4° C.	Katadyn			N/A	Katadyn filter failed unless cleaned regularly; failure was related to mechanical pump forcing organisms through a clogged filter. Recommend prefilter.

and suspended solids, causing particles to stick together on contact because of electrostatic and ionic forces.^{[38] [53]} Lime (alkaline chemicals principally containing calcium or magnesium and oxygen) and alum (an aluminum salt) are commonly used, readily available coagulants. Rapid mixing is important to obtain dispersion of the coagulant. The second stage, flocculation, is a purely physical process obtained by prolonged gentle mixing to increase interparticle collisions and promote formation of larger particles. The flocculate particles can be removed by sedimentation and filtration. Coagulation-flocculation removes most coliform bacteria (60% to 98%), viruses (65% to 99%),^{[47] [159] [189]} *Giardia* (60% to 99%), helminth ova (95%),^[184] heavy metals, dissolved phosphates, and minerals.^{[38] [53] [113] [227]} Organic and inorganic compounds may be removed by forming a precipitate or by adsorbing onto aluminum hydroxide or ferric hydroxide floc particles.^[53] Despite removal of most microorganisms, a subsequent disinfection step is advised.

The sequential use of coagulation and activated carbon is often beneficial. Coagulation is generally found to remove large molecules that absorb poorly on GAC. On the other hand, carbon has limited effectiveness for removing organic matter from water.^[4]

To clarify water by this means in the field, add 10 to 30 mg of alum per liter of water. The exact amount is not important, so it can be done with a pinch of alum, lime, or both for each gallon of water, using more if the water is very cloudy. Next, stir or shake briskly for 1 minute to mix the coagulant, then agitate gently and frequently for at least 5 minutes to assist flocculation. Settling requires at least 30 minutes, after which the water is carefully decanted or poured through a cloth or paper filter. Finally, filtration or halogenation should be used to ensure disinfection.

TOXICITY.

Questions have been raised concerning the association of aluminum with central nervous system (CNS) toxicity in mammals, but these effects have been observed only after exposures other than ingestion. Most of the aluminum in alum is removed with the floc. A report from the National Academy of Sciences concluded that aluminum in drinking water does not present a significant risk.^[53] Alum is a common chemical used by the food industry in baking powder and for pickling. It can be found in some food stores or at chemical supply stores.

ALTERNATIVE AGENTS.

Many substances can be used as a coagulant, including lime or potash. In an emergency, baking powder or even the fine white ash from a campfire can be used.^[209] Other coagulation-flocculation agents used traditionally by native peoples include seeds from the nirmali plant in southern India and rauwaq (a form of bentonite clay) or seeds from moringa plants in Sudan.^[35]

HALOGENS

Worldwide, chemical disinfection is the most widely used method for improving and maintaining microbiologic quality of drinking water. Halogens, chiefly chlorine and iodine, are the most effective chemical disinfectants. Understanding the principal factors of halogen disinfection allows intelligent and flexible use. Germicidal activity results from oxidation of essential cellular structures and enzymes.^{[33] [107] [134] [139]} Halogenated amines may be synthesized by white blood cells as part of the body's natural defenses to destroy microorganisms.^[220] The disinfection process is determined by characteristics of the disinfectant, the microorganism, and environmental factors.^{[34] [86] [131]} Dilute solutions do not sterilize water.

Variables with Halogenation

Concentration and Contact Time.

The major variables in the disinfection reaction with chlorine or iodine are the amount of halogen (concentration) and the exposure time of the microorganism to the halogen disinfectant (contact time). Concentration of halogen in water is measured in parts per million (ppm) or milligrams per liter (mg/L), which are equivalent. Contact time is usually measured in minutes but ranges from seconds to hours. In field disinfection, concentrations of 1 to 10 mg/L for 10 to 60 minutes are generally effective.

Theoretically the disinfection reaction follows first-order kinetics. The rate of the reaction is determined by the initial concentration of reactants, and a given proportion of the reaction occurs in any specified interval.^{[86] [221]} This means concentration and time are inversely related, and their product results in a constant for specified disinfectant, organism, percent reduction of viable microorganisms, and given conditions of water temperature and pH: concentration \times time = constant ($Ct = K$) ([Figure 51-2](#)).^[221] When concentration and contact time are graphed on logarithmic coordinates, a straight line results. This means that concentration and time can be varied oppositely and still achieve the same result.^[9] In field disinfection this can be used to minimize halogen dose and improve taste or to minimize the required contact time.

In reality the disinfection reaction deviates from first-order kinetics, and Ct values do not follow the exponential rates described by the empiric equation because microorganisms do not act as chemical reagents ($C_n t = K$). An initial lag period may be seen before inactivation begins (e.g., because of penetration of the cyst wall), and inactivation declines for more resistant organisms or those protected by aggregation or association

with other particulate matter ([Figure 51-3](#)).^[77] ^[82] ^[86]

Contaminants.

Organic and inorganic nitrogen compounds from decomposition of organisms and their

1201

Figure 51-2 Relationship of halogen concentration and contact time for a given temperature and pH. The first-order chemical reaction results in a straight line over most values for each microorganism and halogen compound. (Data from *Change SL: J Am Pharm Assoc 47:417, 1958*; and *Water and Sanitation for Health [WASH] Project: Report on mobile emergency water treatment and disinfection units, WASH Field Report No 217, Arlington, Va, 1980.*)

wastes, fecal matter, and urea complicate disinfection with halogens and must be considered in field water treatment. Vegetable matter, ferrous ions, nitrites, sulfides, and humic substances also affect oxidizing disinfectants.^[55] ^[134] ^[221] These contaminants react with halogens, especially chlorine, to form compounds with little or no disinfecting ability, effectively decreasing the concentration of available halogen.

Halogen Demand and Residual Concentration.

Halogen demand is the amount of halogen reacting with impurities. Residual halogen concentration is the amount of active halogen remaining after halogen demand of the water is met. To achieve microbial inactivation in aqueous solution with a chemical agent, a residual concentration must be present for a specified contact time. Failure of chlorination in municipal systems to kill cysts or other microorganisms is usually caused by difficulty maintaining adequate residual halogen concentration and contact times, rather than by extreme resistance of the organism.^[196]

Halogen demand and residual concentration of surface water are the greatest uncertainties in field disinfection. Nitrogen appears in most natural waters in varying amounts, which relate directly to the sanitary quality of water. Cysticidal dose of halogens is strongly affected by the level of contamination (cyst or viral density) in otherwise clean water.^[34] ^[75] ^[196] Scant data are available on halogen demand for surface water ([Table 51-9](#)). Clear water is assumed to have minimal demand and cloudy water high demand. Surface water in the wilderness contains 10 times the organic carbon content

Figure 51-3 Effect of concentration and temperature on *Giardia* cyst inactivation by iodine.

Low concentrations are effective at cold temperatures with prolonged contact time. (From Fraker LD et al: *J Wilderness Med* 3:351, 1992.)

of aquifer groundwater. The green or brown color in stagnant ponds or lakes or in tropical and lowland rivers is usually caused by organic matter with considerable halogen demand. In some cases, such as runoff after storms and snowmelt, cloudy water may be caused by inorganic sand and clay that exert little halogen demand. In general, chlorine demand rises with increased turbidity.^[109] In addition, particulate turbidity can shield microorganisms and interfere with disinfection.^{[47] [98] [109]}

The initial dose of halogen must consider halogen demand. For clear alpine waters, 1 mg/L demand can

TABLE 51-9 -- Halogen Demand of Surface Water

SOURCE	HALOGEN DEMAND (mg/L)	REFERENCE
Cloudy river water, Portland, Oregon	3–4	[93]

be assumed; for cloudy waters the assumption is 3 to 5 mg/L. If a method is used that adds 4 mg/L to clear water, extra time can compensate for the lower expected residual concentration. In cloudy water, however, where the demand may be nearly 4 mg/L, an increased dose of halogen, rather than prolonging the contact time, is needed to ensure free residual. The usual field recommendation to compensate for the unknown demand of cloudy water is a double dose of halogen (to achieve 8 to 16 mg/L). This crude means of compensation often results in a strong halogen taste on top of the taste of the contaminants. If the cause of turbidity is uncertain, the water should be allowed to sit; inorganic clay and sand will sediment, clarifying the water considerably. Other means of clarification, such as coagulation-flocculation or filtration, significantly reduce halogen demand.

Several simple color tests (most often used to test swimming pools and spas) measure the amount of free (residual) halogen in water. Testing in the wilderness for halogen residual may be reasonable for large groups but is not practical for most. Smell of chlorine usually indicates some free residual. Color and taste of iodine can be used as indicators. Above 0.6 ppm, a yellow to brown tint is noted. [221]

pH.

Two other variables in the disinfection reaction are pH and temperature. [55] [107] [134] Halogen oxidizes water to form several compounds, each with different disinfection capabilities. The percentage of each halogen compound is determined by pH. The optimal pH for halogen disinfection is 6.5 to 7.5. [34] [130] As water becomes more alkaline, approaching pH 8.0, much higher doses of halogens are required.

Although pH can be measured in the field, the relationship is too complex to allow meaningful use of the information. Most surface water pH is neutral to mildly acidic, which is within the effective range of the halogens used. Granite keeps many alpine waters mildly acidic. Unfortunately, acid rain is affecting some high mountain lakes. [122] The EPA found the average pH in western alpine lakes to be no less than 5.5; other US lakes are beginning to show lower pH levels. On the alkaline side, some surface water with pH 7.0 to 8.0 begins to affect the chemical species of chlorine, favoring less active forms. [96] Certain desert water is so alkaline that halogens would have little activity; however, these waters are usually not palatable. At this time, compensating for pH is not necessary. Tablet formulations of halogen have the advantage of some buffering capacity.

Temperature.

Temperature influences the rate of the disinfection reaction. Cold water affects germicidal power and must be offset by longer contact time or higher concentration to achieve comparable disinfection. [74] The common rule is a twofold to threefold increase in inactivation rate per 10° C increase in temperature. Unusual retardation of rates as

temperatures approach 0° C has not been seen.^[86]

Temperature can be estimated in the field. Some treatment protocols recommend doubling the dose of halogen in cold water, but if time allows, time can be increased instead of dose. Data for killing *Giardia* in very cold water (5° C) with both chlorine and iodine indicate that contact time must be prolonged three to four times, not merely doubled, to achieve high levels of inactivation.^{[63] [83]} If feasible, raising the temperature by 10° to 20° C allows a lower dose of halogen and more reliable disinfection at a given dose.

Susceptibility of Microorganisms.

The final variable is the target microorganism. Sensitivity to halogen is determined by the diffusion barrier of the cell wall or capsule and the relative susceptibility of proteins and cellular respiration to denaturation and oxidation.^{[33] [134]} Organisms, in order of increasing resistance to halogen disinfection, are enteric (vegetative) bacteria, viruses, protozoan cysts, bacterial spores, and parasitic ova ([Table 51-10](#) and [Table 51-11](#)); for example, *E. histolytica* cysts are 160 times as resistant as *E. coli* and 9 times as resistant as hardier enteroviruses to chlorine (HOCl). Virucidal residuals of I₂ and HOCl are 5 to 70 times higher than bactericidal residuals.^{[33] [134]} Relative resistance between organisms is similar for iodine and chlorine.

TABLE 51-10 -- Disinfection Data for Chlorine

[†]100% kill; viability tested only at 15, 30, 45, 60, and 120 minutes.

BACTERIA.

All vegetative bacteria are extremely sensitive to halogens. Inactivation involves oxidation of enzymes on the cell membrane and does not require penetration.^[221] Little modern work has focused on bacterial agents because they are more sensitive than viruses and cysts, and little difference is evident between the bacterial pathogens.^[86] Although halogens were first used to disinfect water during cholera epidemics in 1850, recent cholera epidemics prompted review of data to ensure the susceptibility of *V. cholerae* to low levels of chlorine and iodine.^[44] *Campylobacter* has susceptibility similar to that of other enteric pathogens.^[19]

Bacterial spores, such as *Bacillus anthracis*, are relatively resistant to halogens, but with chlorine, spores are not much more resistant than *Giardia* cysts.^[9] ^[221] Quantitative data are not available for iodine solutions, but iodine does kill spores. Fortunately, sporulating bacteria do not normally cause waterborne enteric disease.^[84]

VIRUSES.

Enteroviruses are more resistant than enteric bacteria,^[134] but they constitute such a large and diverse group of organisms that generalization is especially difficult.^[33] ^[53] ^[107] Most studies have used poliovirus, a phage virus, or coxsackievirus. The mechanism of action for halogen inactivation of viruses has not been resolved. It is not clear whether the oxidant injures protein on the shell, a process similar to bacterial inactivation,^[23] or penetrates the protein capsid by chemical transformation and then attacks the nucleic acid core, as in cyst inactivation.^[221]

Most viruses tested against chlorine have shown resistance 10 times greater than that of enteric bacteria, but inactivation is still achieved rapidly (0.3 to 4.5 minutes) with low levels (0.5 mg/L) of chlorine.^[56] ^[210] Current data suggest that HAV is not significantly more resistant than other enteric viruses.^[75] ^[151] ^[190] ^[203] In one test using iodine tablets, HAV was inactivated under difficult conditions more readily than poliovirus or echovirus.^[191] Norwalk virus may be more resistant to chlorine than several other viruses, which may account for its importance in waterborne outbreaks.^[101] Powers et

a)^[155] ^[156] found that poliovirus was more slowly inactivated than rotavirus and *Giardia muris* by both chlorine and iodine, but this is inconsistent with other data. Clumping and association of viruses with cells and particulate matter are thought to be significant factors affecting viral disinfection, causing departure from first-order kinetics.^[56] ^[191] ^[210] Cell-associated hepatitis A virus was 10 times more resistant than dispersed hepatitis A virus.

CYSTS AND PARASITES.

Protozoal cysts are considerably more resistant than enteric bacteria and significantly more resistant than enteric viruses, probably because of cysts' physiologically inactive outer shell, which the disinfectant must penetrate to be effective.^[33] ^[221] Early data exist for *E. histolytica*, but recent work on *G. lamblia* indicates similar sensitivity to both iodine and chlorine.^[94] Higher pH and lower temperature decrease the effectiveness of halogens on *Giardia*.^[82] ^[91] ^[191] Review literature frequently attributes exaggerated resistance of *Giardia* to halogens; Hoff^[85] traced this to misquoted data. Jarrol et al^[92] ^[93] tested two chlorine methods and four iodine methods for effectiveness against *Giardia* cysts. They found all methods effective in warm water, but only two methods destroyed all cysts in cold water in recommended doses. Higher doses or longer contact times would make all these methods effective. Halogens can be used in the field to inactivate *Giardia* cysts² (see [Figure 51-3](#)). However, longer contact time is required in cold and dirty water.^[73]

Cryptosporidium oocysts differ greatly from other protozoan cysts and are highly resistant to halogens. The Ct constant for *Cryptosporidium* in warm water with chlorine was estimated at 9600.^[29] From 65% to 80% of *Cryptosporidium* oocysts were inactivated after 4 hours by two iodine tablets in "general case" water.^[73] This implies that 3-log inactivation could have been achieved after 3 to 4 more hours. Although halogens can achieve disinfection of *Cryptosporidium* in the field, this is not practical.^[48] ^[174] ^[221] The resistance of *Cyclospora* and microsporidia is not well studied, but the oocysts are similar to *Cryptosporidium* and thus may resemble this protozoa more than *Giardia*.

Schistosome cercariae are susceptible to low concentrations of chlorine.^[223] Limited data on parasitic helminth larvae and ova indicate such high levels of resistance that chemical disinfection is not useful.^[104] ^[134] ^[184] However, these are not common waterborne pathogens and can be readily removed or destroyed by heat, filtration, or coagulation-flocculation.

DISINFECTION CONSTANT.

The best comparison of disinfection power is the disinfection constant (Ct). Disparate results may be caused by lack of standardized experimental conditions of pH, temperature, chemical species of halogen, and species of microorganism or by different techniques for concentrating, counting, and determining viability of organisms.^[86] ^[134] The latter is especially a problem for cysts and viruses, which cannot be cultured easily.^[182] The end point for disinfection effectiveness is now becoming standardized by the EPA guidelines, but most older studies used 99.9% for all organisms, with some using 99%

or 99.99%. Differences between laboratory and field conditions also make extrapolation from data to practice inaccurate and suggest the need for a safety factor in the field. Despite variation, Ct remains a useful and widely used concept; values provide a basis for comparing the effectiveness

* References [\[63\]](#) [\[83\]](#) [\[86\]](#) [\[91\]](#) [\[154\]](#) [\[155\]](#) [\[156\]](#) [\[180\]](#) .

1205

of different disinfectants for inactivation of specific microorganisms.^[86] To use halogens for disinfection, a *consensus organism* (the most resistant target) determines the Ct.^[86] [\[107\]](#) [\[221\]](#) For wilderness water this has been protozoan cysts. The resistance of *Cryptosporidium* will not raise the threshold for halogen use; rather, it will force an alternative or a combination of methods to ensure removal and inactivation of all pathogens.

Chlorine

Chlorine has been used as a disinfectant for 200 years. Hypochlorite was first used for water disinfection in 1854 during cholera epidemics in London and was first used continuously for water treatment in Belgium in 1902. It is currently the preferred means of municipal water disinfection worldwide, so extensive data support its use^[221] (see [Table 51-10](#)).

Chemistry.

Chlorine reacts in water to form the following compounds^[55] [\[221\]](#) :

At neutral pH, negligible amounts of diatomic chlorine are present. The major disinfectant is hypochlorous acid (HOCl), which penetrates cell and cyst walls easily. Dissociation of HOCl to the much weaker disinfectant hypochlorite (OCl⁻) depends on temperature and pH. In pure water at pH 6.0, 97% of chlorine is HOCl; at pH 7.5, HOCl/OCl⁻ ratio is 1:1; and above pH 7.5, OCl⁻ predominates.^[221] The combination of these two compounds is defined as *free available chlorine*. Both calcium hypochlorite (Ca[OCl]₂) and sodium hypochlorite (NaOCl) readily dissociate in water, allowing the same equilibrium to form as when elemental chlorine is used.^[107] [\[221\]](#) Chloride ion (Cl⁻, NaCl, or CaCl₂) is germicidally inactive. In addition, chlorine readily reacts with ammonia to form monochloramines (NH₂Cl), dichloramines, or trichloramines, referred to as *combined chlorine*. In field disinfection these compounds are not considered, and

only free residual chlorine should be measured. However, chloramines have weak disinfecting power and are calculated as a disinfectant in municipal sewage plants.^[86] ^[130]
^[134] ^[221]

Toxicity.

Acute toxicity to chlorine is limited; the main danger is irritation and corrosion of mucous membranes if concentrated solutions (for example, household bleach) are ingested. Numerous cases have been reported of short-term ingestion of very high residuals (50 to 90 ppm) in drinking water; one military study used 32 ppm for several months without adverse effects.^[221] Animal studies using long-term chlorination of drinking water at 100 to 200 ppm have not shown toxic effects.^[134]

Sodium hypochlorite is not carcinogenic; however, reactions of chlorine with certain organic contaminants yield chlorinated hydrocarbons, chloroform, and other trihalomethanes, which are considered carcinogenic.^[53] ^[134] Public health departments limit residual chlorine in public systems to decrease ingestion of trihalomethane. The concern is now fueled more by public fears than by scientific conclusion.^[221] The risk of death from infectious diseases if disinfection is not used is far greater than any risk from chlorine disinfection by-products.^[53] These compounds are not likely to form in clean wilderness surface water, since the organic precursors are not present.

Formulations.

Chlorine is available in liquid and tablet forms for field use ([Table 51-12](#) and [Table 51-13](#)).

BLEACH.

Liquid household bleach is a hypochlorite solution that comes in various concentrations, usually 5.25%. This has the convenience of easy availability, low cost, high stability, and administration with a dropper. If bleach containers break or leak in a pack, the liquid is corrosive and stains clothing.

Sodium hypochlorite solutions are vulnerable to significant loss of available chlorine over time. Stability is greatly affected by heat and light. Five percent solution loses about 10% available chlorine over 6 months at 21° C (70° F) and freezes at -4.4° C (24° F).

TABLETS

Halazone.

Tablets contain a mixture of monochloraminobenzoic and dichloraminobenzoic acids.^[55] Each tablet releases 2.3 to 2.5 ppm of titratable chlorine.^[140] These tablets have been criticized because the alkaline buffer necessary to improve halazone dissolution

decreases disinfectant efficiency, requiring unacceptably high concentrations and contact times (6 tablets = 15 mg/L for 60 minutes) for reliable disinfection under all conditions.^[172] Tablets have the advantage of easy administration and can be salvaged if the container breaks. However, they lose effectiveness with exposure to heat, air, or moisture. Although no significant loss of potency results from opening a glass bottle intermittently over weeks, 75% of activity is lost after 2 days of continuous exposure to air with high heat and humidity. The shelf life is 6 months; potency decreases 50% when stored at 40° to 50° C (104° to 122° F). A new bottle should be taken on each major trip or changed every 3 to 6 months. Halazone is being replaced by newer formulations of chlorine tablets.

Aquaclear and Puritabs.

Each tablet contains 17 mg of sodium dichloroisocyanurate (NaDCC) in a paper/foil laminate. The effervescent tablet releases 10 mg of free chlorine (HOCl) when dissolved in 1 L of water. Fifty percent of the available chlorine remains in compound

TABLE 51-12 -- Water Disinfection Techniques and Halogen Doses

IODINATION TECHNIQUES	ADDED TO 1 L OR QT OF WATER	
	AMOUNT FOR 4 ppm	AMOUNT FOR 8 ppm
Iodine tabs: tetraglycine hydroperiodide	½ tab	1 tab
EDWGT (emergency drinking water germicidal tablet)		
Potable Aqua		
Globaline		
2% iodine solution (tincture)	0.2 ml	0.4 ml
	5 gtts	10 gtts
10% povidone-iodine solution*	0.35 ml	0.70 ml
	8 gtts	16 gtts
Saturated solution: iodine crystals in water	13 ml	26 ml
Saturated solution: iodine crystals in alcohol	0.1 ml	0.2 ml
CHLORINATION TECHNIQUES	AMOUNT FOR 5 ppm	AMOUNT FOR 10 ppm

Household bleach: 5% sodium hypochlorite	0.1 ml	0.2 ml
	2 gtts	4 gtts
AquaClear: sodium dichloroisocyanurate		1 tab
AquaCure, AquaPure, Chlor-floc: chlorine plus flocculating agent		8 ppm/tab

Measure with dropper (1 drop = 0.05 ml) or tuberculin syringe.

*Povidone-iodine solutions release free iodine in levels adequate for disinfection, but scant data are available.

TABLE 51-13 -- Recommendations for Contact Time with Halogens in the Field

CONCENTRATION OF HALOGEN	CONTACT TIME IN MINUTES AT VARIOUS WATER TEMPERATURES		
	5° C	15° C	30° C
2 ppm	240	180	60
4 ppm	180	60	45
8 ppm	60	30	15

Recent data indicate that very cold water requires prolonged contact time with iodine or chlorine to kill *Giardia* cysts. These contact times have been extended from the usual recommendations in cold water to account for this and for the uncertainty of residual concentration.

and is released as free chlorine is consumed by halogen demand. NaDCC is a stable, nontoxic chlorine compound that forms a mildly acidic solution, which is optimal for hypochlorous acid, the most active disinfectant of the free chlorine compounds. To disinfect large quantities of water, tablets are also available in 340 and 500 mg of NaDCC and in screw-cap tubs.

Chlorination-flocculation.

Chlor-floc, AquaPure, and AquaCure tablets were devised for the military in South Africa and are now becoming widely available in the United States. They contain alum and 1.4% available chlorine in the form of dichloroisocyanurate (sodium dichloro-s-triazinetrione) with proprietary flocculating agents. Bicarbonate in the tablets promotes rapid dissolution and acts as a buffer. One 600-mg tablet yields 8 mg/L of free chlorine. In clear water without enough impurities to flocculate, the alum causes some cloudiness and leaves a strong chlorine residual. However, this is an excellent one-step technique for cloudy and highly polluted water. After treatment, water should be poured through a special cloth to remove floc and decrease turbidity. Testing by the U.S.

military demonstrated biocidal effectiveness similar to iodine tablets under most conditions.^[153] ^[155] ^[156] Extended contact time was necessary for complete viral removal in some of the tests. Because of the ability to flocculate turbid water, the action was superior to iodine in some poor-quality water. The tablets are stable for 3 years if stored in their packaging out of the heat. (See [Table 51-15](#).)

SUPERCHLORINATION-DECHLORINATION.

The Sanitizer is a method of field chlorination that uses first superchlorination and then dechlorination. High doses of chlorine are added to the water in the form of calcium hypochlorite crystals. Concentrations of 30 to 200 ppm of free chlorine are reached at the recommended doses. These extremely high levels are above the margin of safety for field conditions and rapidly kill all bacteria, viruses,

1207

and protozoa but probably not *Cryptosporidium*. After at least 10 to 15 minutes, several drops of 30% hydrogen peroxide solution are added. This reduces hypochlorite to chloride, forming calcium chloride (a common food additive), which remains in solution, as follows:

Excess hydrogen peroxide reacts with water to form oxygen and water. Chloride has no taste or smell. Hydrogen peroxide is also a weak disinfectant,^[229] although not in common use.

The process of superchlorination-dechlorination with different reagents is used in some large-scale disinfection plants to avoid long contact times and to remove tastes and smells. High doses of chlorine remove or oxidize hydrogen sulfide and some other chemical contaminants that contribute to poor taste and odor. Chlorine bleaches organic matter, making water sparkling blue, as in swimming pools.^[221]

The minor disadvantage of a two-step process is offset by excellent taste. Measurements to titrate peroxide to the estimated amount of chlorine do not need to be exact, but some experience is needed to balance the two and achieve optimal results. This is a good technique for highly polluted or cloudy water and for disinfecting large quantities. It is the best technique for storing water on boats or for emergency use. A high level of chlorine prevents growth of algae or bacteria during storage; water is then dechlorinated in needed quantities when ready to use.

The two reagents must be kept tightly sealed to maintain potency of the reagents.

Properly stored, calcium hypochlorite loses only 3% to 5% of available chlorine per year. Thirty-percent peroxide is corrosive and burns skin, so it should be used cautiously.

Iodine

Iodine has been used as a topical and water disinfectant since the beginning of the twentieth century.^[107] Iodine is effective in low concentrations for killing bacteria, viruses, and cysts, and in higher concentration against fungi and even bacterial spores, but it is a poor algicide^[34] ^[74] ^[134] (see [Table 51-11](#) and [Figure 51-3](#)). Iodine has been used successfully in low concentrations for continuous water disinfection of small communities.^[103] Despite several advantages over chlorine disinfection, it has not gained general acceptance because of concern for its physiologic activity.

Chemistry.

Iodine is the only halogen that is a solid at room temperature. Of the halogens, it has the highest atomic weight, lowest oxidation potential, and lowest water solubility. Its disinfectant activity in water is quite complex because of formation of various chemical intermediates with variable germicidal efficiencies. Seven different ions or molecules are present in pure aqueous iodine solutions, but only elemental (diatomic) iodine (I_2) and hypoiodous acid (HOI) play major roles as germicides. Diatomic iodine reacts in water to form the following compounds^[34] ^[74] :

I_2 is two to three times as cysticidal and six times as sporicidal as HOI, because it more easily diffuses through the cyst wall. Conversely, HOI is 40 times as virucidal and three to four times as bactericidal as I_2 , since inactivation of organisms depends directly on oxidation potential, without involving cell wall diffusion.^[33] Their relative concentrations are determined by pH and concentration of iodine in solution.^[34] At pH 7.0 and 0.5 ppm of iodine, the concentrations of I_2 and HOI are approximately equal, resulting in a broad spectrum of germicidal action. At pH 5.0 to 6.0, most of the iodine is present as I_2 , whereas at pH 8.0, 12% is present as I_2 and 88% as HOI. At higher concentrations of iodine, more HOI is present. Under field conditions, I_2 is the major disinfectant for which doses are calculated.^[34]

Other chemical species, including triiodide (I_3^-), iodate (HIO_3), and iodide (I^-), form under certain conditions but play no role in water disinfection.^[34] ^[47] Iodide is important because it readily forms when reducing substances are added to iodine solution. Iodide ion is without any effect for water disinfection and also has no taste or color, but is still physiologically active.

Toxicity.

The main issue with iodine is its physiologic activity, potential toxicity, and

allergenicity.^[147] Acute toxic responses generally result from intentional overdoses of iodine, with corrosive effects in the gastrointestinal tract leading to hemorrhagic gastritis. Mean lethal dose is probably about 2 to 4 g of free iodine or 1 to 2 ounces of strong tincture.^[62] Toxicity is limited by rapid conversion of iodine to iodide by food (especially starch) in the stomach and early reflex vomiting. Iodide is absorbed into the bloodstream but has minimal toxicity (it is used widely for radiographic imaging).

Sensitivity reactions, including rashes and acne, may occur with usual supplementation levels of iodine. Given the necessity of iodine, it is not clear why some people react to certain forms of the substance, such as iodized salt. As with other sensitivity reactions, these may occur with very low doses. Acute allergy to iodide is rare and manifests as individual hypersensitivity, such as angioneurotic and laryngeal edema.^[147]

Chronic iodide poisoning, or iodism, occurs after prolonged ingestion of sufficiently high doses, but marked individual variation is seen. Symptoms simulate

1208

upper respiratory illness, with irritation of mucous membranes, mucus production, and cough.

A major disadvantage of iodine is its physiologic activity with effects on thyroid function. Iodine is an essential element for normal thyroid function and health in small amounts of 100 to 300 µg/day, but excess amounts can result in thyroid dysfunction. Maximum safe level and duration of iodine ingestion are not clearly defined, making it difficult to provide recommendations for prolonged use in water treatment.

THYROID EFFECTS OF EXCESS IODINE INGESTION.

Most persons can tolerate high doses of iodine without development of thyroid abnormalities, because the thyroid gland has an autoregulatory mechanism that effectively manages excessive iodine intake. Initially, excess iodine suppresses production of thyroid hormone, but production usually returns to normal in a few days.

Iodine-induced hyperthyroidism can result from iodine ingestion by persons with underlying thyroid disease or when iodine is given to persons with prior iodine deficiency.^{[21] [179]} During the worldwide campaign to eliminate endemic goiter and cretinism, 1% to 2% of residents developed hyperthyroidism from small amounts of dietary iodine supplementation. Groups at higher risk were elderly persons, Graves' disease patients (especially after antithyroid therapy), and patients taking pharmacologic sources of iodine. Hyperthyroidism has been reported from iodine use as a water disinfectant in two travelers. Both were from iodine-sufficient areas and had antithyroid antibodies, suggesting underlying thyroiditis; one had a mother and sister with Hashimoto's thyroiditis.^[111]

Iodine-induced hypothyroidism or goiter is much more common from excessive iodine

intake. Hypothyroidism is attributed to prolonged suppression of thyroid hormone production induced by excess iodine levels, but the mechanism through which iodide goiter is produced is not well understood. The incidence of goiter varies and does not correlate well with quantity of iodine or with the level of hypothyroidism. Recently, goiters were discovered among a group of Peace Corps volunteers in Africa and were linked epidemiologically to the use of iodine resin water filters.^[102] Forty-four (46%) of the volunteers had enlarged thyroids, but 30 of these had normal thyroid function tests.

Iodine-induced hypothyroidism or goiter may occur with or without underlying thyroid disease but is more common in several groups^{[21] [179] [224]} : (1) those with underlying thyroid problems, including prior treatment for Graves' disease or subtotal thyroidectomy; (2) fetuses and infants, from placental transfer of iodide from mothers treated with iodides; (3) persons with subclinical hypothyroidism, especially elderly persons, in whom the incidence is 5% to 10%; and (4) patients with excessive iodide from medications (formerly potassium iodide; currently amiodarone).

Neonatal goiter is especially worrisome because it can lead to asphyxia during birth or hypothyroidism with mental impairment. Daily intakes as small as 12 mg have been reported to produce congenital iodide goiters, but generally much higher doses are required.

DOSE-RESPONSE OR THRESHOLD LEVEL.

It is unclear what percent of the population will respond adversely to excess iodine or what should be defined as excess intake. The majority of people can tolerate high doses of iodine with no ill effects.^[21] The reported incidences of goiter, hypothyroid effects, and hyperthyroid response vary so widely that they provide no clear dose limits.^[147] The use of iodine for decades in the military and civilian population without reports of associated clinical thyroid problems suggests that the risks are minimal and would be outweighed by the risk of enteric disease. However, biochemical assays show that changes in thyroid function tests are common with excess iodine intake.

In controlled trials, iodine was administered to healthy volunteers, 30 to 70 mg/day for 14 to 90 days.^{[132] [171]} Two studies simulated field use of four iodine tablets (32 mg) per day.^{[69] [110]} All found the same changes in thyroid function: an increase in thyroid-stimulating hormone (TSH) and decrease in triiodothyronine (T_3) and thyroxine (T_4) within 1 to 2 weeks and persisting throughout iodine ingestion. Paul et al,^[145] studied the minimum dose that would cause alterations in thyroid function and found that 1.5 mg/day decreased TSH, but not 500 and 750 μ g/day. These changes were statistically significant from baseline but usually remained within the range of normal values. Even when outside the normal range, the changes in thyroid function remained sub-clinical. Thyroid enlargement was sometimes noted when evaluated by ultrasound. All changes reverted to normal within weeks to months without persistent thyroid disease.

Studying longer duration of ingestion, Freund^[65] found minimal changes and no clinical problems when water with 1 mg/L of iodine was given to prisoners for up to 3 years.

Referring to the same project, Thomas et al ^[201] reported that after 15 years of ongoing iodine use at 1 mg/L, iodinated water caused no decrease in serum concentrations of T₄ below normal values and no allergic reactions. Patients with prior thyroid disease had no recurrence with iodinated water; four patients with active hyperthyroidism were treated in standard fashion, and their condition remained well controlled despite the extra iodine intake. Also, 177 inmates gave birth to 181 full-term infants, and no neonatal goiters were detected.^[200]

The military studied long-term toxic effects of iodine, adding sodium iodide to drinking water at a naval base for 6 months.^[129] The estimated daily dose of iodine per person was 12 mg for the first 16 weeks and 19.2 mg for the next 10 weeks. No evidence of functional changes or damage in the thyroid gland, cardiovascular

1209

system, bone marrow, eyes, or kidneys was noted. No increase in skin diseases, no sensitization to iodine, and no impaired wound healing or resolution of infections was evident.

Treatment of subclinical thyroid disease is controversial, even the chronic cases found on a serologic diagnostic battery.^[41] ^[80] With a history of excess iodine ingestion, most experts would first stop the iodine intake and follow thyroid function before treating hypothyroidism.

Recommendations.

The tenth edition of the recommended dietary allowances (RDAs, 1989) set the allowable dose to 1.0 mg/day for children and up to 2.0 mg/day for adults (increased from 0.5 to 1.0 mg in the ninth edition, 1980), primarily based on the data from Freund and Thomas.^[147]

Possible toxicity with intermediate- to long-term use of iodine and the question of iodide toxicity remain controversial. The EPA and the World Health Organization (WHO), supported by the American Water Works Association (AWWA), have recommended iodine use for water disinfection only as an emergency measure for short periods of about 3 weeks.^[218] ^[233] However, this period of short use appears arbitrary.

The following groups should not use iodine for water treatment because of their increased susceptibility to thyroid problems:

Pregnant women

Persons with known hypersensitivity to iodine

Persons with a history of thyroid disease, even if controlled by medication

Persons with a strong family history of thyroid disease (thyroiditis)

Persons from areas with chronic dietary iodine deficiency

Available data suggests the following:

1. High levels of iodine, such as those produced by recommended doses of iodine tablets, should be limited to periods of 1 month or less.
2. Iodine treatment that produces a low residual (1 mg/L or less) appears safe, even for long periods in people with normal thyroid function. Iodine resin devices with a charcoal stage to remove residual iodine, or iodination followed by microfiltration that includes a charcoal stage, should allow prolonged use. Concern for International Space Station crew members who would be using iodinated water for 6 months prompted the National Aeronautics and Space Administration (NASA) to use an exchange resin to reduce residual iodine concentration from 3 or 4 to 0.25 mg/L. ^[121]
3. Persons planning to use iodine for a prolonged period should have the thyroid gland examined and thyroid function measured to ensure that a state of euthyroidism exists.

TABLE 51-14 -- Iodine Solutions

PREPARATION	IODINE (%)	IODIDE (%)	TYPE OF SOLUTION
Iodine topical solution	2.0	2.4 (sodium)	Aqueous
Lugol's solution	5.0	10.0 (potassium)	Aqueous
Iodine tincture	2.0	2.4 (sodium)	Aqueous-ethanol
Strong iodine solution	7.0	9.0 (potassium)	Ethanol (85%)

Formulations.

Several forms of iodine are available for field use ([Table 51-12](#) , [Table 51-13](#) , [Table 51-14](#)).

IODINE SOLUTIONS.

Iodine solutions commercially sold as topical disinfectants are inexpensive and can be measured accurately with a dropper but are staining and corrosive if spilled. These contain iodine, potassium, or sodium iodide in water, and ethyl alcohol or glycerol ([Table 51-14](#)). Iodide improves stability and solubility but has no germicidal activity and adds to the total amount of iodine ingested and absorbed into the body.

Iodophors are solutions in which diatomic iodine is bound to a neutral polymer of high molecular weight, giving the iodine greater solubility and stability with less toxicity and corrosive effect.^[34]^[74] Povidone-iodine is a 1-vinyl-2-pyrrolidinone polymer with 9% to 12% available iodine. The iodophors are routinely used for topical disinfection, since they have less tissue toxicity than iodine solutions. Although they are not approved for water disinfection in the United States, they are used in other countries for this purpose.^[10] According to the manufacturer, approval for this use in the United States was not pursued because the anticipated use did not justify the expense. Povidone is nontoxic and was used as a blood expander during World War II.

In aqueous solution, povidone-iodine provides a sustained-release reservoir of halogen; free iodine is released in water solution depending on the concentration (normally, 2 to 10 ppm is present in solution). In dilutions below 0.01%, povidone-iodine solution can be regarded as a simple aqueous solution of iodine.^[74] One report found these compounds similar in germicidal efficiency to other iodine-iodide solutions.^[34] Data indicate persistence of about 2 ppm of free iodine at a 1:10,000 dilution,^[74] which corresponds to a 0.001% solution made by adding 0.1 ml (2 drops) to 1 L of water. However, another study found conflicting values for

1210

available iodine and free iodine (measured by different techniques). Bactericidal effect on *Pseudomonas* and *Staphylococcus* bacteria increased at dilutions of 1:100, compared with 10% stock solutions, but dilutions of 1:10,000 were not bactericidal.^[14] The complex chemistry of povidone-iodine solutions accounts for these conflicting data. Since free residual iodine can be measured at the concentration used for water disinfection, it should be effective. Personal and anecdotal experience of others attest to its effectiveness in field use.^[10]

TABLETS.

The two types of iodine tablets are those that depend on a chemical reaction to convert iodide into iodine and those in which the iodine exists as hydroperiodide.^[172] The tablets used by the U.S. military and sold in the United States for water disinfection contain tetraglycine hydroperiodide, which is 40% I₂ and 20% iodide.^[34]^[131] Tetraglycine hydroperiodide tablets are sold as Globaline, Potable Aqua, and EDWGT (emergency drinking water germicidal tablet). Each tablet releases 8 mg/L of elemental iodine into water.^[34]^[131]^[140]^[172] An acidic buffer provides a pH of 6.5, which supports better cysticidal than virucidal capacity but should be adequate for both. Tablets have the advantages of easy handling and no danger of staining or corroding if spilled. They are stable for 4 to 5 years under sealed storage conditions and for 2 weeks with frequent opening under field conditions, but they lose 30% of the active

TABLE 51-15 -- Data on Microcidal Efficacy of Iodine and Chlorine Tablets

FRH, Free residual halogen.

iodine if bottles are left open for 4 days in high heat or humidity.

Tetraglycine hydroperiodide was originally developed and chosen as a preferred technique by the military for individual field use because of its broad-spectrum disinfection effect, ease of handling, rapid dissolution, stability, and acceptable taste.^[34]
^[99] ^[131] ^[140] ^[154] The military requirements dictated a short contact time (10 minutes in clear, warm water)-thus the relatively high concentration of iodine (8 ppm) compared with other iodination techniques. The recommended dose has been increased to two tablets in cold water to ensure disinfection with short contact times. With adequate contact time, one tablet can be added to 2 quarts of water to yield 4 ppm of free iodine (

[Table 51-15](#)).

Potable Aqua is now sold with "neutralizing" tablets made of ascorbic acid. Ascorbic acid converts iodine to iodide, removing the taste and color and stopping the disinfection action of iodine, but does not change the physiologic load of ingested iodine.

The Australian military developed the other type of iodine tablet (e.g., Afses). The tablet contains a combination of potassium iodide and potassium iodate together with an acidic material (potassium permanganate) that catalyzes a reaction to form iodine.^[172] The advantage is this tablet's resistance to thermal deterioration, but it is highly sensitive to traces of moisture. It is formulated to release 8 mg/L of free iodine, but the

1211

actual amount measured in water is more variable than that released by Potable Aqua, so its biocidal performance is not as good. The tablet also contains more iodide than Potable Aqua, which contributes to potential adverse effects.^[202]

CRYSTALS (SATURATED SOLUTION).

Because of limited solubility in water, iodine crystals may be used for disinfection. In one technique for field use, 4 to 8 g of crystalline iodine is put in a 1- to 2-ounce bottle, which is then filled with water.^[99] A small amount of elemental iodine goes into solution (no significant iodide is present); the saturated solution is used to disinfect drinking water. Water can be added to the crystals hundreds of times before they are completely dissolved.

Since the amount of iodine dissolved depends on the temperature of the solution (200 ppm at 10° C, 300 ppm at 20° C, 400 ppm at 30° C),^{[34] [74] [221]} the bottle should be kept warm or the amount added to drinking water adjusted for temperature of the iodine crystal solution. In the field, it may be easier to warm the bottle in an inner pocket than to estimate temperature and adjust the dose. The supernatant should be carefully decanted or filtered to avoid ingestion of the crystals^[232] ; this is aided by the weight of the crystals, which causes them to sink. Many people prefer crystalline iodine because of its large disinfectant capacity, small size, and light weight. A commercial product (Polar Pure) has made iodine crystals readily available in camping supply stores.

An alternative technique is to add 8 g of iodine crystals to 100 ml of 95% ethanol.^[222] Increased solubility of iodine in alcohol makes the solution less temperature dependent and allows much smaller volumes to be used (8 mg/0.1 ml), which can be measured with a 1-ml syringe or dropper (2 drops).

The stability and simplicity of iodine crystals have led to their testing for in-line systems that provide continuous water disinfection for remote households and small

communities. In these designs, residual iodine is removed with GAC.^[57]^[205]

RESINS.

Iodine resins have great potential for water disinfection in individual or small systems and have been incorporated into many different filter designs available for field use. They provide many advantages over chlorination systems by eliminating the need for chemical feed systems, residual monitoring, and contact time.^[218] Iodine resins are considered demand disinfectants because they are minimally insoluble in water and little iodine is released into aqueous solution. However, when a microorganism comes into contact with the resin, iodine apparently transfers to the microorganism aided by electrostatic forces, binds to the wall or capsule, penetrates and kills the organism.^[116]

Iodine resins are engineered to produce low residuals in effluent water. The initial iodine residual with pentaiodide resin produces a constant 1 to 2 ppm after initial use, whereas triiodide resin produces a residual iodine concentration of less than 0.20 ppm at equilibrium.^[116] The concentration in the eluent of triiodide resin is temperature dependent. Concentrations less than 1.0 ppm were obtained with water at 42.2° C (108° F), but this increased to a total iodine content of 6 to 10 ppm at 71° C (160° F). After returning to room temperature, the iodine residual returned to nominal values.^[116]

Measurable iodine is attached to bacteria and cysts after resin treatment, effectively exposing the organisms to high iodine concentrations. This allows reduced contact time compared with dilute iodine solutions.^[61]^[116] Some contact time still appears necessary.^[117] Fifty percent of *Giardia* cysts were viable 10 minutes after passage through a triiodine resin. Viable *Giardia* cysts could be recovered in 4°-C (39.2°-F) water 40 minutes after passage through an iodine resin.^[117] PUR Traveler cup filters failed to pass the EPA protocol for "worst-case" water unless water was passed through the filter twice. The data implied that a holding (contact) time could have achieved the same results.^[70] The Canadian Health Department, challenging an in-line triiodine resin with highly polluted water, also found that a 15-minute contact time was necessary for warm water and 30-minute contact time for cold water.^[57] The EPA conducted tests of triiodide resin against *E. coli* but not against other organisms, for which it relied on independent testing. It concluded that the product depends on a 0.2-ppm residual and that additional testing would be necessary below this level.

Resins are chemically and physically stable during conditions of dry storage at room temperature. Aqueous suspensions or resins retain biocidal potential for 15 years. No alteration in activity was observed after dry storage for 1 month at 50° C (122° F).^[116]

Resins have proved effective against bacteria, viruses, and cysts but not against *Cryptosporidium parvum* oocysts or bacterial spores.^[116] When *Cryptosporidium* oocysts were passed through a triiodide resin column, most were retained in the resin column, probably by electrostatic attraction to the resin. Of those that passed through, only a small percentage were inactivated within 30 minutes by the iodine.^[208]

Despite the controversy regarding contact time, most of the testing done with iodine resins has shown high levels of effectiveness, and products have demonstrated their

ability to meet the EPA guidelines for reduction of microorganisms (see [Table 51-8](#)). Recently, however, iodine resin products from two different companies (SweetWater with Viralguard and PUR filters) were withdrawn from the market when company testing showed that they failed to meet viral inactivation standards of 4-log reduction. The units had previously

1212

obtained EPA registration on the basis of successful testing contracted through a laboratory that does the majority of testing for the filter industry. This variation of test results is disconcerting for several reasons, including the source of test variability, credibility of the original laboratory, and the effectiveness of the iodine resin, which is used in the products of other manufacturers.

Iodine resin filters.

Iodine resins have been incorporated into a broad line of filters for field use (see [Appendix](#)). Optimal designs incorporate two stages in addition to the iodine resin. A microfilter, generally 1 micron (micrometer), effectively removes *Cryptosporidium*, *Giardia*, and other halogen-resistant parasitic eggs or larva. Since iodine resins kill bacteria and viruses rapidly, no significant contact time is required for most water.^[70] The addition of a third stage of activated charcoal removes dissolved residual; however, the importance of iodine residual for disinfection has not been determined.^{[117] [205]} Testing by one filter company demonstrated that a carbon block could reduce 16 mg/L of iodine to less than 0.01 mg/L for 150 gallons, which was close to the expected lifetime of its ceramic filter.^[181] The effective removal of residual iodine makes the iodine resin filters safe for long-term use. For effective performance of activated charcoal, it must be replaced periodically.

In conclusion, iodine resins are effective disinfectants that can be engineered into attractive field products, including use in the space shuttle and large-scale units for international disasters. They may prove useful for small communities in undeveloped and rural areas where chlorine disinfection is technically and economically unfeasible. However, more testing is needed on specific products to ensure adequate resin contact, to define the need for contact time, and to confirm whether a residual iodine concentration is needed.

Chlorine vs. Iodine

A few investigators have reported data suggesting ineffectiveness of common halogen preparations. Jarroll et al^{[93] [94]} tested six methods of field disinfection and found that none achieved high levels of *Giardia* inactivation at the recommended dose and times. However, this failure simply reflected the need for longer contact times in cold water.^[112] Ongerth et al^[143] tested seven chemical treatments for *Giardia* inactivation in clear and turbid water at 10° C (50° F). None achieved 99.9% reduction in 30 minutes. All iodine-based chemical methods were effective at 8 hours, but none of the chlorine

preparations was effective, even after this extended time. Although these results after 30 minutes in cold water are to be expected, the 8-hour results do not conform with other experimental data on chlorine. Unfortunately, the authors did not test for residual halogen, although initial levels achieved should have been effective, and they did not test at regular time intervals to determine when the iodine methods had achieved the target reduction of organisms.

A large body of data proves that both iodine and chlorine are effective disinfectants with adequate concentrations and contact times (cold temperatures equate with slow disinfection time for both). Comparing effectiveness between chlorine and iodine is difficult because of the different ionic species and compounds that may exist under varying conditions.^[84] Chlorine and iodine tablets have been directly compared under identical water test conditions and found to be similar in their biocidal activity in most conditions using recommended dose and contact time^[153] (see [Table 51-12](#) , [Table 51-13](#) , and [Table 51-15](#) .) Contact times in [Table 51-13](#) are extended from the previous recommendations for treatment in cold water to provide a margin of safety and to ensure high levels of cyst destruction.

