Wilderness pain control may be difficult to achieve because of complex physiologic and environmental challenges. The primary goal should be safety and the secondary goal effective pain relief. However, failure to provide adequate analgesia may place a sick or injured person, as well as the rescue party, at grave risk.

The nature of the injury or illness is assessed and the diagnosis determined while addressing the need for and choice of pain therapy. It is often important to withhold pain therapy until a reasonable diagnosis can be determined, which may be difficult without sophisticated diagnostic equipment. However, history taking and physical examination should lead to an appropriate diagnosis.

Evaluation of the Pain Patient

Through the medical history, the location of the pain, time of onset, precipitating or aggravating factors, frequency and duration, character, severity, and previous treatment are established. Included is past medical and surgical history; menstruation and pregnancy; environmental exposures; dietary intake; medications; and associated symptoms of nausea or vomiting, fever, vertigo, and dyspnea. Many wilderness injuries are reasonably straightforward to diagnose, but pain related to medical illness may be a dilemma. Open-ended questioning may provide greater insight than direct questioning. Changes in cognition may compromise victim evaluation. Pretravel history forms and information or observations of traveling companions may be critical in evaluating a painful condition.

If pressed by critical environmental or patient conditions, the physical examination is performed quickly and systematically, targeted by clues obtained during the history. When possible, a focused examination including a general assessment of contributing factors such as blood pressure and pulse, mental status, cranial nerve function, motor and sensory function, deep tendon reflexes, and strength may provide vital information.^[12]

Physical Methods for Treatment of Pain

Wilderness pain management includes simple physical measures, such as applying pressure, cold, heat, or splinting, which are important adjuncts to narcotic analgesics, anesthetics, and other pharmaceutical agents using topical, oral, intranasal, rectal, or parenteral administration ([Box 16-2](#)). Additionally, pain

treatment modalities characterized as "complementary and alternative" therapies may provide significant pain relief with less physiologic risks.

Compression Analgesia.

Although compression is taught more as a method for establishing hemostasis than for pain management, compression can reduce pain. An injured extremity is wrapped distal to proximal, with a cloth wrap or rubber Esmarch bandage, or a simple constiction band may be placed on the limb proximal to the site of the injury. Resultant anesthesia may occur because of compression of the peripheral nerves.^[34] Compression anesthesia may be safe and appropriate in a wilderness setting if other methods or pharmacologic agents are unavailable or contraindicated.

Cryoanalgesia.

Hippocrates first recorded the use of ice and snow packs to relieve pain in the fourth century BC. Cryoanalgesia experienced a significant modification by Richardson in 1866 with the introduction of refrigerant ether spray, subsequently replaced by the use of ethyl chloride spray in 1890. Cooper advanced cryoanalgesia in 1961 through the development of the liquid nitrogen probe, which served as prototype for the current generation of nitrous oxide or carbon dioxide cryoanalgesia devices in common use today.^[34] ^[41]

Wilderness cryoanalgesia may be applied with ice, snow, or frigid water. Additionally, metal cylinders containing gasoline or ethyl alcohol (freezing point -114.5° C [-174.1° F])^[9] remain liquid at temperatures below water's freezing point and may be used to provide a dry cold compress.^[49] These containers of subzero temperature liquids may

lead to serious frostbite injury. As cold absorbs heat from the adjacent tissues, nerve conduction is reversibly blocked. Conduction ceases in the larger myelinated fibers before the unmyelinated fibers; all nerve conduction ceases at 0° C (32° F). Upon rewarming, nerve conduction resumes, unless the intracellular contents have turned to ice crystals. Extreme cryotherapy leads to wallerian degeneration of axons and myelin sheaths, although the perineurium and epineurium may remain intact and sometimes allow regeneration.^[41]

Although a selective cryolesion is the goal of many pain management treatments in chronic pain clinics, this deliberate cell injury is not appropriate in a wilderness setting. Prevention of iatrogenic frostbite and generalized hypothermia while using cold therapy is critical. How long a tissue will tolerate a cold compress before experiencing cellular damage depends on pre-existent tissue hypothermia, peripheral vs. central nature of the tissue, and temperature and pressure of the cold compress. Cold water immersion may induce frostbite in persons with snakebite because of venom-compromised tissues. Cold packs are beneficial for marine envenomations^[16] (see [Chapter 60](#) and [Chapter 61](#)). Commercial cold packs typically contain a gel of water and propylene glycol, or other similar antifreeze and heat exchange substances, which may be cooled in cold water or snow.^[23] A reasonable guide is to place a dry, thin cotton cloth or foam between the skin and cold metal cylinders, ice, or snow, or cold packs and to remove cold therapy each 15 minutes to assess tissue status.