Iodine has several advantages over chlorine. Of the halogens, iodine has the lowest oxidation potential, reacts least readily with organic compounds, is least soluble, is least hydrolyzed by water, and is less affected by pH, all of which indicate that low iodine residuals should be more stable and persistent than corresponding concentrations of chlorine.^{[47] [74] [103] [134]}

Taste

Objectionable taste and smell are the major problems with acceptance of halogens. These depend on specific chemical compounds. Most people are familiar with the taste of chlorine (hypochlorite); tap water usually contains 0.2 to 0.5 ppm of chlorine, swimming pools 1.5 to 3.0 ppm, and hot tubs 3.0 to 5.0 ppm. Most persons note a distinct taste at 5 ppm and a strong, unpleasant taste at 10 to 15 ppm.^[172] Hypochlorous acid and chloride have no taste or odor.^[221] Most objectionable tastes in treated water are derived from dissolved minerals, such as sulfur, and from chlorine compounds, chloramines, and organic nitrogen compounds, even at extremely low levels.

Elemental iodine at 1 mg/L is undetectable. Most persons can detect iodine solutions at 1.5 to 2 mg/L but do not find it objectionable.^{[17] [47] [66]} Eight ppm of iodine produces a distinct taste and odor; however, tablets yielding these concentrations were preferred by military personnel over tincture of iodine in equivalent doses.^{[34] [131]} Iodide ion has no color or taste.

Taste tolerance or preference for iodine over chlorine is individual. Opposite preferences have been documented when direct comparisons are done.^{[140] [155]} I believe that most persons prefer the taste of iodine to chlorine at concentrations typically used in the field. In addition, iodine forms fewer organic compounds that produce highly objectionable taste and smell.

Minimal Dosage.

Taste can be improved by several means ([Box 51-3](#)). One method is to use the relationship

1213

between halogen concentration and time and to give the minimum necessary dose, allowing a longer contact time (see [Table 51-13](#)). *Giardia* cysts and viruses can be killed with doses of chlorine or iodine of 2 ppm or less (see [Figure 51-3](#)).^[63] ^[83] ^[107] Wilderness travelers usually can allow a longer contact time for water disinfection.

**Box 51-3. IMPROVING THE TASTE OF
HALOGENS**

Decrease dose and increase contact time.

Clarify cloudy water, allowing decreased halogen.

Use iodine resin.

Remove halogen:

Granular activated carbon

Chemical reduction

Ascorbic acid

Sodium thiosulfate

Chlorination-dechlorination
(Sanitizer)

KDF (zinc-copper) brush or
media

Use alternative techniques:

Heat

Filtration

Theoretically, doubling the contact time allows a 50% reduction of halogen dose at any level. Although this relationship holds true at the higher field doses of halogens, as the levels drop, the reaction departs from mathematical models, and the straight-line graph has a "tail" (see [Figure 51-2](#)). This departure from strict first-order kinetics and the uncertainty of halogen demand in field disinfection mean that a margin of safety must be incorporated into contact times at lower doses.

Of all standard iodine doses, iodine tablets yield the highest dose (8 mg/L with an intended contact time of 10 minutes in warm water). The tablets cannot be broken in half but can be added to 2 quarts instead of 1 quart to yield concentrations consistent with the other preparations. In recommended doses the liquid preparations of iodine yield 4 mg/L. Since even clear surface water has some halogen demand, this dose of 4 mg/L should generally not be reduced. The exception would be for backing up tap water in developing countries, when the dose may routinely be cut in half for an added dose of 2 ppm with a few hours of contact time. For chlorination methods that add 5 mg/L, adding half the amount to clean surface water should be adequate if the contact time is tripled. Even less could be used for tap water. None of these concentrations will destroy *Cryptosporidium* oocysts.

Effective disinfection with low iodine residual can also be achieved by use of iodine resin filters.

Temperature and organic matter in the water may be manipulated. Increasing the temperature of the water, especially when initially near 5° C, decreases the Ct constant (see [Table 51-13](#) and [Figure 51-2](#)). Filtering water before adding halogen improves the reliability of a given halogen dose by decreasing halogen demand, allowing a lower dose of halogen.^[134] Sedimentation or coagulation-flocculation cleans cloudy water and lowers the required halogen dosage considerably, in addition to removing many of the contaminants that contribute to objectionable taste.

Dehalogenation.

Halogen can be removed from water after the required contact time. Activated charcoal removes iodine or chlorine, allowing standard or even high doses to be used without residual taste. The relative instability of chlorine in dilute solutions can be used to decrease taste over time. Chlorine residual in an open container decreases 1 mg/L in the first hour, then 0.2 mg/L in the next 5 to 8 hours, for a total of 2.0 to 2.5 mg/L in 24 hours. Ultraviolet light also depletes free chlorine.^[221]

Alteration of Chemical Species (Reduction).

Several chemical means are available to reduce free iodine or chlorine to iodide or chloride that have no color, smell, or taste. These "ides" have no disinfection action, so the techniques should be used only after the required contact time. The Sanitizer uses

hydrogen peroxide to "dechlorinate" the water by forming calcium chloride. This reaction with hydrogen peroxide works best if calcium hypochlorite is used as a disinfectant. If bleach (sodium hypochlorite) is used, hydrogen peroxide reacts with chlorine in water to form hydrochloric acid in harmless amounts.

Two other chemicals that may be safely used with any form of chlorine or iodine are ascorbic acid (vitamin C) and sodium thiosulfate. Ascorbic acid is widely available in the crystalline or powder form. Grinding up tablets that have binders may cloud the water. Ascorbic acid is a common ingredient of flavored drink mixes, which accounts for their effectiveness in covering up the taste of halogens. [\[140\]](#) [\[172\]](#)

Sodium thiosulfate similarly "neutralizes" iodine and chlorine. A few granules in 1 quart of iodinated water decolorizes and removes the taste of iodine by converting it to iodide. In reaction with chlorine, it forms hydrochloric acid, which is not harmful or detectable in such dilute concentration. Thiosulfate salts are inert in vivo and poorly absorbed from the gastrointestinal tract. Sodium thiosulfate is available at chemical supply stores.

Zinc-copper alloys act as catalysts to reduce free iodine and chlorine through an electrochemical reaction. They also remove or reduce dissolved metals, including heavy metals such as lead, selenium, and mercury. One product incorporated such an alloy into the bristles of a small brush to be stirred in the water after halogen disinfection. It is effective but slow, which limits its

1214

use to small volumes of water. Stirring for 1 minute removes 10 mg/L of chlorine from 250 ml of water.

Environmental Protection Agency Registration

Products that are used for treating municipal or private water supplies for drinking are considered pesticides and must be registered by the EPA Pesticide Branch. Registration signifies the following:

1. The composition is such as to warrant the proposed claims.
2. The labeling and other material required to be submitted comply with the requirements of the act.
3. The method will perform its intended function without unreasonable adverse effects on the environment.
4. When used in accordance with widespread and commonly recognized practice, the method will not generally cause unreasonable adverse effects on the environment.

Thus EPA registration implies only that the "pesticide" agent is not released into the

water at unsafe levels.^[24]^[39] This is less stringent than for filters that contain halogens.

MISCELLANEOUS DISINFECTANTS

Silver

Silver ion has bactericidal effects in low doses. The literature on antimicrobial effects of silver is confusing and contradictory.^[88] ^[134] ^[221] ^[226] Concentrations in water less than 100 parts per billion (ppb) are effective against enteric bacteria. The reaction follows first-order kinetics and is temperature dependent. Calcium, phosphates, and sulfides interfere significantly with silver disinfection. Organic chemicals, amines, and particulate or colloidal matter may also interfere, but no more than with chlorine.

Silver is physiologically active. Acute toxicity does not occur from small doses used in disinfection, but argyria, which is permanent discoloration of the skin and mucous membranes, may result from prolonged use. For this reason a maximum limit of 50 ppb of silver ion in potable water is recommended. At this concentration, disinfection requires several hours.

Experimental results indicate 18% survival of *E. coli* at 3 hours at 40 µg/L. *Salmonella typhi* was reduced more than 5 log at 50 µg/L with a 1-hour exposure; poliovirus was not reduced at 50 µg/L with a 1-hour exposure.^[11]

Water disinfection systems using silver have been devised for spacecraft, swimming pools, and other settings.^[221] The advantage is absence of taste, odor, and color. Persistence of residual silver concentration allows reliable storage of disinfected water. Silver can be supplied through a silver nitrate solution, desorption from silver-coated materials, or electrolysis. When coated on surfaces, silver acts as a constant-release disinfectant that produces aqueous silver ion concentrations of 0.006 to 0.5 ppm, which are sufficient to disinfect drinking water.^[116] Because of this attractive feature, silver-based devices are being designed and tested in developing countries. In Pakistan a nylon bag with silver-coated sand was designed to be placed in earthenware pitchers that store water. Silver incorporated into alum is also being tested in India.^[35]

Filters and granular charcoal media are sometimes coated with silver to prevent bacterial growth on the surface, but this does not maintain sterility. A slow, selective action against total coliform count is noted, but none against total bacterial count. Long-term use might overcome any bacteriostatic action initially shown.^[68] In an EPA study, effluent populations from the silver-containing units were about as large as those from the units without silver.^[11] Bacteria can develop resistance to silver ions through generation of silver reductase.

Large-scale use of silver for water disinfection has been limited by cost, difficulty

controlling and measuring silver content, and physiologic effects. Short-term field use is limited by its marked tendency to adsorb onto the surface of any container (resulting in unreliable concentrations) and interference by several common substances. Data on silver for disinfection of viruses and cysts indicate limited effect, even at high doses.^[33]

^[134]

The use of silver as a drinking water disinfectant has been much more popular in Europe where silver tablets (MicroPur) are sold widely for field water disinfection. They have not been approved by the EPA for this purpose in the United States, but they were approved as a water preservative to prevent bacterial growth in previously treated and stored water.

Potassium Permanganate

Potassium permanganate is a strong oxidizing agent with some disinfectant properties. It was used extensively before hypochlorites as a drinking water disinfectant.^[131] It is still used for this purpose and also for washing fruits and vegetables in parts of the world. It is used in municipal disinfection to control taste and odor and is usually employed in a 1% to 5% solution for disinfection.

Bacterial inactivation can be achieved with moderate concentrations and contact times (45 minutes at 2 mg/L, 15 minutes at 8 mg/L). A 1:5000 (0.5%) solution controlled *V. cholerae* and *S. typhi* contamination of fruits and vegetables. The virucidal action has been tested, but without titrations of virus that remained after various periods of contact time, so the rate of action is not known. In most instances, however, a 1:10,000 solution destroyed the infectivity of virus suspensions in ½ hour at room temperature; 30 mg/L was effective in inactivating HAV within 15 minutes.^[203] Although potassium

permanganate clearly has disinfectant action, it cannot be recommended for field use, since quantitative data are not available for viruses and no data are available for protozoan cysts, despite the chemical's frequent use in some parts of the world. Packets of 1 g to be added to 1 L of water are sold in some countries. A French military guide from 1940 instructed users: "To sterilize water, use a solution of 1 gram of KMnO_4 for 100 grams of water. Add this solution drop by drop to the water to sterilize until the water becomes pink. The operation is considered sufficient if the water remains pink for half an hour."^[36] The solutions are deep pink to purple and stain surfaces. The chemical leaves a pink to brown color in water at concentrations above 0.05 mg/L. Small deposits of brown oxides settle to the bottom of the water container. A few drops of alcohol will cause this residual color to disappear.

Hydrogen Peroxide

Hydrogen peroxide is a strong oxidizing agent but a weak disinfectant.^{[20] [134] [229]} Small

doses (1 ml of 3% H₂O₂ in 1 L water) are effective for inactivating bacteria within minutes to hours, depending on the level of contamination. One million colony-forming units/ml of seven bacterial strains were killed overnight, with 80% kill in 1 hour. Viruses require extremely high doses and longer contact times. Although information is lacking on the effect of hydrogen peroxide on protozoa, it is a promising sporicidal agent in high (10% to 25%) concentrations.

Hydrogen peroxide was popular as an antiseptic and disinfectant in the late nineteenth century and remains popular today as a wound cleanser; for odor control in sewage, sludges, and landfill leachates; and for many other applications. It is considered safe enough for use in foods. It is naturally present in milk and honey, helping to prevent spoilage. It yields the innocuous end products oxygen and water. Solutions lose potency in time, but stabilizers can be added to prevent decomposition.^[20]

Although hydrogen peroxide can sterilize water, lack of data for protozoal cysts and quantitative data for dilute solutions prevents it from being useful as a field water disinfectant. Its application in superchlorination-dechlorination is effective.

Ultraviolet Light

The germicidal effect of ultraviolet (UV) light is the result of action on the nucleic acids of bacteria and depends on light intensity and exposure time. It is well established that UV light can inactivate bacteria, viruses, and protozoans when administered in sufficient dose. However, cysts should probably be removed by filtration. UV treatment does not require chemicals and does not affect the taste of the water. It works rapidly, and an overdose to the water presents no danger; in fact, it is a safety factor. UV light has no residual disinfection power; water may become recontaminated, or regrowth of bacteria may occur.^[58] Particulate matter can shield microorganisms from UV rays.

UV disinfection units are cumbersome and require power, so they are not well adapted to use by small groups in the wilderness. However, an intriguing question is whether direct sunlight can disinfect small quantities of water. One investigation tested the ability of sunlight to disinfect oral rehydration salt solution in clear polyethylene bags or plastic containers contaminated by sewage.^[4] After 1 hour in sun the coliform bacteria count was zero. UV and thermal inactivation were strongly synergistic for the solar disinfection of drinking water in transparent plastic bottles that was heavily contaminated with *E. coli* for temperatures above 45° C (113° F). Above 55° C (131° F) thermal inactivation is of primary importance.^[120] Whereas thermal inactivation is effective in turbid water, UV effects are inhibited.^[97] Where strong sunshine is available, solar disinfection of drinking water is an effective, low-cost method for improving water quality and may be of particular use in refugee camps and disaster areas. However, thermal effects of sunshine are probably more important than UV rays, with insufficient data to quantify UV results.

Copper and Zinc

A copper and zinc alloy (KDF) has electrochemical properties that can aid in water

treatment. Its main actions are through its strong oxidation-reduction (redox) potential of 500 millivolts due to its propensity to exchange electrons with other substances. It is bacteriostatic with some bactericidal activity. Microorganisms are killed by the electrolytic field, and by formation of hydroxyl radicals and peroxide water molecules. Although KDF has been ruled a "pesticidal device" by the EPA and is used in industry to decrease bacteria levels and control bacterial growth, it should not be used as the sole means of water treatment. KDF is most often used to reduce or remove chlorine, hydrogen sulfide, and heavy metals from water. The redox reactions change contaminants into harmless components: chlorine into chloride, soluble ferrous cations into insoluble ferric hydroxide, and hydrogen sulfide into insoluble copper sulfide. Up to 98% of lead, mercury, nickel, chromium, and other dissolved metals are removed by KDF simply by bonding to the media. KDF controls the buildup of bacteria, algae, and fungi in GAC beds and carbon block filters, extending the life of carbon and improving its effectiveness. KDF media can be manufactured as brushes with wire bristles, fine steel woollike media, or granules.

A KDF brush removes the taste of chlorine or iodine from treated water. KDF has been incorporated into a few portable field filters but has not yet gained widespread use. In series with charcoal, KDF extends the life of charcoal and increase its effectiveness. Products that

1216

claim to be purifiers, with KDF destroying all microorganisms, should be rigorously tested to prove the claims.

Ozone and Chlorine Dioxide

Ozone and chlorine dioxide are highly effective disinfectants widely used in municipal water treatment plants, but until recently, not available in stable form for field use.^[221] These are the only disinfectants that have been demonstrated effective against *Cryptosporidium* in typical concentrations.^[146]

Two products currently being tested may revolutionize the use of chemicals for field water disinfection. A stabilized solution of chlorine dioxide (Aquamira, McNett Corp., Bellingham, Wash.) is mixed with phosphoric acid, which activates the chemical and is then mixed with water for disinfection. EPA registration for use as a water purifier is pending. Testing data will be available from the company when EPA approval is obtained.

Developed for military use, an electrochemical process converts simple salt into a mixed-oxidant disinfectant containing free chlorine, chlorine dioxide and ozone (MIOX Corp., Albuquerque, NM).^[215] The device is currently used in large- and medium-volume water treatment operations but has been reduced to a cigarsized unit that operates on camera batteries. This will be developed for the civilian market after testing is

completed.

Other Disinfection Products

Other products marketed for water disinfection for travelers cannot be recommended until more data become available. These were initially introduced into the health food market but are now being offered to the general travel market.

Citrus juice has biocidal properties. Lemon juice has been shown to destroy *V. cholerae* at a concentration of 2% (equivalent of 2 tablespoons per liter of water) with a contact time of 30 minutes. A pH less than 3.9 is essential, which depends on the concentration of lemon juice and the initial pH of the water. Its activity is greatly reduced in alkaline water. ^[50]

Traveler's Friend is a product marketed for water disinfection that contains citrus extract. Company-sponsored data are convincing for antibacterial and antiviral activity. However, the product was not tested against *Giardia* cysts. The active chemical disinfectant has not been identified, and a time/dose response has not been generated. Without better data, this product cannot be recommended.

Aerobic Oxygen is advertised not only as a water disinfectant, but also as a cure for headaches and tropical fish diseases. Company literature implies that the active disinfectant could be chlorine dioxide or ozone, but this is not chemically feasible. Company-sponsored testing demonstrates activity against bacteria and viruses, but not against cysts. No dose/time response has been developed to compare the product against other disinfectants.

PREFERRED TECHNIQUE

Field disinfection techniques and their effects on microorganisms are summarized in [Table 51-16](#) . The optimal technique for an individual or group depends on the number of persons to be served, space and weight available, quality of source water, personal taste preferences, and availability of fuel ([Table 51-17](#)). The most effective technique may not always be available, but all methods will greatly reduce the load of microorganisms and reduce the risk of illness. For alpine camping with a high-quality source water, any of the primary techniques is adequate. The only limitation for halogens is *Cryptosporidium* cysts, but in high-quality pristine surface water the cysts are generally found in insufficient numbers to pose significant risk. Surface water, even if clear, in undeveloped countries where there is human and animal activity should be considered highly contaminated with enteric pathogens. Optimal protection requires either heat or a two-stage process of filtration and halogens. Iodine resin filters that combine microfiltration, halogen, and activated charcoal are a simple alternative to a two-stage process, but questions have recently surfaced concerning effectiveness against viruses under all water conditions. New techniques utilizing chlorine dioxide may prove to be highly effective.

Water from cloudy low-elevation rivers, ponds, and lakes in developed or undeveloped countries that does not clear with sedimentation should be pretreated with coagulation-flocculation, then disinfected with heat or halogens. Filters can be used but will clog rapidly with silted or cloudy water. Even in the United States, water with agricultural runoff or sewage plant discharge from upstream towns or cities must be treated to remove *Cryptosporidium* and viruses. In addition, water receiving agricultural, industrial, or mining runoff may contain chemical contamination from pesticides, other chemicals, and heavy metals. A filter containing a charcoal element is the best method to remove most chemicals. Coagulation-flocculation or KDF resin will also remove some chemical contamination.

Halogens need to be used when water will be stored, such as on a boat, in a large camp, or for disaster relief. When only heat or filtration is used before storage, recontamination and bacterial growth can occur. Hypochlorite still has many advantages, including cost, ease of handling, and minimal volatilization in tightly covered containers.^[126] A minimum residual of 3 to 5 mg/L should be maintained in the water. Superchlorination-dechlorination

TABLE 51-16 -- Summary of Field Water Disinfection Techniques

	BACTERIA	VIRUSES	GIARDIA, AMEBAE	CRYPTOSPORIDIUM	NEMATODES, CERCARIAE
Heat	+	+	+	+	+
Filtration	+	±*	+	+	+
Halogens	+	+	+	-†	±‡

*Reverse osmosis is effective. Most filters make no claims for viruses; however, General Ecology claims 4-log virus removal.

†Chlorine dioxide may be effective.

‡Eggs are not susceptible to halogens but have a low risk of waterborne transmission.

TABLE 51-17 -- Advantages and Disadvantages of Disinfection Techniques

	HEAT	FILTRATION	HALOGENS	FILTRATION PLUS HALOGEN	CLARIFICATION (C-F) PLUS SECOND STEP
Availability	Wood can be scarce	Many commercial choices	Many common and specific products	Includes iodine resin filters	Readily available
Cost	Fuel and stove costs	Moderate expense	Inexpensive	Mainly filter costs	Depends on second stage
Effectiveness	Can sterilize or pasteurize	Most filters not reliable against viruses	<i>Cryptosporidium</i> and some parasitic eggs are resistant	Covers all organisms	Highly effective because most microbes removed by C-F
Optimal application	Clear water, but effective for cloudy water	Clear or slightly cloudy; turbid water clogs filters rapidly	Clear; need increased dose if cloudy	Clear; need increased dose if cloudy	Cloudy / turbid water
Taste	Does not change taste	Can improve taste, especially if charcoal stage	Tastes worse unless remove or "neutralize" halogen	Depends on sequence; can improve if allows reduced halogen dose or if filter has charcoal	Improves

Time	Boiling time (minutes)	Filtration time (minutes)	Contact time (minutes to hours)	Combination of two processes	Combination of two processes
Other considerations	Fuel is heavy and bulky	Adds weight and space; requires maintenance to keep adequate flow	Works well for large quantities and for water storage; some understanding of principles is optimal; damaging if spills or if container breaks	Use halogens first if filter has charcoal stage	Best means of cleaning turbid water, followed by halogen, filtration, or heat

C–F, Coagulation-flocculation.

is especially useful in this situation because high levels of chlorination can be maintained for long periods, and when ready for use, the water can be poured into a smaller container and dechlorinated. Iodine works for short-term but not prolonged storage, since it is a poor algicide. Silver has been approved by the EPA for preservation of stored water. Storage techniques can decrease risk of contamination. For prolonged storage, a tightly sealed container is best. For water access, narrow-mouth jars or containers with water spigots prevent contamination from repeated contact with hands or utensils. ^[188]

On oceangoing vessels where water must be desalinated during the voyage, only reverse-osmosis membrane filters are adequate. Halogens should then be added to the water in the storage tanks.

PREVENTION AND SANITATION

In remote settings in developing countries, potable water alone does not necessarily make a substantial difference in the incidence of many gastrointestinal diseases. A study in a Brazilian village showed no reduction in incidence of diarrhea with use of disinfected water. This emphasizes the importance of general hygiene, which requires education and sanitation.^[35] A combination of drinking water treatment and sanitation can decrease episodes of diarrhea.^{[90] [124]}

Hygiene is also essential for wilderness travelers. A *Shigella* outbreak among river rafters on the Colorado River was investigated and assumed to be waterborne from adjacent Native American communities, but no source was found in the tributaries. It was finally traced to infected guides who were shedding organisms in the stool and contaminating food through poor hygiene.^[123] Personal hygiene, mainly handwashing, prevents spread of infection from food contamination during preparation of meals.^[123] Simple handwashing with soap and water purified with hypochlorite (bleach) significantly reduced fecal contamination of market-vended beverages in Guatemala.^[188] No one with a diarrheal illness should prepare food.

Dishes and utensils should be disinfected by rinsing in chlorinated water, prepared by adding enough household bleach to achieve a distinct chlorine odor.

Prevention of food-borne contamination is also important in preventing enteric illness (see [Chapter 52](#)). Washing fruits and vegetables in purified water is a common practice, but little data support its effectiveness. Washing has a mechanical action of removing dirt and microorganisms while the disinfectant kills microorganisms on the surface. However, neither reaches the organisms that are embedded in surface crevices or protected by other particulate matter. When lettuce was seeded with oocysts, then washed and the supernatant examined for cysts, only 25% to 36% of *Cryptosporidium parvum* and 13% to 15% of *C. cayetanensis* oocysts were recovered in the washes. Scanning electron microscopy detected oocysts on the surface of the vegetables after washing.^[144] Chlorine, iodine, or potassium permanganate are often used for this purpose. Higher concentrations can be used than would normally be palatable for drinking water. With superchlorination-dechlorination, high-chlorine concentrations are used to rinse vegetables because the chlorine can be removed with the second step. Aquaclear (NaDCC) chlorine tablet instructions suggest 20 mg/L for washing vegetables. Although effective against most microorganisms, these levels would not be effective against *Cryptosporidium* or *Cyclospora*.

The ultimate responsibility is proper sanitation to prevent contamination of water supplies from human waste. UV rays in sunlight eventually inactivate most microorganisms, but rain may first wash pathogens into a water source. In the soil, microorganisms can survive for months.^[211] A Sierra Club study found more prolonged survival in alpine environments.^[160] The investigator marked group latrines in alpine terrain and returned 1 to 2 years later to dig test trenches. He found a thin crust of decomposition covering unaltered raw waste with high coliform bacteria counts. Microorganisms may percolate through the soil. Most bacteria are retained within 20 inches of the surface, but in sandy soil this increases to 75 to 100 feet^[209]; viruses can move laterally 75 to 302 feet.^[182] When organisms reach groundwater, their survival is prolonged, and they often appear in surface water or wells.^[211]

Some suggest that campers smear feces on rocks. Although desiccation occurs, UV disinfection is not reliable, and feces may wash into the watershed with rain runoff.^[37] Moreover, it will be repulsive to other campers. In the Sierras, feces left on the ground generally disappeared within 1 month, but it was not known whether disinfection occurred before decomposition or whether the feces washed away, dried, or were blown in the wind.^[160] Despite more rapid decomposition in sunlight rather than underground, burying feces is still preferable in areas that receive regular use. The U.S. military and U.S. Forest Service recommend burial of human waste 8 to 12 inches deep and a minimum of 100 feet from any water.^[209] ^[213] Decomposition is hastened by mixing in some dirt before burial. Shallow burying is also not recommended because animals are more likely to find and overturn the feces. Judgment should be used to determine a location that is not likely to allow water runoff to wash organisms into nearby water sources. Groups larger than three persons should dig a common latrine to avoid numerous individual potholes and inadequate disposal. To minimize latrine odor and improve its function, it should not be used for disposal of wastewater.

In some areas the number of individual and group latrines is so great that the entire area becomes contaminated. Therefore sanitary facilities (outhouses) are becoming common in high-use wilderness areas. Popular river canyons require camp toilets, and all waste must be carried out in sealed containers.

PRODUCT	PRICE	STRUCTURE/FUNCTION
KATADYN		
(Suunto USA, 2151 Las Palmas Dr #F, Carlsbad, CA 92009; 800-543-9124)		All filters contain a 0.2 micron ceramic candle filter, silver impregnated to decrease bacterial growth. Large units also contain silver quartz in center of filter.
Pocket Filter (Figure 51-4)	\$250	Hand pump; 40-inch intake hose and strainer, zipper case; size: 10 × 2 inches; weight: 23 oz; flow: 0.75–1.0 L/min; capacity: 13,000–50,000 L.
Replacement filter element	\$165	
Minifilter (Figure 51-5)	\$90	Smaller, lighter hand pump; 31-inch intake hose and strainer; hard plastic enclosure and pump; size: 7 × 2.75 × 1.75 inches; weight: 9 oz; flow: 0.5 L/min; capacity: about 7000 L.
Combi (Figure 51-6)	\$160	Small hand pump with ceramic filter and activated charcoal stage; can brush ceramic to clean or separately replace elements; size: 2.4 × 10.4 inches; weight: 19 oz; flow: 0.5 L/min; capacity: up to 50,000 L, 200 L for charcoal.
KFT Expedition (Figure 51-7)	\$1150	Large hand pump with steel stand; size (packed in case): 23 × 6 × 8 inches; weight: 12 lb; flow: 4 L/min; capacity (per filter element): 100,000 L.
Replacement filter element	\$90	

Figure 51-4 Katadyn Pocket Filter.

Figure 51-5 Katadyn Minifilter.

*Prices vary considerably and product lines change regularly.

1220

PRODUCT	PRICE	STRUCTURE/FUNCTION
Drip filter TRK (Figure 51-8)	\$275	Gravity drip from one plastic bucket to another with 3 ceramic candle filter elements; size: 18 × 11-inch diameter (26 inches high when assembled); weight: 9 lb 4 oz; flow: 1 pt/hr (10 gal/day); capacity: 100,000 L.
Replacement filter (same filter element as hand pump)	\$80	
Syphon (Figure 51-9)	\$100	Gravity siphon filter element: 12 × 2 inches; weight: 2 lb; flow: 2 gal/hr; capacity: 5000–20,000 L.

Claims

Filter removes bacterial pathogens, protozoan cysts, parasites, and nuclear debris and clarifies cloudy water. If filter clogs, brushing the filter element (which can be done hundreds of times before replacing filter element) can restore flow. Claims for removal of viruses not made in United States, although testimonials imply effectiveness in all polluted waters. Pocket Filter has a lifetime warranty.

Figure 51-6 Katadyn Combi.

Figure 51-7 Katadyn KFT Expedition filter.

1221

Comments

Well-designed, durable products are effective for claims. However, high filter volume capacity is optimistic and not likely to be achieved filtering average surface water. Field tests found the flow comparatively slow, requiring more energy to pump and frequent cleaning. Abrading the outer surface can effectively clean ceramic filters, but the gauge must be used to indicate when filter thickness is excessively diminished.

Pocket Filter is the original, individual or small-group filter design. Metal parts make it durable but the heaviest for its size. Minifilter was designed to be lighter and more cost competitive. Expedition filter is popular for larger groups, especially river trips, where weight is not a factor. Complete virus removal cannot be expected, although most viruses clump or adhere to larger particles and bacteria that can be filtered. Silver impregnation does not prevent bacterial growth in filters.

Figure 51-8 Katadyn drip filter TRK.

Figure 51-9 Katadyn Syphon.

PRODUCT	PRICE	STRUCTURE/FUNCTION
GENERAL ECOLOGY, INC.		
(151 Sheree Blvd, Exton, PA 19341; 610-363-7900; www.general-ecology.com)		All filters (except Microlite) contain 0.1-micron (0.4-micron absolute) Structured Matrix filter in removable canister.
First-Need Deluxe direct-connect water filter (Figure 51-10)	\$70	Hand pump with intake strainer; outflow end connects directly to common water bottle; self-cleaning prefilter float; size: 6 × 6 inches, weight: 15 oz; flow: 1.6 L/min; capacity: 100–400 L.
Extra canister	\$32	
Prefilter replacement	\$7	
New pump assembly	\$23	
Filtermate	\$8	Connects older-design filter to wide-mouth Nalgene bottle.
Matrix pumping system	\$9	2-L carry bag, polyethylene liners; 18-inch hose and hose adapter for creating gravity filter unit from filter elements.
Microlite (Figure 51-11)	\$30	Structured Matrix filter 0.5 μm (nominal) with activated carbon; hand pump, 24-inch intake hose and strainer; attaches directly to wide-mouth or bike bottle, soda bottle, or outlet spout; size: 5.5 × 2.5 inches; weight: 8 oz; flow: 0.5 L/min; capacity: 50 L/cartridge.
Replacement cartridges (set of two)	\$10	
Trav-L-Pure (Figure 51-12) (carrying case included)	\$120	Filter and hand pump in rectangular housing (1.5-pt capacity); pour water into housing, then pump through prefilter and microfilter; size: 4.5 × 3.5 × 6.75 inches; weight: 22 oz; flow: 1–2 pt/min; capacity: 100–400 L.
Replacement canister	\$30	

Base Camp (Figure 51-13) (carrying case included)	\$500	Stainless steel casing and hand pump connected with tubing; capacity 1000 gal; canister size: 4.8 x 5.4 inches; pump: 1.5 x 10.5 inches; weight: 3 lbs; flow: 2 L/min
Replacement cartridge	\$60	

Figure 51-10 General Ecology First-Need Deluxe unit.

Figure 51-11 General Ecology Microlite unit.

1223

Claims

First-Need filter is a proprietary blend of materials including activated charcoal. "Microfiltration removes bacteria and larger pathogens" (cysts, parasites). "Adsorption and molecular sieving": carbon absorbers remove chemicals and organic pollutants that cause color and taste; cavities in surface of adsorption material draw particles in deeper. Filter does not remove all dissolved minerals or desalinate. Proprietary process also creates ionic surface charge that removes colloids and ultrasmall particles, *including viruses*, through "electrokinetic attraction."

Microlite removes sediment, protozoan cysts, algae, and chemicals (including iodine) and improves color and taste of water. Iodine tablets are included to kill bacteria and viruses when these organisms are a concern.

Comments

Reasonable design, cost, and effectiveness. All units (except Microlite) use the same basic filter design. Most testing with *E. coli* and *Giardia* cysts show excellent removal. Charcoal matrix will remove chemical pollutants. This is the only company that claims to meet EPA standards for 4-log reduction of viruses through mechanical filtration, not inactivation. However, they do not claim to remove all viruses, since they have not been able to test with the hepatitis virus. Despite viral claims, recommend caution in highly polluted water; prior disinfection with halogen would guarantee disinfection, and carbon would remove halogen. The filter cannot be cleaned, although it can potentially be back-flushed, so it must be replaced when clogged.

Microlite is designed primarily for day use or light backpacking. Used alone, it makes microbiologic claims for protozoan cysts (*Giardia* and *Cryptosporidium*) only. Iodine tablets or solution should be used as pretreatment with this filter for all water except pristine alpine water in North America. This filter is compact, lightweight, and designed for low-volume use with inexpensive, easily changed filter cartridges. Base Camp is for large groups. It also comes with an electric pump and can be hooked up in parallel to provide large quantities of water for disaster relief.

Figure 51-12 General Ecology Trav-L-Pure.

Figure 51-13 General Ecology Base Camp.

PRODUCT	PRICE	STRUCTURE/FUNCTION
STERN'S OUTDOORS (FORMERLY BASIC DESIGNS)		
(Box 1498, St Cloud, MN 56302; 800-697-5801; www.stearnsinc.com)		

High-flow ceramic water filter (B240) (Figure 51-14)	\$45	Ceramic filter with 0.5-micron absolute retention size and carbon center; gravity filtration with element placed near the end of a 6-foot outflow tube connected to a 7.5-L heavy plastic collection bag, providing 2–3 lb of hydrostatic pressure through the in-line filter; packing size: 4 × 4 × 8 inches; weight: 13 oz; flow rate: 15 L/hr; capacity: 1000 L.
Replacement filter	\$29	
Water carrier bag, 2.5 gal with fitting for filter output	\$9	
Ceramic Filter Pump (Figure 51-15)	\$22	
Replacement filter	\$12	

Claims

Ceramic filter removes *Giardia*, bacteria, *Cryptosporidium*, cysts, tapeworm, flukes, and other harmful pathogens larger than 1 micron. Carbon removes color, tastes, and odors. Filter can be cleaned with an abrasive pad. Pump is easily serviced in the field; ceramic cartridge is replaceable.

Comments

Ceramic candle filters are effective filtering elements, and charcoal is an effective adsorbent. No claims for virus removal. Although the pore size is larger than most filters, the low pressure depth filter increases retention of bacteria. The simple gravity design decreases cost and moving parts. Filtration rate will be slow, and this filter could clog rapidly, since there is no prefilter for larger particles. Gravity drip can be convenient after making camp, if no time restraints. The filter pump is the most practical and is reasonably priced, but the ceramic filter can break. The intake is close to the pump, which can be awkward, and the foam sleeve makes it float, requiring an extra hand to hold underwater. This filter rated poorly on field user tests. Fifteen liters per hour is not realistic for a gravity filter.

Figure 51-14 Stern's Outdoors high-flow ceramic water filter (B240).

Figure 51-15 Stern's Outdoors Ceramic Filter Pump (B250).

1225

PRODUCT	PRICE	STRUCTURE/FUNCTION
MSR AND MARATHON		
(3800 First Ave S, Seattle, WA 98124; 800-877-9677; www.msrcorp.com; www.marathonceramics.com)		
MSR Waterworks II (Figure 51-16) total filtration system	\$140	Four filter elements of decreasing pore size: porous foam intake filter, 10-micron stainless steel wire mesh screen, cylindric ceramic filter with block carbon core, then 0.2-micron pharmacologic-grade membrane filter; pressure relief valve releases at 90–95 psi; hand pump with intake tubing; storage bag (2 or 4 L) attaches directly to outlet of pump; size: 9 x 4 inches diameter; weight: 17 oz; flow: 1 L/90 sec; capacity: 100–400 L.
Dromedary beverage bag (All filter elements and parts replaceable.)	\$20	
Miniworks (Figure 51-17)	\$65	Similar external design to Waterworks II but slightly different ceramic filter and lacks final membrane filter; weight: 16 oz; flow rate 1 L/70 sec; capacity: 100–400 L.
Replacement filter	\$30	
Newton-Water	\$249	High-retention ceramic filters with compressed block carbon core; gravity microfilter system with four ceramic filter elements; two stacked stainless steel 3-gal buckets; size: 12 x 22 inches; weight: 11 lbs; capacity: 25 gal/day.
e-water siphon filter	\$35	Same filter element as above with siphon tubing; use any two containers to siphon water through filter; size: 2 x 7 ½ inches; weight 1 lb; capacity: 6–10 gal/day.

E-water Group Siphon Filter	Not yet available	Multiple ceramic filters with integral carbon block, in parallel to provide 1–2 L/min with no power or line pressure (other than gravity) required; size: 7 × 21 × 30 inches with case; weight 45 lbs.
-----------------------------	-------------------	--

Claims

Filter removes protozoa (including *Giardia* and *Cryptosporidium*), bacteria, pesticides, herbicides, chlorine, and discoloration. Both filters meet EPA standards for removal of cysts and bacteria. Ceramic filters reduced turbidity from 68.8 to 0.01 NTU. Carbon has been shown to reduce levels of iodine from 16 to less than 0.01 mg/L for at least 150 L. Ideal for emergency needs or for remote locations.

Comments

Excellent filter design and function. Prefilters protect more expensive inner, fine-pore filters. Effective for claims, high quality control, and extensive testing. No claims are made for viruses, although clumping and adherence remove the majority (currently 2 to 3-log removal, but not 4-log required for purifiers). The company is working on a microfilter that will effectively remove viruses. Until they succeed, the filter should not be considered reliable for complete viral removal from highly polluted waters in developing countries. Reservoir bag that attaches to outflow for filtered water storage is convenient. Design and ease of use are distinct advantages. Filter can be easily maintained in the field; maintenance kit and all replacement parts available. Ceramic filters can be effectively cleaned by abrading outer surface many times before compromising the filter. A simple caliper gauge indicates when filter has become too thin for reliable function. Miniworks was rated very highly in field tests.

Marathon ceramic products will soon be available. The gravity drip buckets are excellent products for field camps and expatriates. Iodine or chlorine can be used to ensure viral destruction, and the carbon will remove excess halogen, allowing long-term safe use of iodine. Siphon filter is inexpensive and compact.

Figure 51-16 MSR Waterworks II.

Figure 51-17 MSR Miniworks.

1226

PRODUCT	PRICE	STRUCTURE/FUNCTION
PENTAPURE (FORMERLY WTC—WATER TECHNOLOGY CORP)		
(150 Marie Ave East, West St Paul, MN 551187; 651-450-4913; www.pentapure.com)		All products use PentaPure iodine resin.
PentaPure Sport (Figure 51-18)	\$35	Drink-through sport bottle with internal (Pentacell) three-stage cartridge: 1-micron filter, iodine resin, and charcoal filter; filter and charcoal stages can be replaced independently; size: 11.5 × 3 inches; weight: 8 oz; capacity: 375 L.
Replacement cartridges		
PentaCell complete	\$26	
Cysts Filter	\$14	
EcoCell Filter	\$9	
Spring	\$25	Drink-through sport bottle with filter and charcoal, but no iodine resin; otherwise similar to Sport.
<p>The following are considered "international" products. They are not marketed in the United States, but are available for export, which includes purchase for use outside the United States. They can be ordered from several companies, including TealBrook (800-222-6614). Availability is variable.</p>		
Penta-Pour bucket (Figure 51-19)	\$170	Gravity drip bucket with 22-L storage capacity; sediment filter (30 micron), 1-micron filter; pentacide and carbon cartridge; size: 12 × 30 inches; weight: 3 kg; flow: 30 L/hr; capacity: 6500 L.
Ecomaster Outdoor Ecopour		
Travel Tap (Figure 51-20), Traveler		Pentacide and carbon cartridge; rubber cup and hose fitting on cartridge unit fits any faucet; flow: ½ gal/min; capacity: 1000 gal.

Outdoor 500 (Figure 51-21)	\$1475	Expedition-size hand-lever filter with steel frame; sediment filter, iodine resin, carbon block; each can be independently replaced; size: 14 x 9.5 x 18.5 inches; weight: 7 kg; flow: 300 L/hr; capacity: 30,000 L.
Outdoor M1, Survivor		Drink-through straws; cartridge with prefilter, granular activated carbon filter sandwiched between two stages of PentPure resin; size: 5.5 inches long; weight: 1 oz; capacity: 100 gal (M1), 25 gal (Survivor).

Claims

Resin releases iodine "on demand" on contact with microorganisms; minimal iodine dissolves in water: effluent 1.0 to 2.0 ppm iodine. Charcoal removes residual dissolved iodine. Tested effective for bacteria, *Giardia*, schistosomiasis, and viruses, including hepatitis. PentaCell tested against the new EPA protocol that requires removal of 10⁵ bacteria, 10⁴ viruses, and 10³ *Giardia* cysts. Charcoal stage absorbs bad tastes and odors.

Comments

Resin is essentially inexhaustible because the filter will become irreversibly clogged long before the resin is exhausted. However, the carbon filter may become fully absorbed with iodine and other impurities allowing iodine in the effluent. Although the amount of iodine in the outflow water is supposed to be low (1 to 2 ppm), higher concentrations have been measured. For long-term use, carbon filters should be changed regularly.

The company has narrowed their product line for field use and has dropped the small group hand-pump filters because of similar products on the market. They have also dropped the Travel Cup, a small pour-through plastic cup. The Sport Bottle is handy for individual use among hikers, bikers, and travelers. Pressure is generated by a combination of sucking and squeezing. Users must adapt to the effort and the slower flow compared with a regular sport bottle. Drink-through straws have limited applications, mainly survival and emergency situations. The "international" products are some of the most useful ones. Penta-Pour bucket is an excellent product for expatriates and field camps. The Outdoor series would work well for stationary or vehicle-based groups. Large units are available for large groups and disaster relief. The Traveler (formerly Travel Tap) is a small, portable unit that hooks to the end of a faucet and could be very useful for expatriates and frequent travelers.

PRODUCT	PRICE	STRUCTURE/FUNCTION
TIMBERLINE FILTER		
(PO Box 20356, Boulder, CO, 80308; 800-482-9297)		

Timberline Eagle (Figure 51-22)	\$24	1-micron fiberglass and polyethylene matrix; hand pump; size: 9 × 1–3 inches; weight: 6 oz; flow: 1 qt in 1.5 min.
Replacement element	\$12	

Claims

Removes *Giardia* cysts. No claims for bacteria or viruses.

Comments

Effective for claims; intended only for high-quality North American backcountry use where *Giardia* is a possible contaminant, but should also remove *Cryptosporidium*. Lightest pump filter available. Cartridges cannot be cleaned but are replaceable. The intake is close to the pump, which can be awkward.

Figure 51-22 Timberline Eagle filter.

PRODUCT	PRICE	STRUCTURE/FUNCTION
PUR/RECOVERY ENGINEERING, INC.		
(9300 N 75th Ave, Minneapolis, MN 55428; 800-845-7873)		

Explorer (Figure 51-23)	\$140	Hand pump with 130-micron prefilter; replaceable cartridge with 0.3-micron pleated glass-fiber filter and triiodine resin (Tritek); internal brush cleans filter with twist of handle; combination carbon cartridge and bottle adapter attaches to end of outflow tubing and removes residual dissolved iodine and other chemicals; size: 10.75 × 2.25 inches; intake and output hoses: 3 ft; weight: 21 oz; max flow: 1.5 L/min; capacity: 100 gal/cartridge.
Replacement parts		
Tritek cartridge	\$45	
Pump	\$45	
Intake filter/hose	\$16	
Carbon cartridge and bottle adapter	\$15	
Carbon refill pack	\$6	
Scout (Figure 51-24)	\$90	Hand pump with 150-micron intake filter; 0.3-micron pleated filter and triiodine resin and carbon cartridge; size: 9.5 × 2.25 inches; weight: 14 oz; max flow: 1.0 L/min (36 stokes/L); capacity: 100 gal/cartridge.
Replacement cartridge	\$35	
Optional carbon cartridge	\$20	
Pioneer (Figure 51-25)	\$30	Hand pump filter (0.3-micron fiberglass disk) attaches to top of water bottle; size: 2.5 × 4.5 inches; weight: 8 oz; flow: 1 L/min; capacity: 20 gal.
Extra filters (2 pack)	\$8	
Hiker (Figure 51-26)	\$50	Hand pump with 0.3-micron pleated glass fiber with 160-inch ² surface; microfilter and activated carbon core; size 7.5 × 2.5 × 3.5 inches; weight: 11 oz; flow: 1 L/min (40 stokes/L); capacity: 200 gal.
Replacement filter	\$25	
Voyageur	\$70	Voyager uses same body and filter as Hiker but includes iodine resin; intake filter for particles; capacity: 100 gal until cartridge replacement.

Figure 51-23 PUR Explorer.

Figure 51-24 PUR Scout.

1230

Claims

Explorer, Scout, and Voyager are purifiers that meet EPA test standards to remove or destroy all types of microorganisms. Microfilter removes cysts, and iodine resin kills bacteria and viruses on contact. Explorer has self-contained brush to clean filter without disassembling. Filter will clog before resin is exhausted. The iodine resin filters will purify (render microbiologically safe) water of any quality. However, two passages through the filter are recommended for "worst case" water (below 5° C, cloudy and highly polluted). Easily replaced carbon cartridge attaches to the outflow tubing and scavenges residual iodine. This reduces the iodine concentration from an average of 2 ppm to less than 1 ppm, leaving no iodine taste.

The Hiker and Pioneer are microfilters, without iodine resin, designed for higher quality surface water, not international travel. It will "eliminate *Giardia* and most bacteria;" activated carbon core "reduces chemicals and pesticides, plus improves taste of water." Filter surface area of 160 square inches is "guaranteed not to clog for 1 year." The Pioneer is effective against *Giardia*, *Cryptosporidium*, and most bacteria.

Comments

The Explorer is a well-designed, lightweight unit for individual or small-group use in any wilderness environment. The pumping action is very easy, and the internal brush seems to effectively restore flow. The Scout and Voyager are smaller, less expensive, and contain the same elements except for the internal brush. The Hiker and Pioneer were designed for the domestic backpacking market with access to higher water quality, where cysts and bacteria are a threat, but viruses are less of a problem. The Hiker received top ratings for field tests evaluating user-friendliness.

Instructions for the water purifier advise passing cold, highly polluted water through this filter twice, but an alternative would be to allow 30 to 40 minutes of contact time. The company is hesitant to recommend a contact time, believing that the public expects a filter to render water safe immediately after passage, so they offer the more cumbersome recommendation of filtering twice. In fact, the conditions of worst-case water will rarely, if ever, be encountered; most would not attempt to drink such water unless desperate. *NOTE: Repeat testing of the iodine resin filters demonstrated failure to inactivate 4-log of viruses under certain conditions, leading to a product recall in 2000. The company is investigating the role of activated carbon and the need for contact time. They hope to have products back on the market early in 2001.*

PRODUCT	PRICE	STRUCTURE/FUNCTION
RECOVERY ENGINEERING		
Reverse-osmosis filters Survivor 06 (Figure 51-27)	\$550	Hand pump, reverse-osmosis membrane filter with prefilter on intake line; size: 2.5 × 5 × 8 inches; weight: 2.5 lb; flow: 40 strokes/min yields 1 L/hr.
Survivor 35 (Figure 51-28)	\$1425	Hand pump, reverse-osmosis membrane filter with prefilter on intake line; size: 3.5 × 5.5 × 22 inches; weight: 7 lbs; flow: 1.2 gal/hr.

Claims

Reverse-osmosis units desalinate, removing 98% salt from seawater by forcing water through a semi permeable membrane at 800 psi. In the process, bacteria are filtered out. The manual operation of these units makes them useful for survival at sea or for use in small craft without power source. Larger, power-operated units are also available.

Comments

Reverse-osmosis units are included here because sea kayaking and small boat journeys in open water are becoming more popular. Most large oceangoing boats use reverse-osmosis filters. These units can obviate the need for relying solely on stored water or can be carried for emergency survival. The military uses truck-mounted reverse-osmosis filters on land for their ability to handle brackish water and remove all levels of microorganisms. Reverse-osmosis filters could be used for land-based travel but are prohibitively expensive for most people, and the flow rates are inadequate (1 L/hr, not per minute). Desalination units will remove microorganisms, including viruses, that are larger than sodium molecules. The company does not make claims for viral removal because they assume that the membrane is imperfect and some pores will be imprecise, perhaps allowing viral passage.

Carrying bag	\$6	
Global Water Express	\$90	
Walkabout (Figure 51-30)	\$35	Lightweight version with similar filter element; size: 6.5 inches high; weight: 9 oz; flow: 0.75 L/min; capacity: 125 gal.

Claims

SweetWater filter eliminates *Giardia*, *Cryptosporidium*, and other critical bacterial and protozoan pathogens, as well as pollutants, heavy metals, pesticides, and flavors. Kills viruses when used with the Viral Guard cartridge accessory. Lighter, more compact, and durable than comparable models, and easiest to clean or replace. Filter cartridges are recycled by the company.

Comments

Well-designed filter at a reasonable price. The three major water treatment components—filtration, GAC, and iodine resin attachment—offer broad protection and maximum flexibility. Practical design features include universal bottle adapter. Pressure-release valve indicates when filter needs cleaning, but this can be a problem as the filter clogs. A brush is provided for cleaning, and cartridges are replaceable. *NOTE: Viral Guard iodine resin was recently taken off the market due to company testing that demonstrated failure to inactivate viruses, despite prior testing in outside laboratories that passed EPA standards.*

Chapter 52 - Infectious Diarrhea from Wilderness and Foreign Travel

Javier A. Adachi
Howard D. Backer
Hebert L. DuPont

Acute diarrhea is one of the most common medical problems in all populations, second only to acute upper respiratory diseases. Worldwide, diarrheal diseases were reported to cause nearly 1 billion episodes of illness in 1996.^{[45] [60] [61] [181]} The rates of illness among children in developing areas of the world range from 5 to 15 bouts per child per year, with diarrhea being the most important cause of morbidity and mortality in many regions. Readily available oral rehydration solutions prevent great numbers of dehydration-associated deaths related to acute diarrhea, especially in developing areas, but invasive bacterial enterocolitis (caused by *Shigella* species and *Campylobacter jejuni*) and persistent diarrhea (defined as illness lasting 14 days or longer) still cause significant morbidity and mortality.^{[45] [89] [181]}

Specific groups of U.S. populations with diarrhea rates similar to those in the developing world include travelers, gay males, non-toilet-trained toddlers in day-care centers, and mentally impaired residents of custodial institutions.^{[60] [89]}

This chapter provides information to help to decrease exposure to enteropathogens and risk factors, reducing the chance of acquiring illness. The clinical features of acute diarrheal illnesses often do not permit differentiation of the specific etiologic agent, but fortunately, the majority of these infections do not require etiology-specific treatment.^{[45] [60] [61]} We formulate a clinical approach to self-therapy that is likely to minimize the complications and suffering caused by these illnesses. For the purpose of this discussion, "traveler" includes business or pleasure travelers as well as wilderness venturers.

GENERAL PRINCIPLES OF ENTERIC INFECTIONS

Epidemiology

Transmission.

Fecal-oral contamination, through ingestion of contaminated water and food, is the usual route of transmission for enteric pathogens causing infectious diarrhea. Other, less common routes of fecal-oral transmission are through aerosols (viruses), contaminated hands or surfaces, and sexual activity. The relative importance of food and water depends mainly on location and precautions taken. Waterborne pathogens from drinking untreated surface water or from an inadvertent ingestion during water recreational activity account for most infectious diarrhea acquired in the U.S. wilderness.^{[89] [125] [131]} Waterborne diarrheal diseases include typhoid fever, cholera, *Campylobacter* enteritis, cryptosporidiasis, giardiasis, and hepatitis A infection. They are usually preventable by proper sanitation and water disinfection. Enterotoxigenic *Escherichia coli*, enteroinvasive *E. coli*, *Aeromonas* species, *Plesiomonas shigelloides*, *Shigella* species, *Vibrio cholerae*, *Campylobacter jejuni*, and *Yersinia enterocolitica* can be foodborne as well as waterborne. Person-to-person transmission is seen in selected populations whose habits expose them to high levels of pathogens (e.g., infants in day-care centers, homosexuals, persons with minimal access to water); prevention of these illnesses includes adequate handwashing and personal hygiene.^{[45] [60] [61]}

Location.

In several areas of Africa, Asia, and Latin America, where satisfactory sanitation is lacking, diarrhea is still the leading cause of infant morbidity and mortality. Good sanitation is related to a much lower incidence of infectious diarrhea in industrialized areas of the world. Travelers to foreign countries and wilderness areas often leave behind sanitation in the form of flush toilets and safe tap water, as well as proximity to advanced medical care. Similar hygienic conditions are created in other settings.

Outbreaks of infectious diarrhea in day-care centers among non-toilet-trained toddlers are associated with *Giardia lamblia*, *Shigella*, *Campylobacter jejuni*, and *Cryptosporidium*, which have a small infectious dose. Hospitals, especially intensive care units and pediatric wards, institutions for mentally handicapped patients, and nursing homes are also locations with high incidence of diarrheal diseases. *Clostridium difficile*-associated diarrhea, *Salmonella* species, rotavirus, and enteropathogenic *E. coli* are the most common etiologic agents reported^{[60] [89] [158]} ([Table 52-1](#)).

Antimicrobial Therapy.

C. difficile-associated diarrhea is frequently related to recent use of an antimicrobial agent (or cytotoxic agent), usually during the last 2 to 4 weeks before the beginning of diarrheal illness. ^[30] ^[70] ^[104]

Age.

In developing areas of the world, children below 5 years of age have higher morbidity and mortality

rates related to dehydration, from an estimated five to 15 episodes of diarrhea per year, superimposed on malnutrition. The enteropathogens more common in infectious diarrhea during childhood are rotavirus, enterotoxigenic *E. coli*, enteropathogenic *E. coli*, *C. jejuni*, and *G. lamblia* (see [Table 52-1](#)). Residents in industrialized countries, such as the United States, have only one to two bouts of diarrhea per person per year, with no difference between age groups. Complications, including death, are more common in elderly persons. ^[45] ^[60] ^[76]

Reservoirs of Infection.

Organisms are shed in the stools during asymptomatic and symptomatic infection and for a period after illness. Long-term shedding or chronic carrier states are reported only

with typhoid fever, amebiasis, giardiasis, cryptosporidiasis, and enteroaggregative *E. coli* infection. These cases may act as reservoirs for spreading infection, even in areas with low risk for infection by contaminated water. A few enteric pathogens that are zoonotic (animal reservoirs) can increase the risk for certain persons (e.g., veterinarians, field biologists) and account for wilderness-acquired infections. These zoonotic organisms include *Salmonella*, *Yersinia*, *Campylobacter*, *Giardia*, *Balantidium coli*, *Entamoeba*, *Sarcocystis*, and *Cryptosporidium* ^[45] ^[60] (see [Table 52-1](#)).

Incubation Period.

Food intoxication caused by ingestion of preformed toxins from *Staphylococcus aureus* or *Bacillus cereus* usually has a short incubation period (7 hours or less) and may have a common source reported by multiple victims. An outbreak by any enteropathogen

that must first infect the intestine usually has an incubation period of 8 or more hours.

Immunocompromised Status.

Immunocompromised patients, including those infected with human immunodeficiency virus (HIV), are prone to acquire infection by a wide variety of enteropathogens, to develop infectious diarrhea, and to experience relapses or reinfections. HIV patients with advanced acquired immunodeficiency syndrome (AIDS) often experience malabsorption and chronic diarrhea because of changes in the intestinal function secondary to HIV or because of reduced immunity that allows coinfection with other enteropathogens. The agents responsible for diarrheal diseases in HIV patients are common enteric agents, *Mycobacterium avium-intracellulare* complex, *Cryptosporidium*, *Giardia*, *Isospora*, *Cyclospora*, *Microsporidium*, cytomegalovirus, herpes simplex virus and HIV. Treatment of HIV with highly active antiretroviral therapy and treatment of the enteric infection are associated with improved symptomatology and decreased rates of infection.

Etiology

Enteropathogens are the most common etiologic agents of infectious diarrhea and include bacteria, viruses, and protozoa. Fungal agents have been reported rarely. [Table 52-2](#) lists the etiologic agents often associated with travel to developing tropical areas or with wilderness travel in an industrialized region. Foodborne illness may consist of food "poisoning" or food "infection." In food poisoning an intoxication results when toxins

produced by bacteria are found in food in sufficient concentrations to produce symptoms. The major forms of intoxication result from *S. aureus* or *B. cereus*. A rare cause of food poisoning is botulism, caused when the neurotoxin of *Clostridium botulinum* is ingested. Other food borne pathogens are viruses, including rotavirus and small round viruses (Norwalk virus, astrovirus), and intestinal protozoal

TABLE 52-3 -- Bacterial Enteropathogens: Virulence Properties and Distribution

PATHOGEN	VIRULENCE PROPERTIES	DISTRIBUTION
<i>Vibrio cholerae</i>	Heat-labile enterotoxin	Endemic areas in Asia, Africa, and Latin America

Preformed toxins

Worldwide

agents, including *G. lamblia*, *Entamoeba histolytica*, and *Cryptosporidium*.

Pathophysiology

Three intestinal mechanisms lead to diarrhea. The most common pathophysiologic mechanism in acute infectious diarrhea is alteration of fluid and electrolyte movement from the serosal to the mucosal surface of the gut (secretory diarrhea). This alteration may occur as a result of cyclic nucleotide stimulation (as a second messenger) or by an inflammatory process that releases cytokines. The second mechanism, malabsorption or presence of nonabsorbed substances in the lumen of the bowel, and third, acceleration of intestinal motility, are more important in chronic forms of infectious and non-infectious diarrhea, such as tropical and nontropical sprue, Whipple's disease, scleroderma, malabsorption, irritable bowel syndrome, and inflammatory bowel disease. [Table 52-3](#) shows the virulence factors of the most important enteric pathogens related to infectious diarrhea.^[42] ^[60]

In general, enteropathogens cause diarrhea by the first mechanism and can be subdivided into noninvasive and invasive groups. Noninvasive microorganisms primarily colonize the proximal small bowel and cause secretory diarrhea without disruption of the mucosal surface. The unformed stools are usually voluminous and rarely bloody, and high fever is unusual. The common pathogens in this group include *V. cholerae*, enterotoxigenic *E. coli*, preformed enterotoxins, Norwalk virus, rotavirus, *Giardia*, and *Cryptosporidium*. Dehydration is the major complication, especially in the extremes of age, and without adequate therapy it can be followed by renal insufficiency. Invasive pathogens involve the distal ileum and colon, damaging the mucosa and eliciting an inflammatory response. Stools are typically liquid, small volume, and may contain blood and many leukocytes. The common microorganisms in this group are *Shigella* species, *Salmonella* species, enteroinvasive *E. coli*, enterohemorrhagic *E. coli*, *Y. enterocolitica*, *C. jejuni*, *Aeromonas* species, *V. parahaemolyticus*, and *E. histolytica*. Complications include dehydration and systemic involvement, especially in children with malnutrition.^[42]

^[43]

TRAVELER'S DIARRHEA

Traveler's diarrhea (TD) is the most important travel-related illness in terms of frequency and economic impact. Point of origin, destination, and host factors are the main risk determinants.^{[60] [158]} International travel is more often associated with enteric infection and diarrhea, particularly when the destination is a developing tropical region, although the same infections can be contracted domestically. The 2% to 4% rate of diarrhea for people who take short-term trips to low-endemic areas (e.g., United States, Canada, Northwestern Europe, Australia, Japan) may be related to more frequent consumption of food in public restaurants, increased intake of alcohol, or stress. This rate of diarrhea increases to about 10% for travelers from these low-endemic areas to northern Mediterranean areas, China,

1241

Russia, or some Caribbean islands. This incidence increases as high as 40% to 50% for short-term travelers from low-risk countries to high-risk countries (developing tropical and sub-tropical regions of Latin America, southern Asia, or Africa). More than 25 million persons travel each year from these industrialized countries to high-risk areas, resulting in over 7 million travelers with diarrhea.^{[45] [60] [61]} Multiple episodes of diarrhea may occur on the same trip.^[158] Attack rates remain high for up to 1 year,^{[45] [60]} then decrease, but not to the levels of local inhabitants. Immunity to enterotoxigenic *E. coli* (ETEC) infection, either asymptomatic or symptomatic, occurs after repeated or chronic exposure,^[141] which supports the feasibility of developing a vaccine.

TD is a syndrome, not a specific disease.^{[45] [60] [158]} Although any waterborne or foodborne enteropathogen may cause TD, bacteria are the most common etiologic agents among persons traveling to high-risk areas. The bacterial flora of the bowel changes rapidly after arrival in a country with high rates of TD. At least 15% of travelers remain asymptomatic despite the occurrence of infection by pathogenic organisms, including ETEC and *Shigella*. However, most infected patients become ill.

Definition

TD refers to an illness contracted while traveling, although in 15% of sufferers symptoms begin after the return home.^[44] Most studies define TD as the passage of three or more unformed stools in a 24-hour period in association with one or more enteric symptoms, such as abdominal cramps, fever, fecal urgency, tenesmus, passage

of bloody, mucoid stools, nausea, and vomiting. ^[45] ^[60] ^[158]

Etiology

Since the incidence of TD reflects in part the extent of environmental contamination with feces, the etiologic agents are pathogens causing illness in local children. The list of etiologic agents changes as laboratory techniques identify new enteropathogens ([Table 52-4](#)). Twenty years ago, specific pathogens were found in only 20% of cases. ^[112] ^[113] Currently, etiologic agents can be identified in up to 80% of TD episodes. ^[60] ^[158] In most studies, however, causative pathogens are not identified in 20% to 40% of cases. In most of these cases, antimicrobial therapy shortens illness, suggesting that this subset of diarrhea is caused by undetected bacterial pathogens. ^[23] ^[57] ^[63] ^[80] Overall, the major etiologic agents and their frequency of isolation are remarkably similar when one region of the world is compared with another.

Enterotoxigenic *E. coli* has proved to be the most common cause of TD worldwide, ^[60] ^[141] ^[158] ^[178] accounting for about one third to one half of cases. *Shigella* and *Aeromonas/Plesiomonas* species are second to ETEC and

TABLE 52-4 -- Major Pathogens in Traveler's Diarrhea (Travel to Developing Tropical Regions)

AGENT	FREQUENCY (%)
BACTERIA	40–80
Enterotoxigenic <i>Escherichia coli</i>	5–40
Enterocaggregative <i>E. coli</i>	0–40
<i>Salmonella</i>	0–15
<i>Shigella</i>	0–15
<i>Campylobacter jejuni</i>	0–30
<i>Aeromonas</i>	0–10
<i>Plesiomonas</i>	0–5
Other	0–5
VIRUSES	0–20
Rotavirus	0–20
Small round viruses	0–10
PROTOZOA	0–5
<i>Giardia lamblia</i>	0–5
<i>Entamoeba histolytica</i>	0–5
<i>Cryptosporidium parvum</i>	0–5

cause 20% of illness. Other causes of TD include *Salmonella* (4% to 5% of cases), *Campylobacter* (3%), *Vibrio*, viruses (10%), and parasites (2% to 4%). Specific pathogens may predominate at a particular time or location. ETEC is more common in semitropical countries, including Mexico and Morocco, during rainy summer seasons and occurs less often in drier winters. ^[133] A recent study showed that enteroaggregative *E. coli* is the second most common etiologic organism in TD in Guadalajara (Mexico), Ocho Rios (Jamaica), and Goa (India). ^[3A]

Clinical Syndromes

[Table 52-5](#) outlines the major syndromes in patients with enteric infection. The typical clinical syndrome experienced by travelers with diarrhea secondary to the major infectious causes (e.g., ETEC) begins abruptly with watery diarrhea and abdominal cramping. Most cases are mild, consisting of passage of one to two unformed stools per day associated with symptoms that are tolerable and do not interfere with normal activities. Approximately 30% of victims experience moderately severe illness, with three to five unformed stools per day and distressing symptoms that force a change in activities or itinerary. Only 10% to 20% of persons with TD experience severe illness with more than five unformed stools passed per day, incapacitating symptoms that force confinement to bed, or any number of unformed stools with concomitant fever and dysentery. ^[60] ^[158] Only 4% of persons with TD consult a local

TABLE 52-5 -- Pathophysiologic Syndromes in Diarrheal Disease

SYNDROME	AGENT
Acute watery diarrhea	Any agent, especially toxin-mediated diseases (e.g., enterotoxigenic <i>Escherichia coli</i> , <i>Vibrio cholerae</i>)
Febrile dysentery	<i>Shigella</i> , <i>Campylobacter jejuni</i> , <i>Salmonella</i> , enteroinvasive <i>E. coli</i> , <i>Aeromonas</i> spp., noncholera <i>Vibrio</i> spp., <i>Yersinia enterocolitica</i> , <i>Entamoeba histolytica</i> , inflammatory bowel disease
Vomiting (as predominant symptom)	Viral agents, preformed toxins of <i>Staphylococcus aureus</i> or <i>Bacillus cereus</i>
Persistent diarrhea (> 14 days)	Protozoa, small bowel bacterial overgrowth, invasive or inflammatory enteropathogens (e.g., <i>Shigella</i> , enteroaggregative <i>E. coli</i>)
Chronic diarrhea (> 30 days)	Small bowel injury, inflammatory bowel disease, irritable bowel syndrome, Brainerd diarrhea

physician, and less than 1% are admitted to a local hospital while traveling. Approximately one third of travelers are confined to bed or need to alter their travel plans when a diarrheal illness develops. Although the average duration of diarrhea is 3 to 4 days, 50% of cases resolve within 48 hours, 8% to 15% last longer than 1 week, and 1% to 3% last 1 month or longer. TD is rarely life threatening.

Clinical Examination

The etiologic organism of TD cannot be diagnosed reliably based only on clinical manifestations, because illnesses caused by different microorganisms share similar clinical features.^{[37] [60] [143] [158] [184]} Although noninvasive organisms rarely cause dysentery, invasive organisms often cause watery diarrhea without dysentery or a sequential illness beginning with watery diarrhea and progressing to bloody dysentery. If multiple people acquire the illness shortly after eating a shared meal, food poisoning caused by ingestion of preformed toxins in food should be suspected, especially if the illness has a short incubation period (8 hours or less), predominant vomiting, and resolution within 24 hours.

Investigators have studied the reliability of clinical factors to predict which persons will have a positive stool culture.^{[37] [143] [184]} Bacterial pathogens are suspected when the sufferer has a large number (more than six) of stools per day, has a fever, and has had the ailment for more than 24 hours but less than 1 week. Regardless of the clinical similarities of enteropathogens causing TD, certain differences exist, with distinct clinical findings.

Dehydration.

An important part of the initial assessment is to measure the level of hydration, which includes a determination of vital signs, orthostatic pulse and blood pressure, mental status, skin turgor, hydration of mucous membranes, and urine output. Dehydration is most common in pediatric and elder populations.

Fever.

Fever is a reaction to an intestinal inflammatory process. High fever suggests a pathogen invasive to the intestinal mucosa, which classically includes bacterial enteropathogens such as *Shigella*, *Salmonella*, and *Campylobacter jejuni*. Fever can also be produced by enteroinvasive *E. coli*, *Vibrio parahaemolyticus*, *Aeromonas*, *Clostridium difficile*, and viral pathogens.

Vomiting.

Vomiting as the predominant symptom suggests food intoxication secondary to enterotoxin produced by *Staphylococcus aureus* or *Bacillus cereus* or gastroenteritis secondary to viruses, such as rotavirus in infants or Norwalk virus in any age group.

Dysentery.

Dysentery is defined as the passage of small-volume stools with gross blood and mucus. Common causes include *Shigella*, *C. jejuni*, *Salmonella*, *Aeromonas*, *V. parahaemolyticus*, *Yersinia enterocolitica*, enteroinvasive *E. coli*, enterohemorrhagic *E. coli*, *Entamoeba histolytica*, and inflammatory bowel disease. Invasive organisms most often cause dysentery. Up to 30% to 50% of cases of shigellosis or campylobacteriosis are reported to cause dysenteric diarrhea in the United States. Other enteric symptoms are tenesmus (straining without passing stools) and fecal urgency (voluntary inability to delay stool evacuation by 15 minutes), which are more common with dysentery.

Abdominal Findings.

The abdominal examination in persons with TD often shows mild tenderness but should not demonstrate signs of peritoneal irritation. A rectal examination may reveal tenderness in enterocolitis, and the victim may have painful external hemorrhoids, a result of the excess stooling.

Systemic Involvement.

Some of the enteric pathogens produce both diarrheal and systemic disease, such as hemolytic-uremic syndrome related to infection with shigellosis or enterohemorrhagic *E. coli*, Reiter's syndrome or glomerulonephritis related to *Y. enterocolitica*, and typhoid fever secondary to *Salmonella typhi* and *S. paratyphi*.

TABLE 52-6 -- Indications for Laboratory Test in Diarrheal Diseases and Possible Diagnosis

LABORATORY TEST	INDICATION	DIAGNOSIS/AGENT
Fecal leukocytes or lactoferrin	Moderate to severe cases	Diffuse colonic inflammation, invasive enteropathogen
Stool culture	Moderate to severe diarrhea, fever, persistent diarrhea, fecal leukocytes, male homosexuals, food or water outbreaks	Any bacterial enteropathogen
Blood culture	Enteric fever, sepsis	<i>Salmonella</i> , less likely <i>Campylobacter</i> , <i>Shigella</i> , <i>Yersinia</i>

Parasite examination	Persistent diarrhea, travel to specific areas, day-care centers, male homosexuals, immunocompromised persons	Any protozoan parasite
Amebic serology	Persistent diarrhea, liver abscess	<i>Entamoeba histolytica</i>
Rotavirus antigen	Hospitalized infants	
<i>Clostridium difficile</i> toxin	Antibiotic-associated diarrhea	<i>C. difficile</i>

Laboratory Findings

Several laboratory tests are useful in evaluating patients with diarrheal disease ([Table 52-6](#)). For most cases of TD, laboratory testing is reserved for illness continuing after the patient returns home. Persons with mild acute diarrhea usually need only clinical evaluation. An etiologic assessment is unnecessary, and treatment can be given empirically. Laboratory tests are reserved for persons with moderate to severe diarrhea and those with persistent diarrhea.

Fecal Leukocyte Test.

The presence of fecal leukocytes is a reliable indicator of invasive and inflammatory distal gastrointestinal (GI) infection. For all moderate to severe illness, this is the most rapid, useful test and the ideal screening procedure. The fecal leukocyte test should be performed on a fresh sample. A mucus strand, if available, or liquid stool is stained with a drop of dilute methylene blue and observed under a microscope. The stool can be heat-fixed and examined under oil immersion or viewed as a wet-mount preparation under a coverslip with the "high dry" objective of the microscope. Leukocytes are easily seen, although they can be confused with protozoal cysts. A large number of polymorphonuclear leukocytes (PMNs) per high-power field (hpf) indicates diffuse colonic inflammation ([Figure 52-1](#)) rather than a specific etiology but correlates most significantly with invasive bacterial infection caused by *Shigella*, *Salmonella*, or *C. jejuni*. Other organisms and conditions that may lead to presence of fecal leukocytes in the stools are *C. difficile*-associated diarrhea, *Aeromonas*, *Y. enterocolitica*, *V. parahaemolyticus*, EIEC, idiopathic ulcerative colitis, and allergic colitis. Fecal leukocytes are less likely to be seen in noninvasive infections, such as diarrhea caused by

Figure 52-1 Methylene blue stain of a fecal smear from a patient with bacillary dysentery (400×). Numerous polymorphonuclear leukocytes are present, which indicates the presence of

diffuse colonic inflammation.

enterotoxigenic *E. coli*, *G. lamblia*, and viral pathogens, but they are often observed in culture-negative stools.^[92] Not all patients with invasive infectious diarrhea will have leukocyte-positive stools.

Stool Culture.

Bacterial infection is specifically diagnosed by stool culture, although routine stool testing identifies few pathogens. A routine laboratory should be able to recover *Shigella*, *Salmonella*, and *Campylobacter* from a stool culture and, if specifically requested, *Vibrio cholerae* and *V. parahaemolyticus*, *Aeromonas*, *Y. enterocolitica*, and *C. difficile*. In the United States, only about 10% of stool cultures are positive. The percentage is higher (12% for adults, about 50% for children or travelers) among patients in developing countries when research laboratories look for all the important agents, including ETEC.^[158] ^[184] The major indications for performing a stool culture are

1244

moderate to severe diarrhea, febrile and dysenteric disease, persistent diarrhea, and presence of fecal leukocytes in fecal smears.

Blood Culture.

Blood culture(s) should be performed in all patients who are hospitalized with GI symptoms or those who have enteric symptoms and high fever. Systemic infections by *S. typhi* and non-*typhi* *Salmonella*, *Shigella*, *Campylobacter fetus*, and *Y. enterocolitica* may be diagnosed by blood culture.

Parasite Examination.

In cases of TD, direct examination of stool samples looking for a parasite infection is less useful as a routine test than is stool culture. When using microscopy to search for parasites, multiple samples may have to be examined to identify the causative agent. Immunologic techniques to detect antigens of protozoan parasites are more efficient and in common use for parasites that inhabit the duodenum (e.g., *Giardia*, *Cryptosporidium*, *E. histolytica*, microsporidia).^[89] ^[131] At times, intestinal parasites are better detected using a sample from duodenal aspiration or intestinal biopsy.^[89] ^[131] Indications to perform parasitic examination are persistent diarrhea, diarrhea during or shortly after travel within mountainous areas of the United States or Russia, diarrhea in someone who has regular contact with an infant day care center, or diarrhea in a male homosexual or immunocompromised person.

Special Tests.

The Enterotest is a gelatin capsule affixed to a nylon string that is swallowed after the end of the string is taped to the cheek. After the patient consumes a meal or after the string has been attached to the cheek overnight, it is removed so that mucus and other intestinal secretions can be scraped off and studied for enteropathogens. It may be useful to sample small bowel mucus to diagnose cases of typhoid fever, giardiasis, and strongyloidiasis.

A serologic diagnostic test for typhoid fever (Widal's reaction) is only useful in endemic areas, because exposure to cross-reacting gram-negative rods other than *S. typhi* can lead to false-positive serologic results in areas where typhoid fever is not common.^[136] In a patient with a typhoidlike systemic illness who has taken one or more doses of an antimicrobial, culture of bone marrow aspiration may help to identify the bacteria. Antibody-specific serologic tests are now widely used for the diagnosis of invasive amebiasis.^[75]

Rotavirus antigen testing of stool is sensitive and easy to perform. It is indicated to screen infants less than 3 years of age to help guide therapy (fluids without antimicrobials are given when the test is positive).^[153]

C. difficile toxin assay by tissue culture or serology is indicated for diagnosing antibiotic-associated colitis. Many

TABLE 52-7 -- Empiric Treatment of Diarrhea in Adults

CLINICAL MANIFESTATIONS	RECOMMENDATIONS
Watery diarrhea with mild symptoms (no change in itinerary)	Provide oral fluids and saltine crackers plus symptomatic treatment as needed with loperamide or bismuth subsalicylate.
Watery diarrhea with moderate symptoms (change in itinerary but able to function)	Administer symptomatic treatment with loperamide or bismuth subsalicylate.
Watery diarrhea with severe symptoms (incapacitating)	Perform stool culture and fecal leukocytes; consider antimicrobial drugs,* plus loperamide.
Dysentery or fever	Perform stool culture and fecal leukocytes; consider antimicrobial drugs,* no loperamide.
Persistent diarrhea (> 14 days)	Perform stool culture and parasite examination; consider empiric trial with metronidazole.
Vomiting, minimal diarrhea	Administer bismuth subsalicylate.
Diarrhea in pregnant women	As above; administer fluids and electrolytes; consider attapulgite, no fluoroquinolones.

*Fluoroquinolones (norfloxacin, ciprofloxacin, or levofloxacin) are recommended.

of the commercial serologic kit tests are easier to perform, but they detect only toxin A and are less sensitive than the tissue culture procedure. Infants and children may normally carry *C. difficile* toxin in the stools, negating the value of this test.^[104]

Sigmoidoscopy and Colonoscopy.

In selected cases, particularly clinical colitis and diarrhea persisting for 14 days or longer, sigmoidoscopy or colonoscopy is used to study colonic lesions and collect samples for culture and microscopy. Mucosal changes may not be specific, except when pseudomembranes are sought. In homosexual male patients with acute diarrhea, examination of the distal colon may show evidence of proctitis (mucosal inflammation in the distal 15 cm of the colon), proctocolitis (inflammation beyond 15 cm), or enteritis.

Acute Diarrhea

Where routine laboratory evaluation is available, logical approaches to patients with acute diarrhea depend on the clinical syndrome. The illness, not the infection,

TABLE 52-8 -- Nonspecific Drugs for Prophylaxis and Therapy in Adults

AGENT	THERAPEUTIC DOSE
Attapulgate	3 g initially, then 3 g after each loose stool or every 2 hours (not to exceed 9 g/day); should be safe during pregnancy and childhood.
Loperamide	4 mg initially, then 2 mg after each loose stool (not to exceed 8 to 16 mg/day); do not use in dysenteric diarrhea.
Bismuth subsalicylate	30 ml or two 262-mg tablets every 30 minutes for 8 doses; may repeat on day 2.

should be treated, so most persons can be managed on the basis of symptoms and stool appearance. In certain situations, empiric therapy may be given without establishing an etiologic agent; in other cases, specific therapy follows laboratory confirmation of an etiologic agent ([Table 52-7](#) and [Table 52-8](#)). In patients with watery diarrhea and mild symptoms, only clinical evaluation is needed. An etiologic assessment is unnecessary, and symptomatic treatment can be given empirically. Persons with moderate to severe diarrhea, dysentery, fever, or presence of fecal leukocytes should have their stool cultured, if laboratory assessment is feasible, and should start empiric antimicrobial therapy.

Persistent and Chronic Diarrhea

Diarrhea may persist after the traveler returns home. Up to 3% of persons with TD in high-risk areas will develop persistent diarrhea. Persistent diarrhea is defined as illness lasting 14 days or longer, whereas diarrhea is considered chronic when the illness has lasted 30 days or longer.^[44] ^[60] ^[158] The etiology of persistent or chronic diarrhea often differs from that of acute diarrhea. Important causes of persistent diarrhea include (1) protozoal parasitic agents (*G. lamblia*, *Cryptosporidium*, *Cyclospora*, *E. histolytica*), (2) bacterial infection (*Salmonella*, *Shigella*, *Campylobacter*, *Y. enterocolitica*), (3) lactase deficiency induced by a small bowel pathogen (*G. lamblia*, viral enteropathogen such as rotavirus or Norwalk virus), and (4) a small bowel bacterial overgrowth syndrome secondary to small bowel motility inhibition (as a result of enteric infection) or secondary to antimicrobial use. Occasionally, other parasitic enteric infections can cause more persistent illness. These include *Strongyloides stercoralis*, *Trichuris trichiura*, and severe infection by *Necator americanus* or *Ancylostoma duodenale*. In rare cases, more protracted diarrhea may be a prominent symptom in persons with schistosomiasis, *Plasmodium falciparum* malaria, leishmaniasis, or African trypanosomiasis.^[44] ^[60] ^[158]

When chronic diarrhea occurs, the following possibilities should also be considered:

1. After eradication of microbial pathogens, bowel habits may not return to normal for several weeks. Postdysenteric colitis resembling ulcerative colitis occasionally follows infection with invasive pathogens, especially infection caused by *E. histolytica*. This could represent slow repair of the damage to the intestinal mucosa.
2. Postinfective malabsorption can persist for weeks to months after acute diarrhea; it is especially common after giardiasis.^[44] ^[61] ^[158]
3. A poorly defined condition, tropical sprue, may explain prolonged diarrhea in a traveler. Onset usually follows an episode of acute enteritis and is associated with substandard hygiene and longer stays. The cause may involve small bowel bacterial overgrowth, since small bowel incubation may yield a heavy growth of bacteria, and patients often respond to antimicrobial therapy.
4. An underlying condition such as inflammatory bowel disease, irritable bowel syndrome, or celiac sprue may worsen after an episode of acute enteritis.
5. Brainerd diarrhea, named after a community outbreak in Brainerd, Minnesota, may be the explanation for chronic diarrhea. This condition follows the consumption of raw (unpasteurized) milk^[150] or untreated water.^[155] There is no diagnostic test or therapy and the diagnosis is suspected based on the epidemiologic history (exposure to unpasteurized milk or untreated water just before onset of illness).^[23]

The approach to evaluate persistent or chronic diarrhea in travelers should begin with diagnostic tests for conventional bacterial pathogens in stools and at least three parasitologic evaluations in stools. Dietary modification in all cases should include avoidance of lactose. Treatment should be specific, following the results of the microbiologic tests. Because most of these chronic forms of diarrhea are self-limiting, it is unwise to keep treating these patients with multiple antibiotics, which only alters the gut ecology and encourages diarrhea. An empiric trial with metronidazole is an option if all tests are negative (see [Table 52-7](#)). If stools contain leukocytes, sigmoidoscopy or colonoscopy should be performed, along with empiric treatment for *Shigella* or

Campylobacter infection. If there are no leukocytes, duodenal mucus should be examined for *G. lamblia*, followed by empirical treatment for *Giardia*, if metronidazole has not already been given. The next steps are tests for malabsorption and biopsy of the small bowel mucosa.

Treatment

In all cases of diarrhea, fluid and electrolyte replacement should be the primary therapy. Outpatient treatment

1246

with instructions for oral rehydration can be used in the vast majority of adults and children. Significant dehydration from diarrhea in travelers is unusual. Treatment with intravenous (IV) fluids is indicated for patients with hypotension, inability to retain oral fluids, or systemic compromise (high fever and toxicity), moderate toxicity or dehydration and a severe underlying disease, or at extremes of age. Selected patients may benefit from symptomatic therapy, and others may receive empiric antimicrobial therapy (see [Table 52-7](#)). The main goal for using therapy, such as an antimotility drug or an antimicrobial agent, is to attenuate the severity and duration of diarrhea and concomitant symptoms.

Diet and Lifestyle.

Supplemental nutrition is beneficial (essential in undernourished populations) and can be given as soon as fluid deficit losses are replaced, usually after the first 4 hours. During acute diarrheal disease the intestinal tract cannot process complex dietary products, so patients are often told to avoid solid foods. As stooling decreases and appetite improves, staple foods, such as cereals, bananas, crackers, toasts, lentils, potatoes, and other cooked vegetables, are well tolerated and can be gradually added to the diet to facilitate enterocyte renewal, with progression to white meats, fruits, and vegetables. Dairy products and red meats are recommended only after diarrhea has resolved, usually after 2 to 3 days. Only foods and drinks that prolong diarrhea or increase intestinal motility should be avoided, such as those that contain lactose, caffeine, alcohol, high fiber, and fats. Breast-feeding of infants should not be suspended or should be resumed as soon as possible.^{[41] [45] [60] [61] [185]} Patients with TD should avoid excessive physical therapy to reduce the risk of dehydration.

Fluid Treatment.

The major cause of morbidity and mortality from acute diarrheal disease is depletion of body water and electrolytes. Rehydration is an essential part of therapy, especially in the extremes of age and during pregnancy. Most patients with TD do not become dehydrated, and hydration can be maintained by ingesting fluids such as sodas, juices, soup, and potable water in conjunction with a source of electrolytes (e.g., salted

crackers).^{[23] [45] [60] [61]}

The most significant advance in the therapy of diarrhea in the past 25 years has been development of the oral rehydration concept. Oral rehydration solution (ORS) was first developed for treatment of cholera and has saved countless lives, primarily children. ORS precludes extensive use of scarce and expensive IV fluids in developing countries, and its use is the cornerstone of the World Health Organization (WHO) program to combat diarrheal diseases.^{[23] [45] [60] [61]} The discovery that glucose-enhanced intestinal absorption of sodium remains intact despite active diarrhea or vomiting was the key to development of ORS.^{[133] [170]} Other electrolytes are also absorbed nonselectively when ORS is administered.

Watery diarrhea, often caused by release of an enterotoxin, has an electrolyte composition similar to plasma, varying somewhat with type of infection and age of the patient. The formula packaged and promoted by the WHO and United Nations International Children's Emergency Fund (UNICEF) contains powder to be mixed with 1 L of disinfected water, with the following concentrations: sodium 90 mEq, potassium 20 mEq, chloride 80 mEq, bicarbonate 30 mEq, and glucose 111 mmol. Newer formulations use trisodium citrate instead of sodium bicarbonate and complex carbohydrates instead of glucose. Cereal-based products are also available. Although this concentration of electrolytes is ideal for treating purging diarrhea associated with cholera and other dehydrating forms of diarrhea, most TD can be adequately managed with readily available soft and sport drinks, fruit juice or salt solutions, taken with salted crackers and the foods listed earlier.^{[23] [45] [60] [61]}

Fluid status in the field must be guided by physical signs related to hydration, including pulse, mucous membranes, skin turgor, and urine output. Urine color and volume are excellent measures. For travelers in the wilderness or tropics, fluid replacement must equal basic needs plus volume of diarrhea plus estimated sweat loss.

Nonspecific Therapy.

Symptomatic medications are useful for treatment of mild to moderate diarrhea, since they decrease symptoms and allow patients to return more quickly to normal activities (see [Table 52-7](#) and [Table 52-8](#)). Nonantibiotic therapies that may be used in addition to fluids are best classified by their effects on pathophysiologic mechanisms.

ALTERATION OF INTESTINAL FLORA.

Lactobacillus preparations and yogurt are safe, but evidence is insufficient to establish their value in the therapy of acute diarrhea.^{[23] [45] [60] [61] [94]}

ADSORBENTS.

Adsorbent agents bind nonspecifically to water and other intraluminal material, including bacteria and toxins, and potentially to other medications such as antibiotics. The most common medication in this group is attapulgite (see [Table 52-8](#) for dosing), a

nonabsorbable magnesium aluminum silicate that is more active than the combination of kaolin and pectin.^[23] By adsorbing water, these agents give stools more form or consistency but do not decrease stool frequency, cramps, or duration of illness. They are reliable and should be safe in all persons, although adsorbents are not approved for use in young infants and pregnant women.^[169]

ANTIMOTILITY DRUGS.

Narcotic analogs related to opiates are the major antimotility drugs. In addition to slowing

intestinal motility, these drugs alter water and electrolyte transport, probably affecting both secretion and absorption.^{[23] [45] [60] [61]} Compared with placebo, antimotility drugs reduce the number of stools passed and the duration of illness by about 80% during their administration.^{[55] [56]} The most frequently used product is loperamide (Imodium), 4 mg initially, followed by 2 mg after each unformed stool, not to exceed 8 to 16 mg/day. Loperamide also has a weak antisecretory effect through inhibition of intestinal calmodulin. Diphenoxylate with atropine (Lomotil) is less expensive than loperamide but has greater central opiate effects, in case of accidental overdose by a child, and more side effects without antidiarrheal benefits because of the atropine, which is added only to prevent overdoses. Tincture of opium or paregoric opium preparations are rapidly and equally effective and offer a modest relief of symptoms.

Antimotility drugs should never be used alone in patients who have dysenteric or febrile diarrhea, since inhibition of gut motility may facilitate intestinal infection by invasive bacterial enteropathogens.^{[23] [46]} However, this theoretic deleterious effect does not appear to be an issue when loperamide is used concurrently with an effective antimicrobial agent.^{[63] [64] [187]} Antimotility drugs should not be given to children under age 3 years because of the danger of central nervous system (CNS) depression.^[23] They are not recommended for more than 48 hours in acute diarrhea.

TABLE 52-9 -- Antibacterial Therapy for Diarrhea in Adults

DIAGNOSIS	RECOMMENDATION
EMPIRIC THERAPY IN BACTERIOLOGICALLY UNCONFIRMED DISEASE	
Traveler's diarrhea or febrile dysenteric disease	Norfloxacin 400 mg bid, ciprofloxacin 500 mg bid, or levofloxacin 500 mg qd for 1 to 3 days
Persistent diarrhea	Trial with metronidazole 250 mg qid for 7 days
ORGANISM-SPECIFIC THERAPY IN LABORATORY CONFIRMED DIARRHEA	

Enterotoxigenic and enteroaggregative <i>Escherichia coli</i> diarrhea	Ciprofloxacin 1000 mg single dose or 500 mg bid for 3 days; norfloxacin 400 mg bid or levofloxacin 500 mg qd for 1 to 3 days.
Cholera	Ciprofloxacin 1000 mg single dose or 500 mg bid for 3 days; norfloxacin 400 mg bid or levofloxacin 500 mg qd for 3 days; doxycycline 300 mg single dose
Salmonellosis (typhoid fever or systemic infection)	Norfloxacin 400 mg bid, ciprofloxacin 500 mg bid, or levofloxacin 500 mg qd for 7–10 days; in patients with underlying disease or immunocompromised persons.
Salmonellosis (intestinal nontyphoid salmonellosis without systemic infection)	Antimicrobial therapy controversial (see text)
Shigellosis	Norfloxacin 400 mg bid, ciprofloxacin 500 mg bid, or levofloxacin 500 mg qd for 3 days
Campylobacteriosis	Erythromycin 500 mg qid for 5 days; azithromycin 500 mg qd, norfloxacin 400 mg bid, ciprofloxacin 500 mg bid, or levofloxacin 500 mg qd for 3 days
Enteropathogenic <i>E. coli</i> diarrhea	Unclear if antimicrobial therapy is necessary
<i>Clostridium difficile</i> colitis	Metronidazole 250 mg tid for 7 to 14 days

Bid, Twice daily; *qd*, daily.

ANTISECRETORY DRUGS.

Since increased secretion of water and electrolytes is the major physiologic derangement in acute watery diarrhea, therapy aimed at this effect is appealing. Although aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs) inhibit secretion, their usefulness is limited, primarily because of mucosal toxicity.^{[23] [61]} The salicylate moiety of bismuth subsalicylate reduces the number of stools passed and duration of diarrhea by about 50%, primarily by blocking the effect of the enterotoxin on the intestinal mucosa.^{[23] [56]} Bismuth subsalicylate also has antimicrobial and antiinflammatory properties. New compounds are being developed that have antisecretory properties without motility effects.^[58]

Antimicrobial Therapy.

Although most enteric infections do not require antibiotics, empiric antimicrobial therapy is indicated in acute TD and febrile, dysenteric illness because of the high frequency of bacteria as etiologic agents ([Table 52-9](#)).^{[23] [61]} Therapy for specific infections is discussed in the corresponding sections. At times, treatment is indicated regardless of symptoms to prevent person-to-person spread (e.g., for food handlers, river guides,

day-care workers) or to eradicate pathogenic strains and prevent conversion from asymptomatic to symptomatic illness (e.g., *E. histolytica*).^{[22] [163]}

Only fluoroquinolones and to a lesser extent trimethoprim/sulfamethoxazole (TMP/SMX) retain

1248

enough activity against enteric pathogens to be considered useful for empiric therapy. The drug of choice for empiric therapy of TD in adults is an oral fluoroquinolone for 1 to 3 days.^{[23] [60] [61]}

Fluoroquinolones, including those evaluated in TD (norfloxacin, ciprofloxacin, ofloxacin, levofloxacin), represent the treatments of choice for TD when individuals are traveling to areas where TMP/SMX resistance among bacterial enteropathogens is common or has not been determined. Potential advantages of the quinolones include a high degree of in vitro activity against virtually all bacterial etiologic agents (including *Campylobacter*) and the potential for less bacterial resistance.^{[23] [57] [63]} Ciprofloxacin (500 mg twice a day) was equally effective in treating TD compared with TMP/SMX in an area where trimethoprim resistance was unusual.^[63] TMP/SMX (160/800 mg) and trimethoprim (200 mg) twice a day for 5 days were equally effective in reducing the number of unformed stools, duration of illness, and abdominal symptoms compared with placebo.^[51] Reduced duration of illness was reported in infections caused by ETEC or *Shigella* and also in the group without identifiable pathogens. The main problem with TMP/SMX is the increasing in vitro resistance to this antibiotic in several areas of the world.^{[23] [60] [61]}

Because fluoroquinolones are not yet approved for use in children, TMP/SMX plus a macrolide, nalidixic acid, or azithromycin may be given, although a two-drug regimen is a major disadvantage. Azithromycin alone or a short course of a fluoroquinolone may soon be proven safe and efficacious.^{[118] [168]}

Travelers to high-risk regions should carry an antibacterial drug and a symptomatic drug, such as loperamide. Persons should be instructed to take an antimicrobial after passing the third unformed stool in all cases and to take loperamide only if they have no fever.^{[60] [64] [65] [187]} In persons who pass a third stool in less than 24 hours, illness is likely to progress without therapy. Loperamide induces more rapid relief of symptoms, and the antimicrobial exerts curative effects. The duration of antimicrobials needed in TD appears to be short. Many cases respond to single-dose treatment, and no person needs more than 3 days of treatment.^{[23] [57] [60] [64]}

In cases of dysenteric diarrhea the same antimicrobial regimen is given promptly. Empiric therapy should be with fluoroquinolones in adults and with TMP/SMX plus a macrolide or nalidixic acid in children. Azithromycin is an alternative antimicrobial agent under current study.

The antibiotic regimens are not effective against diarrhea caused by *Campylobacter* (in

the case of TMP/SMX or trimethoprim therapy), viruses, parasites, or other noninfectious causes. Therefore antibiotics should not be continued in the face of persistent or worsening diarrhea.

Prevention and Prophylaxis

Dietary Precautions.

Food and water transmit the pathogens that cause infectious diarrhea and TD.^{[23] [45] [60] [61] [62]} When diarrhea occurs, however, the exact source cannot be determined. It is clear that education can play an important role in prevention of TD, but dietary habits usually cannot be rigidly controlled. Food in developing countries is often contaminated with fecal coliforms and enteropathogens.^[3] *Vibrio cholerae* remains viable for 1 to 3 weeks in food,^[71] and *Salmonella* can survive 2 to 14 days in water or in the environment in a desiccated state.^[62]

Risk of illness appears to be lowest when most of the meals are self-prepared and eaten in a private home, intermediate when food is consumed at public restaurants, and highest when food is obtained from street vendors.^{[15] [62]} The following standard dietary recommendations for prevention are based more on known potential vehicles for transmission of illness than on strong evidence, because most of the studies evaluating risk have found little correlation between routine precaution and presence of diarrhea^{[45] [61] [62]} :

1. *Avoid tap water, ice made from untreated water, and suspect bottled water.* Bottled and carbonated drinks, beer, and wine are probably safe. Boiled or otherwise disinfected water is safe. Waterborne epidemics of almost all the enteric pathogens have occurred worldwide.^[62] Tap water in high-risk countries is difficult to implicate in TD, but has been shown to contain enteric bacteria and pathogenic viruses and parasites.^{[62] [131]} Tap water and occasionally even bottled water may be unsafe, but bottled carbonated beverages are considered safe because of the antibacterial effects of the low acidity. Alcohol in mixed drinks does not disinfect, so these may not be safe, but bottled beer and wine have not been found to be contaminated. Most enteric organisms can survive freezing and melting in common drinks, so ice is not considered safe unless made from treated or previously boiled water. Ice in block form is often handled with unsanitary methods.^{[43] [62]}
 2. *Avoid unpasteurized dairy products.* These may be the source of infection with *Salmonella*, *Campylobacter*, *Brucella*, *Listeria monocytogenes*, *Mycobacterium tuberculosis*, and others.^[161]
 3. *Avoid raw food.* Raw vegetables in salads may be contaminated by fertilization with human waste or by washing in contaminated water.^[62] Anything that can be peeled or have the surface removed is safe. Fruits and leafy vegetables can also be disinfected by immersion and washing in iodinated water or by exposure to boiling water for 30 seconds. Raw seafood, including that in such traditional dishes as ceviche and sashimi, has been associated with increased risk of TD. Shellfish concentrate enteric organisms from contaminated
-

water and can carry hepatitis A, Norwalk virus, *Aeromonas hydrophila*, *Y. enterocolitica*, *V. cholerae*, and *V. parahaemolyticus*. Raw fish can carry parasites such as *Anisakis simplex*, *Clonorchis sinensis*, and *Metagonimus yokogawai*. Raw meat is a source of *Salmonella* and *Campylobacter* and the vehicle for *Trichinella*, *Taenia saginata* and *T. solium* (beef or pork tapeworm), and *Sarcocystis*. Although adequate cooking kills all microorganisms and parasites, if food is left at room temperature and recontaminated before serving, it can incubate *Salmonella*, *E. coli*, or *Shigella*. Food served on an airplane, train, boat, or bus probably has been catered in the country of origin. The problems of food hygiene pertain to these forms of public transportation, even if the employees handling the food are from the United States.

Safe foods are those served steaming hot, dry foods such as bread, freshly cooked food, foods that have high sugar content (e.g., syrups, jellies), and fruits that have been peeled.^{[23] [62]}

Prophylactic Medication.

Chemoprophylaxis may be useful for certain people making critical trips or for travelers with underlying medical conditions. It should only be used for 3 weeks or less and should be always approved by a physician and after a complete understanding of all risks and benefits. Despite the restrictive recommendations, 10% to 25% of European travelers to high-risk areas and up to one third of U.S. travelers to Mexico take prophylactic medication to prevent TD.^{[62] [113]} Compared with empiric therapy with a single dose of an antimicrobial agent and loperamide, chemoprophylaxis is cost-effective only when its use does not exceed a few days^[62] ([Table 52-10](#)).