Heat Therapy.

Heat application is not usually recommended for initial (up to 48 hours) pain management of acute trauma because it may lead to increased edema and bleeding. However, heat can be used for pain management in the wilderness. Muscle relaxation, attributed to decreased gamma fiber activity, has been demonstrated after applying heat to the overlying skin. Collagen tissues become more extensible with heat therapy, requiring less force for movement and resulting in less mechanical damage with stretching. These effects may be useful for patients pursuing wilderness travel, especially with chronic pain conditions. Further, heat applied to the skin of the abdomen may markedly reduce gastrointestinal (GI) peristalsis and uterine contractions and thus decrease pain associated with these organs.^[46]

Application of heat need not be extreme. Temperatures of 37.8° to 40° C (100° to 104° F) for 10 to 20 minutes generally provide comfort without thermal injury. Heat therapy should be avoided in cognitively impaired patients and for tissue that is anesthetic or ischemic, to prevent further unintended tissue injury. Heat therapy may improve or worsen marine envenomations, or lead to lymphangitis ^[17] (see [Chapter 60](#) and [Chapter 61](#)).

Liniments and balms are not true heat transfer agents but consist of multiple botanical or chemical substances that make the tissue feel warm through counterirritant effects

and subsequent vasodilation. These substances may help a traveler's soreness and stiffness abate. Common ingredients include menthol, camphor, mustard oil, eucalyptus oil, methyl nicotinate, methyl salicylate, and wormwood oil. [6] These products are generally only recommended on intact skin with a light cloth or plastic covering and should not be placed on mucous membranes; neither should they be used with tight compresses or external heat sources.

Splinting.

Splinting allows positioning and immobilization of injured body parts and prevents further damage to soft tissues, blood vessels, nerves, and bones. Preventing bony fragments from damaging surrounding tissue diminishes pain and often facilitates mobilization and extrication of a victim.

Splints (see [Chapter 18](#)) should be padded to prevent further surface trauma. They may be accompanied by pressure dressings or cold compresses for additional pain management. Regular reevaluation of tissue circulatory status is critical to prevent damage from swelling, frostbite, or ischemia in immobile, splinted limbs.

Pharmacologic Treatment of Pain

Analgesics ([Table 16-1](#) and [Table 16-2](#))

NARCOTIC ANALGESICS.

Opium emerged as the first widely used narcotic analgesic by the time of the Renaissance, generally as a powder or sticky gum. It was often combined with alcohol to form laudanum. Prussian pharmacist Frederich Sertürner isolated morphine from opium. Development of the hypodermic needle and syringe by Rynd in Ireland and Pravaz in France greatly enhanced morphine's clinical utility in pain management. [34]

Narcotic agonists affect the opiate receptors in the central nervous system (CNS). [40] Morphine and other opioids are administered orally, intranasally, [43] sublingually, transdermally, subcutaneously, intramuscularly, intravenously, and rectally. Morphine is metabolized primarily in the liver; approximately 10% is excreted through the kidneys. Hepatic and renal damage affects the recipient's response, so that tolerance for a given dose must not be presumed with these conditions. Morphine is a potent analgesic with sedative and euphoric effects that also depresses the CNS and respiratory drive. Critical patient assessment is always required when using narcotic analgesics to detect respiratory depression and hypotension.

Other narcotic agonists include codeine, which is a "controlled substance" in the United States but available over the counter (OTC) in most other countries, and meperidine, methadone, propoxyphene, and hydromorphone. Newer semisynthetic narcotics that exhibit much shorter durations of action include fentanyl and sufentanil.

Potential adverse side effects may include anaphylaxis, nausea, vomiting, rash,

respiratory depression, and hypotension. Narcotic antagonists such as naloxone and other emergency resuscitative medications should be available when using narcotics in the wilderness, just as in the contemporary clinical setting. Do not give potent narcotic analgesics to victims with suspected head injury or neurologic illness.^[50]

Naloxone (Narcan) is a narcotic antagonist that may reverse narcotic effects. Doses of 0.2 mg intravenously (IV) or 0.4 mg IV, intramuscularly (IM) or subcutaneously (SC), may be given and repeated each 2 to 5 minutes until CNS, respiratory, or hypotensive narcotic symptoms are reversed, to a maximum dose of 10 mg. Nalmefene is a similar narcotic antagonist with longer duration of action initially given in IV doses of 0.25 mg each 2 to 5 minutes to a total dose of 1 mg (4 doses).^[6] Continuous monitoring of blood pressure, mental status, and respiratory status is critical, with possible repeat doses necessary in 1 to 2 hours. Pain may return with aggressive narcotic reversal, and a balance between pain alleviation and physiologic stability is desired. Additionally, narcotic antagonists may lead to acute narcotic withdrawal symptoms in persons with a tolerance to and dependence on narcotics.