Several nonantimicrobial agents have been studied for prevention of TD, with some found to be minimally effective. Lactobacilli have been tested on the assumption that they are safe and favorably modify intestinal flora, but they did not invariably reduce the incidence of TD and provided protective efficacy only up to 47%.^[94] Antimotility drugs, such as loperamide, have adverse effects when used for prophylaxis.^{[23] [56] [62]}

Of the nonantibiotic drugs, only bismuth subsalicylate (BSS), the active ingredient of Pepto-Bismol, has been shown by controlled studies to offer reasonable

TABLE 52-10 -- Prophylactic Medications for Prevention of Traveler's Diarrhea*

AGENT	PROTECTIVE EFFICACY	PROPHYLACTIC DOSE	COMMENT
Bismuth subsalicylate	65%	Two 262-mg tablets before meals and at bedtime	Safe, temporary darkening of stools and tongue

Fluoroquinolones	90%	Norfloxacin 400 mg, ciprofloxacin 500 mg, or levofloxacin 500 mg once a day	Side effects, increased bacterial resistance
------------------	-----	--	---

*Not generally recommended for travelers, only in special situations (see text) and for no longer than 3 weeks.

protection and safety. Several studies with volunteers and in the field have demonstrated that the use of BSS gives a protection rate from 40% to 77%,^{[53] [62]} with fewer abdominal symptoms. Since the volume required is quite large with the liquid preparation, BSS in tablet form was also evaluated. The currently recommended dose of BSS is two tablets four times a day (2.1 g/day).^{[23] [45] [53] [60] [61]} Mild side effects include constipation, nausea, tinnitus, and temporarily blackened tongue or stools. In areas where doxycycline is used for malaria prevention, concurrent BSS should be avoided because it may bind to the antimicrobial and prevent absorption.^{[53] [62]} Ninety percent of salicylate from liquid BSS is absorbed and excreted in the urine of children.^[53] Whether this salicylate cross-reacts with aspirin is unknown. However, BSS should not be used by someone with a history of aspirin allergy. Caution is recommended in small children, children with chickenpox or influenza (because of the potential risk of Reye's syndrome), patients with gout or renal insufficiency, and persons taking anticoagulants, probenecid, methotrexate, or other aspirin-containing products. BSS is not approved for children under 2 years old and is not recommended as prophylaxis for more than 3 weeks. The precise mechanism by which BSS prevents diarrhea is still unknown. Salicylate released during dissociation in the stomach exhibits antisecretory activity after exposure to bacterial enterotoxin on intestinal mucosa, and bismuth salts have antimicrobial activity.^[53] Adherence of bacteria to intestinal mucosa may be affected.

Since the first studies in the 1950s, a protective effect of antimicrobials in TD has been demonstrated. Several antimicrobial agents are highly effective in preventing TD when given over short periods when at risk. Protection levels of 80% to 90% have been found with antimicrobial prophylaxis, provided that enteropathogens in the area were susceptible to the agent under investigation.^{[45] [61] [62]} The most experience has been obtained with doxycycline, TMP/SMX, and the fluoroquinolones. Other antimicrobials (streptomycin and sulfonamides, erythromycin, mecillinam) have shown significant protection but have not been well studied.^{[61] [141]} Studies of U.S. students in Mexico taking trimethoprim (160 mg) and sulfamethoxazole (800 mg) twice daily for 3 weeks or once daily for 2 weeks demonstrated 71% and 95% protection, respectively.^{[50] [52]}

The fluoroquinolones (e.g., ciprofloxacin, ofloxacin, norfloxacin, pefloxacin, fleroxacin, levofloxacin) have been shown to be highly protective when employed as prophylactic agents. Because of the emergence of resistance among enteropathogens to tetracyclines, doxycycline can no longer be recommended for prophylaxis unless the

susceptibility of prevalent organisms is known. Similarly, TMP/SMX resistance has been reported in many regions of the developing world,^{[60] [62]} including areas where resistance to this agent has not been previously reported.^[24] With the antibiotics evaluated, the effect lasted only as long as the drug was continued. Subjects who remained in a high-risk area experienced an increased incidence of diarrhea during the week after cessation of prophylaxis.^{[44] [62]}

Despite dramatic protection against diarrhea, investigators do not recommend widespread use of these medications for prophylaxis by travelers because of the following reasons^{[23] [60] [62]} :

1. *Side effects.* These include GI symptoms, photosensitivity, and other cutaneous eruptions and reactions. Pregnant women and children should not use fluoroquinolones for this reason. With larger numbers of people using these drugs, more serious side effects (e.g., Stevens-Johnson syndrome, hemolytic or aplastic anemia, antibiotic-associated colitis, anaphylaxis) will undoubtedly result.
2. *Alteration of normal bacterial flora.* Broad-spectrum antimicrobials may increase risk of infection with other antibiotic-resistant bacteria. Severe pseudomembranous colitis caused by colonic overgrowth with *Clostridium difficile* has occurred after therapy with most antibiotics. Vaginal candidiasis and GI side effects, including diarrhea, are common with antibiotic therapy. Changes in anaerobic flora can cause long-term alterations in the metabolism of bile acids and pancreatic enzymes, although clinical effects are unknown.
3. *Development of antimicrobial resistance.* Overuse of antimicrobial agents increases the prevalence of resistant strains.^{[49] [60] [84] [176]}
4. *False sense of security.* Travelers taking antibiotics may relax their vigilance of dietary precautions and increase their risk of acquiring enteric infections.
5. *High cost of fluoroquinolones and rapid effectiveness of presumptive therapy,* often limiting the illness to 12 to 24 hours.

Although the consensus is that not all travelers should use antibiotic prophylaxis, this approach may be appropriate for some.^{[23] [45] [60] [61] [62]} Potential candidates would be residents of a low-risk country going to a high-risk area for short stays who have one or more of the following conditions or requirements:

1. An underlying illness that increases the risk of enteric infection or morbidity, such as gastric achlorhydria (from surgery or taking proton pump inhibitors), AIDS, inflammatory bowel disease, diabetes on insulin treatment, or a cardiac, renal, or CNS disorder.
2. An itinerary that is so rigid and critical to the overall mission that travelers would not tolerate even minor schedule changes caused by illness
3. Travelers who prefer prophylaxis after hearing the pros and cons of the approach

No studies have evaluated prophylaxis of TD in young children, although they may be at higher risk for infectious diarrhea. Because of potential side effects, prophylaxis with BSS or antibiotics cannot be recommended in children under 5 years of age.

Immunoprophylaxis.

Spurred by the emergence of in vitro resistance to antimicrobial agents among enteropathogens, including the fluoroquinolones, prophylaxis with vaccines is being developed to control bacterial diarrhea. Recent studies support the concept of immunoprophylaxis against rotavirus, *Shigella*, *V. cholerae*, and ETEC.^[45] ^[60] ^[61]

BACTERIAL ENTEROPATHOGENS

Escherichia Coli

E. coli is the most prevalent facultative gram-negative rod in feces. Diarrheagenic *E. coli* is a heterogeneous group of organisms that belong to one taxonomic species, but with different virulence properties, epidemiologic characteristics, and clinical features. At least six groups have been characterized, based on either genotypic or phenotypic markers.^[141]

Enteropathogenic *E. coli*.

EPEC strains were the first of the diarrheagenic *E. coli* described between the 1920s and 1940s, as causes of hospital nursery outbreaks.^[141] Usually identified by serotypes, they are also characterized by a localized adherence pattern to a specialized cell line (HEp-2 cells).^[194] EPEC strains have worldwide distribution, and their most accepted virulence property is enterocyte attachment with selective damage of the surface without cell invasion. They induce production of a receptor interacting with host cells' intima, and this interaction leads to intracellular changes in the enterocyte.^{[83] [115] [141]}

Enterotoxigenic *E. coli*.

ETEC strains, first identified in the 1970s, produce one or two enterotoxins that act on the small intestine through different mechanisms and time responses.^[141] One of these toxins is a heat-labile cholera-like toxin (LT), a high-molecular-weight protein immunologically and physiologically similar to cholera toxin. Human ETEC strains also have a low-molecular-weight, poorly antigenic toxin that is heat stable (ST).^[165] Both enterotoxins inhibit sodium reabsorption and increase secretion of anions and fluid into the intestinal lumen, resulting in secretory diarrhea without inflammatory exudate.^{[43] [60] [141]} One

common method for the diagnosis of ETEC is identification of specific deoxyribonucleic acid (DNA) plasmid sequences, using a hybridization technique.^[141] Recently, polymerase chain reaction (PCR) has been used to improve the level of detection.^{[189] [203]} ETEC has worldwide distribution and is the major cause of TD, accounting for 20% to 50% of cases in series from all parts of the world.^{[60] [141] [158]} It also accounts for a large percentage and frequently the majority of enteritis in local pediatric populations of

developing countries, where contaminated food and water are the primary sources of infection.^[141] Most outbreaks of ETEC in the United States have been waterborne.^[141] ^[165] Person-to-person spread is infrequent because of the large infectious dose (10^6 to 10^{10} organisms).^[43] ^[141] Contamination of different types of food with these strains has been reported.^[141]

Enteroinvasive E. coli.

As with *Shigella*, EIEC strains possess the property of bowel mucosa invasion, resulting in microabscesses and ulcer formation. Because of the presence of the same invasive plasmid and other antigens of *Shigella*,^[166] EIEC must be considered in the differential diagnosis of febrile dysenteric diarrhea, with *Shigella*, *Salmonella*, *Y. enterocolitica*, *E. histolytica*, *V. parahaemolyticus*, and inflammatory bowel disease. EIEC strains are found worldwide and have been associated with food-borne outbreaks, especially in areas of South America and Eastern Europe.^[43] ^[141] ^[196]

Enterohemorrhagic E. coli.

EHEC strains are also known as verotoxin-producing *E. coli* or Shiga toxin-producing *E. coli*. They have caused outbreaks of diarrhea associated with consumption of contaminated beef, often obtained at a fast-food hamburger chain, or unpasteurized apple juice. Contact with contaminated swimming pools and exposure to farm animals have also been associated with this infection.^[31] ^[135] ^[141] ^[154] ^[179] EHEC produces copious bloody diarrhea with fecal mucus (hemorrhagic colitis), but fever is either low grade or absent. The most important EHEC strain thus far identified is O157:H7. The production of Shiga or a similar toxin by these strains may be related to the hemolytic-uremic syndrome (HUS), a common complication in children infected with EHEC O157:H7 and Shiga toxin-producing *Shigella*. HUS may be life-threatening, and no evidence indicates that HUS is prevented by antimicrobial therapy of EHEC disease.^[72] ^[135] ^[156]

Enteroaggregative E. coli.

EAEC strains are the most recent addition to the group of diarrheagenic *E. coli*. They are non-EPEC and do not produce ETEC LT or ST. EAEC adhere to HEp-2 cells in a typical aggregative pattern. The pathophysiology of these strains is uncertain; some studies suggest that they should be considered a phenotypically and genotypically heterogeneous group.^[36] ^[120] ^[141] ^[142] These strains have been associated with persistent illness and malnutrition in children with diarrhea, especially in the developing world, but recent studies have demonstrated their association with diarrhea in adults. EAEC is also identified as an important cause of TD,^[77] ^[80] second only to ETEC in some areas of the world.

Diffusely Adherent E. coli.

Known also as enteroadherent *E. coli*, these non-EPEC strains show a diffuse adherence pattern to HEp-2 cells. Although associated with cases of diarrhea, the pathogenicity of these isolates has not been established in outbreaks or volunteer

studies. The pathophysiology and importance of these strains are still not completely understood, and some propose that they be categorized as a subtype of EAEC.^{[36] [141] [142]}

Diagnosis.

Laboratory culture cannot differentiate the various diarrheagenic strains of *E. coli* from normal bowel flora or from one another. Specialized assays such as DNA probing and HEp-2 adherence technique are specifically used for research purposes.^[141] New serologic techniques or PCR systems may become available in the future to help differentiate these organisms.

Treatment.

Most cases of *E. coli* diarrhea are brief and self-limited, and their therapy should be primarily supportive with oral fluid replacement and maintenance, empirically based on the clinical manifestations. Dysenteric illness is the exception and should always be treated with antibacterial drugs, whether in a developing country or an industrialized region. In developing tropical countries, TD associated with the passage of numerous watery stools is often caused by both ETEC or EAEC, and antibiotics may shorten the duration of illness, especially when started within 48 to 72 hours of symptom onset.^{*} Because of the increasing resistance of ETEC strains to antimicrobial agents, including fluoroquinolones, new therapeutic agents are actively being sought, such as rifaximin and azithromycin.^{[59] [84] [136] [141] [176]} Since resistance patterns vary with geographic area and season, it is necessary to monitor susceptibility of bacterial isolates in various regions of the world. Susceptibility testing is required when treating diarrhea caused by EPEC, since strains are invariably resistant to a broad range of drugs.

Immunoprophylaxis.

Oral immunization with inactivated ETEC with or without cholera toxin B subunit was shown to be safe and immunogenic in phase III trials in Egypt.^{[172] [173]} A new vaccine, using a *Salmonella typhimurium* vaccine vector expressing recombinant ETEC fimbria, elicited immunogenic response in mice.^[6]

*References ^{[23] [54] [65] [80] [141] [187] [197]} .

A live vaccine could offer advantages over a killed preparation in terms of duration and protection.

Salmonella

Salmonella infections may result in four different clinical syndromes: gastroenterocolitis, enteric (typhoid) fever, bacteremia with focal extraintestinal infection, and asymptomatic

carriage,^[17] ^[171] depending on the type of organism and the host characteristics. Gastroenterocolitis is usually a mild to moderately severe, self-limited illness, with preferential involvement of the lower intestine. Enteric fever is characterized by septicemia with a prolonged toxic course if not treated. In patients infected with *Salmonella choleraesuis* strains, or with sickle cell disease or immunosuppression (e.g., splenectomy, HIV infection, malignancy, immunosuppressive therapy, newborns, elderly persons), nontyphoid salmonellae may disseminate and produce localized infection, including osteomyelitis or meningitis. A person with an abdominal aortic aneurysm is prone to develop *Salmonella* infection, leading to aneurysm perforation. As many as 1% to 3% of patients who have recovered from typhoid fever may become chronic carriers who continue to shed the organism in the intestinal tract for 1 year or longer. Characteristically, the chronic typhoid carrier is an adult woman with cholelithiasis.^[17]

Microbiology.

The following discussion pertains to nontyphoid *Salmonella*, unless otherwise stated. Salmonellae are nonsporulating, facultative, gram-negative rods. The genus *Salmonella* is composed of more than 2000 serotypes that infect humans and animals. Enteric fever results from infection by *Salmonella typhi* or by *S. paratyphi* A, B, and C, which usually cause milder disease. *S. typhi* and *S. paratyphi* are further distinguished by their adaptation to humans as the only host. Although numerous other serotypes are capable of causing enteric fever, illness is usually limited to gastroenteritis.^[60] ^[136] ^[158] ^[171] New serotypes occasionally become prominent, but most human infections are caused by only 10 serotypes, with *S. typhimurium* the most common.

Epidemiology.

Nontyphoid *Salmonella* organisms infect nearly all animal species and cause zoonotic infections. They can persist in fresh water for 2 to 14 days, but they also may remain dormant in a desiccated non-sporulating state.^[17] Human salmonellosis is a worldwide problem, remaining endemic in large areas of the developing world, where it is passed primarily through contaminated food and water. The Centers for Disease Control and Prevention (CDC) estimates that the 25,000 human cases of nontyphoid salmonellosis reported annually in the United States represent less than 1% of the actual number of clinical cases.^[134] ^[136] A recent report of typhoid fever in the United States from 1985 to 1994 showed that travel to underdeveloped countries is still a risk factor for this disease.^[136]

Salmonella is the most common identifiable cause of foodborne illness. Contamination may occur from the animal feed, at slaughter, or most often, during food preparation. Because the infectious dose is relatively high, averaging 10^3 to 10^6 organisms (lower in water),^[17] ^[136] the bacteria must multiply on or in food. This accounts for the high summer case incidence, when refrigeration may not be adequate.^[136] The foods most commonly implicated are meat, dairy products (especially unpasteurized), poultry, and eggs. Recent outbreaks of salmonellosis have been related to different foods from toasted oat cereal to alfalfa sprouts and infant formula.^[28] ^[136] ^[191] Person-to-person spread accounts for 10% of cases, but 20% to 35% of household contacts may become infected.^[136]

Salmonella is an occasional cause of TD, accounting for up to 15% of cases.^{[60] [158]}

Normal gastric acid, gut motility, bacterial flora, and poorly understood immune factors are elements in host resistance. Bacterial virulence factors, the vehicle of transmission, and infectious dose are the major determinants of infection.^{[17] [136] [171]} Salmonellosis primarily affects children and elderly persons. Fifty-five percent of reported isolates in the United States are from persons under 5 years of age. The organism has an unexplained propensity to infect infants under 1 year of age, who may experience serious systemic infection, including sepsis and meningitis. Greater susceptibility has also been observed in patients with gastrectomy-induced hypochlorhydria, hemolytic disorders (e.g., sickle cell anemia), parasitic infections (e.g., malaria, schistosomiasis), and chronic illness (e.g., malignancies, liver disease).^{[134] [136]}

Pathophysiology.

Salmonellosis involves mucosal invasion and possibly enterotoxin production.^{[105] [171]} After surviving the gastric acid barrier, the organisms reproduce in the gut, where they attach to the wall of the ileum and colon, inducing local degeneration of the microvilli. Invasion occurs through vacuolization, discharging the bacteria into the lamina propria, from where they gain entry into the bloodstream. At this point, only the strains that cause enteric fever enter and multiply within lymphatic tissue and phagocytic cells. The mechanism of diarrhea in enterocolitis is not clear. A heat-stable enterotoxin has been identified. In most cases, local inflammation of the bowel wall is not severe enough to cause mucosal sloughing and dysentery.

Recent studies of pathogenesis demonstrated that interleukin-18 and γ -interferon contribute to host resistance and that deficiency of interleukin-12 or nitric oxide is related to severity of infection.^{[126] [132]} Protection against typhoid fever is associated with the cystic fibrosis

1253

gene, called *cystic fibrosis transmembrane conductance regulator* (CFTR), similar to the protection of sickle cell against plasmodium infestation. Apparently, *S. typhi* uses this gene to invade the intestinal epithelial cells.^{[106] [160]}

Clinical Syndromes.

Although the incubation period for typhoid fever is usually 1 to 2 weeks, it is only 8 to 48 hours for intestinal infections with non-typhoid *Salmonella*.^[171] Nausea, vomiting, malaise, headache, and low-grade fever may precede abdominal cramps and diarrhea. Stools are usually foul, and green-brown to watery, with variable amounts of mucus, blood, and leukocytes. Cholera-like fluid loss or dysentery with grossly bloody and mucoid stools occurs less often. The acute phase lasts only a few days. Asymptomatic excretion of organisms in the stool continues for 4 to 8 weeks, and chronic carriers are rare. Infants less than 3 months of age experience longer illnesses (average 8 days)

with more complications. Among all ages, transient bacteremia is common, accounting for significant isolation of *Salmonella* types from blood. Fever and malaise occurring more than 1 week after resolution of diarrhea suggest a complication or another diagnosis.^{[136] [171]} In healthy adults, *Salmonella* bacteremia occurs in 5% to 10% of infections and is not distinguishable from other causes of sepsis. Focal infections may be seen in any organ, but sites adjacent to the bowel are most common. Mortality is highest at the extremes of age, but deaths occur in all age groups.^[136]

Diagnosis.

Diagnosis of enterocolitis can be made by clinical manifestations and isolation of *Salmonella* organisms from stool or rectal swabs cultured onto selective media (MacConkey or *Salmonella-Shigella* agar). Blood cultures are useful to identify a systemic non-typhoidal salmonellosis. Blood cultures (or culture of bone marrow aspirates) for *S. typhi* or *S. paratyphi* are also used to diagnose enteric fever. Stool cultures are often negative early in the disease. Widal's serum test is useful for diagnosing typhoid fever in areas with high prevalence, but not in industrialized areas, because of the more frequent occurrence of cross-reaction with other gram-negative organisms.

Treatment.

Supportive treatment with fluids is sufficient therapy for most cases of uncomplicated *Salmonella* enterocolitis. Antibiotics are not indicated because they do not shorten the illness, and they slightly prolong the carrier state and increase the risk of developing resistant strains.^{[7] [136]} Antimicrobial therapy is indicated for persons who have symptomatic *Salmonella* infection with fever, systemic toxicity, or bloody stools. Patients with underlying debility that may predispose to septicemia or localized infection (e.g., immunosuppression), young infants (less than 3 months), elderly persons (more than 65 years), and sickle cell patients should be treated with antimicrobial agents. Fluoroquinolones are the treatment of choice because they shorten the duration of fever and diarrhea in salmonellosis.^{[7] [136]} Doses are the same as those recommended to treat shigellosis, although treatment is continued for 7 days (14 days if the patient is immunosuppressed).

In cases of enteric (typhoid) fever, septicemic salmonellosis, or local tissue suppuration, antibiotic therapy is indicated. The drugs of choice for enteric fever in the United States are the fluoroquinolones. These drugs can be given for a shorter duration (10 vs. 14 days), resistance to them is still low, and posttreatment carriage of *S. typhi* is reduced.^{[7] [66]} In many developing countries the drug of choice is still chloramphenicol (25 to 50 mg/kg/day in divided doses every 6 hours) because of its low price and predictable activity. Alternative empiric therapy in the United States is a third-generation cephalosporin. Other traditional options, such as ampicillin or TMP/SMX,^[24] have low in vitro activity in many areas. Local suppuration may require 2 to 6 weeks of antibiotics, depending on the adequacy of surgical drainage.

As with *Shigella*, *Salmonella* species are showing increasing resistance to multiple

antimicrobial agents worldwide.^[81] ^[87] ^[136] ^[177]

Immunoprophylaxis.

Immunity to *Salmonella* is serotype specific. Vaccines have not been successful for nontyphoid *Salmonella* because of the number of serotypes. For typhoid fever, immunoprophylaxis is possible, and currently, three protective vaccines are commercially available. The traditional killed vaccine is associated with high reaction rate and has limited use in young children traveling in highly endemic areas. The two live attenuated typhoid vaccines are preferred for antityphoid immunizations. The first is a live attenuated strain Ty21a that is given as one oral dose every other day for four doses.^[78] The second is a Vi polysaccharide preparation given as a single parenteral immunization.^[1] Both preparations are of approximately equal cost and effectiveness. New vaccines are under evaluation. One new live attenuated *S. typhimurium* mutant is highly immunogenic and protective in animal models and induces cross-reactive antibodies to other enteric pathogens.^[190]

Shigella

Microbiology.

Dysentery has been described since the beginning of recorded history. At the end of the nineteenth century, Shiga first identified *Shigella dysenteriae* as the cause of an outbreak of dysenteric diarrhea in Japan, and since then, shigellosis has become synonymous with bacterial dysentery. Other bacteria and protozoa are also capable of producing the bloody and mucoid stools that define this syndrome.

1254

Shigellae are thin, nonmotile, nonsporulating, gramnegative rods in the Enterobacteriaceae family. There are four species or groups: A (*S. dysenteriae*), B (*S. flexneri*), C (*S. boydii*), and D (*S. sonnei*); the first three contain numerous serotypes.

Epidemiology.

Shigellosis occurs worldwide. *S. dysenteriae* 1 (Shiga bacillus), which causes severe disease, is most common in developing countries. In the US and in many other areas, particularly in more industrialized regions, *Shigella* remains endemic, with *S. sonnei* replacing *S. flexneri* as the most common isolate.

Humans and certain primates are the only hosts for *Shigella*. Fecal-oral contamination is the mode of spread. Common source infections occur through water or food prepared by contaminated hands. *Shigella* can survive freezing and thawing in ice cubes. With an infectious dose as low as 10 to 200 organisms, person-to-person spread is common.^[54] Even in countries with good sanitation, *Shigella* accounts for persistent endemic foci

and high rates of transmission, especially among groups in close physical contact (e.g., male homosexuals, children in day-care centers), groups with poor hygiene (e.g., mentally impaired patients), and those who lack sanitary facilities and water (e.g., populations in developing countries, Native Americans on reservations). Long-term carriage of *Shigella* is less common than for *Salmonella*. *Shigella* is a potential pathogen in the American wilderness. Environmental persistence averages 3 to 4 weeks, with best survival in cool fresh water.

Pathophysiology.

The essential virulence factor of *Shigella* is invasiveness associated with a large (120- to 140-megadalton) plasmid. *Shigella* organisms invade and proliferate within the epithelium of the large bowel, producing well-demarcated ulcers with cellular infiltrates (chiefly PMNs) and overlying suppurative exudates. These organisms interact with the epithelial cells through an initial type III secretory system, with invasion of these cells and reorganization of their cytoskeleton.^{[40] [83] [144]} Organisms have also been demonstrated in the small bowel, but these have reduced potential for invasion or changes in the mucosa, causing a profuse watery diarrhea, possibly mediated by an enterotoxin.^{[40] [43]}

Despite similarities in pathogenesis between EIEC and *Shigella* strains, random amplified polymorphic DNA and typing techniques were not able to characterize and differentiate them.^{[11] [166]}

Clinical Syndromes.

As with most enteric pathogens, infection with *Shigella* may be asymptomatic, mild, or severe. Rarely a chronic carrier state may develop, depending on a combination of host and organism factors. Two distinct diarrheal syndromes may occur separately or sequentially in shigellosis. After a short incubation period of 1 to 3 days, illness begins with malaise, headache, nausea, fever, abdominal cramps, and watery diarrhea, representing small bowel infection. Children may present with fever, with diarrhea developing later. In the second and classic form of shigellosis, after 1 to 3 days of small bowel disease, colonic involvement causes progression to clinical dysentery. In this dysenteric form the volume of stools decreases and the frequency increases, with passage of up to 20 to 30 movements a day, containing gross blood and associated with fecal urgency and often tenesmus. Fever is common in dysenteric cases, found in up to one half of cases of shigellosis overall. Mild abdominal tenderness is also common, but without peritoneal signs.

The natural history of shigellosis is varied, with most cases resolving spontaneously within 7 days, but with others persisting for weeks.^{[43] [47]} The mortality rate is as high as 25% in developing countries when *S. dysenteriae* 1 (Shiga bacillus) diarrhea is untreated, but it decreases to less than 1% with adequate antimicrobial therapy.

Complications.

Several potential complications of shigellosis may occur. Severe anemia and hypoalbuminemia may result from blood and protein losses. Febrile convulsions are seen in young children with shigellosis. Pneumonitis may complicate *Shigella* infection. A severe leukemoid reaction with white cell count up to 50,000 may result after apparent clinical improvement in patients. In some patients infected by strains that produce Shiga toxin, HUS syndrome develops, probably induced by formation of immune complexes. Reiter's syndrome has also been reported in patients with *S. flexneri* infection who are HLA B27 positive. Septicemia was found in less than 5% of *Shigella* infections, with fewer cases of metastatic abscesses.^{[47] [54]}

Diagnosis.

Laboratory tests often show a mild leukocytosis with a shift to the left (increase in number of immature granulocytes). If colitis is present, microscopic examination of the stool shows countless white (PMNs) and red blood cells, but this is not specific to shigellosis. Diagnosis is made by stool culture on selective media (MacConkey or *Salmonella-Shigella* agar), which is positive in most infected patients.^[47] Fresh stool or sigmoidoscopic biopsy is the best source of culture material, while rectal cotton swabs, although not as reliable, can be used if plated rapidly or placed in a holding medium. In hospitalized patients, blood cultures should be obtained.

Treatment.

Therapy first involves fluid replacement. Although large-volume diarrhea is unusual, significant

dehydration may occur, especially in children. Antimotility drugs are controversial in patients with signs of toxicity^[46]; however, these medications are unlikely to be detrimental if antibiotics are used concurrently.^{[23] [64] [65]} Patients with fever and dysentery should be treated with antimicrobial agents, since these drugs decrease duration of fever, diarrhea, and excretion of *Shigella* in stool. Antibiotic-resistant strains are emerging worldwide, with recent reports in Asia, Oceania, and Latin America,^{[24] [81A] [99] [183]} showing that most of the strains are resistant to ampicillin and TMP/SMX, whereas the fluoroquinolones remain active. The current recommendation for treatment is with a fluoroquinolone: norfloxacin 400 mg, ciprofloxacin 500 mg, or levofloxacin 500 mg daily, for a total of 3 to 5 days. Single-dose therapy is probably effective in milder forms of illness.^{[23] [57] [63] [65] [187]} Fluoroquinolones currently are contraindicated in infants and children because of the possible effects on articular cartilage. However, short-course fluoroquinolone therapy appears to be safe. Alternative treatments for children in areas where TMP resistance occurs are nalidixic acid and furazolidone.^[168] Other options that need further testing are azithromycin and rifaximin.^[59]

Immunoprophylaxis.

Temporary immunity to homologous *Shigella* strains follows natural infection.^{[48] [145]} A vaccine composed of specific polysaccharide conjugates of *S. flexneri* and *S. sonnei* has been shown to be safe and immunogenic in children.^[8] Other attenuated or killed strains or specific synthetic polysaccharides have shown promise in animal studies.^{[32] [162]}

Campylobacter

Microbiology.

The organism is a small, curved, gramnegative rod, initially classified as *Vibrio*. *Campylobacter jejuni* strains are widespread in the environment. The major reservoir is animals, including dogs, cattle, birds, horses, goats, pigs, cats, and sheep.^{[16] [60] [158]} A reemergent species, *C. upsaliensis*, has been recently associated with diarrheal disease, persistent diarrhea in HIV patients, and a few cases of HUS.^[21]

Epidemiology.

Most epidemics of gastroenteritis have been caused by contaminated food. The most important source for human illness is poultry, but epidemics have also been associated with ingestion of raw milk.^{[16] [18]} *C. jejuni* has been isolated from surface water and can survive up to 5 weeks in cold water, ensuring its potential for wilderness waterborne spread. Person-to-person spread occurs but is uncommon. The prevalence of *C. jejuni* as a cause of TD varies with time of year. TD is caused by *C. jejuni* in about 3% of cases in rainy summertime and in up to 15% of cases during drier wintertime.^{[16] [133]} Studies in the United States and abroad have demonstrated that *C. jejuni* accounts for up to 25% of patients with infectious diarrhea and is often more common than *Salmonella* or *Shigella* species.^{[16] [19]} *C. jejuni* is now the most common cause of bacterial gastroenteritis in developed countries. Rates are highest among children and young adults.^{[16] [18]}

Pathophysiology.

The complete pathogenic mechanisms are unclear. All segments of the small and large intestine may be affected, accounting for the variety of diarrheal symptoms. Evidence of invasiveness includes recovery of bacteria from blood and presence of colitis, with cellular infiltration on intestinal biopsy. A heat-labile enterotoxin may play a role in disease pathogenesis.

Clinical Syndromes.

The incubation period of *C. jejuni* enteritis is 2 to 7 days. Clinical symptoms are extremely variable and nonspecific. Victims often have a 1-day prodrome of general

malaise and fever, followed by abdominal cramps and pain that herald the onset of diarrhea, with up to eight bowel movements a day. The diarrhea is initially watery, followed by passage of stools that are bile stained or bloody. The frequencies of reported symptoms are diarrhea (75% to 95%), cramps and abdominal pain (80% to 90%), nausea (20% to 50%), headache (50%), fever (50% to 80%), vomiting (20%), and bloody diarrhea (10% to 50%).^[16] Tenesmus is unusual. Physical examination is nonspecific, with variable degrees of fever (averaging 40° C [104° F]), abdominal tenderness, and dehydration. Microscopic evaluation of stool shows blood and PMNs in 60% to 75% of samples. The enteric symptoms subside in 2 to 4 days, and the entire illness resolves spontaneously within 1 week. Organisms are shed in the stool for 3 to 5 weeks after resolution of symptoms, but chronic carrier states have not been described. Up to 20% of victims may show clinical relapse, which is usually less severe than the original symptoms.^[16] Chronic diarrhea caused by *C. jejuni* has been reported in children and adults but is usually associated with significant underlying disease.

Complications.

C. jejuni infection has been associated with Guillain-Barré syndrome.^{[16] [139] [164]} *C. jejuni* infection often precedes development of the syndrome and in more severe cases is associated with axonal degeneration, slow recovery, and severe residual damage.^[164]

Diagnosis.

Definitive diagnosis is made by stool culture on a selective medium (e.g., Skirrow, Butzler, Campy-BAP), with isolation rates directly related to the severity of the disease. Extraintestinal sources account for 0.4% of positive *Campylobacter* cultures in the United States and usually are preceded by GI infection. Blood is the most common site, followed by the gallbladder and cerebrospinal fluid (in children), but since blood

cultures are rarely drawn in the evaluation of gastroenteritis, the real frequency of bacteremia is unknown. The serologic tests available are still not well standardized and need further evaluation.

Treatment.

Treatment is primarily supportive with oral fluids; dehydration is usually mild. Most patients have improved by the time the culture results return and do well without antibiotics. Antibiotic treatment does not conclusively improve *C. jejuni* gastroenteritis, but earlier therapy appears to be effective^[19] and eradicates the organism from the stool within 48 hours. The antimicrobial antibiotic of choice is erythromycin or a fluoroquinolone. Fluoroquinolones are given in the same doses as for shigellosis because they are active against all the major causes of dysentery (*C. jejuni*, *Shigella*, *Salmonella*). In children, because fluoroquinolones are contraindicated, erythromycin (20 to 50 mg/kg every 6 hours for 5 days) is an option. Another alternative, in view of

increased resistance to fluoroquinolones by *Campylobacter* strains,^{[79] [176]} is azithromycin, a newer macrolide that can be used in children and is active against all major bacterial enteric pathogens.^{[84] [118]}

Vibrio

Microbiology.

Cholera is a severe form of watery diarrhea often associated with dehydration. The disease is caused by *Vibrio cholerae* O group 1 (O1), a motile, curved, gram-negative rod. These microorganisms have two major biotypes, classic and El Tor, which produce similar clinical illness, and each one contains two main serotypes, Ogawa and Inaba. Non-O1 *V. cholerae* strains also produce diarrheal illness, but they show less potential for epidemic disease.^[107] Nine other species have been associated with human disease. *V. parahaemolyticus*, *V. fluvialis*, *V. mimicus*, *V. hollisae*, and *V. furnissii* are associated with GI disease. Others, mainly *V. vulnificus*, are associated with wound infections and septicemia. All are halophilic, gram-negative rods that reside in seawater and on marine organisms, and infection is acquired by ingesting infected and undercooked seafood or by contamination of a wound with infected water.^[107]

Epidemiology.

V. cholerae is endemic in areas of Asia, Africa, and the Middle East. It has accounted for seven deadly worldwide pandemics since the early 1800s. The last began in 1961 in Indonesia and spread throughout Southeast Asia, the Middle East, Africa, parts of the Pacific and Europe, and in the 1990s to Latin America. In 1973, cholera resurfaced in the United States after an absence since 1911. Since then, a small number of cases have occurred along the Gulf Coast of Louisiana and Texas. Only 10 cases of cholera were reported in travelers returning from endemic areas between 1961 and 1981. In January 1991 a new outbreak of cholera started in Latin America along the coast of Peru. Since then, this disease has become endemic in most regions of Latin America, moving as close to the United States as northern Mexico.^[107] The infection is associated with consumption of uncooked or poorly handled seafood and spreads rapidly because of a highly susceptible population that has not been exposed to cholera for almost a century and because of inadequate water supply and sewage service. Cholera continues to be a disease of poor and lower socioeconomic groups, and the Indian subcontinent and southwestern Asia are still the areas with the highest prevalence.^[68]^[107] The risk to travelers has been estimated at 1:500,000 during a journey to an endemic area,^{[60] [158]} which should be further reduced with dietary discretion.

Nonhuman reservoirs for *V. cholerae* O1 include marine or brackish waters.^{[68] [107] [158]} As with other strains (*V. parahaemolyticus*, non-O1 *V. cholerae*), shellfish ingest and carry these organisms. Fecal-oral spread is the major mechanism of transmission, and water is the most common vehicle, followed by food.^[68] The organism remains viable for days to weeks in various foods. Because of the large infective dose of 10^6 to 10^{10} organisms,^{[98] [158]} person-to-person spread is uncommon.

Most cases of gastroenteritis caused by noncholera vibrios have been associated with ingestion of raw seafood. Cases have been reported from travelers, particularly after visits to coastal areas of Southeast Asia and Latin America. *V. parahaemolyticus* causes 70% of cases of foodborne gastroenteritis in Japan (where large amounts of raw seafood are eaten), leads to sporadic outbreaks in the United States, and is a common cause of TD in Thailand.^[20]

Pathophysiology.

After passing through the stomach, the organism multiplies and colonizes the small bowel. The local effects of enterotoxin account for the pathophysiology of cholera. No pathologic changes are noted in the bowel wall. The binding subunits of toxin attach to the membrane of the mucosa, after which the adenylate cyclase-activating B subunit enters the cell. The enzyme acts inside the serosal cell, enhancing production of cyclic adenosine monophosphate. This molecule produces a 70% reduction in influx of water, saline, and a wide range of other substances into the gut mucosal cells, resulting in watery diarrhea. Glucose, potassium, bicarbonate, and most significantly, absorption of sodium and water linked to glucose remain intact. Thus, although plain water worsens cholera diarrhea, the addition of glucose renders the water and essential electrolytes absorbable, forming the basis for oral rehydration therapy.^{[107] [137] [159] [170]} *V. cholerae* has the bacteriophage VP1phi, which encodes a receptor used by enterocytes for the phage CTXphi, which encodes the cholera toxin.^[110]

1257

Details of the pathogenesis of infection by the noncholera vibrios remain unclear. Some strains produce an enterotoxin, but generally it is not cholera-like toxin. In the case of *V. parahaemolyticus*, a hemolytic toxin was thought to explain its effects, but the dysenteric illness that typically develops implies invasion. Another enterotoxin has been found in some strains.^[20]

Clinical Syndromes.

Some cholera infections are asymptomatic, and 60% to 80% of clinical cases are presented as mild diarrhea that never raise suspicion for cholera.^{[98] [158]} After an incubation period of 2 days (range 1 to 5 days), fluid accumulates in the gut, causing intestinal distention and diarrhea. Diarrhea may begin as passage of brown stools but soon assumes the translucent gray watery appearance known as "rice water" stools. In serious cases, stool volume may reach 1 L/hr, leading to severe dehydration, acidosis, shock, and death. Vomiting may occur as a result of gut distention or acidosis.^[107]

The clinical syndrome caused by noncholera vibrios is not characteristic. Intestinal illness is associated with diarrhea, abdominal cramps, and fever, with nausea and vomiting in about 20% of cases. Diarrhea may be severe, with up to 20 to 30 watery stools per day. In outbreaks of *V. parahaemolyticus* infection, explosive diarrhea

associated with abdominal cramps and nausea is often described, with vomiting in about 50% and fever in about 30% of cases. In Asia, a dysentery-like syndrome with mucoid bloody diarrhea is often seen.^[20] Infections are usually brief, lasting an average of 3 days, with spontaneous resolution.

Diagnosis.

Diagnosis for any of the vibrio diarrheas can be made by stool culture on suitable media (e.g., thiosulfate-citrate-bile salts-sucrose or TCBS agar). Vibrios can survive for 1 week on a stool-saturated piece of filter paper sealed in a plastic bag, before placing it in the culture media.^[107] In the case of *V. cholerae*, another way to diagnose infection is using a darkfield microscopic examination of fresh stools, which may reveal the characteristic helical vibrio motion.

Treatment.

Aggressive replacement of fluid and electrolytes is the cornerstone of therapy for cholera, especially in severe cases. Severe untreated cholera has a 50% mortality, which may be reduced to 1% with appropriate treatment. Children are at higher risk for complications and death.

With fluid replacement, most cases of cholera last 3 to 5 days, with the peak fluid losses 24 hours after the onset of illness. When hypotension or persistent vomiting is present, IV fluids are necessary, but as soon as initial rehydration is complete, ORS is used for maintenance. Less than 5% of patients require IV maintenance after initial rehydration, and ORS alone is successful in 90% of cholera cases without shock. With voluminous losses, ORS can be given by nasogastric tube to continue fluids during the night. A normal or light diet should be resumed early in the course of treatment, after initial rehydration. Success of fluid replacement therapy was clearly demonstrated by the low mortality rate seen during the cholera outbreak in Peru, where principles of rehydration were applied.^{[68] [107]}

Antibiotics shorten the duration of diarrhea and excretion of organisms in severe cholera and reduce fluid losses but they are not as important as fluid therapy. Oral antibiotics can be started within a few hours of initial rehydration. The drug of choice is doxycycline, 300 mg single dose in adults or 50 mg/kg/day in four divided doses for children. This is perhaps the only indication for the use of tetracycline in children because a short course (2 to 4 days) is unlikely to stain teeth. Furazolidone (100 mg every 6 hours for adults and 5 mg/kg/day in four divided doses for children) for 2 days is an alternative. *Vibrio* strains are also susceptible to fluoroquinolones, but these medications are more expensive.^{[23] [45] [60] [107]}

Treatment of patients infected with noncholera vibrios should also focus on fluid replacement. Little information exists on the benefit of antibiotic therapy for GI disease, but antimicrobials may be reasonable in dysentery-like cases or prolonged illness. The same antimicrobial agents used in cholera could be used against this infection.

Immunoprophylaxis.

Temporary immunity to homologous, but not to heterologous, strains of cholera develop after infection.^[107] The current parenteral vaccine has no antitoxin activity and is only about 50% effective in reducing attack rates over a 3- to 6-month period for those living in endemic areas. It is recommended for persons who live and work under poor sanitary conditions in highly endemic areas and for those with known achlorhydia. It is not recommended for travelers to endemic areas.^[107]

A recent advance was the development of transgenic potatoes that synthesized cholera toxin subunit B without requiring a cold chain. This is a promising option for an inexpensive, effective vaccine for the developing world. New vaccines are in different stages of evaluation. Two studies in adult volunteers, one using a polysaccharide-cholera toxin conjugate and the other using a new El Tor strain that was CTXphi negative and hemagglutinin/protease defective, have shown promising results. A study of CVD103-HgR strain in Austrian travelers confirmed the tolerance of this oral vaccine. Finally, a bivalent (CVD103-HgR plus CVD 111) oral vaccine has been shown to be more effective than the monovalent one.^{[13] [90] [188]}

Yersinia Enterocolitica

Microbiology.

Y. enterocolitica is a facultative anaerobic, gram-negative rod in the Enterobacteriaceae family, with different serogroups found to cause human infection.

1258

Epidemiology.

The major natural reservoir of the organism is wild, farm, and domestic animals. In the United States and Europe the organism resides in surface and unchlorinated well waters. Evidence indicates that persistence in warm water ranges from days to weeks, with longer survival at colder temperatures. Human isolates of *Y. enterocolitica* are found worldwide, but with preference for colder regions such as Canada and Northern European countries, with an incidence equal to or greater than those of *Salmonella* and *Shigella*.^{[130] [158]} Transmission occurs from fecal-oral contamination, through food and water, and probably through person-to-person or animal-to-person contact.^{[130] [158] [192]} Raw milk and oysters have also been implicated as vehicles of transmission. The infectious dose and attack rate are not well studied, but yersiniosis is suspected to be caused by ingestion of a large infectious dose based on a common source of transmission. The incubation period averages from 3 to 7 days. Patients with β -thalassemia show a greater risk for acquisition of yersiniosis.^[4]

Pathophysiology.

Illness caused by *Y. enterocolitica* may involve three pathogenic mechanisms: bowel mucosal invasion, release of a heat-stable enterotoxin similar to that produced by ETEC, and elaboration of a cytotoxin.^{[43] [130]} The organism multiplies in the small bowel and characteristically invades the mucosa in the region of the terminal ileum and colon. The mucosa may be diffusely inflamed with small and shallow ulcerations. Also, some bacteria migrate through lymphatics to mesenteric lymph nodes, producing adenitis with focal areas of necrosis.

Clinical Syndromes.

The most common clinical presentation in yersiniosis is gastroenteritis, characterized by diarrhea, fever, and abdominal pain, with nausea and vomiting in 20% to 40% of cases and dysentery (passage of bloody stools) in 10% to 25%.^{[130] [192]} Fever or abdominal pain without important diarrhea may be the most prominent sign, mimicking appendicitis in 20% of patients with positive stool cultures.^[10] Although acute appendicitis has been associated with serologic evidence of *Y. enterocolitica* infection, the usual surgical findings are mesenteric adenitis or terminal ileitis. Severe colitis rarely results in septicemia, extensive necrosis, or perforation. Numerous extraintestinal manifestations of *Y. enterocolitica* infection include skin rash (erythema nodosum or maculopapular) and arthritis, probably related to an immune reaction. Extraintestinal infection involving lung, joints, lymph nodes, wounds, or septicemia may occur with or without enteritis. In the majority of intestinal infections, illness is mild and self-limited, with duration averaging 1 week, but some patients experience prolonged symptoms.^{[130] [192]} Excretion of the organism in stool continues for a few weeks to months. Complications may be related to particularly severe disease and a misdiagnosis of Crohn's disease or appendicitis and development of Reiter's disease or collagenous colitis.^[128]

Diagnosis.

The diagnosis of yersiniosis is usually made by stool culture, but it can grow also from blood or surgical samples. The organism grows better at lower (22° to 25° C [71.6° to 77° F]) temperatures, which inhibit most other enteric bacteria. Abnormalities related to ileitis or colitis seen on contrast radiography and colonoscopy may be mistaken for other causes of colitis.^{[10] [130]} Serologic tests are also diagnostic and especially helpful to diagnose *Yersinia* arthritis.

Treatment.

Tetracyclines have been suggested as the drug of first choice for chronic or fulminant infections,^{[10] [23]} but *Yersinia* is also susceptible *in vitro* to streptomycin, chloramphenicol, aminoglycosides, fluoroquinolones, and trimethoprim/sulfamethoxazole. Most are resistant to penicillins and cephalosporins and variably resistant to erythromycin and sulfonamides.^{[23] [130]}

Aeromonas Species and Plesiomonas Shigelloides

Aeromonas species and *P. shigelloides* are gram-negative, facultatively anaerobic, nonsporulating rods. Their normal habitats are water and soil, and these bacteria have been implicated in a variety of human illnesses, most often gastroenteritis. [60] [96] [97] [101] [158] [195]

Aeromonas was previously part of the Vibrionaceae family, until the family Aeromonadaceae was established to include the 14 species so far identified. Only five species (*A. hydrophila*, *A. caviae*, *A. veronii*, *A. jandaei*, and *A. schubertti*) have been associated with a variety of human diseases, including gastroenteritis, soft tissue infections, HUS, burn-associated sepsis, and respiratory infections. [101] [195] *A. hydrophila* is the most commonly isolated species, but its real prevalence is still uncertain. *A. hydrophila* has been associated with diarrheal illness in the United States, Australia, India, and southwestern Asia. [96] [101] [195] Association of illness with drinking untreated spring or well water was demonstrated in the United States. Pathogenicity includes production of cytotoxin, enterotoxin, and proteases, as well as the capacity of adhesion and invasion, but the exact mechanisms of disease pathogenicity remain controversial. [101] [174]

Clinical illness associated with enteric infection by *A. hydrophila* varies from acute to chronic diarrhea and from passage of watery stools to dysentery with colitis. [101] [195] Median duration of diarrhea is 2 weeks, with occasional cases that persist a month or longer. Asymptomatic carriers have been identified. Non-GI infections, such as those of soft tissue and septicemia, have been associated with exposure of wounds to water.

1259

Aeromonas strains are susceptible to chloramphenicol, tetracycline, TMP/SMX, fluoroquinolones, and aminoglycosides but are resistant to ampicillin and erythromycin. [101]

P. shigelloides has been isolated from patients with gastroenteritis, both in sporadic cases and outbreaks. [60] [97] [158] Infection has been associated with recent travel and ingestion of raw or inadequately cooked shellfish. *Plesiomonas* may cause dysenteric illness suggestive of an invasive organism, but its pathogenic mechanisms remain poorly defined. [97]

Miscellaneous Bacterial Agents

Klebsiella pneumoniae and *K. oxytoca* have been reported to occasionally cause diarrhea, but they are usually commensals of the GI flora. [88] Another cause of severe diarrhea in hospitalized (usually postoperative) patients receiving antibiotics is *Staphylococcus aureus*. The causative organism may be methicillin-resistant *S. aureus*.

VIRAL ENTERIC PATHOGENS

Recent studies have identified viruses as major causes of acute nonbacterial GI infections.^{[151] [29] [93]} The most important defined agents are Norwalk virus and other caliciviruses, enteric adenoviruses, astrovirus, and rotavirus. Usually they cause vomiting with or without mild and self-limiting watery diarrhea. Transmission occurs through fecal-oral contamination or person-to-person transmission. Respiratory symptoms are common in patients with viral gastroenteritis.

Caliciviruses and astroviruses are similar to Norwalk virus in structure and clinical presentation. They generally infect in early childhood and provide apparently lifetime immunity.^{[151] [152]}

Norwalk and Norwalk-like Viruses

Norwalk virus was the first well-described etiologic agent in nonbacterial gastroenteritis outbreaks; an elementary school outbreak occurred in Norwalk, Ohio.^[108] Soon after, several other small round viruses were identified as causes of nonbacterial gastroenteritis.^{[151] [152]}

Norwalk virus and the related viruses are nonsymmetric, single-stranded ribonucleic acid (RNA) viruses, recently classified within the family Caliciviridae.^{[103] [119]} They are the main cause of outbreaks of epidemic nonbacterial GI illness worldwide. They also cause "winter vomiting disease" because of their wintertime predisposition and common association with vomiting.

These viruses are highly infective (10 to 100 organisms per inoculum), and the infection is spread by common-source vehicles with a propensity for secondary person-to-person spread (high secondary attack rate).^{[93] [119]} Humans are the only known carriers of these viruses. Outbreaks have been recognized in family settings, health care facilities, nursing homes, schools, and travel settings, characteristically affecting both children and adults in the United States. They are found less often in neonates and toddlers. Contaminated water supplies, drinking water in cruise ships, recreational swimming pools, and commercial ice cubes have been implicated in outbreaks.^{[93] [119]} Also, vehicles identified for food-borne outbreaks may be contaminated shellfish, salads, bakery products, cold foods, cooked meat, and fresh fruits.^[152] Between 20% to 67% of outbreaks of Norwalk virus have been associated with food.^{[26] [147]}

After invasion of the enterocytes, the viral particles replicate inside, resulting in damage of the villi and crypt cell hyperplasia.^[151] Malabsorption of fat, lactose, and xylose occurs with these histologic changes. The exact mechanisms of diarrhea production in viral

gastroenteritis are not completely understood. Small numbers of viral particles are shed in stool during the acute illness, but prolonged carrier states are not seen.

In the United States, antibodies in stools typically appear during late adolescence, but in tropical, developing countries, children acquire antibodies at a young age. Although antibodies persist in most people, they do not provide protection from clinical illness.^[151]

Transmission is followed by an incubation period of 24 to 48 hours, and illness begins abruptly with vomiting, abdominal cramps, and diarrhea. Stools are watery and usually do not contain blood or leukocytes. Other common symptoms include low-grade fever, malaise, myalgias, respiratory symptoms, and headache. Illness is almost always mild and self-limited, lasting 1 to 2 days. Complications and mortality are extremely rare and usually involve elderly and debilitated patients. Some malabsorption of fats and disaccharides persists after the acute illness. Supportive treatment with oral fluids and electrolytes is sufficient in the vast majority of cases.^[151]

Historically, and because of the difficulty or impossibility of growing these viruses in cell culture, electron microscopy was the initial means of detecting these viruses. Currently, there are immunoassays and molecular techniques (reverse-transcription PCR) available for detection of these small round RNA viruses in stool.^{[85] [102] [140] [151]}

Vaccine development is not currently feasible because of difficulties culturing the virus and lack of animal models.

Rotavirus

Rotaviruses are 70-nm double-stranded RNA viruses that are classified by the capsid antigens, with group A and serotype G1 being the most common in human infections worldwide. Most severe infections in children are caused by serotypes G1 to G4.^{[14] [153]} Rotavirus is the most common enteric pathogen in children causing diarrhea worldwide, resulting in up to 800,000 deaths per

year.^{[29] [93] [153]} Infection tends to be endemic, with peak incidence during winter months in temperate climates. Transmission is by person-to-person contact or as a result of common-source outbreaks. Viral shedding occurs in stools, and particles can retain infectivity for months. Rotaviruses have been found in almost every animal species, and in general, animal strains have reduced virulence for humans.^{[14] [29]}

Rotavirus infects humans repeatedly, at any age. It is the most frequently isolated pathogen in infantile diarrhea and is responsible for a disproportionate amount of hospitalization for dehydration.^{[14] [153]} The majority of symptomatic infections occurs in children under 3 years old, with peak incidence in children 6 months to 2 years of age. Rotavirus can also cause illness in adults, usually associated with secondary spread

within a family.^[14]

Nonspecific pathologic changes are seen in small bowel epithelial cells, with particles identified intracellularly. The exact mechanism of diarrhea is unknown, but a net secretion of water, sodium, and chloride occurs during the illness. Diarrheal losses contain 30 to 40 mEq/L each of sodium and potassium. Lactose malabsorption may persist for 1 to 2 weeks, associated with continued viral excretion in stool. Large numbers of viral particles are shed in the stool of ill patients, but prolonged excretion is unusual.^[153]

After an incubation period of 24 to 72 hours, illness begins with vomiting, followed by diarrhea associated with abdominal cramps, low-grade fever, and malaise. Vomiting usually resolves within 2 days (range 1 to 5), but the diarrhea may last 3 to 8 days or longer. Natural infection reduces the incidence and severity of subsequent episodes. Serum antibody levels are demonstrated within the first few years of life and in almost all adults but appear to be nonprotective. Severity of illness usually decreases with age. Adults are more likely to have asymptomatic or mild illness with less vomiting. Dehydration frequently occurs in children, accounting for appreciable mortality in developing countries. Fortunately, oral fluid and electrolytes can be successfully used in most cases.^[153]

The first rotavirus vaccine approved by the U.S. Food and Drug Administration (FDA) in 1998 is a tetravalent rhesus-human strain that provides coverage against the four common G serotypes of human rotavirus.^[146] ^[153] ^[193] In clinical trials in industrialized countries, this vaccine provided 50% to 70% protection (up to 60% to 100% in severe cases). The recommendation was to give this vaccine to all children by mouth at 2, 4, and 6 months of age,^[146] but concerns of vaccine-associated intussusception will delay routine use. The vaccine's efficacy and cost-effectiveness in developing countries and travelers should be further evaluated.

INTESTINAL PROTOZOA

Protozoal infections may be pathogenic or commensal (little or no effect) to the human host. Most protozoal infections are suspected on the basis of subacute or chronic GI symptoms, which may fluctuate over time. Although acute self-limited diarrheal illness may occur, the symptoms are nonspecific, and the diagnosis is often made on stool examination.

Several factors have increased the prevalence of intestinal parasites in the United States and worldwide: increase in immunocompetent persons who frequently become infected by these organisms, improvement in diagnostic techniques, changes in social behaviors (increased use of day care and nursing homes, more frequent international travel), and in the United States, increased immigration of people from Asia, Africa, and Latin America. [\[60\]](#) [\[89\]](#) [\[109\]](#) [\[158\]](#)

As with enteric bacteria, symptoms from infection by intestinal protozoa depend on the level of bowel colonized. Those colonizing the small intestine, such as *Giardia* and coccidia, cause a wide spectrum of GI complaints, including malabsorption (foul stools and flatulence) and weight loss in persistent infections. Although many protozoa are capable of superficial mucosal invasion, only *Entamoeba histolytica* and *Balantidium coli*, which colonize the colon, can ulcerate the bowel wall, cause dysentery, and spread to other tissues. [\[89\]](#)

All intestinal protozoa are transmitted by the fecal-oral route, so infection rates are highest in areas and groups with poor sanitation, close contact, or particular customs favoring transmission. These reemerging infections have been related to large outbreaks of communicable diseases in the United States, often secondary to water contamination. Protozoal parasites were the most frequent etiologic agent detected in waterborne outbreaks from 1991 to 1994. [\[116\]](#) [\[131\]](#) [\[138\]](#) In addition to spread by food, water, and person-to-person contact, mechanical vectors such as flies may spread these organisms. Transmission of intestinal protozoa is favored by a hardy cyst, which is passed in the feces of an infected host. In addition to an infective cyst, the life cycle for most intestinal protozoa includes a trophozoite, which is responsible for reproduction and pathogenicity. Only a single host is required, except for *Sarcocystis*, which requires ingestion of raw meat from an intermediate host. Zoonotic spread to humans has been documented for *Giardia*, *Cryptosporidium*, *Entamoeba polecki*, and *B. coli*. Treatment of intestinal protozoan infections is summarized in [Table 52-11](#) .

Giardia Lamblia

G. lamblia is a flagellate protozoan that was first observed in 1681 by Leeuwenhoek. In

the last 30 years it

TABLE 52-11 -- Antiparasitic Therapy for Infectious Diarrhea in Adults

DIAGNOSIS	RECOMMENDATION
Giardiasis	Metronidazole 250 mg tid (15 mg/kg/day for children), Albendazole 400 mg qd, or quinacrine* 100 mg tid for 7 days, or tinidazole* 2000 mg single dose
<i>Entamoeba histolytica</i> excretion (asymptomatic)	Iodoquinol 650 mg tid for 20 days or paromomycin 500 mg tid for 7 days
<i>E. histolytica</i> diarrhea	Metronidazole 750 mg tid for 5 to 10 days or tinidazole* 1000 mg bid for 3 days, followed by iodoquinol 650 mg tid for 20 days or paromomycin 500 mg tid for 7 days
Cryptosporidiosis	None; in severe cases or AIDS patients, consider paromomycin 500–750 mg tid or qid for about 2 weeks or azithromycin 1200 mg qd for 4 weeks
Cyclosporidiosis	TMP/SMX 160 mg/800 mg bid for 7 days, followed by 160 mg/800 mg 3 times/week in AIDS patients
Isosporiasis	TMP/SMX 160 mg/800 mg qid for 10 days, followed by 160 mg/800 mg bid for 3 weeks, or pyrimethamine 75 mg qd with folinic acid 10 mg qd for 2 weeks
Microsporidiosis	Albendazole 400 mg bid for 2 to 4 weeks, followed by chronic suppression for AIDS patients

TMP/SMX, Trimethoprim and sulfamethoxazole; *tid*, 3 times a day; *qd*, daily; *qid*, 4 times a day; *bid*, twice daily.

*Not available in the United States.

has gained recognition as an important human pathogen.^{[67] [123]} The classification of *Giardia* species remains controversial.

The life cycle of *Giardia* involves two stages. Active trophozoites are responsible for symptomatic illness. The organisms attach to the mucosa of the duodenum and proximal jejunum, where they multiply rapidly through binary division. Trophozoites are rarely infective because they rapidly die outside the body and are less resistant to gastric acidity. Responding to unknown stimuli, some trophozoites encyst during passage through the colon and are eliminated in the stools of infected hosts. Cysts are infectious as passed in the host stool; no period of maturation or intermediate development stage is required. Furthermore, they are very hardy in the external

environment. When ingested by a potential host, excystation is stimulated by passage through the stomach, and the motile trophozoite migrates to the small bowel to complete the cycle.^{[67] [123] [148]}

Giardia is the most common protozoal intestinal parasite isolated worldwide. All age groups are affected.^{[67] [109] [148]} Giardiasis usually represents a zoonosis, with cross-infectivity from animals to humans, and vice versa. *Giardia* has been found in stools of beavers, cattle, dogs, cats, rodents, and sheep.^[148]

The infective dose of *Giardia* for humans is low: 10 to 25 cysts caused infection in eight of 25 subjects; more than 25 cysts caused infection in 100%.^[148] Person-to-person spread may be the most common means of transmission for humans. Twenty-five percent of family members with infected children become infected.^[67] Areas and populations with poor hygiene and close physical contact have higher rates of infection. Venereal transmission occurs among homosexuals through direct fecal-oral contamination.^[67] Epidemics and carrier rates of 30% to 60% have been found among children in day-care centers and in Native American reservations. Water is a major vehicle of infection in community outbreaks.^[131] Cysts retain viability in cold water for as long as 2 to 3 months. In the United States from 1964 to 1984, 90 outbreaks (24,000 cases) of giardiasis were linked epidemiologically to water, and it is still the most frequently identified cause of waterborne diarrhea outbreaks. Most of these occurred in small water systems that used untreated or inadequately treated surface water.^{[121] [122] [131]} Clear and cool mountain water has been so often associated with giardiasis that the illness has been called "backpacker's diarrhea" or "beaver fever" (although fever is not usually seen). An outbreak in Aspen, Colorado, in 1964 was the first well-documented waterborne outbreak in the United States, and recent outbreaks around the same area indicate that this area remains endemically infected with *Giardia*. In the northeastern states, large outbreaks have occurred in the mountain communities of Rome, New York, and Berlin, New Hampshire. Every U.S. region has experienced waterborne outbreaks, but the western mountain regions (Rocky Mountains, Cascades, Sierra Nevada) have reported the majority, where giardiasis must be considered endemic.^{[67] [131] [148]}

Giardia accounts for a small percentage of TD.^{[60] [158]} It has been identified in a large percentage of cases among travelers to St. Petersburg, Russia, where tap water is the usual source. Because of the relatively long incubation period and persistent symptoms, *Giardia* is more likely to be found as the cause of diarrhea that occurs or persists after returning home from travels to any developing region.^{[42] [60] [158]}

The pathophysiologic mechanisms of diarrhea and malabsorption in giardiasis are poorly understood.^[148] Reversible malabsorption of fats, vitamins A and B, folate, and disaccharides has been demonstrated in some patients with diarrhea. Malabsorption may result from (1) physical blockade by large numbers of trophozoites blanketing the intestinal mucosa; (2) deconjugation of bile acids; (3) bacterial or fungal overgrowth in the small intestine; (4) increased turnover of cells on the mucosa of the villi, which do not absorb normally; and (5) epithelial damage. Altered gut motility and hypersecretion

of fluids, perhaps through increased adenylate cyclase activity, may play a role. Histologic changes of villous atrophy and inflammatory infiltrates with epithelial cell destruction have been observed. In some series, these changes correlated with degree of malabsorption and reverted to normal after treatment. However, most small bowel biopsies in human patients demonstrate minimal or no changes, with only occasional mucosal invasion (with trophozoites found intracellularly and extracellularly) and no local inflammatory response.^[67] Enterotoxins have not been found. More than one mechanism is probably involved. Infectivity apparently depends on both host and parasite factors.^[148]

Most infections are asymptomatic, and in endemic areas, *Giardia* is found in healthy people. The attack rate for symptomatic infection in the natural setting varies from 5% to 70%.^[148] Asymptomatic carrier states with high numbers of cysts excreted in stools are common. Correlation between inoculum size and infection rates has been noted, but not with numbers of cysts passed or severity of symptoms. Hypochlorhydria, certain immunodeficiencies, blood group A, and malnutrition apparently predispose to symptomatic infection.^[67] ^[148]

The incubation period averages 1 to 2 weeks, with a mean of 9 days and a wide clinical presentation. A few people experience abrupt onset of explosive watery diarrhea accompanied by abdominal cramps, foul flatus, vomiting, low-grade fever, and malaise. This typically lasts 3 to 4 days before transition into the more common subacute syndrome. In most patients the onset is more insidious and symptoms are persistent or recurrent. Stools become mushy, greasy, and malodorous. Watery diarrhea may alternate with soft stools and even constipation. Upper GI symptoms, typically exacerbated postprandially, accompany stool changes but may be present in the absence of soft stool. These include mid-abdominal and upper abdominal cramping, substernal burning, acid indigestion, sulfurous belching, nausea, distention, early satiety, and foul flatus. Constitutional symptoms of anorexia, fatigue, and weight loss are common.^[67] ^[148] Unusual presentations include allergic manifestations, such as urticaria, erythema multiforme, and bronchospasm. Some *Giardia* infections are associated with a chronic illness. Adults may have a longstanding malabsorption syndrome and marked weight loss, and children may have a failure-to-thrive syndrome.^[44] ^[148]

Laboratory confirmation of giardiasis can be difficult. Stool examination remains the primary means of diagnosis ([Figure 52-2](#)) but is being replaced by newer immunodiagnostic tests. Trophozoites may be found in fresh, watery stools but disintegrate rapidly. Although trophozoites remain in fresh stools for at least 24 hours, stools should be preserved in a fixative such as polyvinyl alcohol or a formalin preparation if not immediately examined. Cyst passage is extremely variable and not related to clinical symptoms.^[148] In the office, fresh stool can be mixed with an iodine solution (e.g., Gram's iodine) or methylene blue and examined for cysts on a wet mount. Many antibiotics, enemas, laxatives, and barium studies mask or eliminate parasites from the stools, so examinations should be delayed for 5 to 10 days after these interventions. Trichrome stain is better than the formalin-ether concentration technique for identification of protozoal cysts and trophozoites.^[75] The current recommendation is to examine three samples taken at intervals of 2 days. Another noninvasive office test is duodenal mucus sampling, using a string test (Enterotest), which has a reported

sensitivity of 10% to 80%.^[75]^[148] Duodenal biopsy is rarely necessary but may be the most sensitive test.^[75]

A commercial enzyme immunoassay (EIA) has shown the same sensitivity as microscopic examination, but has 100% specificity, making it a convenient screening method. EIA is much easier and requires less experience than microscopy, but can not differentiate between cysts and trophozoites.^[5] Immunofluorescent techniques using monoclonal antibodies can detect low numbers of organisms in short time but require centrifugation of the sample.^[74] Molecular techniques need further development.^[148]^[199]

Figure 52-2 *Giardia lamblia* trophozoite seen by methylene blue wet mount staining under oil (1000×). The finding of cysts or trophozoites in a patient with diarrhea is sufficient to make a tentative diagnosis of giardiasis.

1263

Immunologic responses to *Giardia* infection are complex. Epidemiologic studies show acquired resistance, with lower rates of infection and illness (1) among residents of endemically infected areas compared with visitors and (2) among adults compared with children. However, reinfection does occur. Levels of IgG antitrophozoite antibodies rise with both symptomatic and asymptomatic infections, helping to clear the infection. Hypogammaglobulinemic patients have a higher incidence of symptomatic giardiasis, implying an important protective function of immunoglobulins.^[67]^[148] Effects of mucosal secretory antibodies in humans have not been clearly demonstrated, although mouse studies show a protective effect of IgA secretory antibodies. Both cellular and humoral responses to *Giardia* have been demonstrated. Immunologic responses are effective in the majority of infections because spontaneous clinical recovery is common with or without the disappearance of organisms. Average duration of symptoms in all ages ranges from 3 to 10 weeks.^[44]^[148]

Given the difficulty and expense of confirming the diagnosis in some patients, a therapeutic trial of drugs may be attempted when suspicion is high. Imidazole derivatives, (e.g., metronidazole) affect bacterial flora as well, so they are less specific but still better for empiric (unproven diagnosis) therapy because of their wide activity.

Symptomatic patients should be treated for comfort and to prevent the development of chronic illness. Asymptomatic carriers in nonendemic areas should be treated when identified because they may transmit the infection or develop symptomatic illness. No drug is effective in all cases. In resistant cases, longer courses of two drugs taken concurrently have been suggested. Relapses occur up to several weeks after treatment, necessitating a second course of the same medication or an alternative drug. Malabsorption usually resolves with treatment, but persistent diarrhea may result from

lactose intolerance or a syndrome resembling celiac disease rather than treatment failure.^[148]

Three groups of drugs are currently being used: nitroimidazoles (metronidazole, tinidazole, albendazole, ornidazole, nimorazole), nitrofurans (furazolidone), and acridine compounds (mepacrine, quinacrine). Metronidazole (Flagyl, 250 mg three times a day for 5 days for adults) is often used in the United States. Cure rates of 85% to 90% are comparable to those with quinacrine, but with better tolerance. Tinidazole (Fasigyn, 2000 mg single dose) has the same success rate with better compliance but is not available in the United States. Quinacrine (Atabrine, 100 mg three times a day for 5 days for adults and 7 mg/kg/day in three divided doses for children for 5 days), with cure rates of about 95%, has been considered the drug of choice in adults. Unfortunately, quinacrine is no longer available in the United States because it produces more frequent side effects, especially in children. No pediatric liquid form is always available. In severely symptomatic individuals, paromomycin (Humatin, 25 to 30 mg/kg in three divided doses for 5 to 10 days) has been effective.^{[67] [123] [148]}

Entamoeba

Lösch described the trophozoite form of *Entamoeba* in 1875 and Quincke and Ross the cyst form in 1893. Recently molecular biologic studies confirmed the existence of an invasive parasite (*Entamoeba histolytica*) and a noninvasive, commensal organism (*E. dispar*).^{[100] [124]} Isoenzyme analysis has recognized 22 different zymodemes of *E. histolytica*, which may explain the pathogenic and commensal strains and the geographic differences in rates of invasive disease.^{[22] [124] [163]}

The life cycle of *E. histolytica* involves two forms and one host. The reproductive form is the trophozoite, which resides in the large intestine of the host and can cause illness. Encystment occurs in the gut, and cysts pass in the stool. The early cyst matures within the host or externally by undergoing two nuclear divisions. Usually the cysts are infectious when passed. Although sensitive to boiling, adequate chlorination, and complete desiccation, cysts may survive drying or freezing and persist for months in a moist environment. After cysts are ingested, they undergo nuclear division in the small intestine, resulting in eight trophozoites per cyst.^{[22] [124]} Humans are the primary reservoir of *E. histolytica*. Infected individuals may pass up to 45 million cysts per day.

E. histolytica is found worldwide. Approximately 12% of the world's population is infected.^[163] The higher prevalence in tropical countries (30% to 50%) is related to increased risk of fecal-oral contamination, which depends on sanitation, cultural habits, crowding, and socioeconomic status.^{[22] [124]} It is the third most important cause of death by parasitic infection worldwide. Similar conditions create pockets of endemic infection in the United States among institutional inmates, Native Americans on reservations, and homosexuals. Importation of infections by travelers and immigrants accounts for most cases in the United States and other temperate countries.^[117] Attack rate and prevalence are difficult to determine because the majority of infections are asymptomatic, and screening with single stool samples is likely to identify only 20% to 50%.^{[22] [124]} The 10% to 15% of the U.S. population once infected with *E. histolytica* has decreased to 1% to 5% overall, primarily because of adequate water and sewage

treatment.^[109] ^[117] Between 1946 and 1980, six waterborne outbreaks of amebiasis were reported in the United States.^[131] ^[125] Amebiasis accounts for less than 1% of TD.^[60] ^[124]
^[158]

Pathogenicity of *E. histolytica* is not well understood.^[124] Invasion may be a function of motility or lytic

1264

enzymes. The cecum and ascending colon are most frequently involved, followed by the rectum and sigmoid colon. Five different lesions of increasing severity can be distinguished in the colon: (1) diffuse inflammation with cellular infiltrate and an intact epithelium, (2) superficial erosions, (3) early invasion followed by shallow ulceration, (4) late invasive lesions forming the classic flask ulcers with skip lesions, and (5) loss of mucosa and muscularis, resulting in exposure of underlying granulation tissue. Extraintestinal spread is hematogenous. Abscesses containing acellular debris develop primarily in the liver but may involve the brain and lung.^[124]

Although 80% to 99% of infections result in asymptomatic carriers, a spectrum of GI diseases may result. The incubation period ranges from 1 to 4 months, depending on the area of endemicity. Most often, colonic inflammation without dysentery causes lower abdominal cramping and altered stools, sometimes containing mucus and blood.^[124] ^[163] Weight loss, anorexia, and nausea may be present. Symptoms commonly fluctuate and continue for months. The subacute infection may evolve into a chronic, nondysenteric bowel syndrome, with intermittent diarrhea, abdominal pain, weight loss, and flatulence. Dysentery may develop suddenly after an incubation period of 8 to 10 days or a period of mild symptoms. Affected persons may have frequent passage of bloody stools, tenesmus, moderate to severe abdominal pain and tenderness, and fever. There is considerable variation in severity.^[124]

Humoral antibodies increase with invasive disease and persist for long periods. Although they do not protect against reinfection or bowel invasion, they show antiamebic action in vitro and may prevent recurrent liver infection, which is uncommon. Once the infection is cleared, recurrence is unusual, but asymptomatic cyst shedding and active GI illness may persist for years, indicating lack of consistent immune response in the intestinal lumen.^[124] ^[163]

The fatality rate for amebic dysentery and its complications is about 2%. Complications of intestinal involvement develop in 2% to 20% of cases and include perforation, toxic megacolon, and ameboma. An ameboma is an annular inflammatory lesion of the ascending colon containing live trophozoites. It may be improperly diagnosed as a pyogenic abscess or a carcinoma. A postdysenteric syndrome can occur in patients with acute amebic dysentery and can be confused with ulcerative colitis.

The diagnosis of intestinal amebiasis is made by identification of cysts or trophozoites in stool. Mucus from fresh stools or sigmoidoscopic scrapings and aspirates mixed with a

drop of saline may show trophozoites if examined within an hour. For delayed examination, stool must be preserved in polyvinyl alcohol or other fixative and may later be examined with trichrome stain.^{[75] [124]} The same limitations and problems discussed with *Giardia* apply to *E. histolytica*. Fecal shedding of cysts is irregular. Three stools on alternate days identify most infections. Overdiagnosis may result from misidentification of leukocytes. Sigmoidoscopy or colonoscopy is useful for viewing the pathologic lesions and obtaining selective samples of mucus and biopsies of mucosal ulcers, which usually contain organisms.^[75] Finding cysts does not confirm the diagnosis of symptomatic intestinal amebiasis. The key to establish the diagnosis is finding motile trophozoites with ingested red blood cells. Culture techniques have been developed that identify infection in some cases when small numbers of cysts are missed in stool examinations, but culture techniques are expensive and time-consuming.^[75] Serologic tests are not useful for identifying asymptomatic carriers but are positive in 85% to 95% of patients with dysentery and 90% to 100% of patients with liver abscess.^{[75] [91] [157]} Also, new antigen detection techniques can differentiate between *E. histolytica* and *E. dispar*.^{[100] [111]} Recently, PCR techniques have been developed, showing greater than 95% sensitivity and specificity.^{[2] [199]}

Treatment of amebiasis is based on the location of infection and degree of symptoms. Medications are divided into tissue amebicides, which are well-absorbed drugs that combat invasive amebiasis in the bowel and liver (e.g., metronidazole, tinidazole, emetine, dehydroemetine, chloroquine), and poorly absorbed drugs for luminal infections (e.g., iodoquinol, paromomycin, diloxanide furoate). In general, treatment is effective for invasive infections but disappointing for intestinal colonization. U.S. guidelines suggest that asymptomatic carriers should be treated, since a cyst passer represents a potential health hazard to others and reinfection in the United States is uncommon. Routine screening of asymptomatic persons of high-risk groups is not cost-effective, except perhaps for food handlers.^[124]

The current drug of choice for asymptomatic carriers is iodoquinol (650 mg 3 times a day for adults and 40 mg/kg/day in three divided doses for children for 20 days). Side effects are mild and consist of abdominal pain, diarrhea, and rash. Diloxanide furoate (Furamide) is another drug of choice (500 mg 3 times a day for adults and 20 mg/kg/day in three divided doses for children for 10 days), but in the United States it is classified as an investigational drug, available only through the CDC. Side effects are limited to flatulence and other mild GI symptoms.^[124] Paromomycin is also effective (500 mg 3 times a day for adults and 30 mg/kg/day in three divided doses for children for 7 days). Although metronidazole has been used in asymptomatic carriers with 90% success, most reserve this drug for invasive and symptomatic infections.

Invasive disease is treated with a tissue-active drug, followed by a luminal agent (in the same doses as just

listed). For oral therapy, metronidazole is the drug of choice (750 mg 3 times a day for adults and 50 mg/kg/day in three divided doses for children for 5 to 10 days), followed

by iodoquinol. Tinidazole (1000 mg twice daily for 3 days), is not available in the United States but appears to be effective and is well tolerated for intestinal and hepatic amebiasis. Emetine and dehydroemetine (1 mg/kg/day, maximum 90 mg/day) are used parenterally in severe cases of amebiasis, primarily extraintestinal, followed by iodoquinol for 20 days. These two drugs have frequent systemic side effects, including the development of cardiac arrhythmias requiring hospitalization for cardiac monitoring. Since this class of drugs is related to ipecac, they also cause vomiting. [\[23\]](#) [\[124\]](#)

Another species, *Entamoeba polecki*, although usually nonpathogenic, has been suspected of causing lower intestinal symptoms in sporadic cases involving heavy infection. [\[167\]](#) Cysts are passed in stool and may be confused with *E. histolytica*, which they closely resemble. Successful resolution of symptoms has been reported with metronidazole followed by diloxanide furoate in the same doses as for amebiasis and balantidiasis.

Cryptosporidium

Cryptosporidium is a coccidian parasite that belongs to the phyla Sporozoa. It is a reemergent enteric pathogen in humans. *Cryptosporidium parvum*, the only human pathogen of this genus, was originally described in 1912 but first identified in humans in 1976. [\[34\]](#) [\[35\]](#) [\[86\]](#)

Ingested thick-walled oocysts release sporozoites, which invade small bowel enterocytes, then develop into trophozoites that reside intracellularly but are extracytoplasmic (beneath the host cell membrane, similar to a vacuole). Trophozoites divide by asexual multiplication into merozoites (type I meront), with each one containing six to eight nuclei. From this stage they continue with asexual multiplication as type I meronts, which can infect other enterocytes (merogonic or schizogonic stage), or they develop into a type II meront and initiate sexual multiplication and oocyst development (sporogonic or gametogonic stage). About 80% of zygotes develop into thick-walled oocysts (each with four sporozoites) that are released in the stool, while the rest develop into thin-walled oocysts that participate in autoinfection of the host. [\[82\]](#)

C. parvum is a ubiquitous zoonosis with a worldwide distribution. *Cryptosporidium* infects a wide variety of young animals, including domestic calves, birds, piglets, horses, pigs, kittens, puppies, and wild mammals, such as raccoons, beavers, squirrels, and coyotes. [\[86\]](#) Prevalence of infection in human populations varies from 0.1% to 3% in cooler, developed countries (Europe, North America) to 0.5% to 10% in warmer areas (Africa, Asia). The infection has been described in those who have contact with animals, such as veterinarians and farmers; infants in day-care centers; travelers to endemic areas; and AIDS or other immunocompromised patients. It may infect large numbers of individuals in community-wide waterborne outbreaks. [\[35\]](#) [\[86\]](#) [\[131\]](#) The infective dose of *Cryptosporidium* for humans is low, similar to *Giardia* species. Sporulated oocysts are infective as passed in the stool, so fecal-oral contamination is the mode of transmission. [\[86\]](#) The different routes of transmission are waterborne, especially in large community outbreaks; person to person, especially in day-care centers, custodial institutions, and hospitals; food-borne disease, through apple cider, uncooked sausage, and raw milk; sexual, with no association with specific behavior; and zoonotic. [\[73\]](#) [\[86\]](#) [\[121\]](#)

[122] In 1993 in Milwaukee, *Cryptosporidium* caused the largest waterborne outbreak of protozoal parasites in the United States. [127] The pathophysiologic mechanisms of diarrhea and malabsorption are not completely understood. The initial invasion of parasites may activate cellular and humoral immune and inflammatory responses, leading to cell damage with villi atrophy and crypt hyperplasia, ultimately producing malabsorption and osmotic diarrhea. [82] [86]

The clinical manifestations depend on immune status, but asymptomatic infection occurs in both normal and immunocompromised hosts. [86] In immunocompetent persons the usual incubation period of *Cryptosporidium* is from 5 to 28 days. Symptoms consist of watery diarrhea associated with cramps, nausea, flatulence, and at times, vomiting and low-grade fever. The syndrome is generally mild and self-limited, with a duration of 5 to 6 days in some groups (range 2 to 26 days). In contrast, immunocompromised hosts experience more frequent and prolonged infections, with profuse chronic watery diarrhea, malabsorption, and weight loss lasting months to years. Fluid losses can be overwhelming in a fulminant cholera-like illness, with high mortality. Cyst passage in stool usually ends within 1 week of symptom resolution but may persist for up to 2 months after recovery. Reinfection of an immunocompetent person has been documented.

Rarely, *Cryptosporidium* can infect the respiratory system, which may be fatal in the immunocompromised host. The other extraintestinal manifestations relate to involvement of the liver and biliary system, particularly in immunocompromised persons. Cholangitis may not respond to common luminal agents used to treat intestinal cryptosporidiasis, requiring sphincterotomy for therapy. [86]

Diagnosis in initial case descriptions was made by small bowel biopsy, but oocysts can be found in the stools routinely in intestinal infections, even though shedding may be intermittent. Concentration techniques, such as formalin-ether or sucrose flotation, and subsequent staining with modified acid-fast, Giemsa, or Ziehl-Neelsen techniques facilitate identification of

Cryptosporidium oocysts. The Enterotest is also useful in the diagnosis of cryptosporidiosis. Newer immunologic techniques are faster and have adequate sensitivity and excellent specificity. Several other methods (flow cytometry using monoclonal antibodies, PCR, RFLP analysis) have been developed, but their efficacy in the clinical setting is not yet known. [25] [74] [86] [114]

No clearly effective treatment has been found for cryptosporidiosis. Because this disease is usually mild and self-limited in immunocompetent hosts, only supportive care is needed. Anticryptosporidial agents, such as paromomycin (500 to 750 mg 3 or 4 times a day for 2 weeks) and azithromycin (1200 mg daily for 4 weeks) may be used in immunocompetent persons with persistent infection and in immunocompromised patients. Paromomycin, azithromycin, roxithromycin, ionophores, sulfonamides,

mefloquine, and nitazoxanide have been tested against cryptosporidiosis, especially in AIDS patients with chronic diarrheal disease, with variable but generally positive effects.^{[86] [180] [201]} Further studies with these and other new agents, including clinical trials using immunotherapy options, are in progress.^{[33] [86]}

Isospora belli

I. belli is also a coccidian protozoal parasite. The first description of *Isospora* was in 1915. More recently, *I. belli* was identified as the pathogenic species for humans. It is an uncommon cause of diarrhea in humans, but as with *Cryptosporidium*, its prevalence has been increasing in immunocompromised patients.^{[33] [82] [129] [131] [200]}

Humans are the only host, and infections are transmitted by fecal-oral contamination through direct contact of food and water. *I. belli* is endemic in areas of South America, Africa, and Asia. The prevalence is not precisely known but it ranges from 0.2% to 3% in United States AIDS patients and 8% to 20% in Haitian and African AIDS patients. This parasite has also been associated with outbreaks in custodial institutions, in day-care centers, and among immigrants. Infection rates in otherwise healthy persons with diarrhea are usually low. Most cases have been identified in tropical regions among natives, travelers, and the military.^{[82] [131]}

Life cycle and pathogenesis of *I. belli* are similar to *Cryptosporidium*. The organism invades mucosal cells of the small intestine, causing an inflammatory response in the submucosa and variable destruction of the brush border.^[82]

In immunocompetent persons, the *I. belli* infection may be asymptomatic or cause mild transient diarrhea and abdominal cramps. Other symptoms include profuse watery diarrhea, flatulence, anorexia, weight loss, low-grade fever, and malabsorption.^[82] Generally infection is self-limited, ending in 2 to 3 weeks, but some persons have symptoms lasting months to years, clinically similar to giardiasis. Recurrences are common. Infections in immunocompromised patients tend to be more severe and follow a more protracted course.^[129] Rarely, acalculous cholecystitis or reactive arthritis has been reported in isosporiasis.^[12]

Diagnosis can be made by identification of immature oocysts in fresh stool. However, excretion may occur sporadically and in small numbers, so concentration techniques are usually required. Staining with modified Ziehl-Neelsen and auramine-rhodamine are also useful. When stools are negative, the organism can be recovered from the jejunum through a biopsy or string test. Unlike the other intestinal protozoa, *I. belli* may cause eosinophilia.^[75]

Successful treatment has been reported with TMP/SMX (160/800 mg 4 times a day for 10 days, then 2 times a day for 3 weeks in normal hosts). Other options are pyrimethamine (75 mg daily for 14 days) with folinic acid, and metronidazole (for patients allergic to sulfonamides). In HIV patients, chronic lifetime suppression therapy is indicated with either TMP/SMX (160/800 mg 3 times a week) or pyrimethamine (25

mg) plus folinic acid (5 mg) daily.^{[82] [129]}

Cyclospora Cayetanensis

Cyclospora species were first discovered in moles in 1870 and were identified as human pathogens in 1979. They were initially thought to be blue-green algae (cyanobacteria-like organism).^{[149] [182] [202]} The life cycle and pathogenesis of *C. cayetanensis* are not completely understood.

The organism has shown to be an important cause of acute and protracted diarrhea. *C. cayetanensis* is endemic in many developing countries in all continents, with the highest rates occurring in Nepal, Haiti, and Peru. In the United States, most of the native outbreaks have been from areas east of Rocky Mountains, usually associated with ingestion of contaminated imported raspberries.^{[27] [82]} Fecal-oral transmission also occurs through water and soil.^[182] *Cyclospora* infection is closely associated with diarrhea in travelers to endemic areas.^{[82] [95] [131] [202]}

The onset of diarrhea is usually abrupt with symptoms lasting up to 7 weeks or even longer.^[82] In AIDS patients the duration may be longer and the severity greater.^[129] Small spherical organisms can be detected in fresh or concentrated stool, and they show variable staining with acid-fast methods. *C. cayetanensis* stains best with carbolfuchsin.^[202] Phase-contrast microscopy and autofluorescence are also useful in the diagnosis.^[75] A PCR method is still used only for research.^[131]

The treatment of choice is TMP/SMX (160/800 mg 4 times a day for 10 days). This treatment provides more rapid clinical and parasitologic cure, with fewer recurrences.^{[82] [182]} In AIDS patients, chronic suppression with TMP/SMX may be required.^[129]

Miscellaneous Parasitic Agents

Microsporidia.

More than 100 genera and 1000 species of microsporidia exist in the phylum Microspora. Most

species infect insects, birds, and fish. Since the first description in humans in 1985, only 12 species have been reported to infect humans: *Enterocytozoon bieneusi*, three *Encephalitozoon* species, three *Nosema* species, two *Trachipleistophora* species, *Pleistophora*, *Vittaforma corneae*, and *Microsporidia* species. Microsporidians cause a wide spectrum of disease, but only two, *E. bieneusi* and *E. intestinalis*, have been found to cause diarrhea.^{[38] [82] [198] [200]}

Transmission is thought to be fecal-oral or urinary-oral^[38] and the infection zoonotic.

Waterborne transmission also occurs.^[131] Prevalence of microsporidiosis in AIDS patients with chronic diarrhea is 7% to 50%.^{[9] [198]}

The clinical manifestations of intestinal microsporidiosis are chronic diarrhea, loss of appetite, weight loss, malabsorption and fever.^{[9] [198]} Acute self-limited diarrhea has been reported in immunocompetent hosts. Other infections include keratoconjunctivitis, hepatitis, peritonitis, myositis, CNS infection, urinary tract infections, sinusitis and disseminated disease. Diagnosis involves trichrome staining of concentrated stools or intestinal biopsy sampling, but electron microscopy is considered the gold standard. Immunologic and molecular biologic techniques are still under evaluation.^{[69] [198]}

The most effective drug is albendazole (400 mg twice a day for 2 to 4 weeks). It is effective against most species, but results are variable with diarrhea from *E. bienensis*.^[39] Other drugs show different efficacy and include thalidomide, fumagillin, atovaquone, metronidazole, furazolidone, azithromycin, itraconazole, and sulfonamides.^[38]

Sarcocystis.

Few human infections with *Sarcocystis* have been reported. Infection may be asymptomatic or associated with diarrhea, abdominal pain, nausea, and bloating. Symptoms typically improve within 48 hours of onset of illness. Diagnosis is based on identification of cysts in concentrated feces. No specific treatment has been established, but TMP/SMX and furazolidone have had variable efficacy.^[200]

Balantidium.

Balantidium coli is a rare pathogen in humans.^{[186] [200]} Although many aspects of the epidemiology are unclear, pigs appear to be the primary reservoir and source of human infection. Clinical features also resemble amebiasis, with a spectrum including asymptomatic infection, chronic intermittent diarrhea of variable intensity, acute dysentery with mucosal invasion, and rarely, metastatic abscesses. Diagnosis is made by observing the organism in stool. Trophozoites are seen much more often than are cysts. Recommended treatment is tetracycline (500 mg 4 times a day for 10 days) or metronidazole (750 mg 3 times a day for 10 days).^[200]

Blastocystis.

The role of *Blastocystis hominis* in diarrheal disease is still controversial, although it is often identified in stool samples. *B. hominis* has not been directly correlated with symptoms,^[200] which could be caused by other undetected pathogens. When found in large numbers as the sole pathogen, *B. hominis* is suspected as the potential etiologic agent of diarrheal illness.

Dientamoeba.

Dientamoeba fragilis occasionally causes diarrhea, occurring characteristically in residents of or visitors to developing tropical regions. It may be found in stools of

persons without enteric symptoms. Because cyst forms have not been identified, the mode of transmission remains unknown. Illness caused by the parasite typically resembles giardiasis, but treatment of these two parasitic infections is different. Iodoquinol and tetracyclines are effective against *D. fragilis*.^[200]

Chapter 53 - Nutrition, Malnutrition, and Starvation

E. Wayne Askew

How does it feel to starve? A test subject in the Minnesota Starvation Study made the following observation after 24 weeks of semistarvation (1570 kcal/day, 24% weight loss)^[35] :

I am hungry. I am always hungry ... at times I can almost forget about it but there is nothing that can hold my interest for long ... I am cold ... my body flame is burning as low as possible to conserve precious fuel and still maintain my life processes ... I am weak. I can walk miles at my own pace in order to satisfy laboratory requirements, but often I trip on cracks in the sidewalk. To open a heavy door it is necessary to brace myself and push or pull with all my might. I wouldn't think of throwing a baseball and I couldn't jump over a twelve inch railing if I tried. This lack of strength is a great frustration. It is often a greater frustration than the hunger ... And now I have edema. When I wake up in the morning my face is puffy ... Sometimes my ankles swell and my knees are puffy ... Social graces, interests, spontaneous activity and responsibility take second place to concerns about food ... I lick my plate unashamedly at each meal even when guests are present ... I can talk intellectually, my mental ability has not decreased, but my will to use my ability has.

Nutrition is essential to proper human physiology and daily functioning but is often unappreciated in wilderness expedition planning. Many enthusiasts do not consider food as critical as gear and equipment, medical supplies, physical fitness, and other logistical considerations. In temperate environments, where food and water are plentiful and resupply is feasible, the importance of nutrition diminishes. When a stressful physical environment is superimposed on physically demanding wilderness tasks, however, the role of nutrition becomes crucial to maintain performance and prevent disease and injury, as evidenced from the description of Napoleon's disastrous 1812 winter retreat from Moscow by Baron D.J. Larrey^[50] :

The ice and deep snow with which the plains of Russia were covered,

impeded ... calorification in the capillaries and pulmonary organs. The snow and cold water, which the soldiers swallowed for the purpose of allaying their hunger or satisfying their thirst ... contributed greatly to the destruction of these individuals by absorbing the small portion of heat remaining in the viscera. The agents produced the death of those particularly who had been deprived of nutriment.

Although they usually have food, misfortune can strike the best-prepared adventurers. A wrong turn on the trail, injury, unanticipated terrain, an unexpected storm, or a downed airplane can isolate a victim from anticipated food sources. Food is often the most important item in a survival situation, particularly as the supply is exhausted. Although a concern, a shortage of food does not necessarily mean disaster. Humans are remarkably adaptable and can subsist on non-ideal dietary patterns for prolonged periods without disastrous effects on health and performance. A baseline level of energy intake ensures a minimal intake of vitamins and minerals, forestalling malnutrition and nutrient deficiency states. Hunger is uncomfortable and may hinder performance, but a food-deprived individual can still function for an extended time.

This chapter discusses three nutritional states or situations in terms of wilderness environments: (1) nutrition for optimal or effective functioning in environmental extremes; (2) malnutrition or suboptimal nutrition; and (3) starvation, or lack of nutrition. Preventive dietary planning for wilderness expeditions and emergency nutrition measures after rescue from starvation will be discussed.

ENVIRONMENTAL STRESS AND NUTRIENT REQUIREMENTS

The physical environment plays a significant role in determining survival time in the absence of food or water. The most important nutrient is water.^[9] If an adequate supply of water is not available, death occurs from dehydration before depletion of energy stores. Humans can survive complete food deprivation for weeks or even months depending on body fat. A nonobese adult fasting in a clinical setting can live as long as 60 to 70 days, with loss of all their body fat and one-third their lean body mass.^[32] One climber survived 43 days and was near death when rescued from a cave in the Himalayas with water but no food.^[55] Time to death after complete water deprivation is 6 to 14 days, depending on the rate of water loss. Death from starvation in nonobese individuals is imminent if approximately 50% of body weight has been lost. This discussion on energy restriction assumes an adequate supply of water (see [Chapter 10](#) and [Chapter 11](#)).

Modern camping foods and military field rations can support health and performance in a variety of temperate environments.^[41] The situation may change rapidly, however, in wilderness environments characterized by more extreme temperatures and terrain.^{[40] [42]}

1272

Figure 53-1 (Figure Not Available) Influence of extreme wilderness environments on food and fluid intake and physical and mental performance. (From Askew EW: *Nutrition and performance under adverse environmental conditions*. In Hickson JF Jr, Wolinski I, editors: *Nutrition in exercise and sport*, Boca Raton, Fla, 1989, CRC Press.)

Stress, whether heat, cold, altitude, level of exertion, or food restriction, influences nutrient requirements.^{[7] [53]} Superimposed stressors, such as extreme altitude or sleep deprivation, jeopardize both physical and mental performance.^{[10] [26] [40] [42] [43]} (Figure 53-1 (Figure Not Available)).

Energy and fluid deficits arising from the interaction of environment and nutrition can potentially negatively impact both physical^[27] and mental^[43] performance.

Energy Needs

Cold and altitude stress and its influence on macronutrient and vitamin requirements have been a major focus of military and civilian research.^[8] Vitamin and mineral requirements are not significantly increased by cold exposure, although caloric requirements for thermogenesis may be elevated.^[42] Work in cold environments can be

adequately supported by combinations of fat, carbohydrate, and protein, although certain macronutrients may be more beneficial.^[4] The macronutrient source is not as important as consuming enough total calories to support activity and thermogenesis. When wilderness activities shift from sea-level cold weather to moderate or high altitude, however, the importance of the macronutrient mixture should be reconsidered. Fat is an efficient energy source during cold weather activities at sea level but is not as well tolerated at altitude.^[5]

The substitution of carbohydrate for fat and partly for protein can help an individual's oxygen economy while working at altitude.^[3] Carbohydrate is more efficient fuel at altitude than fat because it is already partially oxidized and requires less oxygen to combust its carbon skeleton to CO₂. The metabolism of carbohydrate for energy requires approximately 8% to 10% less inspired oxygen than that required to process a similar amount of calories from fat. A high-carbohydrate diet can reduce the symptoms of acute mountain sickness, enhance short-term high-intensity work as well as long-term submaximal efforts,^[3] ^[11] ^[24] and "lower the effective elevation" as much as 300 to 600 m (about 1000 to 2000 feet) by requiring less oxygen for metabolism. Initial altitude exposure results in anorexia and subsequently reduces energy and carbohydrate intake.^[20] Food intakes usually improve with time and acclimatization but, depending on the altitude, may never match those at sea level. Weight loss and performance decrements are common under these conditions.

Carbohydrate supplementation of the diet at elevations exceeding 2200 m (7218 feet) is usually an effective method to increase carbohydrate and total energy intakes.^[3] ^[20] ^[25] Carbohydrate supplementation at altitude may reduce symptoms caused by acute altitude exposure,^[24] but not all studies have demonstrated this benefit.^[62] The most effective form of carbohydrate supplementation is usually liquid beverages; people will drink even when they are reluctant to eat.^[20] ^[25] Also, increasing fluid intake is beneficial at high altitudes, where increased fluid losses occur with diuresis and respiration in the dry atmosphere.^[9]

Nutritional requirements for males in environmental extremes are well studied, but little research has been done on female requirements.^[36] Studies in the late 1960s reported that female soldiers deployed to moderate to high altitude would require supplemental dietary iron for optimal support of the hematopoietic response to hypoxia.^[30] Subsequent research on iron requirements and the thermogenic response to cold identified iron as a key micronutrient for females in a cold environment.^[17] ^[39] Females usually consume less total food calories

than males because of their reduced body size and therefore are at increased risk for reduced vitamin and mineral intakes. Fortunately, the need for these vitamins and minerals (except iron) is related to lean body mass, and females usually have less lean body mass than males.

Performance across a broad spectrum of backcountry tasks is not always severely degraded by suboptimal energy and carbohydrate intakes. Soldiers can maintain relatively normal work capacities for short periods (less than 10 days) of food restriction.^[26] The Minnesota starvation studies conducted during World War II demonstrated that energy deficits resulting in less than 10% body weight loss did not impair physical performance; however, underconsumption of calories for longer periods with continued body weight loss produced significant deficits in physical performance.^[63]

Restricted energy and dietary carbohydrate content over 30 days supported light to moderate activity level without evidence of greatly impaired physical performance capabilities.^[12] On the other hand, longer periods of caloric restriction (8 weeks) and higher levels of energy expenditure have been associated with significantly reduced physical performance capacity.^[48]

It is difficult to derive a closely predictable relationship between energy deficit and performance. Some indicators of performance, such as grip strength, appear to be well preserved until nutritional status is severely compromised, whereas other measures, such as the maximal lift test, maximal jump height, isometric leg extension, and maximal oxygen uptake, appear to be more sensitive predictors of impaired performance.^[34] Nonobese individuals seem to maintain strength with up to 5% body weight loss. Aerobic capacity and strength are reduced when body weight loss exceeds 10%. Friedl^[26] concluded that changes in oxygen capacity in response to modest caloric restriction influence performance less than reductions in muscle strength in response to weight loss. The primary concern with weight loss from inadequate energy during extended wilderness activities may be loss of muscle strength, which is significant with 5% to 10% body weight loss. Significant declines in aerobic capacity can also occur after weight losses of this magnitude, but the decline in aerobic capacity appears to have relatively little effect on individual performance at moderate (less than 50% oxygen capacity) sustainable workload levels.^[26] Thus a prior food restriction with significant loss of body weight may not preclude a gradual trek to the summit, but a short-term rigorous push for the summit to avoid impending bad weather might be compromised.