Narcotic agonist-antagonist combinations first became popular with pentazocine, which has less addictive potential than pure narcotic agonists. However, these agents may depress the brain and respiration.^[35] These may be of special significance in a high-altitude setting where impaired pulmonary and cerebral function may occur. These medications do not provide narcotic agonist effects needed in narcotic-dependent persons, and they may experience withdrawal symptoms without narcotic agonists. Familiar drugs in this class include buprenorphine, butorphanol, and nalbuphine.

NONNARCOTIC ANALGESICS.

Nonnarcotic analgesics provide mild to moderate pain relief and are generally safer than narcotics. Acetylsalicylic acid (aspirin) reduces fever, inhibits platelet function, and diminishes inflammation. It has significant GI effects, including gastric irritability, erosion, and bleeding ulcers, and is often better tolerated in an enteric-coated formulation.

TABLE 16-1 -- Common Oral Analgesics: Dosage Recommendations in 70-kg Adults*

DRUG	DOSAGE (mg)	INTERVAL (hr)	RISKS, PRECAUTIONS
SALICYLATES			
Acetylsalicylic acid (aspirin)	325–650	3–4	GI distress, inhibits platelet function, contraindicated in children with viral illnesses
Diflunisal	300–600	8–12	Similar to aspirin

?-AMINOPHENOL

Acetaminophen	300–650	4–6	Hepatic toxicity in overdose
---------------	---------	-----	------------------------------

INDOLES

Indomethacin	50	4–6	Similar to aspirin
Sulindac	50–75	4–6	Similar to aspirin
Ketorolac	30–60	4–6	Similar to aspirin

PROPIONIC ACIDS

Fenoprofen	400–600	4–6	Similar to aspirin
Ibuprofen	300–400	4–6	Similar to aspirin
Naproxen	250–500	8–12	Similar to aspirin

COX-2 INHIBITORS

Rofecoxib	12.5–50	24	GI distress, hypertension
Celecoxib	100–200	12–24	GI distress, skin rash

NARCOTIC AGONISTS

Codeine	30–60	3–4	Narcotic side effects
Oxycodone	5–10	4–6	Narcotic side effects
Methadone	2.5–10	8	Narcotic side effects
Propoxyphene	32–65	4–8	Narcotic side effects

TABLE 16-2 -- Common Parenteral Analgesics*

DRUG	DOSAGE (mg)	INTERVAL (hr)	RISKS, PRECAUTIONS
NARCOTIC AGONISTS			
Codeine	15–60 IM	4–6	Narcotic side effects
Hydromorphone	1–4 IM	2–3	Narcotic side effects
Morphine	10–20 IM, 2.5 IV	2–4	Narcotic side effects
Meperidine	50–100 IM, 25–50 IV	2–4	Narcotic side effects

NARCOTIC AGONIST/ANTAGONISTS

Buprenorphine	0.3–0.6 IM	6–8	May precipitate withdrawal
Butorphanol	2–4 IM	3–4	May precipitate withdrawal
Dezocine	5–20 IM, 5–10 IV	2–4	May precipitate withdrawal
Nalbuphine	10–20 IM, 1–5 IV	3–6	May precipitate withdrawal

NSAID

Ketorolac	15–30 IM, 2–5 IV	4–6	Similar to aspirin
-----------	------------------	-----	--------------------

DISSOCIATIVE ANALGESIC/ANESTHETIC

Ketamine	50–75 IM, 15–30 IV	2–4	Increased intracranial pressure
----------	--------------------	-----	---------------------------------

* Data from Burham T et al, editors: *Drug facts and comparisons*, St Louis, 1999, *Facts and Comparisons*; and Lubenow TR, McCarthy RJ, Ivankovich AD: *Management of acute postoperative pain*. In Barash PG, Cullen BF, Stoelting RK, editors: *Clinical anesthesia*, ed 2, Philadelphia, 1993, JB Lippincott.