The effects of energy restriction on performance involve other factors besides strength and aerobic capacity. Weight losses up to 6% over 10 to 45 days generally do not significantly impair cognitive performance, but habitual or forced consumption resulting in a 50% loss of energy requirements may degrade cognition.^[43] Reduced food intake coupled with other stressors, such as high rates of energy expenditure and sleep deprivation, can also impair immune function.^{[37] [45]}

Carbohydrate

Both the time provided for dietary adaptation to carbohydrate restriction and the level of carbohydrate in the diet can influence the level of aerobic endurance.^[2] Performance can be reduced by 40% after only 4 days on a calorie-adequate but low-carbohydrate (10% of kcal) diet.^[29] Another calorie-adequate low-carbohydrate (5% of kcal) diet for 2 weeks also reduced performance, but only by 15%, presumably because of metabolic

adaptations to the shift in energy sources.^[52]

More than any macronutrient other than water, reduced carbohydrate intake can negatively influence muscle glycogen levels and endurance.^[2] Certain types of performance, such as backpacking, cross-country skiing, and climbing, may be influenced by an acute shortage of carbohydrate in the diet, depending on the intensity of the workload. Inadequate carbohydrate and successive days of intense prolonged exercise may result in gradual reduction of glycogen stores, deterioration of performance, and perception of fatigue. Furthermore, perceived exertion for certain wilderness activities, such as load bearing, may be assumed to be a function of the dietary carbohydrate and its effect on muscle glycogen levels. Carbohydrates may extend or enhance performance when ingested before, during, and after moderate to intense aerobic exercise.^[33] This requires daily consumption of approximately 500 to 550 g of carbohydrate. Typical dietary carbohydrate intakes of male soldiers fed a variety of rations during 18 field studies in temperate, hot, and cold environments ranged from 244 to 467 g/day.^[15] It is also probable that daily carbohydrate intakes for wilderness activities would be less than the 500 to 550 g/day recommended for optimal physical performance, since total caloric intake during outdoor work is often less than that required to maintain energy balance.^[41] Most people do not selectively consume low-carbohydrate diets during wilderness activities; however, total carbohydrate intake is often low because of its relationship to total energy intake and to limited food choices. In the short term, lack of energy (calories) is not as significant to performance as lack of carbohydrate.^[26]

Definitive field studies demonstrating a positive effect of dietary carbohydrate supplements on performance are lacking.^[6] When field conditions can be modeled under well-controlled laboratory settings, results suggest that carbohydrate supplementation benefits performance. One study tested the concept that soldiers would benefit from carbohydrate supplementation under conditions simulating field operations.^[47]

Supplemental carbohydrate permitted a higher level of physical performance or aerobic power. Run times to exhaustion were increased approximately 6% with single carbohydrate feeding and 17% with divided doses. The ingestion pattern influenced performance, indicating that a supply of easily consumed carbohydrate supplement or food item ingested before, during, and after field activities is an effective method to sustain or boost physical performance.

Protein

Considerable discussion of the proper amount of protein to maintain muscle mass, prevent "wasting," and maintain performance under conditions of physical stress exists in the literature. However, despite all the controversies, recommendations concerning the amount of protein in the diet have changed little since World War I, as evidenced by reviewing a 1919 report by Murlin and Miller^[46] : "The amount of protein ... sufficient to

repair all of the wastes of the body and to supply an adequate reserve is 13% of the total energy intake. It seems a matter of indifference to the muscles whether they receive their energy from carbohydrate or from fat ... Hard muscular work, therefore can be done on a diet high in carbohydrate or upon a high fat diet. It is of general experience, however, that muscular work is done with less effort if there is a plentiful supply of carbohydrate."

"Thirteen percent" of the energy intake translates to an intake of 65 g of protein on an energy-restricted intake of 2000 kcal/day, or 130 g of protein for a 4000-kcal diet. This quantity of dietary protein is easy to obtain (e.g., one stick of beef jerky or one serving of peanut butter contains 6 to 8 g of protein). Although dietary protein is important, the quantity of carbohydrate in a food-restricted diet is more closely related to nitrogen balance or the preservation of lean body mass than to the absolute amount of protein. Carbohydrates apparently "spare" amino acids derived from dietary protein from subsequent deamination and oxidation for energy. Approximately 40 g of dietary protein seems to be a *minimum* daily amount required to prevent excessive nitrogen loss under food restriction.

Vitamins

Vitamins are coenzymes of important biochemical reactions in energy metabolism. Vitamins E and C and the precursor of vitamin A (β -carotene) also exert important protective actions as antioxidants. Oxidative stress may be significant during work in environmental extremes.^[7]

Prevention of vitamin deficiencies is poorly understood in short-term and long-range nutrition planning. Body stores of some vitamins (primarily the water-soluble vitamins) are limited, and, vitamin deficiencies

Figure 53-2 Impact of restricted vitamin intake on functional performance.

Experimental conditions: diet, 3070 kcal; % U.S. RDA: thiamin 28%, riboflavin 31%, vitamin B₆ 16%, vitamin C 10%; performance test—incremental cycle ergometer. (Data from van der Beek EJ: *Marginal deficiencies of thiamin, riboflavin, vitamin B₆, and vitamin C: prevalence and functional consequences in man, Amsterdam, 1992, TNO.*)

can occur with prolonged periods of dietary restriction. Tissue depletion of thiamin, riboflavin, and pyridoxine can occur in 11 weeks with a calorie-adequate but vitamin deficient, experimental diet composed of common food products.^[66] Van der Beek et al^[65] ^[66] ^[67] studied the maintenance of human physical performance with varying degrees of vitamin restriction. With vitamin intakes significantly less than the recommended dietary allowances (RDAs), vitamin deficiencies manifested slowly in terms of physical performance impairments. Restricted intakes (percent U.S. RDA) of thiamin (28%), riboflavin (31%), pyridoxal phosphate (16%), and ascorbate (vitamin C,

10%) resulted in less than a 20% decrease in cycle ergometer performance (maximum workload) after 8 weeks at this level of restriction ([Figure 53-2](#)).

The effect of vitamin restriction on performance contrasts with the more immediate effects of acute or long-term dietary carbohydrate restriction. Physical performance impairment is much more sensitive to the amount of dietary carbohydrate in the short term (1 to 3 days) than to dietary vitamin, protein, or fat in the long term (6 to 8 weeks).^[2]

A vitamin deficiency is a progressive process with four stages and a spectrum of physiologic manifestations ([Box 53-1](#)).

The possibility that certain nutrients might help people "adapt" or in some manner function more efficiently in stressful environments has intrigued explorers and scientists for years. Perhaps the most thorough exploration of this possibility was conducted in 1953 in the "Medical Nutrition Laboratory Army Winter Project: Vitamin Supplementation of Army Rations Under Stress Conditions in a Cold Environment—The Pole

1275

Mountain Study." The objective of this study was to determine if supplementation with large quantities of ascorbic acid and B-complex vitamins would influence the physical performance of soldiers engaged in high levels of physical activity in a cold environment, both with and without caloric restriction.^[8] The investigators concluded that supplementing the diet of men engaged in high levels of physical activity in the cold, with or without caloric restriction, did not result in significantly better physical performance.^[8]

Box 53-1. FOUR STAGES IN DEVELOPMENT OF A VITAMIN DEFICIENCY

1. PRELIMINARY STAGE

Inadequate amount from poor dietary patterns or altered availability in the diet

Often occurs after short-duration wilderness activities (<30 days) with poor nutritional planning

Consequence: none, except progressing to stage 2

2. BIOCHEMICAL DEFICIENCY

The body's pool of the vitamin is decreased

May occur after long-term wilderness activities (> 30 days) accompanied by suboptimal daily nutrient intakes

Consequence: rates of enzyme-catalyzed reactions may be slightly altered

3. PHYSIOLOGIC OR "SUBCLINICAL" DEFICIENCY

Can be detected by some functional tests

May occur after extended periods of consuming foods low in vitamins or periods of food restriction

Consequence: performance may be impaired slightly

4. CLINICAL DEFICIENCY

Specific symptoms manifested; detectable in a clinical setting

May occur after starvation or extended periods of food deprivation

Both health and performance may be impaired

**Box 53-2. CONDITIONS THAT MAY
REQUIRE VITAMIN
SUPPLEMENTATION**

Energy intake less than 1200 to 1600
kcal/day

Meals routinely missed

Poor or bizarre eating habits

Increased oxidative stressors
(ultraviolet light exposure, high rates of
energy expenditure, lack of fruits and
vegetables)

The vitamin concerns for wilderness exertions are not as critical as total energy and carbohydrate provision. Vitamin supplementation is recommended in certain situations under conditions of environmental extremes and food restriction ([Box 53-2](#)).

Certain vitamins, such as E and C, may have important functions beyond their conventional essential roles, such as preventing degradation of the immune response and maintaining red blood cell flexibility and oxygen delivery under conditions of increased oxidative stress. In light of uncertainties regarding the quantity and quality of food and oxidative stressors encountered during wilderness activities, it seems prudent to include a multivitamin supplement with the food supplies.

Minerals

The mineral content of the diet is usually of secondary concern, provided that a mixed diet is consumed daily in amounts close to energy requirements. Adequate dietary sodium is usually the mineral of primary concern because of its loss in sweat, especially in hot environments (see [Chapter 10](#) and [Chapter 11](#)). Appropriate acclimatization to the heat and sodium conservation by the kidney reduce the amount of sodium required for work. Laboratory studies have shown that heat acclimatization can occur with as little as 4 to 8 g of sodium chloride (NaCl) ingested per day.^[4] Whether this is adequate NaCl for safe work in the heat depends on degree of acclimatization and amount of sweating. Altered dietary patterns or excessive sweating can influence sodium balance. Starvation can lead to plasma volume depletion because of insufficient sodium in the circulation to enable osmotic forces to retain water.^[32] Acute exposure of nonacclimatized humans to simultaneous food restriction and high sweat rates can result in excessive loss of sodium, leading to dizziness, syncope, and even collapse. These problems can be avoided by ensuring that extra salt is included in the food provisions and is used during

and after high sweat losses.

Another form of sodium deficit is dilutional hyponatremia caused by overhydration and low sodium intake. Hyponatremia from overconsumption of fluids rarely occurs when regular meals are consumed. As a complication of overhydration when food is often neglected, hyponatremia has been described for hot and cold wilderness environments.^[13] ^[68] Calorie deprivation can alter sodium requirements. In addition to reduced intake of sodium in food, severe caloric restriction leads to marked natriuresis. The increased loss of sodium in turn leads to fluid volume depletion, impaired cardiovascular function, and reduced work capacity, separate from the

1276

effects of energy restriction. The accompanying increased aldosterone levels in response to reduced plasma volume can also lead to accelerated potassium wasting.^[51]

MALNUTRITION AND STARVATION

There is little uniformity in the terminology used to describe the physiology of human starvation. Hoffer^[32] has suggested the following definitions:

Fasting: total absence of food intake.

Starvation: physiologic condition that develops when macronutrient content is inadequate for a prolonged time.

Semistarvation or food restriction: more commonly encountered condition of insufficient energy and protein provision.

Malnutrition: general term for the condition resulting from longstanding inadequate consumption of nutrients, abnormal absorption of nutrients, or unusual demands on certain nutrients, usually accompanied by suboptimal food intake and/or consuming food of poor nutrient density, resulting in micronutrient and macronutrient deficiencies.

Protein-energy malnutrition (PEM): inadequate intake of energy, protein, or both for prolonged periods. Two specific types of interrelated PEM are *marasmus*, primarily an energy deficiency, and *kwashiorkor*, primarily a protein deficiency; they occur across a spectrum of conditions and share many of the same symptoms. PEM frequently results from starvation, but all starvation does not necessarily lead to PEM. The development of PEM depends on body energy reserves, length of the fast, age, and presence or absence of disease.

Cachexia: more specific term referring to the wasting that results from metabolic stress; sometimes called *cytokine-induced malnutrition* to distinguish from simple food deprivation in the absence of stress. The inanition of advanced-stage cancer patients is an example of cachexia.

Various metabolic and physiologic consequences of starvation or energy restriction might be encountered in wilderness settings. Unplanned emergencies may result in shortage of food, and wilderness rescue operations may involve victims of unintentional starvation. In these settings the duration of food restriction is usually shorter than that associated with famine, war, crop failures, and disease.

Solomons^[59] has stated that malnutrition simply means "bad" nutrition and has listed six possible causes of nutrient deficiencies leading to malnutrition: (1) reduced intake, (2) decreased absorption, (3) decreased utilization, (4) increased destruction, (5) increased

wastage, and (6) increased requirement. Primary malnutrition is caused by reduced intake of food, the most common cause of malnutrition in wilderness settings. Reduced intake and increased requirement contribute to the development of nutrient deficiencies during expeditions in environmental extremes. Secondary causes of nutrient deficiencies can contribute significantly if disease or illness strikes the wilderness traveler. Impaired immune function, decreased resistance to infection, and prolonged recovery from injury are consequences of long-term food restriction.^{[22] [27] [37] [57] [58]}

Starvation can be acute or chronic and total or partial. Different forms of starvation are similar but not identical. Two major sequences of metabolic adaptations occur in the progression of starvation: metabolic responses during acute energy restriction and metabolic changes in chronically undernourished individuals as a result of long-term low energy intakes.^[56]

Acute Energy Restriction

A rapid progression of events occurs in response to acute energy inadequacy, such as a 50% shortfall of food during the second week of a 2-week backpacking trip. The body reacts quickly to an energy shortage by utilizing readily available muscle and liver glycogen stores. When the body's carbohydrate stores have been depleted, the glucagon level rises, the insulin level falls, and the process of gluconeogenesis accelerates, converting noncarbohydrate precursors such as lactate, glycerol and amino acids into glucose to maintain blood glucose and prevent hypoglycemia ([Figure 53-3](#)).

The reduction in carbohydrate intake during food restriction is compensated largely by accelerated gluconeogenesis. About 100 g of protein from endogenous tissue sources can provide approximately 55 g of carbohydrate. The glycerol from 100 g of mobilized fat can yield 10 to 15 g of carbohydrate through gluconeogenesis.^[19] Simultaneous with glycogen depletion, catecholamine

Figure 53-3 Influence of energy balance on hormonal control of blood glucose.

When food is consumed, insulin is released, lowering blood glucose. When no food is consumed, gluconeogenic hormones are released, raising blood glucose.

production rises, facilitating fatty acid mobilization from adipose depots. Once mobilized, fatty acids are taken up by muscle in proportion to their concentration in the blood and are oxidized for energy. [Figure 53-4](#) shows the metabolic events of a short-term fast.

Long-Term Energy Restriction

A fast longer than 2 to 3 days exhausts liver glycogen and uses up about half the muscle glycogen stores.^[32] Thereafter, glucose utilized by the body (in the absence of food consumption) must be synthesized from endogenous precursors through gluconeogenesis.

Ketone bodies in the blood, breath, and urine result from the low insulin/glucagon ratio accompanying a prolonged fast. Ketone bodies are a metabolic consequence of vigorous fatty acid oxidation from adipose tissue engendered by starvation in the absence of significant carbohydrate intake. During fasting, production of acetoacetate and β -hydroxybutyrate increases greatly during the first 7 to 10 days and stabilizes after 2 to 3 weeks.^[18] Ketone bodies can be increasingly used for energy by muscle and brain as energy restriction becomes prolonged. Even a short-term fast elicits a significant production of ketone bodies (see [Figure 53-4](#)). Ketone body production may stop, however, if 150 g of carbohydrate is ingested daily to supply the brain with glucose for energy.^[19] ^[32] Normally, in the fed state,

Figure 53-4 Fuel utilization in short-term starvation. Metabolic rates in grams per day after a 24-hour fast, with energy expenditure of 1800 kcal/day. RBC, WBC, red and white blood cells. (Adapted from data published in Bursztein S et al: *Energy metabolism, indirect calorimetry, and nutrition*, Baltimore, 1989, Williams & Wilkins.)

ketone body oxidation accounts for less than 3% of total energy requirement. Longer periods (7 to 10 days) of fasting are accompanied by greatly increased ketone bodies, which can provide as much as 40% of the total energy expenditure and greater than 50% of the brain's glucose requirement. The switch to using ketone bodies for energy by the brain is controlled by the concentration of ketone bodies in the blood rather than by a direct hormonal effect on the brain.^[18] [Figure 53-5](#) shows metabolic changes during a long-term fast (about 30 days).

With increasing duration of the fast and depletion of muscle and liver glycogen, ketones and glucose derived from gluconeogenesis of amino acids contribute to the energy requirements of the brain. As starvation is prolonged, less and less glucose is used, thereby reducing the amount of protein that must be catabolized to support gluconeogenesis. Blood levels of branched chain amino acids (leucine, isoleucine, valine) are preferred amino acid substrates for muscle energy metabolism and double by 3 to 5 days of fasting, but levels fall during prolonged fasting. These branched chain amino acids are believed to augment gluconeogenesis until fat metabolism has adapted to fasting.^[18]

The amino acid glutamine has special importance during fasting as a precursor of

glucose, an energy source, and a transporter of amino acid nitrogen in the

1278

Figure 53-5 Fuel utilization in long-term starvation. Metabolic rates in grams per day after a prolonged fast of 5 to 6 weeks, with energy expenditure of 1450 kcal/day. (Adapted from data published in Bursztein S et al: *Energy metabolism, indirect calorimetry, and nutrition*, Baltimore, 1989, Williams & Wilkins.)

form of ammonia to the kidney for excretion. Urea is the major nitrogen excretory product in the urine during the fed state but is greatly reduced as the fast progresses. Ammonia nitrogen increases in the urine during a fast as urea nitrogen decreases. The increase in ammonia nitrogen is believed to buffer ketoacids during their excretion in the urine. Glutamine is released from muscle during fasting (NH₃ formed from amino acid deamination by muscle is transaminated to glutamate to form glutamine) and serves as a special energy source for the gut and as a gluconeogenic substrate for the kidney. With increasing ketone body production the liver reduces its rate of gluconeogenesis, and the kidney becomes the major organ of gluconeogenesis, producing more than half the body's glucose requirement. Glutamine is the predominant substrate for kidney gluconeogenesis and provides the ammonia required to buffer ketoacid excretion produced by ketogenesis from fat oxidation.^[18]

Fortunately, muscle proteolysis does not continue at the high initial rate indicated by negative nitrogen balances of 10 to 12 g/day during the first 7 to 10 days of fasting. After this time, adaptation in the nitrogen economy of the body reduces nitrogen loss in the urine to less than half the initial rate.^[32] The "signal" that causes muscle to reduce its catabolic rate is probably related to the shift to ketone body utilization by the brain and to the shift to fatty acid oxidation by muscle. When adaptation to food restriction is not successful or food restriction is too severe, nitrogen can be lost from both the central (visceral) and the peripheral (skeletal muscle) sites. Development of central protein deficiency can lead to anergy and hypoalbuminemia. Reduced plasma albumin lowers plasma oncotic pressure, which allows fluid to migrate out of the vasculature into the extracellular space, resulting in edema of the extremities. Edema is not present in all victims of starvation, but its presence indicates severe metabolic stress and central protein deficiency, and edema is a potentially dangerous condition.^[32]

The net result of short-term and long-term metabolic adaptations in energy restriction is an increased efficiency of the body's metabolism. Over 14 days, during which body weight decreases 8% to 10%, the basal metabolic

rate (BMR) can decrease about 21%. This short-term decrease in BMR is greater than would be predicted from the decrease in metabolically active lean tissue mass. Bines ^[18] suggests that the reduction in BMR during energy restriction occurs in two different phases. The initial decrease in BMR is not attributable to changes in body weight or body composition. Then, with continued energy restriction, BMR is further reduced by loss of metabolically active tissue. Several physiologic mechanisms operate to down-regulate metabolic activity in the active tissue mass and increase its metabolic efficiency. The decreased energy flux reduces activity of the sympathetic nervous system and lowers secretion and activity of three thermogenic hormones: catecholamines, triiodothyronine (T_3), and insulin. Other activities that require energy activities, such as the sodium-potassium pump and "futile" metabolic cycling (e.g., phosphorylating and dephosphorylating metabolic intermediates), may also be reduced during starvation.

Tissue Utilization during Starvation

A hierarchy of fuel sources is used during starvation. During extended fasting, muscle mass is more likely to be reduced than the viscera. ^[56] Important internal organs, such as the liver, show no evidence of dysfunction after 7 days of fasting, ^[54] whereas muscle cell mass decreases in a linear fashion with the severity and duration of a fast. ^[56] Adipose mass decreases along with muscle but not as rapidly, perhaps due to the energy density of the fat depot and the low amount of associated water. The body may "defend" a certain amount of body fat as essential for nerve sheath insulation, brain neurolipids, cell membrane integrity, and hormone synthesis. [Figure 53-6](#) shows the general progression of energy source utilization.

The largest energy reserves are found in the largest organs of the body, specifically muscle (about 28 kg) and adipose tissue (15 kg) ([Table 53-1](#)). Critical internal organs, such as the liver, brain, heart, and kidneys, have a collective mass of less than 9 kg and are not good fuel source candidates, since they begin to lose function (decompensation) as they become energy sources during starvation. Sex hormone synthesis is depressed during extended periods of food restriction, ^[27] ^[28] since reproduction is not a high priority during starvation. As the fast progresses, eventually visceral organs are utilized as the body decompensates, or "feeds on itself." Organ failure and death ultimately result unless nutritional intervention occurs before decompensation (internal organ catabolism, loss of integration of bodily systems, deterioration of homeostasis).

Limits of Human Starvation

The following are James Scott's observations near the end of a 43-day period of starvation while lost in the Himalayas ^[55] :

Figure 53-6 Hierarchy of energy sources utilized during progressive stages of starvation.

TABLE 53-1 -- Utilizable Energy Stores in Sedentary 70-Kg Man

ENERGY SOURCE	MASS (kg)	ENERGY (kj)
Fat (adipose tissue)	15	590
Protein (muscle)	6	100
Glycogen (muscle)	0.15	2.51
Glycogen (liver)	0.075	1.25
Plasma glucose	0.020	0.33
Plasma free fatty acids	0.0003	0.012
Plasma triglycerides	0.003	0.125

From Cahill GF: N Engl J Med 282:668, 1970.

There were horrific changes in my body. My buttocks were bones jutting against skin. I could no longer warm my hands by nestling them between my thighs. Now I could push a clenched fist between my legs without touching either thigh. I continually felt nauseated. The nausea became so severe I retched uncontrollably. This went on night after night. Death was closing in. My body was conceding defeat.

Body fat of nonobese humans can be considered "beneficial" fat when viewed in the context of surviving starvation.^[49] Body fat level approaching 6% indicates impending lean body mass deterioration in the fasting individual.^[28] Essential fat stores (fat in bone marrow, heart, lungs, liver, kidneys, intestine, muscle cell membranes, and the central nervous system) are necessary to maintain of life and prevent decompensation. Essential fat stores constitute 3% to 4 % of body weight. Total body fat depletion in previously nonobese individuals occurs at approximately 50% body weight loss. In fasting uncomplicated by disease the time until death is largely determined by the size of fat stores and the time to reach the 3% level of essential fat. Low fat stores are not the cause of death, but their diminution contributes to breakdown of homeostasis

and impairment of physiologic function. Fat stores protect function. Typical fat stores in

humans are 10 to 15 kg (including 2.1 kg of "essential" fat), or approximately 27% of body weight. A well-nourished adult has sufficient fat stores to sustain life for 60 to 70 days. Death has been reported sooner in voluntary hunger strikers and may be related to simultaneous fluid restriction and the lack of "will to live."

A loss of greater than 50% of the lean body mass is also predictive of death. Remaining body fat and protein reserves are difficult to measure accurately. The body mass index (BMI, weight in kg divided by height in m²) is a convenient method to assess risk of mortality in severely starved individuals. Before the unfortunate war and famine in Somalia, the lowest BMI compatible with life was thought to be 13 in males and 11 in females.^[31] Collins^[23] found that a BMI of 10 could be compatible with life under conditions of specialized hospital care. A BMI of 10 may be compatible with life among certain somatotypes in a warm climate, but other races in colder climates may face death before reaching the low BMI level noted in Somalia.

Age and Gender Differences

Persons possessing the most limited amount of body reserves, such as the elderly and the very young, are at increased risk for early mortality during extended periods of starvation. Children have increased nutrient requirements for growth and develop deficiency symptoms rapidly when faced with severe food restriction.

Evidence of unintentional situational starvation in both men and women indicates that women may possess certain metabolic advantages over men that may lead to reduced mortality from severe starvation. Wartime and famine observations demonstrate the disproportionate survival of women over men.^[26] ^[49] Earlier observations of the survivors of the Mormon handcart trek^[16] and the Donner party^[60] support the conclusion that women are at lower risk for mortality under nutritionally stressful situations. McCurdy^[44] examined the mortality pattern in the Donner party, who became trapped without adequate food supplies in the Sierra Nevada mountains during the winter of 1846–1847 ([Table 53-2](#)). Very young children and males were at the highest risk of mortality during starvation. Women generally have lower body mass and less lean body mass to maintain than do men, as well as more subcutaneous fat, which may have insulative value during cold exposure. Gender-related behavior, such as the performance of strenuous and high-risk tasks by men, may also explain the reduced mortality rate among women during prolonged starvation.

The "gender effect" during starvation may be caused by certain metabolic advantages, such as females' higher initial level of body fat and subsequent reduced loss of protein and lean body mass during fasting. Lowell and Goodman^[38] proposed that protein

TABLE 53-2 -- Demographic Characteristics and Mortality Rate of the Donner Party, 1846–1847

CHARACTERISTIC	FREQUENCY (%)	MORTALITY RATE (%)
Total party	90 (100)	42/90 (47)
AGE (YEARS)		

Less than 5	19 (21)	11/19 (58)
6–14	21 (23)	2/21 (10)
5–34	24 (38)	16/34 (47)
Greater than 35	14 (16)	11/14 (79)
GENDER		
Male	55 (61)	32/55 (58)
Female	35 (39)	10/35 (29)

Data from McCurdy SA: West J Med 160:338, 1994.

sparing in skeletal muscle during prolonged starvation depends on the availability of lipid fuels, which may provide energy and attenuate the rise in catabolic hormones during starvation. Also, fatty acids may specifically modulate the breakdown of myofibrillar protein, independent of their oxidation as a fuel, thus causing direct muscle-sparing effect during prolonged starvation.

REALIMENTATION OF STARVATION VICTIMS

With sophisticated communication and highly trained search and rescue teams, a person lost or injured in a wilderness environment is usually rescued quickly.^[61] One only has to compare the length of time involved in the rescue of the starving Donner party from the Sierra Mountains in 1847^[44] (4 months) with the evacuation of nutritionally depleted Mike Stroud and Ranulph Fiennes^[61] from Antarctica in 1993 (1 day). Although Stroud and Fiennes voluntarily prolonged their period of starvation before requesting evacuation, most individuals usually do not have to spend longer than a weekend or, at the most, a few days longer than anticipated in uncomfortable circumstances. It is likely that a certain amount of food will be available to the stranded person, since most people do not enter the wilderness totally unprepared. The individual may have consumed the initial food supply and then fasted for several days before rescue or, if disciplined, may have restricted or rationed food intake for a period of several days. Helicopter evacuation can place the rescued individual in a hospital setting within hours. The worst-case scenario would be the rescue of a severely injured or ill person who had not eaten for an extended period and could not be evacuated by helicopter. Refeeding victims of short-term starvation does not involve the complications of prolonged starvation.^[55]

1281

The specific physiologic and metabolic effects induced by refeeding depend on the individual's existing metabolic state and body composition, as well as the composition of the refeeding diet.^[32] The rescuer can offer normal food to most victims of short-term starvation (3 to 5 days). The most common problem may be that the individual wants to eat too much too soon, which is usually self-correcting. The victim should first be reassured and then checked for injuries, illness, and dehydration. Juices, soups, instant oatmeal, granola bars, and small piece of jerky slowly chewed along with the fruit juice are all good choices to prime the digestive system for again processing food. Frequent small feedings are best. Sports drinks are often a good choice for simultaneous rehydration, providing carbohydrates for energy and electrolytes that may be needed for plasma volume expansion.

The priority for realimentation of individuals lost in the wilderness for an extended time is to correct fluid and electrolyte imbalance and halt ongoing protein catabolism. Oral rehydration solutions similar to those used to treat diarrheal disease can be used in wilderness rescue for extremely dehydrated individuals.^[14] Intravenous saline and dextrose may be needed for individuals unable to eat because of shock, injury, or vomiting. Water-borne or food-borne illness may be encountered in backcountry

scenarios. Rescued victims may have diarrheal disease as well as starvation. The World Health Organization (WHO) oral rehydration solution is composed of the following (g/L): glucose (20), NaCl (3.5), potassium chloride (1.5), and trisodium citrate (2.9) (osmolality, 310).³² If trisodium citrate is not available, 2.5 g of common baking soda can be substituted.

Fluids should be continued until the victim is able to urinate every 2 to 3 hours. If the individual does not seem to be especially dehydrated, dilute fruit juices or sports drinks containing 5% to 10% carbohydrate and about 20 mEq (1.2 g) Na⁺ /L are reasonable rehydration fluids. Water is always appropriate, and additional sodium can be provided by liberally salting the solid food offered. A simple rehydration solution can be made by adding ½ tsp of table salt and 3 to 4 tsp of sugar to a quart or liter of water. Sports drinks usually contain 10 to 25 mEq of Na⁺ and 2 to 5 mEq of K⁺ per liter. Bouillon cubes are a good source of sodium and convenient. One bouillon cube contains about 1000 mg of Na⁺ (44 mEq). Providing sodium to a moderately depleted individual is beneficial for restoring plasma volume but should be approached more cautiously in victims with severe malnutrition to avoid overly rapid expansion of plasma volume, which can lead to congestive heart failure.³² Bananas are excellent sources of K⁺ (450 mg/banana) but are perishable and seldom available. Dried banana chips are a good alternative (152 mg K⁺ /ounce).

Box 53-3. STEPS IN REFEEDING SEVERELY MALNOURISHED INDIVIDUALS

1. Normalize and maintain fluid and electrolyte parameters.
2. Provide a mixed diet at the maintenance level to establish tolerance and avoid the refeeding syndrome.
3. Slowly increase energy intake to achieve positive energy balance and promote fat and protein gain.
4. Provide protein intakes of 1.5 to 2.0 g/kg to promote rapid repletion of body protein at any refeeding energy level.

Modified from Hoffer J: Metabolic consequences of starvation. In Shils ME et al, editors: Modern nutrition in health and disease, Baltimore, 1999, Williams & Wilkins.

After correcting for hydration status and electrolyte balance, the victim should be placed on a high-protein, high-energy diet as soon as solid food is comfortably ingested. Some diets are more appropriate for realimenting starvation victims. For example, a diet high in sodium and carbohydrate fed to a severely malnourished individual may rapidly increase extracellular volume, resulting in peripheral edema and fluid accumulation in the heart and lungs. A low-protein, high-energy diet may be beneficial at first but, if continued, may increase fat mass without the desired increase in lean tissue mass. A high-protein diet may halt nitrogen loss but will not lead to simultaneous replenishment of fat stores. An easy-to-prepare high-protein, high-energy liquid food for initial refeeding of severely malnourished and starving individuals consists of powdered cow's milk (140 g), sucrose (100 g), oil (40 g), and water (900 ml), which provides 3 to 4 g protein/dl.^[64]

Victims of prolonged starvation may have hyponatremia, hypocalcemia, hypomagnesemia coupled with severe anemia, and impaired membrane and cardiovascular function. These victims should be realimented cautiously to avoid sudden expansion of intravascular fluid volume. Cardiac failure may develop if high-protein/energy feedings are instituted too soon. Increased sodium and albumin levels from refeeding greatly expand the circulatory volume, leading to pulmonary edema, congestive heart failure, and possibly secondary pulmonary infection ([Box 53-3](#) and [Box 53-4](#)).

NUTRITIONAL PLANNING

Nutritional planning for wilderness activities is often limited by space and weight constraints of gear. In general a daily food ration of 4000 kcal for men and 3500

*Preparation information available at www.rehydrate.org/html/ors.htm; commercially available from Jianas Bros Packaging Co, 2533 SW Blvd, Kansas City, MO 64108.

1282

TABLE 53-3 -- Approximate Daily Calorie Guidelines*

BODY WEIGHT (pounds)	LIGHT HIKING	BACKPACKING	
		LIGHT	HEAVY
100–120	2000	2500	3500
130–150	2500	3000	4000
160–180	3000	3500	4500
180–200	3500	4000	5000

*Target calorie levels for food item selection; modify according to weight and work level and prior experience.

kcal for women adequately covers most situations ([Table 53-3](#)). If the task is hard physical work in the cold, 4000 to 6000 kcal/day may be needed. An allowance of 45 to 55 kcal/kg body weight/day generally covers energy needs for most moderate to moderately heavy levels of exertion (e.g., for a 70-kg individual anticipating moderate work levels: 50 kcal/kg/day × 70 kg body weight = 3500 kcal/day). These are only approximate guidelines because of differences in gender, body size, workload, and environment.

**Box 53-4. HOMEOSTATIC
RESTORATION OF NUTRITIONAL
STATUS IN SEVERELY
MALNOURISHED INDIVIDUALS**

1. Resolve life-threatening conditions first.
2. Initiate restoration of nutrition as soon as possible.
3. Replace nutrient tissue deficits as rapidly and as safely as possible.
4. Begin slowly to avoid metabolic disruptions.
5. Schedule frequent feedings of small amounts every 4 hours.
6. Provide diets that derive 60% to 75% of their energy from fat, which are usually well tolerated.
7. Ensure that protein source is of high biologic value (milk, eggs, meat, fish, soy isolates).
8. Supplement diets to provide K^+ , Mg^{++} , Zn^+ , and Cu^{++} . Begin Fe^{++} supplementation 1 week after the start of diet therapy. Maintain sodium at low levels initially, until peripheral edema has disappeared.
9. Introduce normal foods gradually when edema has disappeared, skin lesions have improved, and appetite has been restored.

*Modified from Torun B, Chew F:
Protein-energy malnutrition. In Shils ME et
al, editors: Modern nutrition in health and
disease, Baltimore, 1999, Williams &
Wilkins.*

The actual macronutrient composition of the food is usually less important than the total energy content, except for efforts over short periods (2 to 3 days), when carbohydrate content may be the most important consideration. If a high level of performance is anticipated (e.g., sustained or repeated high levels of power generation, working at greater than 60% oxygen capacity for prolonged periods), carbohydrate should be emphasized over fat. Approximately 50% to 60% of the daily calories should come from

carbohydrate. If weight of the provisions is an overriding consideration, maximum caloric density may be important. Lower levels of power generation (e.g., working at a slow, steady, sustained rate less than 50% oxygen capacity) can usually be supported by higher levels of dietary fat (about 50% of daily calories). Individuals with diets containing greater than 50% of the energy from fat usually require about 2 weeks to adjust to the high level of dietary fat. Most trail rations (food for 1 day) consisting of typical macronutrient content (50% carbohydrate, 35% fat, 15% protein) weigh approximately 3 to 6 pounds, depending on the degree of dehydration. The protein content of the diet should be 12% to 15% of the calories, or about 60 to 100 g/day. Higher levels of protein are feasible, but may be an inefficient source of energy and may require more water if the amino acids of the protein are deaminated, the nitrogen is excreted as urea, and the carbon skeletons are used for energy.

Palatable and nutritious arrays of backpacking foods are available at most outdoor stores specializing in camping gear. A simpler approach is to purchase packaged military food such as the Meal, Ready-to-Eat (MRE). These packaged military meals contain a balanced macronutrient, vitamin, and mineral profile. A typical MRE contains 1275 kcal (12% protein, 36% fat, 52% carbohydrate) and weighs about 1.25 pounds.* For outdoor "minimalists," commercial food bars are much better than candy bars and other "junk food" items.

Food Bars

The modern equivalents of the early explorer's pemmican are food bars. Although food bars are not as energy dense as pemmican (dried meat pulverized with fat and sometimes berries), they are more palatable and nutritious. Most bars contain 200 to 300 kcal, with significant amounts of carbohydrate and protein ([Table 53-4](#)). Most are low in fat, since they are aimed at replenishing glucose and glycogen supplies during and after physical performance. Because the market is competitive, some manufacturers include "unique" nutrients or herbal compounds, the nutritional merit of which is often more fanciful than efficacious. These additions include vitamins and minerals, medium-chain triglycerides (alternate energy source), branched-chain amino acids (special fuel for muscle), soy protein (anticancer

*Specific nutrient information about the MRE can be found at www.usariem.army.mil/mre/mre17.htm.

TABLE 53-4 -- Key Nutritional Components of Food Bars

COMPONENT	AMOUNT	FUNCTION
Carbohydrate	30 to 40 g/bar	Replenish glycogen stores.
Fiber	3 to 5 g/bar	Fiber-rich foods are scarce on the trail; prevents constipation.

Protein	5 to 10 g/bar	High-quality protein such as casein or soy may be useful in emergencies when other protein sources not available.
Fat	Variable	Usually not critical; bars with more fat are more calorie dense.
Vitamins	Greater than 30% RDA	Not normally needed but can provide "insurance"; antioxidant vitamins E and C are most important.
Minerals	Greater than 30% RDA	Ca ⁺⁺ , Mg ⁺⁺ , and Zn ⁺⁺ are most important; males may want to choose bars without Fe ⁺⁺ (possible promotion of oxidative stress), whereas females may benefit more from Fe ⁺⁺ , especially at altitude.
Temperature stability	Low melting point in heat, but chewable in cold	These factors must be determined by trial and error; frozen bars not easily consumed.
Palatability	Should "taste good"	Taste fatigue can set in rapidly with food bars; variety helps increase food intake.

RDA, Recommended dietary allowance.

effect), ginseng (for "stress"), and ginkgo biloba and choline (to improve concentration).

Emergency Food Supplies

Emergency food supplies of 250 to 350 kcal/day should be included in addition to food for calculated caloric needs. These supplies should be packed separately in case the main food supply is lost or destroyed. Individually packaged food bars, jerky, dehydrated soup mixes, and hard candy should be included, as well as a bottle of multivitamins, extra salt packets, and water disinfection supplies. These small emergency food considerations may not seem important during preparation, but perceptions rapidly change during an emergency. Finally, the most carefully planned food supply is useless unless it is eaten; foods should be palatable and comforting to the traveler, and a hot meal prepared on the trail can boost morale.

Chapter 54 - Seafood Toxidromes

Karen B. Van Hoesen
Richard F. Clark

At least three quarters of the world's population lives within 10 miles of the coast. One of the many reasons why populations congregate near the sea is the abundance of food beneath the ocean's waters. Seafood provides a significant percentage of the protein in diets of many cultures; at present, 200 to 240 million tons of fish are harvested each year, with 50% of the total coming from coastal regions. Only the depth at which we can harvest seafood restricts the variety of organisms that are edible. Americans consume 15 pounds of fish per person per year. It is becoming increasingly clear that the ocean is one of our last great food resources.

Toxic seafood was described in the Bible. Humans have recognized that toxic seafood has been associated throughout time with seasons of the year, phases of the moon, water temperature, weather conditions, waterfowl mortality, and the color of the waves that wash into shore, along with many other things. Unfortunately, none of these methods has proven entirely successful at predicting when seafood poisoning will occur.

Marine creatures that are poisonous to eat include dinoflagellates, coelenterates, mollusks, echinoderms, crustaceans, fishes, turtles, and mammals. Most marine biotoxins are naturally occurring poisons derived directly from marine organisms, including phytotoxins (plant poisons) or zootoxins (animal poisons). Ingestible toxins may be classified by specific toxin or by the donor organ of origin ingested by the victim. *Ichthyosarcotoxin* is a general term for poison derived from the fresh flesh (muscle, viscera, skin, or slime) of any fish. This is further defined by specific organ system. Geographic location, dietary and clinical histories, and appropriate index of suspicion figure prominently in the diagnosis and treatment.

Data on food-borne disease outbreaks in the United States demonstrate that seafood is the third most reported category according to vehicle of transmission (unknown vehicles ranked first and multiple vehicles ranked second).^[71] Some 90% of the outbreaks of seafood-related illnesses and 75% of individual cases come from contaminated raw molluscan seafood (e.g., oysters and clams), histamine poisoning (scombroid) and

ciguatoxin found in reef fish species.[\[299\]](#)

MONITORING PROGRAMS FOR PHYCOTOXIN-PRODUCING MARINE ALGAE AND SEAFOOD POISONINGS

Despite the increasing risk of human intoxication from contaminated seafood, standards and methods of screening and law enforcement vary throughout the world.^[430] According to the U.S. Department of Agriculture, imports account for more than 55% of total U.S. seafood consumption. The largest source of seafood imports comes from Canada, Asia, and Latin America. The U.S. Food and Drug Administration (FDA) has been criticized for inadequate inspection of all food imports.^[299] In 1995 the FDA switched to a new program for seafood safety known as the Hazard Analysis and Critical Control Point (HACCP) system. This program became mandatory for the seafood industry on December 18, 1997.^[137] HACCP focuses on the identification of sources and points of contamination, levels, transmission, rate and transport of microorganisms, and the possibility of exposure of the consumer to the contaminant. HACCP focuses on preventing hazards rather than relying on spot-checks and random sampling of products. The most effective control strategies can then be implemented. For shellfish- and viral-associated diseases, the data suggest that harvesting from unapproved sources is associated with more than 30% of the outbreaks.^[256] For imports the biggest risks relate to histamines and scombroid poisoning, mainly from tuna and mahimahi that is imported from Argentina, Taiwan, and Ecuador. For these foods traveling great distances, refrigeration is the most critical control point.

The United States is the second largest importer of shrimp in the world. Shrimp aquaculture currently accounts for approximately 30% of the world's supply. Antibacterials are routinely used outside the United States for shrimp aquaculture.^[311] Irradiation of seafood products is still being considered for approval by the FDA, although it is currently used in Asian and European markets, especially for shrimp.^[10]

Molluscan poisoning is mainly a problem with domestic seafood. In 1991, California was the first state to require restaurants that serve or sell Gulf Coast oysters to warn prospective customers about possible deleterious effects from *Vibrio* contamination, particularly *Vibrio vulnificus*.^[329] Florida and Louisiana have adopted these warning regulations. Additionally, fishermen are

now required to refrigerate oysters within 6 hours after harvesting from the Gulf of Mexico. Regulations require oyster lot tagging, labeling, and record retention to facilitate trace back investigations of outbreaks. The United States and Canada allow the sale of oysters if there are less than 10,000 colony-forming units (CFU) per gram of *Vibrio*

parahaemolyticus. However, in recent outbreaks in the Pacific Northwest in 1997 and New York in 1998, oysters had less than 200 *V. parahaemolyticus* CFU/g of oyster meat, suggesting that human illness can occur at lower levels.^[73] ^[75]

Approximately a third of U.S. shellfish beds carry bans or limitations on harvesting because of high levels of fecal coliform bacteria. The fecal indicator system for shellfish-harvesting waters has been effective in protecting consumers against general types of bacteria fecal contamination. However, several pathogenic bacteria are not predicted by the system. The efficacy of methods for virus recovery may range from 2% to 47%.^[447] The most promising of the new detection methods are based on molecular techniques. Deoxyribonucleic acid (DNA) hybridization and the polymerase chain reaction (PCR) have an advantage of specificity for particular pathogens, sensitivity, and speed (most assays are completed within a few hours). PCR has been used in shellfish to detect *Salmonella*, *Vibrio* species, and viruses, including hepatitis A virus and Norwalk virus. Phycotoxin-producing marine algae are responsible for the syndromes of paralytic, neurotoxic, and diarrhetic shellfish poisoning. The closure of fisheries (product harvest areas) depends on the density of algae. In some cases the decision to close a fishery is based on the toxicity level in shellfish; in others, algae in the water and toxin in shellfish must both be found. In Florida, more than 5000 cells per liter of *Ptychodiscus breve* must be detected before fisheries are closed. The quarantine level of saxitoxin ranges across countries from 40 to 80 mg of toxin per 100 g of seafood.^[21] The upper number, as determined by mouse bioassay, is used in the United States, as monitored by the Interstate Shellfish Sanitation Conference and the FDA.

The maximum acceptable concentration of diarrhetic shellfish toxin, okadaic acid, also varies between countries because of the lack of precise analytic methods for quantification. Countries with established regulations apply 4 to 5 mouse units or 20 to 25 microgram equivalents of okadaic acid as an acceptance limit. In the United Kingdom the Ministry of Agriculture, Fisheries and Food (MAFF) shellfish surveillance program tests shellfish harvested weekly from April to October and sporadically during the winter for the presence of toxins.^[357] The United States, Canada, and Portugal monitor for domoic acid (cause of amnesic shellfish poisoning) and use 2 mg/100 g of seafood as the threshold. Ciguatoxins are monitored infrequently because of difficulties associated with the assay. In French Polynesia, 0.06 ng/g of seafood of ciguatoxin as determined by mosquito bioassay is considered toxic; in the United States, detection of the toxin at any level by immunoassay (Florida, Hawaii) renders the fish unsaleable.

Two features render toxin surveillance difficult: the performance problems of the assays and the impracticality of surveying every fish. As mentioned above, PCR holds the most promise for rapid, specific, and sensitive detection of pathogens.

ICHTHYOSARCOTOXISM

The term *ichthyosarcotoxism* describes a variety of conditions arising as the result of poisoning by fish flesh. The toxins are generally not destroyed by heat or gastric acid. Various toxins may be contained in the musculature, viscera, blood, skin, and mucus secretions. Further classification can be divided into poisoning based on the specific organ system and includes ichthyocrinotoxins (glandular secretions), ichthyohemotoxins (blood poisoning), ichthyohepatotoxins (liver), ichthyootoxins (toxic gonads), ichthyoallyeinotoxins (hallucinatory fish poisoning), and gempylotoxins.

Ichthyocrinotoxication

Ichthyocrinotoxic fish poisoning is induced by the ingestion of glandular secretions not associated with a specific venom apparatus; this usually involves skin secretions, poisonous foams, or slimes. Examples of toxic fish are certain file fish, puffer fish, porcupine fish, trunk fish, box fish, cow fish, lampreys, moray eels, and toadfish ([Box 54-1](#)). Cyclostome poisoning results from ingestion of the slime and flesh of certain lampreys and hagfishes. Pahutoxin and homopahutoxin have been isolated from the secretion of the Japanese boxfish *Ostracion immaculatus*.^[143]

Ichthyotoxic skin secretions may cause a bitter taste.^[159] Ingestion of ichthyocrinotoxins causes gastrointestinal symptoms within a few hours of ingestion and is characterized by nausea, vomiting, dysenteric diarrhea, tenesmus, abdominal pain, and weakness. Most victims recover within 24 hours; however, some individuals may have symptoms for up to 3 days. Therapy is supportive and based on symptoms. Additionally, some slime, such as "grammistin" from the soap fish (*Rypticus saponaceous* of the family Grammistidae), can cause a contact irritant dermatitis.^[184] The dermatitis is managed with cool compresses of aluminum sulfate and calcium acetate (Domeboro).

All suspect fish should be washed carefully with water or brine solution and skinned before eaten. Puffer skin is extremely toxic. Care must be taken to avoid toxin contact with the eyes.

maculosa*: toadfish

Ichthyohemotoxication

Ichthyohemotoxic fish are perfused with "poisonous blood," the toxicity of which is usually inactivated by heat and gastric juice. Examples are various eels, such as morays, anguilliformes, and congers. The syndrome is predominantly gastrointestinal and should be treated according to symptoms. Hematologic complications are rare. The risk of intoxication is increased by ingestion of raw or undercooked fish.

Ichthyohepatotoxication

Ichthyohepatotoxic fish carry the toxin predominantly in the liver. The remainder of the fish may be nontoxic. Fish that are always toxic fall into two basic groups: (1) Japanese perchlike fish (e.g., mackerel, sea bass, porgy, sandfish); and (2) tropical sharks (e.g.,

requiem fish, sleeperfish, cowfish, great white shark, catfish, hammerhead, angelfish, Greenland fish, dogfish).^[315] In addition, some skates and rays, which share a similar phylogeny with sharks, harbor ichthyohepatotoxins.

Ingestion of the Japanese perchlike fish group causes onset of symptoms within the first hour, with maximum intensity over the ensuing 6 hours. ^[382] Symptoms include nausea, vomiting, headache, flushing, rash, fever, and tachycardia. No fatalities have been reported. Delayed (24 to 48 hours) necrodermolysis is rare.

Ingestion of tropical shark liver (and occasionally of the musculature), such as that of the Greenland shark (*Somniosus microcephalus*), results in "elasmobranch poisoning" ([Box 53-2](#)). ^[28] Symptoms are noted within 30 minutes of ingestion and include nausea, vomiting, diarrhea, abdominal pain, malaise, diaphoresis, headache, stomatitis, esophagitis, muscular cramps, arthralgias, paresthesias, hiccups, trismus, hyporeflexia, ataxia, incontinence, blurred vision, blepharospasm, delirium, respiratory distress, coma, and death. Recovery varies from several days to weeks. If only the flesh is eaten, the symptoms are mild and gastroenteric, with spontaneous resolution.

In 1993, 200 people in Madagascar were poisoned after ingesting a single shark identified as *Carcharhinus leucas*. The attack rate was 100% with a case fatality ratio of 30%. Two liposoluble toxins were isolated from the shark liver and named carchatoxin-A and -B. ^[46] Trimethylamine oxide, which is found in shark liver

and flesh, has also been implicated in shark poisoning.^[13] A similar syndrome occurs in sled dogs that ingest large quantities of shark flesh.

Therapy is supportive and based on symptoms. If the victim is treated within 60 minutes of ingestion of shark liver or other viscera, gastric emptying or lavage followed by administration of activated charcoal (50 to 100 g) may be of value. Fish liver should not be eaten; indeed, neither should any shark viscera. Drying the flesh properly may minimize the toxicity.

Ichthyootoxication

Ichthyootoxic fish possess toxic gonads, which may vary in toxicity with the reproductive cycle. The musculature is generally nontoxic. Examples are the sturgeon, alligator gar, salmon, pike, minnow, carp, catfish, killifish, perch, and sculpin. Sea urchins may be toxic during the reproductive period.^[28] This toxicity is exemplified by *Paracentrotus lividus* (Europe), *Tripneustes ventricosus* (West Africa), and *Diadema antillarum* (West Indies).

Symptoms begin within an hour of ingestion and include nausea, vomiting, diarrhea, headache, dizziness, fever, thirst, xerostomia, bitter taste, tachycardia, seizures, migraine, paralysis, hypotension, and death. Treatment is supportive and based on symptoms. The roe of any fish should not be eaten during the reproductive season. Heat will not inactivate the toxin.

Ichthyoallyeinotoxication

Ichthyoallyeinotoxic fish induce hallucinatory fish poisoning. These fish are predominantly reef fish of the tropical Pacific and Indian reefs, which carry the heat-stable toxins mainly in the head parts, brain, and spinal cord, and in lesser amounts in the musculature. Typical species include surgeonfish, chub, mullet, unicornfish, goatfish, sergeant major, grouper, rabbitfish, rock cod, drumfish, rudderfish, and damselfish. Hallucinatory mullet poisoning has been described as a seasonal condition that occurs only during the summer months in restricted areas on the Hawaiian islands of Kauai and Molokai.^[186] Dangerous species include the mullet, surmullet or goatfish, rudderfish, and surgeonfish.

Symptoms can develop within 5 to 90 minutes of ingestion and include dizziness, circumoral paresthesias, diaphoresis, weakness, incoordination, auditory and visual hallucinations, nightmares, depression, dyspnea, bronchospasm, brief paralysis, and pharyngitis.^[28]

No fatalities have been reported. Various toxins including indoles akin to lysergic acid diethylamide (LSD) have been implicated with sources in algae and plankton eaten by

the fish.^[374]

Therapy is supportive and based on symptoms. Haloperidol may be used as an antipsychotic agent if the victim is psychotic and violent. Mild agitation may be eased with small graded doses of diazepam, particularly if the victim also suffers anticholinergic symptoms. The victim should be observed until a normal mental status is regained. The head, brain, or spinal cord of any tropical fish should not be eaten. Heat does not inactivate the toxin.

Gempylotoxication

Gempylotoxic fishes are the pelagic mackerels, which produce an oil with a pronounced purgative effect. The "toxin" is contained in both musculature and bones. No particular characteristic distinguishes a gempylotoxic fish from a nontoxic fish of the same species. The castor oil fish (*Ruvettus pretiosus*) is named for its purgative properties.

The victim suffers from abdominal cramping, bloating, mild nausea, and diarrhea, usually within 30 to 60 minutes of ingestion. The disorder is self-limited and resolves over 12 to 18 hours. The diarrhea often occurs without concomitant systemic effects. Fever, bloody or foul-smelling stools, or protracted vomiting suggest infectious gastroenteritis. No specific antidote is recommended. If the victim cannot tolerate oral fluids because of nausea or severe abdominal cramping, intravenous fluid supplementation may be initiated. Antimotility agents, such as diphenoxylate with atropine, are not recommended unless the diarrhea is debilitating because inhibition of peristalsis prolongs the transit time of the toxin through the gut and may increase the duration of the disorder.

SPECIFIC FISH-RELATED TOXIC SYNDROMES

Two specific toxic syndromes related to fish consumption are scombroid poisoning and tetrodotoxin (puffer-fish poisoning) ([Table 54-1](#)). Carp gallbladder poisoning is also discussed below.

Scombroid Poisoning

Scombroid fish poisoning, the most commonly reported seafood poisoning in the United States, occurs when certain species of fish are improperly handled and stored after catch. These most often consist of fish from the family Scombridae that includes albacore, bluefin and yellowfin tuna, mackerel, saury, needlefish, wahoo, skipjack, and bonito ([Figure 54-1](#)). Nonscombroid fish that produce scombroid poisoning include mahimahi (dolphin), kahawai, sardine, black marlin, pilchard, anchovy, herring, amberjack (yellowtail or kahala), and the Australian ocean salmon *Arripis truttaceus*.^[273]^[364]^[379]^[407] In Hawaii the most commonly implicated fish is the dolphin *Coryphaena hippurus*. In the northeastern United States, bluefish (*Pomatomus saltratrix*) has recently been linked to scombroticism.^[321] Scombroid poisoning accounts for 5% of food-related outbreaks reported to the Centers for Disease Control

1289

and Prevention (CDC) in Atlanta.^[409] Because greater numbers of nonscombroid fish are now recognized as "scombrototoxic," Prescott^[321] has suggested that the syndrome be more appropriately called *pseudoallergic fish poisoning*.

Pathophysiology.

During conditions of inadequate preservation or refrigeration (optimal temperatures for bacterial growth of 37° to 43° C [98.6° to 109.4° F]), the musculature of dark-fleshed or red-muscled fish undergoes bacterial decomposition.^[33]^[315] The normal piscine surface bacteria *Proteus morgani*, *Klebsiella pneumoniae*, *Aerobacter aerogenes*, *Escherichia coli*, *Alcaligenes metalcaligenes*, and others have been implicated in the putrefactive process, which includes the decarboxylation of the amino acid L-histidine to histamine and saurine (histamine PO₄ and histamine HCl).^[407] The term *saurine* originated because of the association of scombroticism with saury, a Japanese dried fish delicacy.^[193] Because of this process, "scombrotocin" was initially thought to be histamine, which is commonly found in large amounts in the flesh of usually implicated fish. Evidence initially suggesting that histamine may be the causative toxin of

scombroid fish poisoning was presented in an investigation of a small outbreak.^[286] The urinary excretion of histamine and its metabolite, *N*-methylhistamine, was measured in three persons who had scombrotosis after ingestion of marlin. The marlin contained levels of histamine from 842 to 2503 mmol per 100 g of tissue. Urine samples collected 1 to 4 hours after fish ingestion demonstrated histamine and *N*-methylhistamine levels 9 to 20 times and 15 to 20 times the normal mean, respectively. The authors failed to measure any increase in the principal metabolite of prostaglandin D₂, a mast cell secretory product considered to indicate release of histamine from mast cells. This supported the hypothesis that the excess histamine was from the fish rather than endogenously produced in the victims. Histamine levels greater than 20 to 50 mg/100 g are frequently noted in scombrotic fish, and it is not unusual to record levels in excess of 400 mg/100 g. Normal fresh fish contains less than 1 mg/100 g of histamine.^[364] Affected fish typically have a sharply metallic or peppery taste but may be normal in appearance, color, and flavor. However, not all persons who eat a scombrotic- or histamine-contaminated fish become ill, possibly because of uneven distribution of decay within the fish. It is possible that some other compound may be responsible for scombroid symptoms, since the syndrome cannot be reproduced solely by the administration of equal or even massive doses of histamine by the oral route. Histamine is rapidly inactivated by enzymes in the gastrointestinal tract and on first pass through the liver, with very little reaching systemic circulation. It has been speculated that some other compound, such as cadaverine or putrescine, may be present in the decomposed fish flesh that either facilitates the absorption or inhibits the gastrointestinal or hepatic degradation of histamine.^{[345] [407]} The toxin is heat stable and not destroyed by cooking.

Clinical Presentation.

The effects of scombroid fish poisoning occur within minutes of consumption of the fish. Although not an allergic reaction, the symptoms are similar and typically include headache, diffuse erythema, a sense of warmth without elevations in core temperature, nausea, vomiting, diarrhea, abdominal cramps, conjunctival injection, pruritus, dizziness, and a burning sensation in the mouth and oropharynx.^{[220] [273]} Flushing of the head, neck and upper torso is characteristic and may be exacerbated by ultraviolet light. Severe effects, such as bronchospasm, generalized urticaria, hypotension, palpitations, and arrhythmias, have been reported but are not frequent.^{[155] [193]} In most healthy victims the syndrome is self limited, resolving within 8 to 12 hours. In patients with preexisting respiratory or cardiac disease, the effects of the poisoning can precipitate a more severe illness.^{[48] [273]} Scombroid reactions may be markedly more severe in patients concurrently ingesting isoniazid (INH) because of this compound's blockade of gastrointestinal tract histaminase.^[428] Death has never been reported after scombroid poisoning.

Treatment.

The use of emesis or other methods of gastric decontamination for scombroid poisoning is not indicated because symptoms occur rapidly, vomiting can be a primary effect of the toxin, and induced emesis has not been demonstrated to be helpful. The oral administration of activated charcoal may be beneficial, although this has not been studied. Symptoms can be lessened or controlled with the administration of histamine-1

(H₁) receptor antagonists, such as diphenhydramine or hydroxyzine, administered initially in doses of 25 to 50 mg orally or intravenously. The use of histamine-2 (H₂) receptor antagonists (e.g., cimetidine, famotidine) has also been shown to relieve most of the symptoms, and perhaps a combination of H₁ and H₂ receptor antagonists may be most effective.^[44] ^[168] Gastroenteritis is usually controlled by an antihistamine but occasionally requires the addition of a specific antiemetic, such as prochlorperazine. The persistent headache of scombroid poisoning may respond to cimetidine or a similar drug if standard analgesics are not effective.^[19] Intravenous fluids and inhaled bronchodilators should be used as needed. Vasopressors are rarely necessary because hypotension is usually mild.

1290

1291

TABLE 54-1 -- Summary of Fish- and Algae-Related To

TOXIDROME	SEAFOOD INVOLVED	AREAS COMMONLY SEEN	CAUSATIVE ORGANISMS	TOXIN PRODUCED	MECHANISMS OF ACTION
FISH-RELATED TOXIC SYNDROMES					
Scombroid	Albacore, tuna, wahoo, mackerel, skipjack, bonito, mahimahi	Worldwide	Bacteria within the fish transform histidine to histamine	Histamine, saurine	Histamine response
Tetrodotoxin	Puffer fish, "fugu," porcupine fish, sunfish	Tropical and subtropical	? <i>Pseudomonas</i> species	Tetrodotoxin	Na ⁺ channel blocker, blocks axonal transmission

ALGAE BLOOM-RELATED TOXIC SYNDROMES

Ciguatera	Tropical and semitropical reef fish such as barracuda, grouper, snapper, jack	Worldwide, most common in Indian Ocean, South Pacific, Caribbean	<i>Gambierdiscus toxicus</i> and other species	Ciguatoxin, maitotoxin, GT1-4, palytoxin	Na ⁺ channel blocker
Clupeotoxin	Herring, sardines, anchovies, tarpons, bonefish	Caribbean, Indo-Pacific, Africa	<i>Ostreopsis siamensis</i>	Palytoxin	Inhibits Na ⁺ -K ⁺ ATPase
PSP	Shellfish	NE and NW coast of US, Philippines, Alaska, North Sea	<i>Protogonyaulax</i> , <i>Alexandrium catarella</i> , <i>Pyrodinium</i> , <i>Saxidomus</i> , <i>Gonyaulax</i>	Saxitoxin, neosaxitoxins, gonyautoxins	Na ⁺ channel blocker, may suppress AV nodal conduction
NSP	Shellfish	Gulf of Mexico, Florida, Texas, North Carolina, New Zealand	<i>Ptychodiscus breve</i>	Brevetoxins	Modulate Na ⁺ channel
DSP	Shellfish	Japan, Spain, Netherlands, Chile	<i>Dinophysis</i> , <i>Prorocentrum</i>	Okadaic acid and others	Phosphatase A ₁ and A ₂ inhibitor
Domoic acid	Shellfish	Canada, Japan, NE and NW USA	<i>Nitzschia pungens</i> , <i>Pseudonitzschia australis</i>	Domoic acid	Glutamate antagonist

<i>Pfiesteria</i> syndrome	Estuarine fish	Coastal waterways in eastern USA and Gulf coast	<i>Pfiesteria piscicida</i>	Unidentified	Unknown
Haff disease	Buffalo fish	USA, Russia, Sweden	? Blue-green algae	Unknown	Unknown

IVF, intravenous fluid; *ATPase*, adenosine triphosphatase; *PSP*, paralytic shellfish poisoning; *AV*, atric diarrhetic shellfish poisoning.

1292

Figure 54-1 Schooling jacks. This type of fish can cause scombroid poisoning.
(Karen Van Hoesen, MD.)

Prevention.

Scombroid fish poisoning is a preventable illness and can be avoided if the offending fish species are promptly refrigerated below 15° C (59° F) or iced after catch and maintained until the fish is cooked or processed for storage. Recreational fishermen must pay particular attention to their coolers. No fish should be consumed if it has been handled improperly or has the smell of ammonia. Fresh fish generally has a sheen or oily rainbow appearance; "dull" packaged fish should be avoided. If an episode of scombroid poisoning is recognized, it is important to report it promptly to local public health authorities to prevent exposure of additional people, particularly if the food was served in a public eating establishment.^[194]

Tetrodotoxin Fish Poisoning

Tetrodotoxin (TTX) is a potent neurotoxin found in a variety of creatures and has been isolated from animals of four different phyla, including puffer fish, the California newt, the blue-ringed octopus, poison dart frogs, the ivory shell, and the trumpet shell. The puffer fish, also known as the blowfish or globefish, is one of the better-recognized species that contains TTX. These species of fish can be found in both freshwater and

salt water.^[173] In humans the most common exposure to TTX is through the ingestion of fugu, a specially prepared species of puffer fish. Human TTX poisonings have also occurred after consumption of gastropod mollusks.^[461] Envenomation from the blue-ringed octopus is rare.^[135]

Puffer fish poisoning has been recognized for millennia. Ancient Oriental literature documents the dangers of eating puffer fish.^[173] There are references to puffer fish in hieroglyphics of the ancient Egyptian dynasty of 2700 BC. Scholars suggest this fish was known to be poisonous during Egyptian times. Mosaic sanitary laws against eating fish without fins and scales may have been derived to avoid fish containing TTX; the TTX containing fish in the region inhabited by the Israelites were scaleless.^[173]

Captain Cook recorded in 1774 his experience after eating a piece of liver from a puffer fish purchased from a native fisherman.^[438] Before preparing the fish for eating, it was described and drawn. Cook tasted the liver and described a vivid feeling of extraordinary weakness and numbness.^[173] There has been some contention that TTX ("puffer powder") was used as a component of Haitian voodoo potion in the zombie ritual.^[421] This has been challenged on grounds, among others, that under the usual conditions of extreme alkaline storage, any TTX in a "zombie potion" would be decomposed irreversibly into pharmacologically inactive products.^{[217] [464]}

Tetrodotoxin was named around 1911 after searching for the active ingredient in fugu ovaries.^[140] Isolation of the chemical was achieved in the 1950s. In 1964, tarichatoxin, a nonprotein neurotoxin, was confirmed to be the same molecule as TTX.^[287] This compound is found in the California and Japanese newts (e.g., *Taricha granulosa*, *Notophthalmus viridescens*, *Cynops ensicauda*); international salamanders of the family Salamandridae (e.g. *Triturus*, *Pleurodeles*, *Cynops*, *Paramesotriton*, *Tylototriton*); the skin of central American frogs of the genus *Atelopus*; the goby *Gobius criniger*; shellfish (ivory shell, *Babylonia japonica*; lined moon shell, *Natica lineata*; calf moon shell, *Natica vitellus*; bladder moon shell, *Polinices didyma*; and trumpet shell, *Charonia sauliae*); the starfish *Astropecten polyacanthus*; the ribbon worm *Cephalothrix linearis*; the flatworm *Planocera multitentaculata*; the crab *Atergatus floridus*; the horseshoe crab *Carcinoscorpius rotundicanda*; and the Australian blue-ringed octopus (*Hapalochlaena maculosa*).^{[135] [140] [173] [395] [461]} In the 1970s the major toxin in certain poison dart frogs was identified as TTX. In 1978, isolation of crystalline TTX was performed.

Fugu.

TTX is characteristic of the order Tetraodontiformes.^[395] The suborder Tetrodontoidei contains three families of fish (Tetraodontidae, Diodontidae, and Canthigasteridae), including pufferfish ([Figure 54-2](#)) (toadfish, blowfish, globefish, swellfish, balloonfish, toado) and porcupine fish. Sunfish (*Mola* species) are members of the suborder Moloidei. Pufferfish are tropical and subtropical, some of which are prepared as delicacies called fugu.^[70] Pufferfish can inflate their bodies to a nearly spherical shape using air or seawater ([Figure 54-3](#)). At least 50 of the more than 100 species of these fish have been involved in poisonings of humans or may be intermittently toxic.^[344]

Chefs must undergo a rigorous certification process before they are allowed to prepare

fugu. The filet of the puffer fish contains very minute concentrations of TTX. Fugu is served raw with paper-thin slices placed into an ornate configuration. The presence of small

1293

Figure 54-3 Porcupine fish inflated with seawater. (Karen Van Hoesen, MD.)

quantities of TTX gives the desired effect of slight oral tingling. Importation of fugu into the United States is illegal; however, smuggling has resulted in cases of poisoning.

The precise origin of the toxin may be production by *Pseudomonas* species that live on the skin of the puffer fish.^[470] This would explain transmittal of toxicity between toxic and nontoxic fish through skin contact. Other investigators have found the production of tetrodotoxin by *Vibrio* and other species isolated from the intestines of puffer fish.^[443] Radiolabeled tetrodotoxin injected into a puffer accumulated most in skin, liver, intestines, and muscle; however, the toxin is concentrated in the liver, viscera, gonads, and skin of the fish. Female fish are considered more toxic than males especially because there are high concentrations of TTX in ovaries. Musculature is less toxic but still may contain a significant amount of TTX. The toxin is heat stable and is not inactivated by freezing. Seasonal variation of TTX concentration occurs with peak levels during spawning season.

Pathophysiology.

Tetrodotoxin has a unique nonprotein structure and is widely used as a research tool to study sodium channels. Mouse bioassays demonstrate that the minimal lethal dose of TTX by intraperitoneal injection is 8 to 20 $\mu\text{g}/\text{kg}$.^[287] Tetrodotoxin blocks sodium channels during the rising phase of the action potential.^[216] The interaction of TTX with the sodium channel is thought to be stoichiometric with each TTX molecule interfering with one channel. Tetrodotoxin affects the spike generating process of sodium

channels, not the resting or steady state voltage.^[216]

TTX interferes with both central and peripheral neuromuscular transmission. Although it is not a depolarizing agent, in animals it causes depression of the medullary respiratory mechanism, intracardiac conduction, and myocardial and skeletal muscle contractility. At the microcellular level the mechanism of action of TTX is linked to the axon, rather than to the nerve endplate. TTX blocks axonal transmission by interfering with sodium conductance within the depolarized regions of the cell membrane, perhaps by acting at a metal cation binding site in the sodium channel, without affecting the presynaptic release of acetylcholine or its effects on the neuromuscular junction.^[5] ^[188] Saxitoxin, implicated in paralytic shellfish poisoning, has essentially the same action as tetrodotoxin on the nerve membrane, although it is believed to have a discrete receptor.^[219] There is no apparent effect on potassium permeability.^[342] The LD50 for mice is 10 mg/kg when TTX is administered by intraperitoneal, intravenous, or subcutaneous routes. ^[419]

Animal studies suggest that TTX has a peripheral effect that results in vasodilation independent of α or β receptors.^[216] ^[219] Further studies suggest a dose-dependent action. At low doses, systemic blood pressure is lowered, although perfusion pressure is initially maintained. Higher doses of TTX result in a profound fall in blood pressure. ^[216] Experiments with animal models using TTX from blue-ringed octopi demonstrate a similar profound hypotension. α -Agonists have been the most effective agents in raising blood pressure in models of TTX poisoning. ^[135]

Clinical Presentation.

The onset of symptoms after TTX administration can be as rapid as 10 minutes or delayed up to 4 hours, but usually occurs within 30 minutes of ingestion. Death has been recorded within 17 minutes of exposure. The extent and type of symptoms vary according to the individual and the amount of TTX ingested. Paresthesias of the lips and tongue

initially occur and may be rapidly followed by hypersalivation, diaphoresis, lethargy, headache, weakness, ataxia, incoordination, tremor, paralysis, cyanosis, aphonia, dysphagia, seizures, dyspnea, bronchorrhea, bronchospasm, respiratory failure, coma, and hypotension. Gastrointestinal symptoms can be severe and include nausea, vomiting, diarrhea, and abdominal pain.^[375] Paresthesias advance to the extremities often with severe numbness that has been described as a feeling of the body "floating." Hypersalivation with diaphoresis is common. Motor paralysis may occur with the onset of weakness, incoordination, hyporeflexia, and cranial nerve dysfunction. Weakness and paralysis may appear in the upper extremities and descend to the lower extremities.^[344] Early miosis may progress to mydriasis with poor pupillary light reflex.^[419] A disseminated intravascular coagulation-like syndrome may occur and is heralded by petechial skin hemorrhages that can progress to bullous desquamation and diffuse

stigmata of prolonged coagulation. Hypotension can be profound and may be refractory to treatment. Respiratory distress and insufficiency can occur. Bradycardia and atrioventricular node conduction abnormalities may be present. Complete cardiovascular collapse with respiratory paralysis precedes death. Normal consciousness may be maintained until shortly before death.^[140] Sixty percent of victims may die, most of these within the first 6 hours. Survival past 24 hours is a good prognostic sign.

Treatment.

Treatment of TTX is primarily supportive with aggressive airway management and assisted ventilation. Decontamination should be considered with a dose of activated charcoal given on early presentation. Since the toxin may be partially inactivated in alkaline solutions, gastric lavage with at least 2 L of 2% sodium bicarbonate in 200-ml aliquots has been recommended. However, the efficacy of this therapy has never been studied, and since many patients will have gastroenteritis before presentation to a health care facility, this practice is unlikely to be of much benefit. Atropine may be used to treat bradycardia in conjunction with adequate oxygenation. Intravenous fluid resuscitation should be initiated for hypotension; however, use of inotropic agents may be required to maintain perfusion. α -Agonists such as phenylephrine or norepinephrine are more likely to be effective.

Anticholinesterase agents such as edrophonium have been used to treat victims of TTX poisoning with mixed success. There have been case reports that suggest subjective improvement in the neurologic symptoms after administration of anticholinesterase agents.^[83] ^[419] Other case reports noted no improvement after infusion of these compounds.^[263] ^[416] A review of earlier studies shows that TTX is not antagonized by anticholinesterase agents since the toxin interrupts neuromuscular transmission on motor neurons and muscle membranes and not the motor endplate.^[215] The administration of veratrine-like agents, which prolong skeletal muscle contraction without dependence on intact neuromuscular transmission, provides prophylactic protection against the action of TTX on sciatic nerve anterior tibial muscle preparations from rats.^[342] Applicability of this to human clinical situations is unclear. Antihistamines and steroids have also been utilized with no clear benefit.^[263]

No antidote is currently available to treat TTX poisoning; however, studies are ongoing. TTX has been conjugated to keyhole limpet hemocyanin and the conjugate used as an immunogen in rabbits and mice. Mice immunized with the conjugate were protected from a lethal dose of toxin, and passive protection experiments using rabbit antiserum exhibited a dose-related therapeutic activity after toxin challenge.^[141] The shore crab *Hemigrapsus sanguineus* is highly resistant to TTX by virtue of a toxin-binding substance.^[368] Whether this natural phenomenon can be applied to the human situation remains to be seen.

A minor intoxication with TTX may be limited to paresthesias and mild dysphagia. In such a case the victim should be observed in the emergency department or intensive care unit for at least 8 hours to detect deterioration, particularly in respiratory function. The victim should not be discharged until the symptoms are clearly improving. Although

water soluble, TTX is very difficult to remove from fish, even by cooking. It is wisest to avoid all puffers, even when prepared by an expert.

Grass Carp Gallbladder Poisoning

Ingestion of the Asian freshwater grass carp (*Ctenopharyngodon idellus*) or other similar fishes (*Cyprinus carpio*) can lead to serious illness, attributed to the nephrotoxic and hepatotoxic properties of a toxin found in the bile.^[78] The structure of the toxin in *C. carpio* has recently been characterized as 5 μ -cholestane-3 μ , 7 μ , 12 μ , 26,27-pentol 26-sulfate.^[17] Most cases have occurred in Hong Kong, Taiwan, and South Korea. Two recent cases were reported in the United States in immigrants who ate raw gallbladders from carp caught in Maryland.^[68] One of the patients required hemodialysis for acute renal failure. His renal and hepatic function gradually improved.

People eat the raw gallbladder for its putative antirheumatologic properties. Several hours after ingestion, abdominal pain, nausea, vomiting, and watery diarrhea develop, which can be accompanied by marked elevations in concentrations of liver enzymes (aspartate and alanine aminotransferases). The hepatitis is transient and to date has not led to hepatic failure. Nephrotoxicity may be profound, leading to oliguric or nonoliguric renal failure within 48 to 72 hours after ingestion. Renal biopsy demonstrates acute tubular necrosis without evidence of rhabdomyolysis. Therapy

1295

is supportive and based on symptoms. Hemodialysis may be necessary until renal function improves.

POISONINGS ASSOCIATED WITH ALGAL BLOOMS

Although there are thousands of species of microalgae that form the base of the food chain, less than 60 species are toxic or harmful. These toxic species can cause significant kills of fish and shellfish, mortality among seabirds and marine mammals, and human illnesses and death. In the United States, harmful algae blooms now threaten virtually every coastal state with increasing numbers of toxic species. Several distinct clinical syndromes exist: ciguatera fish poisoning, clupeotoxic fish poisoning, paralytic shellfish poisoning, neurotoxic shellfish poisoning, diarrhetic shellfish poisoning, domoic acid intoxication, *Pfiesteria* syndrome, and Haff disease (see [Table 54-1](#)).

Ciguatera Fish Poisoning

Worldwide, ciguatera accounts for more cases of fish-borne illness than any other type of ichthyosarcotoxicosis.^[59] Ciguatera is most commonly seen in the Indian Ocean, South Pacific, and Caribbean. In the United States, ciguatera poisoning is the most common nonbacterial food poisoning associated with fish, with cases having been reported in many states.^{[148] [190] [284] [440]} Outbreaks of ciguatera poisoning are greatest between the months of April and August. In endemic areas the incidence is estimated to be between 500 and 600 cases per 10,000 people.^[237] Worldwide, it has been estimated that ciguatera poisoning may affect over 50,000 persons each year. Most cases in the United States occur in Hawaii and Florida, with the incidence in Florida estimated to be five cases per 10,000 people.^[125] Outbreaks of ciguatera poisoning have been associated with the ingestion of warm water reef-dwelling fish caught between +35 and -35 degrees latitude; however, there have been recent reports of ciguatoxic fish being caught in waters at +33 degrees latitude.^{[30] [174]} In addition, the advent of flash freezing and shipping of fish around the world has accounted for several cases of ciguatera in nonendemic areas.^[190]

More than 400 species of benthic fish have been implicated in ciguatera poisoning, with the greatest concentration in the Caribbean Sea, in the Pacific Ocean around the Indo-Pacific islands, and along the continental tropical reefs. The most frequently implicated reef fishes include the families Muraenidae (moray eels), Mugilidae (mulletts), Serranidae (groupers) ([Figure 54-4](#)), Lutjanidae (snappers), Sparidae and Lethrinidae (porgies), Carangidae (jacks), Labridae (wrasses), Scaridae (parrotfishes), Acanthuridae (surgeonfishes), Balistidae (triggerfishes), and Sphyraenidae (barracuda).^[157] Of reported cases, 75% (except in Hawaii) involve the barracuda, snapper, jack, or grouper. Hawaiian carriers of the toxin include the parrot-beaked bottom feeders and surgeonfishes, particularly those inhabiting waters with high dinoflagellate populations, such as those with disturbed coral reefs.^[202] Other fish that have been reported as ciguatoxic are listed in [Box 54-3](#). Recently, ciguatera poisoning

has been

Figure 54-4 Groupers are often implicated in ciguatera fish poisoning. (*Karen Van Hoesen, MD.*)

1296

reported after the ingestion of farm-raised salmon.^[113] There is one report of ciguatera from the consumption of jellyfish.^[473]

The name *ciguatera* is derived from the Spanish name "cigua" for the sea snail *Turbo pica* found in the Caribbean Spanish Antilles.^[27] ^[414] This neurotoxic syndrome has been recognized throughout history with one of the earliest cases likely reported in the fourth century, when Alexander the Great refused to allow his soldiers to eat fish, and also during the Tang Dynasty in China.^[388] One of the earliest written records of suspected ciguatera poisoning is from the journal of Captain William Bligh, who described symptoms consistent with ciguatera on June 10, 1789, after eating dolphin fish (mahimahi).^[388] In addition, it was also quite possibly ciguatera fish poisoning that was illustrated by Captain James Cook while sailing on the *Resolution* in the South Pacific in 1774.^[312] In this episode, several of his officers were poisoned after eating fish from the island Malicolo in the Pacific nation of Vanuatu.

Pathophysiology.

The blue-green algae and free algae dinoflagellate, *Gambierdiscus toxicus*, is thought to be responsible for producing ciguatoxins.^[388] *Gambierdiscus toxicus* adheres to dead coral surfaces and marine algae, which are consumed by smaller herbivorous fish.^[157] ^[237] Although *Gambierdiscus toxicus* is likely responsible for the majority of ciguatoxins encountered in fish, the cyanobacterium *Trichodesmium erythraeum* can elaborate water- and lipid-soluble precursors to the toxins that may generate ciguatera syndrome.^[124] Other dinoflagellates, such as *Prorocentrum concavum*, *P. mexicanum*, *P. rhathymum*, *Gymnodinium sanguineum*, and *Gonyaulax polyedra*, may generate toxins that play a role in ciguatera syndrome.^[324] ^[417]

Larger reef fish eat the contaminated smaller fish, thereby becoming vectors as ciguatoxin is bioconcentrated up the food chain. As the fish within the food chain become larger and older, the toxin is accumulated.^[93] ^[184] ^[193] ^[315] Experimental induction of ciguatera toxicity in surgeonfish (*Acanthurus xanthopterus*) has been achieved by a diet of ciguatoxic red snapper (*Lutjanus bohar*).^[187] Although the entire fish is toxic, the viscera (particularly the liver) and roe are considered to carry the highest concentrations of toxin.^[29] No plankton feeders have so far been reported to be ciguatoxic.

It has been suggested that the proliferation of toxic algae may be triggered by contamination of the water from a number of sources, including industrial wastes, golf

course runoff, metallic compounds, ship wreckage, or other pollutants. ^[174] In the Marshall Islands (Micronesia), consequent to nuclear testing, the incidence of toxin-producing plankton has tripled. ^[333] Similar observations have been made with respect to various military activities (dumping and explosives) in the Line and Gilbert Islands (Kiribati, Central Pacific), Hao Atoll (Tuamotu Archipelago, French Polynesia), Gambier Islands (French Polynesia), and others. ^[341] Yet another cause for toxic dinoflagellate proliferation may be the transfer and dumping of ballast water in large oceangoing vessels.

Ciguatera fish poisoning is associated with more than five toxins, including fat-soluble quaternary ammonium compounds (ciguatoxins), a water-soluble component (maitotoxin, from the Tahitian vernacular name *maito* for the surgeonfish *Ctenochaetus striatus*), a maitotoxin-associated hemolysin (lysophosphatidyl-choline, or lysolecithin), and a ciguatoxin-associated adenine triphosphatase (ATPase) inhibitor. ^[177] ^[245] ^[251] ^[350] Scaritoxin (isolated from *Scarus gibbus*) is similar to the fat-soluble component and is specific to parrotfishes. ^[87] Lipid-extracted toxins from *Gambierdiscus toxicus* have been designated GT-1, GT-2, and GT-3; a water-soluble toxin is designated GT-4. ^[109] ^[278] Chemical analysis of ciguatoxins demonstrates that they closely resemble brevetoxin C (from *Ptychodiscus brevis*) and okadaic acid, isolated from marine sponges and the dinoflagellate *Prorocentrum lima*. ^[133] ^[290] The identification of okadaic acid from the Caribbean dinoflagellate *Prorocentrum concavum* lends support to the notion that this toxin may be more significant in ciguatera poisoning than previously thought. Another compound named prorocentrolide has also been found in reef-dwelling fish with okadaic acid and has been implicated in diarrhetic shellfish poisoning, another common fish-borne illness. ^[133] ^[192]

Three major ciguatoxins are usually found in the flesh and viscera of ciguateric fishes. They are labeled CTX-1, CTX-2, and CTX-3. Each is found in variable concentrations, which may account for the inconsistency of reported clinical signs and symptoms. ^[251] CTX-2 is a diastereomer of CTX-3. ^[254] Ciguatoxins may result from the oxidation of gambiertoxins, possibly through the cytochrome system in the liver of fish. ^[253] The lipid components have been characterized as crystalline, colorless, heat-stable compounds of approximate molecular weight 1100 daltons, with functional hydroxyl and quaternary nitrogen groups. CTX is excreted in bodily fluids and toxicity can be transmitted by both semen and breast milk. ^[58] ^[283]

Ciguatoxins activate voltage-dependent Na⁺ channels. ^[250] One mechanism of their action may be by falsely occupying calcium receptor sites that modulate sodium pore permeability in neural, muscle, and myocardial membranes. ^[35] This effect could allow increased membrane permeability to sodium and cause sustained depolarization. Electrophysiologic studies of the sural and common peroneal nerves in humans with ciguatera poisoning demonstrating reduced light touch, pain, and vibratory sensation in the extremities showed prolongation of the absolute refractory, relative refractory, and supernormal periods. These findings

indirectly suggest that CTX may abnormally prolong sodium channel opening in nerve membranes.^[60] This influx of sodium is antagonized by the presence of tetrodotoxin.^[40]

In vitro studies have also shown that scaritoxin causes the release of norepinephrine and acetylcholine and increases sodium channel permeability.^[405] Maitotoxin as well may trigger the release of norepinephrine and stimulate cellular uptake of calcium and has been hypothesized to stimulate cholinergic receptors by inhibiting acetylcholinesterase.^[40]^[374] However, evidence suggests that highly purified ciguatoxin preparations may not have anticholinesterase effects in vivo.^[244]

Palytoxin is an extremely poisonous nonprotein agent of low molecular weight that has been isolated from various zoanthid "soft" corals of the genus *Palythoa*, although its true origin is unknown.^[169] In animal models it causes a fast potassium outflow from erythrocytes, increases the permeability of cell membranes to sodium and potassium but not calcium, and inhibits sodium-potassium ATPase. Although palytoxin is presumed to originate in coelenterates or even bacteria, there has been some suggestion that it can be a causative agent for ciguatera poisoning.^[230]^[275]^[304] Ingestion in humans reportedly causes abdominal cramps, nausea, diarrhea, paresthesias of the extremities, muscle spasm, and respiratory distress. Of this cluster of symptoms, the predominant physical findings appeared to be respiratory distress and extreme tonic muscle contractions with massive accumulation of serum creatine kinase and myoglobinuria. Palytoxin has been found in mackerel (*Decapterus macrosoma*), triggerfish (*Melichthys vidua*), and crab (*Demania reynaudii*).^[7]^[142]^[230] Since a rapid and sensitive hemolysis neutralization assay for palytoxin is now available, its presence in toxic seafood, and perhaps its role in ciguatera poisoning, should become easier to determine.^[41]

Hypertension occurring with ciguatera poisoning can be suppressed in animal models with phentolamine, suggesting α -receptor sympathomimetic activity. Although purified ciguatoxin appears to have cardiac stimulatory effects (increasing heart rate and output), maitotoxin is a myocardial depressant in vitro, which may explain the variation in clinical presentation. Isolated human atrial trabeculae show concentration-dependent positive inotropy with CTX-1, which is not reversed with mannitol.^[250] Cardiac calcium conduction effects have been implicated in the activity of maitotoxin because its action is inhibited in the presence of verapamil, magnesium ions, or low-calcium solutions. In mice, injection of maitotoxin can induce a marked increase in total calcium content of the adrenal glands and a rise in plasma cortisol concentration.^[412] When injected into mice, ciguatoxin targets the heart, adrenal glands, and autonomic nervous system.^[414] Ciguatoxin and CTX-4c (a derivative) administered in repeated doses cause the mouse heart to suffer septal and ventricular interstitial fibrosis, accompanied by bilateral ventricular hypertrophy.^[410] Ciguatoxin is a potent substance, with an LD₅₀ in mice of 0.45 mg/kg in purified form. In most toxic fish flesh the concentration is 0.5 to 10 parts per billion. Maitotoxin is even more potent, with an LD₅₀ of 0.13 mg/kg in mice. It is interesting to note that ciguatoxins can become toxic to fish in higher concentrations, thus potentially limiting the levels of these compounds carried by a fish.^[249] However, the toxin or toxins may reside in the skeletal muscle or other tissues of the fish in association with proteins that may be protective of the carrier.^[170]

All toxins associated with ciguatera identified to date are unaffected by freeze-drying,

heat, cold, and gastric acid and do not affect the odor, color, or taste of the fish. There is some evidence that cooking methods can alter the relative concentrations of the various toxins. For example, boiling fish flesh will remove water-soluble toxins, but frying or grilling the flesh may increase toxicity of lipid-soluble toxins as a result of releasing lipid-soluble components from cellular compounds to which they are normally bound.^[123]

Clinical Presentation.

The meal containing ciguatera is generally unremarkable in taste and smell. Symptoms may develop within minutes of ingestion, although they generally occur within 2 to 6 hours after the meal. Almost all victims develop symptoms by 24 hours, and the toxicity can generally be ruled out if the onset is delayed longer than this time.^[27] ^[125] The severity of symptoms seems to follow a dose-dependent fashion, with victims eating larger portions of ciguatoxic fish experiencing more severe symptoms ([Box 54-4](#)).

The most common initial symptoms reported in cases of ciguatera poisoning include acute gastroenteritis, with abdominal cramps, nausea, vomiting, and diarrhea.^[27] These symptoms rarely persist for longer than 24 hours but may require fluid resuscitation.^[125] A myriad of other symptoms have been reported in ciguatoxic patients and are listed in [Box 54-4](#) . Headache is a common symptom, and victims often complain of experiencing a metallic taste. An overall death rate of 0.1% to 12% has been reported with ciguatera poisoning, but the lower percentage seems more likely with modern supportive care. Death is usually attributed to respiratory paralysis.^[211] In a well-described clinical outbreak affecting a group of scuba divers who consumed coral trout (*Cephalopholis miniatus*), the most common symptoms were weakness, cold sensitivity, paresthesias, a taste sensation of "carbonation," and myalgias.^[3] Two men suffering from ciguatera poisoning had painful ejaculation with urethritis, which in turn induced dyspareunia (pelvic and vaginal burning) in their female partners after intercourse.^[238] The variations in symptoms of ciguatera poisoning may result from different concentrations

of specific toxins in different fish.^[229] Characteristics associated with a severe attack include ingestion of a carnivorous fish and a history of previous ciguatoxism.^[158] Neurologic symptoms seem to develop after initial gastrointestinal symptoms. Paresthesias and myalgias are typically seen within the first 24 hours and usually resolve by 48 to 72 hours after ingestion of ciguatoxins, although there have been reports of neurologic symptoms persisting for weeks to months.^[26] ^[242]

Central respiratory failure

Coma

Many case reports of ciguatera poisoning describe symptoms of a sensory perception of "hot and cold reversal," and loose, painful teeth. Although the presence of these symptoms is suggestive of ciguatera poisoning, their absence does not exclude the possibility of the disease.^[26] There have also been reports of a paradoxical reversal to temperature perception only resulting in cold feeling hot rather than hot feeling cold.^[26] However, other reports demonstrated that gross temperature discernment remains intact and the description of paradoxical heat perception may be misleading.^[59] These authors describe the symptoms as intense, painful tingling or "electric shock" rather than true reversal of hot and cold perception.^[59] This peculiar symptom may have a delay in onset of 2 to 5 days, may last for months after ingestion, and is only otherwise seen with neurotoxic shellfish poisoning (brevetoxins), caulerpicin (from the green alga *Caulerpa*) toxicity, or turban shell poisoning.^{[115] [463]} Pruritus is another vague but often described sensation in victims of ciguatera poisoning. The onset of pruritus may be delayed for more than 24 hours but is rarely, if ever, seen in the absence of other symptoms.^{[133] [242]} Pruritus may persist for weeks and be exacerbated by any activity that increases skin temperature (blood flow), such as exercise or alcohol consumption.^[242] Ciguatera-induced pruritus may occasionally become severe and may improve after treatment with histamine receptor antagonists. Delayed symptoms may also include hiccups.

Tachycardia and hypertension are often described in ciguatera poisoning, in some cases after what can be severe transient bradycardia and hypotension.^[80] Hallucinations, flushing, flaccid paralysis, and fever are uncommon. More severe reactions tend to occur in persons previously stricken with the disease. Severely affected persons may report intermittent symptoms for up to 6 months, with a gradual diminution in frequency and intensity. There may be some regional variability to the symptoms of presentation.^{[26] [283]} Persons who have ingested parrotfish (scaritoxin) have been reported to suffer from classic ciguatera poisoning, as well as a "second phase" of toxicity 5 to 10 days after the initial onset, consisting of ataxia, dysmetria, and a resting or kinetic tremor.^[86] Whether ciguatoxin crosses the placenta is not known, but exposures during pregnancy have resulted in normal fetal outcomes.^[360]

In small children, the symptoms of ciguatera poisoning may be no more specific than irritability, sleep disturbance, nausea, and vomiting.^[448] Other reported symptoms have included carpedal spasm, ptosis, and inconsolability.

Diagnosis.

The diagnosis of ciguatera poisoning is based on clinical symptoms. The differential diagnosis includes paralytic shellfish poisoning, eosinophilic meningitis, type E botulism, organophosphate insecticide poisoning, tetrodotoxin poisoning, and psychogenic hyperventilation.^{[26] [340]} Unreliable folklore used in the past to aid in predicting ciguateric seafood includes the advice that a lone fish (separated from the school) should not be

eaten; that ants and turtles refuse to eat ciguatoxic fish; that a thin slice of ciguatoxic fish does not show a rainbow effect when held up to the sun; and that a silver spoon tarnishes in a cooking pot with ciguatoxic fish.^[92] Ciguatoxin may be detected in the flesh of fish by two immunoassay techniques, a mouse bioassay where a sample of the fish is injected intraperitoneally into a mouse and a "rapid" IgG assay.^[190] Rapid immunoassays have largely replaced determination of ciguatera toxicity by injection of fish tissue extracts into mice or by traditional tests of feeding fish to a mongoose or cat to observe for neurologic symptoms or death. High-performance liquid chromatography (HPLC) is also available for ciguatoxins and okadaic acid. Unfortunately, tests for ciguatoxin are still of limited clinical benefit because most institutions do not have the equipment needed for their performance.

Treatment.

If possible, a piece of the implicated fish should be obtained in the event that analysis for ciguatoxins can be performed. The treatment of ciguatera poisoning is primarily supportive. Intravenous hydration with crystalloid and electrolyte replacement may be necessary for dehydration. Severe or refractory hypotension may require a vasopressor such as dopamine. Antiemetics such as droperidol, prochlorperazine, and metoclopramide may be beneficial. Atropine has been shown to be effective in patients with symptomatic bradycardia or excess cholinergic stimulation.^[133] Ipecac-induced emesis or gastric lavage is rarely indicated since presentation is usually delayed and gastroenteritis is usually already present. Activated charcoal may bind some of the toxin in the gastrointestinal tract but is rarely useful given the expected time of presentation.

Many traditional remedies have been used for centuries in the treatment of ciguatera poisoning. Edrophonium, neostigmine, corticosteroids, pralidoxime, ascorbic acid, pyridoxine (vitamin B₆), and salicylic acid-colchicine-vitamin B complex have all been tried with variable success; however, there is no current clinical support for these modalities.^[283] Local anesthetics (e.g., lidocaine, tocainide) have also been administered for treatment of ciguatera.^{[61] [239]} These agents are effective blockers of sodium influx and may antagonize the sodium channel effects of ciguatoxin. In addition, amitriptyline has been used for its sodium channel blocking effects, as well as its potent antimuscarinic effects.^{[53] [58] [103]} Nifedipine has been used to counteract the cellular uptake of calcium caused by maitotoxin and to relieve headache.^[58] Although there is limited experience with most of these therapies, they may be beneficial in cases refractory to supportive care alone.

Recently, mannitol has become the most widely applied therapy in severe cases of ciguatera poisoning.^{[51] [389]} Most of the reports of success with the use of mannitol are based on limited data with small numbers of patients.^{[118] [309] [313] [449]} One series described successful treatment in 24 victims of ciguatera poisoning who received mannitol. Each was infused up to 1g/kg of a 20% mannitol solution intravenously over 30 minutes. None of the victims received more than 250 ml.^[309] The mechanism by which mannitol might be effective in abating the neurologic symptoms from ciguatera poisoning is unknown, but suggested theories have included acting as a free radical scavenger, acting as a competitive inhibitor of ciguatoxin at the cell membrane, and promoting a decrease in Schwann cell edema.^{[313] [449]} It is also possible that the osmotic

action of mannitol may render ciguatoxin inert.^[309] ^[313] Curiously, mannitol therapy seems to have no beneficial effect on mice administered a sublethal intraperitoneal dose of ciguatoxin (CTX-1).^[252] In humans the empiric observation is that mannitol has greater benefit if administered early in the course of the illness. One concern with the administration of mannitol in the setting of ciguatoxin is that patients may present dehydrated. In these cases, patients should be adequately rehydrated before the administration of mannitol. During recovery from ciguatera poisoning, it is recommended that victims exclude fish, shellfish, alcoholic beverages, and nuts and nut oils, which may result in an exacerbation of the syndrome.^[373]

Prevention.

For travelers, common sense dictates avoiding any fish the local fisherman and residents do not eat, or fish caught in known ciguatera-endemic areas. Because of the accumulation of toxin, all oversized fish of any predacious reef species (such as jack, snapper, barracuda, grouper, or parrot-beaked bottom feeder) should be suspected toxic. Moray eels should never be consumed. Internal organs of implicated fish seem to concentrate the toxin and should therefore be avoided. Natural events such as hurricanes and earthquakes have been associated with an increased incidence of ciguatera, presumably because of reef disturbance. The recent El Niño storms may also affect the incidence of ciguatera in the Pacific.^[30]

Clupeotoxin Fish Poisoning

Clupeotoxic fish poisoning involves plankton-feeding fish, which ingest planktonic blue-green algae and dinoflagellates. The poisoning is distinguished from

ciguatera based on its severity and high fatality rate and the implicated clupeoid fish. These fish of the order Clupeiformes are found in tropical Caribbean, Indo-Pacific, and African coastal waters. Examples include the families Clupeidae (herrings and sardines), Engraulidae (anchovies), Elopidae (tarpons), Albulidae (bonefishes), and Pterothrissidae (deep-sea slickheads).^[28] ^[277] Toxicity is reported to increase during the warm summer months. Viscera are considered to be highly toxic.

Previously, the toxin has been poorly characterized as a result of the infrequency of the syndrome and rare access to toxic animals. Recently the first case to shed light on clupeotoxism was reported in a Madagascar woman who died after eating a sardine, *Herklotsichthys quadrimaculatus*. The causative toxin was identified as palytoxin or its analog, which distinctly differed from ciguatoxin. The benthic dinoflagellate *Ostreopsis siamensis* was presumed to be the probable toxin source.^[307] ^[462] This same sardine has been implicated in clupeotoxism in Fiji and the Philippines.^[465] ^[467]

Clinical Presentation.

The onset of symptoms is rapid and characterized as "violent," often within 30 to 60 minutes of ingestion and rarely prolonged beyond 2 hours. Initial signs and symptoms include a marked metallic taste, xerostomia, nausea, vomiting, diarrhea, and abdominal pain. These symptoms are followed by chills, headache, diaphoresis, severe paresthesias, muscle cramps, vertigo, malaise, tachycardia, peripheral cyanosis, hypotension, delirium and death, with a mortality of up to 45%. Severe debility leading to death may occur within 15 minutes of the onset of symptoms.^[174] A postmortem examination in one case after ingestion of *Sardinella marquesensis* (Marquesan sardine) flesh and viscera demonstrated enterocolitis and the sequelae of hypotension and acute heart failure.^[277] As with ciguatera toxin, the poison does not impart any unusual appearance, odor, or flavor to the fish.

Treatment.

Therapy is supportive and based on symptoms. Because of the severe nature of the intoxication, early gastric emptying is desirable; however, the disease is so unusual and so rarely suspected (because of a lack of history) that gastric emptying is not often carried out. Aggressive management and early intensive care are essential.

Prevention.

Clupeotoxic fish should be avoided, especially during summer months, in fish indigenous to the Caribbean, African coastal, or Indo-Pacific waters. The viscera of suspicious fish can be fed to experimental animals to see if an illness is generated.

Paralytic Shellfish Poisoning

Shellfish have been implicated in poisonings for centuries, if not millennia. Epidemics of shellfish toxicity have been linked to the proliferation of dinoflagellates and other small marine organisms that are responsible for "red tides" or "blooms" in oceans around the world. The Bible refers to red tides in Exodus 7:20–21, where "the waters that were in the rivers were turned into blood, and the fish that was in the rivers died; and the river stank ..." The Red Sea was so named by ancient Greeks for its red appearance in certain seasons when red tides occurred. Red tides are described in the *Iliad* and were first recognized by North American Indians as luminescence or "flickering" of ocean waves.^[65]

The first published description in the western world of a patient with clinical findings suggestive of paralytic shellfish toxicity probably dates back to 1689. An article from a French journal named *Ephemerides des curieux de la nature* described a young woman who had ingested mussels.^[82] ^[172] The description notes that her symptoms included fever, chest pain, respiratory insufficiency, nausea, seizures, and tachycardia. She had emesis induced, bringing up the mussels, and eventually recovered. For years after this report, the incidence and cause of paralytic shellfish toxicity were undocumented throughout the world, but epidemics were known to occur in certain seasons and under certain conditions. Improvements in monitoring and public health

reporting have demonstrated patterns of occurrence. Gessner^[149] described 54 outbreaks of paralytic shellfish poisoning (PSP) in Alaska occurring in 117 individuals between 1973 and 1992. The California Paralytic Shellfish Poisoning Prevention Program has been so successful that it has been used as a model of surveillance for many other countries.^[322] PSP has been a reportable condition in California since 1927, with more than 500 cases and 30 deaths reported since that time. In California there is an annual 6-month quarantine (May through October) on mussels, clams, and oysters of local harvest.

Several types of neurologic diseases occur after ingestion of shellfish. PSP is one of the most common. This syndrome is most frequently reported during the summer months when water temperature is highest but has been recorded from May to November.^[160]^[172] Some authors suggest that the toxin responsible for paralytic shellfish poisoning may be of significant concentration in some shellfish, such as the Alaska butter clam, in some areas year round, and that shellfish harvested from untested areas of these regions never be consumed.^[149] The most commonly implicated varieties of shellfish include mussels, clams, oysters, and scallops.^[149]^[172]

Pathophysiology.

The unicellular (*Protogonyaulax* is 0.03 mm in diameter) phytoplankton (phylum Protozoa, class Mastigophora, order Dinoflagellata) is the foundation of the ocean food chain, and in warm summer months these organisms are noted to "bloom" rapidly

in nutrient-rich coastal temperate and semitropical waters. They rank second in abundance to diatoms and are extremely important producers of marine carbohydrates, fats, and proteins. Typical species include *Alexandrium* species and *Gymnodinium catenatum*.

Dinoflagellates produce a number of toxins, the most commonly identified of which is saxitoxin. If a single organism predominates, it can discolor the water, creating a black, blue, pink, red, yellow, brown, or luminescent "tide."^[88] Organisms can multiply rapidly from a concentration of 20,000 per liter to over 20,000,000 per liter. These plankton can release massive amounts of toxic metabolites into the water, at times leading rapidly to enormous mortality in various bird and marine populations, including large mammals such as dolphins and even whales. Large numbers of dead animals on the beach suggest a colored tide. The trend to increased numbers and magnitude of blooms is attributed empirically to many factors, including coastal development, dumping of sewage, fertilizer runoff, and ocean warming. Kills by the dinoflagellate *Ptychodiscus* (formerly *Gymnodinium*) *breve* and estimated at 100 tons of fish per day. The problem is increasing remarkably in Europe.^[431]

A limited number out of approximately 1200 species of dinoflagellates have been implicated in human toxic syndromes.^[349] PSP has been linked to the dinoflagellate

Protogonyaulax, species *catanella* (U.S. Pacific coast) and species *tamarensis* var. *excavata* (U.S. Atlantic coast and Europe).^[272] ^[406] In northwestern Spain, the organism that generates the toxins causing this syndrome is *Gymnodinium catenatum*. These creatures are relatively fastidious and prefer warm, sunlit water of low salinity in which to bloom. Some algal organisms may release their toxin in the form of microscopic cysts, which can overwinter at the sediment-water interface. In mollusks, the greatest concentration of toxin is found in the digestive organs (dark "hepatopancreas"), gills, and siphon.^[362] Toxic benthic dinoflagellate cysts may be transported by dredging operations and potentially introduce a dinoflagellate population into a new region.^[468]

Although the origin of PSP toxins is assumed to be dinoflagellates, the toxins have been isolated in both marine and freshwater bivalves that are not associated with dinoflagellates. It has not been determined how this has occurred.^[302] The bacterium *Moraxella* isolated from *Protogonyaulax tamarensis* has been shown to produce PSP toxins in culture. Toxin production can increase in nutritionally deficient environments.^[231] The paralytic shellfish toxins identified to date are 18 related tetrahydropurine compounds produced mainly by the dinoflagellates of the genus *Alexandrium*. The best characterized is saxitoxin. Saxitoxin (C₁₀ H₁₇ N₇ O₄) takes its name from *Saxidomus giganteus*, the Alaskan butter clam. *Ptychodiscus breve* is a toxic dinoflagellate that produces a milder toxin. Other dinoflagellates considered poisonous to animals or humans include *Gonyaulax acatenella*, *Pyrodinium phoneus*, *Pyrodinium bahamense* var. *compressa*, *Gonyaulax monilata*, *Gonyaulax polyhedra*, *Gymnodinium veneficum*, and *Exuviaella ariaelebouriae*.^[308] The taxonomic differentiation of *Protogonyaulax* from *Gonyaulax* species has only recently been appreciated, as has the relationship to the genus *Gessnerium*.^[406] *S. giganteus* and the Washington clam (*S. nutalli*) may carry the toxin in their neck parts for up to 2 years; however, no physical characteristic distinguishes a carrier animal.

Unfortunately, a direct human serum assay to identify the toxin responsible for PSP is not as yet readily available to the clinician. Paralytic shellfish poison is assessed in foodstuff using the mouse bioassay, in which a 20-g mouse is injected with 1 ml of an acid extract of the shellfish, and the time taken for the animal to die is recorded. One mouse unit (mu) or 0.18 mg is the amount of injected saxitoxin that kills a test mouse in 15 minutes.^[431] In most countries the action level for closure of a fishery is 400 mu/100 g shellfish. Polyclonal enzyme-linked immunosorbent assays (ELISAs) that measure saxitoxin, neosaxitoxin, and gonyautoxins 1 and 3 may be refined soon as reasonable screening techniques. Other testing methods under investigation include a sodium channel blocking assay, spectrometry, thin-layer chromatography, and HPLC. An automated tissue culture (neuroblastoma cell) bioassay may become a valid alternative to live animal testing.^[207]

Saxitoxin and related compounds are water-soluble and heat- and acid-stable. Twelve derivatives of saxitoxin (such as neosaxitoxin) that originate from dinoflagellates of the genus *Protogonyaulax* are formed by the addition to saxitoxin of *N*-1-hydroxyl, 11-hydroxysulfate, and 21-sulfo groups.^[171] Like tetrodotoxin, they can be destroyed to a certain extent in an alkaline medium but not by ordinary cooking. Saxitoxin acts by blocking sodium channels in nerve and muscle cells.^[127] ^[216] Inhibition of sodium flow in these cells arrests impulse conduction along neurons. In addition, saxitoxin may

suppress atrioventricular nodal conduction, directly depress the medullary respiration center, and progressively reduce peripheral nerve excitability. Because of the similarity of the clinical syndrome to tetrodotoxin poisoning, it has been inferred that the same receptors may be blocked. Although the illness-causing levels for humans are not definitively known, it has been suggested that ingestion of 200 to 500 µg would cause at least mild symptoms, 500 to 2000 µg moderate illness, and more than 2000 µg serious or fatal illness. However, serious symptoms have been reported after ingestion of less than 100 µg of saxitoxin in adults. During peak red tide seasons, mussels may accumulate up to 50,000 µg each of saxitoxin. Muscle concentrations of saxitoxin have been recorded to be too high

1302

for consumption when seawater dinoflagellate counts are as few as 200/ml.^[362] A saxitoxin concentration of greater than 75 to 80 µg/100 g foodstuff is considered hazardous to humans. In the 1972 New England red tide, the concentration of saxitoxin in blue mussels exceeded 9000 µg/100 g foodstuff. More recently, after cases of paralytic shellfish poisoning in Massachusetts, saxitoxin concentrations of 24,400 µg/100 g were recorded in raw mussels. With oral ingestion of saxitoxin, the LD₅₀ for mice is 263 µg/kg. It has been estimated that as little as 0.5 to 1 mg of saxitoxin can be fatal in humans.^[362]

Neither steaming nor cooking affects the potency of the toxin. Commercial processing of shellfish does not eliminate the toxin or the potential for toxicity; therefore public health agencies in the United States and Canada strictly monitor these canning industries.

Clinical Presentation.

The onset of symptoms of paralytic shellfish poisoning is rapid. Within 30 to 60 minutes of ingesting toxic shellfish, victims complain of paresthesias, numbness, vertigo, and tingling of the face, tongue, and lips. Cranial nerve dysfunction, including dysarthria, dysphonia, dysphagia, and even blindness, can occur.^{[149] [172] [193] [272]} Other early symptoms include lightheadedness, "floating," ataxia, weakness, hyperreflexia, incoherence, sialorrhea, thirst, abdominal pain, nystagmus, dysmetria, headache, diaphoresis, a sensation of loose teeth, chest pain, and tachycardia. Neurologic symptoms progress to involve the extremities and trunk over the first 1 to 2 hours. Weakness of the limbs may begin anytime after the sensory changes, and gradually progresses to ataxia, inability to use the extremities, and finally paralysis. Reflexes are frequently normal throughout progression of the disease, and patients remain awake and alert. Death results from respiratory failure with diaphragmatic and chest wall muscle paralysis.

Although some victims have nausea, vomiting, or diarrhea, the lack of gastroenteritis and thus early self-decontamination may in part explain why mortality from paralytic shellfish poisoning approaches 25% in some older series.^[27] More recent reports cite a lower incidence of fatalities, likely resulting from improvements in respiratory care.

Hypotension can result from direct action of the compound on vascular smooth muscle.^[216] Toxicity is never delayed more than 10 to 12 hours, with a median onset of 3 hours. Prognosis is good for individuals surviving past 12 hours, but weakness can persist for weeks after recovery. Children seem to be more sensitive to saxitoxins than adults, based on mortality figures from recent outbreaks. In milder cases, alcohol ingestion appears to increase toxicity.

Treatment.

There are currently no antidotes for saxitoxin or paralytic shellfish poisoning. The victim should be closely observed in the hospital for at least 24 hours for respiratory insufficiency. Airway patency and respiratory support are of utmost importance, and even patients with severe symptoms of PSP often do well if expeditiously supported with mechanical ventilation. Although gastric emptying has been advocated by some authors when shellfish suspected of containing saxitoxin are ingested, airway loss can be rapid and emesis should *not* be attempted in most cases.^[193] These toxins bind well to charcoal, and an oral dose of charcoal should be administered if this can be done safely.^[328] Some authors suggest that atropine administration may worsen symptoms of paralytic shellfish poisoning and should be avoided since saxitoxin and its derivatives may have some antimuscarinic effects.^[361] Several studies have also suggested that acidity may enhance the potency of saxitoxin, leading some authors to speculate that serum alkalinization might be of benefit to victims, although the efficacy of this practice has yet to be established.^{[8] [183] [268] [310]} Current research is directed at the development of polyclonal and monoclonal antibodies directed against saxitoxin and neosaxitoxin, for the purposes of diagnosis and therapy. Antivenin raised in rabbits against a saxitoxin-bovine serum albumin conjugate is curative in mice, but the product has not yet been used in humans.

At least one human case report and animal data have implied that dialysis or hemoperfusion may benefit some victims of severe PSP.^{[27] [328]} More recent reports are less optimistic and other *in vitro* trials have demonstrated that dialysis is not effective in removing saxitoxin.^[119] Some authors have suggested enhancing renal clearance with diuresis, but again no study supports this practice. Maintaining urine output in normal quantities should suffice in most cases.

Prevention.

The most important aspect of managing paralytic shellfish poisoning is prevention. Although leeching of shellfish in freshwater for several weeks followed by vigorous cooking may remove up to 70% of the toxin, such procedures are recommended only for persons stranded on desert islands. It has been said that one should not eat shellfish in the Northern Hemisphere in months that contain the letter "r." It has become more apparent with changing ocean conditions that shellfish in many parts of the world may be contaminated throughout the year resulting from high water concentrations of *Gonyaulax*. Because fin fish do not accumulate the toxins in their muscle tissue, there is no risk of PSP from their consumption.^[446] Most coastal agencies monitor dinoflagellate concentrations off the shores of developed countries and restrict shellfish harvesting during high-risk periods. Many recent outbreaks of this illness have occurred on isolated

islands where public health monitoring is infrequent and intensive care medicine resources scarce.

Neurotoxic Shellfish Poisoning

Ptychodiscus brevis is a toxic dinoflagellate that can "bloom" and create a colorful tide. Ingestion of shellfish contaminated with *P. brevis* can induce a milder version of paralytic shellfish poisoning, known as neurotoxic shellfish poisoning (NSP). The condition resembles ciguatera toxin poisoning in symptoms and does not have a major paralytic component. Death has not been reported in humans. Symptoms include circumoral paresthesias and paresthesias of the extremities, dizziness and ataxia, muscle aches, and gastrointestinal symptoms. The median incubation time is 3 hours; the illness lasts several hours to a few days.^[285] Most NSP outbreaks have occurred on the Gulf of Mexico, the west coast of Florida, coastal Texas, North Carolina, and New Zealand.^[285]
^[380]

Unlike other shellfish poisons, NSP can cause a respiratory irritation syndrome. When large blooms of *P. brevis* occur near the shoreline, wind and wave action can aerosolize the toxin; if sea breezes blow the aerosolized toxin onshore, rapidly reversible conjunctivitis, rhinorrhea, and bronchospasm with nonproductive cough can occur in sensitive individuals.^[193] Severe respiratory distress is uncommon. The effects are similar to those of muscarinic stimulation.

P. brevis produces at least 10 toxins, known as brevetoxins.^[24] ^[25] Brevetoxins (designated PbTx-1 to PbTx-10) are potent lipid-soluble cyclic polyether compounds that bind to and modulate voltage-gated sodium channel activity. Brevetoxins produce acute neuronal injury and death in rat cerebellar neurons.^[38] In a canine model, brevetoxins produce depolarization of tracheal and bronchial smooth muscle.^[334] Intratracheal brevetoxin instillation in rats resulted in systemic distribution of brevetoxin, which suggests that the initial respiratory irritation and bronchoconstriction may be only part of the toxicologic syndrome with brevetoxin inhalation.^[36] The brevetoxins are potent ichthyotoxins and are associated with large numbers of dead birds, fish, and mammals. In 1996, 149 manatees died along the southwest Florida coast; brevetoxin was implicated as the primary etiology for the epizootic.^[49] Signs and symptoms of intoxication in fish include violent twisting and corkscrew swimming, defecation and regurgitation, pectoral fin paralysis, caudal fin curvature, loss of equilibrium, quiescence, vasodilation, convulsions, and fatal respiratory failure.^[25] An enzyme immunoassay has been developed to detect these brevetoxins, based on antibodies to PbTx-3.^[422] A newer micellar electrokinetic capillary chromatography (MEKC) detection method allows measurement of brevetoxin at trace levels and is 100-fold better than previous chromatographic or electrophoretic methods.^[365] Brevetoxin A has recently been synthesized and is now synthetically available, allowing for further biochemical studies.^[300]

Diarrhetic Shellfish Illness

Ingestion of shellfish contaminated with the dinoflagellates belonging to the genus *Dinophysis* (*D. fortii*, *D. acuminata*, *D. norvegica*, and *D. acuta*) or *Prorocentrum* (*P. lima* and *P. minimum*) causes diarrhetic shellfish poisoning (DSP). The lipid-soluble toxins accumulate in shellfish fatty tissues and the hepatopancreas of mussels. They exert their effects mainly on the small intestine, leading to diarrhea and degenerative changes of the absorptive epithelium.^[270] ^[431] Symptoms include rapid onset (30 minutes to 2 hours) of diarrhea, nausea, vomiting, abdominal pain, and chills. Rarely, symptoms are delayed up to 12 hours. The syndrome is self-limited and resolves after 2 to 3 days. During the period 1976 to 1982, DSP was diagnosed in at least 1300 persons in Japan, particularly in the northeastern regions. The period of greatest toxicity appears to be May to August. In 1981, more than 5000 cases were reported in Spain.^[466] Other outbreaks have occurred in the Netherlands and Chile.^[176] In 1993, a particularly bad episode occurred in Spain with unusual symptoms; analyses revealed a complex toxin profile with both PSP and DSP toxins present.^[144]

DSP toxins include okadaic acid (OA), OA diolester, dinophysistoxins (DTX-1 to DTX-4), pectenotoxins and yessotoxin.^[21] ^[267] ^[429] ^[451] ^[466] OA was first isolated from a sponge in the Pacific (*Halichondria okadai*).^[397] OA is a specific and potent inhibitor of protein synthesis and inhibits phosphatases A₁ and A₂ in vitro. OA induces diarrhea because of phosphorylation of proteins either controlling the sodium secretion of intestinal cells or influencing the permeability of cell membranes.^[91] ^[108] It is a potent tumor promoter in mouse cells and can act as a genotoxic.^[131] Other DSP toxins exert various effects in experimental animals: pectenotoxins induce liver necrosis, and yessotoxins (from the Japanese scallop *Patinopecten yessoensis*) induce intracytoplasmic edema in cardiac muscle.^[411] ^[413] Minimum doses of OA and DTX-1 necessary to cause DSP symptoms are 40 µg and 36 µg, respectively.^[178] Metals (e.g., aluminum, copper, lead, mercury, cadmium) in concentration ranges at or below acceptable levels in mussels synergistically increase the cytotoxicity of low concentrations of OA in cultured cells.^[423]

Increasing incidences of phytoplankton blooms with the danger of toxin release have necessitated the search for new diagnostic methods that can detect toxin quickly and reliably. A variety of techniques, including a radioimmunoassay using antibodies raised in rabbits, a competitive ELISA, idiotypic anti-idiotypic competitive immunoassay, rapid tissue culture assays, and cytotoxicity assays, can identify the presence of OA.^[84] ^[94] ^[248] ^[366] ^[427] A unified bioscreen for the detection of diarrhetic shellfish toxins and microcystins (as from cyanobacteria *Microcystis aeruginosa* blooms) uses capillary electrophoresis coupled with a

liquid chromatography-linked protein phosphatase bioassay.^[47] A protein phosphatase 2A inhibition assay has been shown to be rapid, accurate, and reproducible; it can detect concentrations as low as 0.063 ng/ml in aqueous solutions and 2 ng/g in mussel

digestive glands.^[426] The Japanese quarantine standard is 200 ng of OA per gram of shellfish tissue. Four times this amount of toxin has been identified recently in northeastern Pacific Ocean mussels.

Domoic Acid Intoxication

Domoic acid is an excitatory neurotransmitter first described in Japan in 1958 isolated from the red algae *Chondria armata*.^[403] The first documented human outbreak of poisoning with this compound was in 1987 from Prince Edward Island, Canada, when more than 100 people became ill after ingesting cultured blue mussels, *Mytilus edulis*, later found to be contaminated with domoic acid.^[316]^[408]^[460] Three of these individuals died, and the clinical description of persistent memory impairment in many survivors prompted the nickname of "amnesic shellfish poisoning."^[134] The source of the toxin in these cases was found to be *Nitzschia pungens*, a pennate diatom that had been ingested by the mussels before human consumption.^[31]^[392] The mussels concentrate the toxin in the hepatopancreas.

Epidemics of domoic acid poisoning have been more prominent in other marine life, especially sea birds.^[445]^[457]^[458] A large number of dead and distressed pelicans and cormorants were noted in Monterey Bay, California, in September 1991.^[457]^[458] Autopsies performed on the dead birds demonstrated they had consumed large quantities of anchovies from the bay. Subsequent testing showed the anchovies contained high levels of domoic acid. This was the first report documenting the presence of domoic acid in the United States. Further studies of mussels taken during the same period from Monterey Bay also revealed the presence of domoic acid.^[445] Water samples taken in the area identified significant quantities of the diatom *Pseudonitzschia australis*, which when grown in a laboratory environment were able to produce domoic acid.^[147]^[457] Three species of *Pseudonitzschia* are now known to produce domoic acid.

Domoic acid has also been detected in Gulf shellfish (Gulf coast oyster, *Crassostrea virginica*) and phytoplankton in the Gulf of Mexico, although no outbreaks of amnesic shellfish poisoning have been recorded in this region. The toxic *N. pungens* forma *multiseriis* has also been confirmed in Korea; Japan; Oslofjord, Scandinavia; the northeastern and northwestern United States; eastern and western Canada; and eastern South America.^[110]

In the fall of 1991, the latest reported epidemic of domoic acid poisoning occurred in Washington State.^[224] Over 20 people who consumed razor clams were involved. Subsequent testing confirmed the presence of domoic acid in razor clams along the coasts of both Washington and Oregon, although mussels tested in these areas were virtually free of toxin. Dungeness crabs collected from these waters were also found contaminated with domoic acid.

Pathophysiology.

After the 1987 epidemic of domoic acid poisoning, significant evaluation was undertaken of the surviving victims. Chemical analysis at various laboratories ruled out all other

known toxic causes of the symptoms displayed by the patients.^[460] Intraperitoneal injection of extracts of the implicated mussels into mice produced a syndrome characterized by reproducible scratching followed eventually by death.^[316] ^[408] The toxin was finally identified as domoic acid.

Domoic acid is a glutamate agonist. After its discovery in 1958, it was investigated for potential use as an antihelminthic in children in Japan at doses of about 0.6 mg/kg, significantly lower than that ingested by affected individuals in Canada.^[460] Domoic acid has also been tested for its insecticidal properties with disappointing results.

Domoic acid is structurally related to kainic acid, a potent neurotoxic amino acid.^[306] ^[354] ^[408] ^[460] This group of compounds is excitatory and acts on three types of receptors in the central nervous system, with the hippocampus being the most sensitive. Domoic acid seems to work by activating kainate receptors in the brain more potently than kainic acid itself. The result of this stimulation is extensive damage to the hippocampus in victims of the poisoning, as well as less severe injury to portions of the thalamic and forebrain regions.^[356] ^[378] ^[408]

It was estimated that mussels implicated in the Canadian outbreak of amnesic shellfish poisoning contained a total amount of domoic acid in excess of 6 kg, with most being concentrated in the digestive glands.^[160] ^[460] When the same toxic blue mussels were placed into tanks of clean water, they rapidly purged themselves of the toxin over several weeks. Other organisms known to produce domoic acid include the phytoplankton *Alsidium corallinum* and *Chondria armata*. Subsequent research suggests that other phytoplankton, such as *Amphora coffaeiformis* can also produce domoic acid. Scientists continue to monitor shellfish and marine microorganisms to determine the presence of other sources.

Clinical Presentation.

Rats injected with high concentrations of domoic acid develop hippocampal seizures and die within several days.^[316] Surviving rats exhibit difficulty in remembering maze pathways they had previously encountered, signifying retrograde amnesia. In these same rats injected with domoic acid, prior maze learning skills are also not retained, suggesting an additional effect on anterograde memory.^[316] ^[408] These

effects are similar to that of intraperitoneally injected kainic acid. Interestingly, pelicans reportedly poisoned by domoic acid containing anchovies in 1991 exhibited a similar "scratching behavior" demonstrated in laboratory rats after domoic acid injection.^[294]

Humans involved in the Canadian epidemic of amnesic shellfish poisoning had initial symptoms of nausea, vomiting, abdominal cramps, and diarrhea 1 to 24 hours after ingestion.^[316] ^[408] Neurologic symptoms initiated by memory loss began within 48 hours after ingestion and progressed in some victims to seizures, hemiparesis,

ophthalmoplegia, and coma. Some victims displayed purposeless grimacing and chewing. Follow-up neuropsychologic testing on affected patients displayed predominantly an anterograde memory disorder, with most other cognitive functions preserved.^[316] The most severely affected individuals also had some retrograde amnesia. A labile blood pressure and cardiac arrhythmias were recorded in a few individuals. Elevations in blood urea nitrogen (BUN) and creatine phosphokinase were also noted in many victims and have been recorded in animals suffering domoic acid poisoning, possibly resulting from exertional myopathies or tremors.^[316] ^[458]

The onset of symptoms in victims of the Prince Edward Island epidemic ranged from 15 minutes to 38 hours, with the average approaching 5 hours.^[316] ^[408] Most fatalities occurred in the oldest victims, with postmortem findings suggesting neuronal loss or necrosis, accompanied by astrogliosis.^[316] The most severe damage was to the hippocampus and amygdala areas. Lesions were also noted in the claustrum, septal, and olfactory regions. No lesions were found in the motor nuclei of the brainstem. Hippocampal lesions in victims at autopsy resembled those seen in the brains of animals injected with kainic acid.^[316] ^[356] ^[378] A follow-up study done on patients from the Montreal area suggested that bronchial secretions became so profuse in the hours after mussel ingestion that half of the severely affected individuals required endotracheal intubation.^[316] Pupillary dilation or constriction and piloerection were also common findings. Approximately 10% of the involved patients demonstrated either persistent memory loss or other neuropathies. Of those patients exhibiting neurologic toxicity, maximal effects were noted within the first 3 days of mussel ingestion, and maximal improvement in the neurotoxicity occurred in 24 hours to 12 weeks after ingestion.

Treatment.

As with most other shellfish toxins, no antidote exists for amnesic shellfish poisoning. Based on the alleged mechanism of action of both domoic and kainic acid, it is possible that benzodiazepines may be beneficial in controlling some of the excessive hippocampal activity and seizures.^[306] ^[458] Animal studies have suggested a lowered mortality in groups in which benzodiazepines are used after domoic acid exposure. Government agencies continue to observe coastal areas for outbreaks of domoic acid toxicity and for the presence of phytoplankton known to produce the compound. "Blooms" of organisms such as *Nitzschia pungens* and *Pseudonitzschia australis* are closely monitored and reported.

Pfiesteria Syndrome

Pfiesteria piscicida is a toxic dinoflagellate that inhabits estuarine and coastal waters of the eastern United States and has been associated with fish kills and human illness. Since 1991, *P. piscicida* and other *Pfiesteria*-like species have been implicated in massive fish kills in estuaries of North Carolina, Maryland, and Chesapeake Bay.^[156] ^[162] ^[370] *P. piscicida* is responsible for a fish disease formally known as *ulcerative mycosis*. *Pfiesteria* is primarily a benthic organism but can exist in at least 24 different life stages. When fish swim into an area with *Pfiesteria*, toxin is produced by the dinoflagellate. These fish develop characteristic ulcerative lesions and erratic swimming behavior. *Pfiesteria* have now been found in coastal waterways extending from Delaware to the

Gulf Coast of Alabama.

The first report of adverse health effects in humans was described after accidental laboratory exposure in which investigators working with *Pfiesteria* developed respiratory and eye irritation, skin rashes, and cognitive and personality changes.^[156] During the 1990s, commercial fishermen who were exposed to waterways with *Pfiesteria* species reported similar symptoms.^[162] ^[164] ^[165] ^[370] The route of exposure is unknown, although it is thought to be either by prolonged direct skin contact with toxin-laden water or via aerosols after breathing the air over areas where fish are dying from toxic *Pfiesteria*.

Individuals with high exposure complain of headache, skin lesions, skin burning on contact with water, eye irritation, upper respiratory irritation, muscle cramps, and neuropsychologic symptoms, including increased forgetfulness and difficulties with learning and higher cognitive function.^[164] No consistent physical findings or laboratory abnormalities have been found. When skin lesions appear, they are erythematous, edematous papules on the trunk or extremities and resolve within a few days to a week after exposure. Thorough neuropsychologic testing has documented deficits in higher cognitive function and learning and functional memory.^[164] The severity of the cognitive dysfunction was directly related to the degree of exposure. The exact nature of the neurocognitive deficit is unknown; however, rats exposed to water containing *Pfiesteria* toxins have shown significant learning impairments.^[246] ^[247] Deficits may be expected to improve significantly within 3 to 6 months after cessation of exposure to affected waters. The natural history

1306

of *Pfiesteria* syndrome is improvement in most symptoms without treatment; however, cholestyramine has been successfully used in five patients with persistent symptoms.^[371]

Diagnosis of *Pfiesteria* syndrome is difficult because the specific toxins at fault have not yet been identified and a biomarker of exposure has not been developed. Current recommendations for diagnosis include (1) developing symptoms within 2 weeks after exposure to estuarine water, (2) memory loss or confusion of any duration and/or three or more symptoms from the complex as described above, and (3) no other cause for symptoms identified.^[76] Currently, a multiplex PCR is being developed for rapid identification of *P. piscicida* and other toxic *Pfiesteria* species.^[282] *Pfiesteria* syndrome is not infectious and has not been associated with eating fish or shellfish caught in waters where *P. piscicida* has been found. No deaths have been associated with exposure to *Pfiesteria* species. People should avoid areas with large numbers of diseased, dying, or dead fish.

Haff Disease

Haff disease is a syndrome characterized by severe muscle pain and rhabdomyolysis after consuming fish; it was first described in 1924 around the shores of the Bay of

Konigsburg Haff on the Baltic Sea.^[474] Further outbreaks have occurred in Sweden and Russia.^{[37] [372] [381]} Twelve cases have been reported in the United States; all have been associated with eating buffalo fish (*Ictiobus cyprinellus*), a bottom-feeding species found in the Mississippi River and its tributaries. Haff disease is most likely the result of a heat-stable toxin in blue-green algae that is eaten by fish; however, the toxin is unidentified.^[74]

Haff disease presents as generalized muscle pain and tenderness, rigidity, weakness, and rhabdomyolysis. Tachycardia, hypertension, tachypnea, and a drop in temperature can also occur. Elevated serum creatine kinase occurs with leukocytosis, myoglobinuria, and elevation of lactate dehydrogenase and other muscle enzymes. Symptoms generally appear approximately 18 hours after eating fish (range: 6–21 hours).^[74] Pathologically, there is neuromyodystrophy with necrosis in motor neurons of the brain and spine, coagulation necrosis of muscle, and myoglobinuric nephrosis. Treatment includes large volumes of intravenous fluids and diuretics to prevent renal failure from myoglobin toxicity. Diagnosis is based on clinical presentation, laboratory data, and food history.

Blue-Green Algae

Blue-green algae are worldwide freshwater cyanobacteria that may proliferate rapidly in a bloom, discoloring the surface of the water and spoiling its odor and taste. Terrestrial, fresh, brackish, and sea-water cyanobacteria produce toxins that cause acute and chronic hazards to human and animal health and are responsible for isolated, sporadic animal fatalities each year. Typical algal species include *Microcystis aeruginosa*, *Anabaena flos-aquae*, *Nodularia spumigena*, *Nostoc*, *Oscillatoria agardhii*, and *Aphanizomenon flos-aquae*.^{[90] [126] [295] [343]}

During conditions of a bloom (warm stagnant water, frequently enhanced by phosphorus and nitrogen fertilizers), the toxins are concentrated to a degree to become a significant hazard to wild and domestic animals and have been responsible for the death of livestock and dogs.^{[90] [122] [181] [297] [432]} In most species of toxic cyanobacteria, the toxins are cyclic heptapeptides called microcystins, or cyanoginosins. More than 60 cyanobacterial toxins have been isolated from blue-green algae.^{[90] [376]} The toxins are of multiple configurations and include alkaloids, polypeptides, and lipopolysaccharides (endotoxins).^[386]

Anatoxin-a and homoanatoxin-a are potent nicotinic agonists that act as postsynaptic, depolarizing neuromuscular blocking agents. These toxins along with saxitoxin cause animals to collapse quickly from neuromuscular paralysis, with features of staggering, muscle fasciculations, gasping, and convulsions.^[180] Anatoxin-a(s) is an anticholinesterase that causes demonstrable cholinergic toxicity in animals.^{[64] [180]} Anatoxin-a and anatoxin-a(s) are both derived from *Anabaena flos-aquae*. Nodularins and microcystins cause hepatotoxicosis. Cylindrospermopsin is a protein synthesis inhibitor and induces necrotic tissue injury of multiple organs. Cyanobacterial lipopolysaccharide endotoxins are responsible for gastroenteritis and skin irritations.^[90] In mice, administration of microcystin-LR causes rapid hepatocellular necrosis with

hemorrhagic shock.^[98] ^[415]

Human exposure to blue-green algae blooms has resulted in allergic reactions, skin irritations, gastroenteritis, pulmonary consolidation, and liver damage.^[90] ^[317] A person who swims through a bloom may suffer local effects, such as conjunctivitis, facial swelling, or papulovesicular dermatitis. Ingestion of contaminated water causes a dysenteric diarrhea, with green slimy stools. This may or may not be associated with elevation of γ -glutamyl-transpeptidase and alanine aminotransferase. Inhalation of toxins is a likely exposure route; microcystin-LR and anatoxin-a cause significant toxicity in mice via intranasal aerosol exposure.^[134]

In 1996, more than 50 people died at a hemodialysis clinic in Brazil with associated liver damage. Microcystins are thought to have been present in the water used for hemodialysis.^[90] ^[117]

Treatment is supportive in humans and animals. Recently, cyclosporine A has been shown to inhibit the fatal effects of microcystins administered to mice. In humans, no special treatment is recommended other than fluid and electrolyte supplementation as needed, since all related afflictions appear to be self-limited.

OTHER SHELLFISH AND INVERTEBRATE POISONINGS

Callistin Shellfish Poisoning

The Japanese *Callista* clam (*C. brevisiphonata*) is toxic during the spawning months of May to September, at which time cholinergic compounds in the ovaries are increased. The intoxication resembles cholinergic crisis, with both muscarinic and nicotinic components. Within an hour of ingestion of the heat-stable toxin, generalized pruritus, urticaria, erythema, facial numbness and paralysis, hypersalivation, diaphoresis, fever, chills, nausea, vomiting, diarrhea, bronchorrhea, bronchospasm, and constrictive dyspnea develop. [28] Therapy is supportive, and recovery is usually complete within 2 days. In severe cases of cholinergic crisis, particularly with marked bradycardia, atropine (0.5 mg intravenously every 5 minutes to a total dose of 2 mg) may be administered.

Venerupin Shellfish Poisoning

The Japanese lake-harvested oyster (*Crassostrea gigas*) and clam (*Tapes semidecussata*) occasionally feed on toxic dinoflagellate species of the genus *Prorocentrum*, posing the greatest risk during the months of December through April. [28] [175] The heat-stable toxin induces the rapid onset of gastrointestinal distress, headache, and nervousness, which are followed over 48 hours by hepatic dysfunction, manifested by elevation of liver enzymes, leukocytosis, jaundice, and profound coagulation defects. Delirium and coma may ensue, with death occurring in 33% of victims. Therapy is supportive and based on symptoms. Any victim who shows the early symptoms of gastroenteritis should be placed on a low-protein diet and observed for 48 to 72 hours for signs of liver failure. There is not yet clinical experience with exchange transfusion, chemotherapy, hemoperfusion, or liver transplantation in the management of profound liver failure associated with this disorder.

Tridacna Clam Poisoning

Giant clams of the species *Tridacna maxima* are eaten in French Polynesia. [28] This species can cause a poisoning characterized by nausea, vomiting, diarrhea, paresthesias, tremor, and ataxia. Severe cases can be fatal. The toxin appears to be concentrated in the mantle and viscera of the clam. Therapy is supportive.

Whelk Poisoning

In Japan, poisoning has followed ingestion of mollusks of the genera *Neptunea*, *Buccinum*, and *Fusitriton* (whelks, or ivory shells). The toxin is located in the salivary glands and has been characterized as tetramine.^[12] Tetramine (trimethylammonium) is a naturally occurring quaternary ammonium compound that has been identified in anemones, gorgonians, jellyfishes, and mollusks.^[11] Symptoms include headache, dizziness, nausea, vomiting, blurred vision, and dry mouth. No fatalities have been reported. Therapy is supportive.^[28]

Ivory Shell Poisoning

Human intoxications have followed consumption of the ivory shell, *Babylonia japonica*, which is widely distributed along the coastline of Japan. The toxin, surugatoxin, located in the midgut of the animal, is reputed to be produced by a gram-negative bacterium on which the snail feeds. Surugatoxin and IS-toxin appear to have autonomic ganglionic blocking action. Symptoms include abdominal pain, diarrhea, nausea, vomiting, oral paresthesias, syncope, and seizures.^[176] Tetrodotoxin has been identified in *B. japonica*.

Abalone Poisoning

Abalone poisoning follows ingestion of the viscera of certain Japanese abalone (tsunowata, or tochiri), particularly from the Island of Hokkaido, where *Haliotis discus* and *Haliotis sieboldi* are found. Symptoms include severe urticaria, erythema, pruritus, edema, and skin ulceration. The reaction appears to be of a photosensitive nature, since the lesions are confined to areas of ultraviolet exposure. The toxin may be derived from chlorophyll contained in the seaweeds on which the abalone feed.^[28] Therapy is supportive.

Cephalopod Poisoning

In certain areas of Japan, intoxications have resulted from ingestion of squid and octopus. Symptoms develop within 10 to 20 hours and consist of nausea, vomiting, diarrhea, abdominal pain, headache, weakness, paralysis, and seizures. Although most victims recover within 48 hours, deaths have occurred.^[28] Therapy is supportive.

Sea Cucumber Poisoning

Sea cucumbers are eaten throughout Asia and in some Pacific islands, where they are known as trepang, sea slugs, cucumbers, erico, or hai shen. Gastroenteritis is induced by saponins of the triterpenoid variety, such as holothurin. The disorder consists chiefly of abdominal pain, nausea, and diarrhea and is self-limited.

Sea Hare Poisoning

Sea hares are marine gastropod mollusks prevalent in certain South Pacific waters, including Fiji. *Aplysia* species have been considered to be toxic since Roman times. *A. juliana* secretes an antibacterial and antineoplastic protein found in the water-soluble fraction of a fetid secretion lethal to crabs. Human poisoning has been reported after ingestion of *Dolabella auricularia* ("veata").^[347] ^[384] The symptoms began approximately 30 minutes after eating and included prickling skin sensation, vomiting, diarrhea, shaking, tremors, fasciculations,

1308

arthralgias, dyspnea, visual disorientation, altered sensorium, and fever. The course of illness exceeded a week. It has been suggested that sea hare poisoning in humans might be a form of subacute organobromine intoxication.

Ingestion of the sea hare *A. kurodai* was associated with acute liver damage with sustained elevations of aminotransferases. Microscopic findings in a liver biopsy specimen revealed characteristic apoptotic hepatocytes accompanied by mitotic hepatocytes. Bioactive substances in the sea hare might induce such apoptosis of hepatocytes in the liver.^[348]

Anemone Poisoning

In the South Pacific, ingestion of the green or brown anemones *Radianthus paumotensis* or *Rhodactis howesii* (*mata-malu samasama*) has been associated with severe illness and death. Accidental deaths generally involve small children, whereas adults may be the unfortunate recipients of improperly cooked anemone or even be intentionally stricken in acts of suicide. The toxic substances are found in the nematocysts and the tentacular tissues. Anemones have been used for criminal purposes in the South Pacific.^[28] *Physobranchia douglasi* is poisonous eaten raw but is reputedly safe if cooked.^[176]

Ingestion of the raw anemone induces altered mental status within 30 minutes, often immediately after the ingestion. The victim becomes agitated or confused, delirious, and then comatose. Other symptoms reported include fever, seizures, myalgias, abdominal pain, respiratory failure, hypotension, and death. Contact with the skin, particularly mucous membranes, is extremely painful with rapid inflammation and vesiculation.

Treatment is symptomatic and supportive. Because of the rapid onset in symptoms the rescuer must be prepared to provide advanced life support within the first hour after ingestion.

A toxic protein has been isolated from the sea anemone *Urticina piscivora*. It is a potent cardiac stimulatory protein and a potent hemolysin on erythrocytes of rat, guinea pig,

dog, pig, and human, causing toxicity as low as 10^{-10} M. [89]

Crab Poisoning

Human intoxications have followed ingestion of crabs in many Indo-Pacific islands. Most of the toxic crab species are members of the family Xanthidae and include the genera *Demania*, *Carpilius*, *Atergatis*, *Platypodia*, *Zosimus*, *Lophozozymus*, and *Eriphia*. Clinical symptoms develop 15 minutes to several hours after ingestion and include nausea, vomiting, diarrhea, perioral and extremity paresthesias, ataxia, aphasia, respiratory distress, altered mental status, coma, and rapid death.

A number of toxins have been isolated from crab species, and there is a marked similarity to PSP and TTX poisoning. Saxitoxin, neosaxitoxin, and gonyautoxins have been isolated from crab species in Okinawa and from *Eriphia sebana* and *Atergatis floridus* off Australian coral reefs. [257] [258] [259] [260] Tetrodotoxin and palytoxin have also been characterized from poisonous crabs. [7] Tetrodotoxin was responsible for an epidemic of 71 persons with 2 deaths in Thailand who ate the toxic eggs of the horseshoe crab *Carcinoscorpius rotundicauda*. [214] The poisonous mosaic crab *Lophozozymus pictor* from the Indo-West Pacific region has caused several fatalities in the Philippines and Singapore. The toxins were concentrated in the gut and hepatopancreas, whereas the muscle was less toxic. Captive crabs lose toxicity such that it almost completely gone by 24 days.

Coconut crab (*Birgus latro*) poisoning is manifested as nausea, vomiting, headache, chills, myalgias, and exhaustion, with occasional deaths. Asiatic horseshoe crabs (*Carcinoscorpius rotundicauda*) are eaten in Thailand, where they cause mimi poisoning. Symptoms include nausea, vomiting, diarrhea, abdominal cramps, dizziness, palpitations, weakness, lower extremity paresthesias, aphonia, perioral burning, pharyngitis, sialorrhea, syncope, paralysis, and death. Again, the toxin appears highly similar to saxitoxin. [81]

Crab lung has followed the aspiration of tiny fragments of North American blue crab shells into the lung, necessitating removal with fiberoptic bronchoscopy. The diagnosis of occult aspiration should be considered in anyone with an unexplained cough who has recently consumed cracked crab, particularly while intoxicated.

Freshwater crabs are a potential source of human paragonimiasis, a parasitic disease that was prevalent in Asia until the 1960s. [85] Paragonimiasis usually causes pulmonary disease with a productive cough and bloody sputum. Central nervous system involvement has also been reported. [323] The disease is contracted by eating raw crab infected with the metacercariae of *Paragonimus* species. Areas known to be endemic are Vietnam, China, Japan, Korea, Equador, and Liberia.*

BACTERIAL AND VIRAL PATHOGENS IN SEAFOOD

Bacterial and viral contamination of shellfish, particularly bivalve mollusks, is implicated more than any other marine animal in seafood-related human illness.^[256] As filter feeders, bivalve mollusks filter large quantities of water unselectively to gather plankton and extract oxygen, which allows concentration of bacteria and viruses (along with biologic toxins, pesticides, industrial chemicals, radioactive wastes, toxic metals, and hydrocarbons). They are sessile invertebrates that generally inhabit shallow waters close to shore and pollution

*References ^[6] ^[85] ^[96] ^[296] ^[323] ^[346] ^[437] .

1309

sources. Standard depuration in purified (with ultraviolet light or ozone) water for 48 to 72 hours may not significantly reduce these contaminants, nor does it appear to remove viruses.^[209] ^[353] Disease and deaths resulting from viruses and naturally occurring bacteria are now of greatest concern because they are the most common causative agent. The greatest risk of death caused by consumption of raw shellfish is among people with underlying health conditions.

Bacteria Associated with Fecal Contamination

Bacterial pathogens associated with fecal contamination have accounted for only 4% of the shellfish associated gastroenteritis outbreaks in the United States.^[336] Important bacteria include *Salmonella*, *Shigella*, *Campylobacter*, *Yersina*, *Listeria*, *Clostridium*, *Staphylococcus*, and *Escherichia coli*.^[200] The incidence of enteric bacteria in seafood has greatly reduced with the development of surveillance programs and standards to minimize fecal contamination.^[336] However, infections continue to occur in other parts of the world.

Salmonella typhi was the most common cause of bacteria-associated shellfish disease until the 1950s. The incidence of *S. typhi* in shellfish has dramatically declined and the risk of infection in the United States is very low.^[336] ^[450] However, *S. typhi* is still responsible for outbreaks of illness in other countries.^[390] ^[391] Nontyphoidal *Salmonella* species, including *S. paratyphi* and *S. enteritidis*, have been detected in shrimp and bivalves. Eight *Salmonella* shellfish infections were reported in the United States between 1984 and 1993, and *S. enteritidis* phage type 19 was responsible for a recent outbreak of infections from cockles in the United Kingdom.^[166] ^[452] *Shigella* was responsible for 111 shellfish cases and 4 outbreaks in the United States.^[336] *Shigella*

has a low infectious dose and long survival time in clams and oysters.

Campylobacter species have been isolated from shellfish; however, their role in seafood infections is not known.^[450] *Listeria monocytogenes* has been identified in high rates in isolates from fresh and processed fish and shellfish.^[199] *Listeria* seafood-borne infections are probably underreported in the United States. *Yersinia enterocolitica* has also been identified in fish and shellfish; however, most *Yersinia* infections are not associated with seafood.^[200] ^[336] *Escherichia coli* has not been an important source of seafood-related illness, although *E. coli* is found in shellfish.^[57]

Viruses Associated with Fecal Contamination

Most infections associated with consumption of shellfish are viral in origin. Over 120 enteric viruses can be found in human sewage. These viruses can produce a variety of symptoms, including gastroenteritis, meningitis, paralysis, myocarditis, and hepatitis. Compared with other food-borne illnesses, those caused by viruses are less severe and seldom fatal. Viruses that have been isolated from seafood include hepatitis (A, non-A, and non-B), enteroviruses (echovirus, poliovirus, coxsackie A and B), adenoviruses, rotaviruses, and small round viruses (Norwalk, calicivirus, Snow Mountain agent, and small rounded structured viruses [SRSV]).

Harvest areas are surveyed and closed for fecal contamination. However, the relative absence of fecal coliform bacteria in areas of shellfish harvesting does not indicate freedom from viral contamination. Recent outbreaks of Norwalk virus and calicivirus were due to oyster harvesters discharging their sewage overboard.^[72] In addition, shellfish depuration processes that eliminate bacteria do not necessarily remove viral contaminants.^[353] Steamed clams probably pose a significant risk because household cooking techniques are often insufficient to kill viruses. Although it takes 4 to 6 minutes of pressure-cooker steaming for the internal temperature of soft-shell clams ("steamers") to reach 100° to 106° C (212° to 222.8° F), it requires only 60 seconds for the shells to open, at which point they may appear cooked.^[223] Poliovirus can survive (7% to 13%) in oysters that are steamed, fried, baked, or stewed.^[112]

New methods using PCR amplification of target viral genomes provide a rapid, specific, and sensitive test for detection of viruses. The amplification of viral ribonucleic acid (RNA), DNA, and complementary DNA (cDNA) has shown a high prevalence of human viruses that would not be detected by the use of classical techniques.^[318] PCR has been used to detect the presence of hepatitis A virus in oysters and scallops during an outbreak and SRSV, adenovirus, enterovirus, and Norwalk virus in shellfish.*

Hepatitis Viruses.

Oysters, mussels, and clams harvested from raw sewage contaminated waters are the most frequent cause of food-borne viral hepatitis A. Often there is a long incubation period of 2 to 8 weeks, so it is common for hepatitis A to occur 3 to 4 weeks after gastroenteritis following consumption of shellfish.^[336] Symptoms include fever, jaundice,

nausea, and abdominal pain, whereas diarrhea is rare. Treatment is supportive.^[42]

Enteroviruses.

Enteroviruses are commonly isolated from marine water and shellfish. In the United States, up to 63% of shellfish in areas closed for harvesting, and up to 40% of shellfish in areas open for harvesting were positive for enteroviruses.^[339] In contaminated waters in Venezuela, 40% of harvested shrimp contained enteroviruses.^[50] Enterovirus outbreaks have not been characterized, and the impact of enteroviruses on public health is not fully appreciated.^[256]

*References ^[15] ^[16] ^[18] ^[95] ^[243] ^[318] ^[353] .

Small Round Viruses.