Persons with a history of GI ulcers or severe indigestion should avoid aspirin. Dosage should not exceed 650 mg orally every 4 hours. Other salicylate analgesics include diflunisal, choline magnesium trisalicylate, and salsalate. The latter two have minimal GI toxicity and antiplatelet effects. Salicylates are contraindicated in persons with known allergy to the class of drugs and in children under age 15 years with viral respiratory illnesses because their use has been linked to Reye's syndrome.^[4]

Acetaminophen is a paraaminophenol that is a mild analgesic and antipyretic.^[10] It has no antiplatelet, antiinflammatory, or antiprostaglandin effect and is less likely to cause serious gastric irritation. Dose should not exceed 650 mg every 4 hours. Ingestion of more than 10 g over 24 hours may lead to severe hepatic damage; the drug should be used with extreme caution in anyone with preexisting liver disease. Many OTC medications contain acetaminophen, so these should not be used in combination with pure acetaminophen or in persons with liver disease.

Indomethacin is an indoleacetic acid derivative with analgesic, antipyretic, and antiinflammatory (antiprostaglandin) effects. Both rectal and oral administration lead to rapid absorption. Use reasonable caution in persons with hepatic or renal dysfunction. GI toxicity has been reported with its use, including gastric ulceration and perforation, as well as bone marrow suppression. Other acetic acid derivatives include sulindac, tolmetin, ketorolac, and diclofenac.

Ibuprofen is a nonsteroidal propionic acid derivative antiinflammatory agent with

prostaglandin antagonist activities. Its analgesic and antipyretic properties are similar to those of aspirin and acetaminophen, but it may be better for women with dysmenorrhea because its antiprostaglandin effects somewhat relax the uterus. Its antiinflammatory properties may be very useful for arthritis and acute injuries. Like aspirin, ibuprofen can be a gastric irritant and should be avoided in persons with a history of GI ulcer, indigestion, or hiatal hernia. Oral and rectal administration leads to rapid absorption. Ibuprofen has been reported to cause nonspecific fluid retention. Although not studied in wilderness medicine research to this point, its potential to aggravate high-altitude illnesses from acute mountain sickness to high-altitude pulmonary or cerebral edema should be considered. Usual dosage is 400 to 600 mg every 4 to 6 hours. Other propionic acid derivatives include naproxen, fenoprofen, ketoprofen, and flurbiprofen.^[10]

The newest class of nonsteroidal antiinflammatory drug (NSAID) medications currently available in the United States is the cyclooxygenase-2 (COX-2) inhibitor group, consisting of rofecoxib and celecoxib. These medications inhibit inflammation and also demonstrate analgesic and antipyretic properties. Mechanism of action is believed to be through inhibition of prostaglandin synthesis via inhibition of COX-2. These medications may be taken orally once per day and are not yet cleared for patients under age 18 years or for patients with advanced renal disease. Elimination is primarily via hepatic metabolism, with little of the drug recovered in the urine. Side effects primarily include GI distress, hypertension, skin rashes, and peripheral edema. The recommended dosage for rofecoxib is 12.5 to 25 mg once daily. Celecoxib may be given either 100 mg bid or 200 mg daily, with no clinical advantage seen with either method of administration.

Local Anesthetics ([Table 16-3](#))

LOCAL ANESTHETIC PHARMACOLOGY.

For centuries, coca shrub leaves indigenous to the Andes Mountains were used, creating a mouth-numbing effect. Gaedicke extracted the alkaloid *erythroxylin* in 1855, from which Niemann isolated cocaine in 1860.^[8] Carl Koller first reported using ophthalmic cocaine anesthesia in 1884. Subsequent enthusiasm led to the use of cocaine for anesthesia of the nasopharynx and oropharynx for surgery of the ear, nose, and throat. Erdtman of Sweden synthesized lidocaine in 1943.^[8]

Local anesthetics block nerve conduction through sodium-blocking properties in free nerve endings, peripheral nerves, spinal roots, and autonomic ganglia. Normally, the cell's sodium-potassium pump constantly pumps sodium out of and potassium into the cell to restore membrane ionic gradients. The anesthetic renders the membrane impermeable to the influx of sodium during depolarization, and the nerve cell thus remains polarized. Anesthetic drug binding occurs within the sodium channel after the drug enters the channel from the intracellular side of the nerve membrane.^[11] Variables such as nerve length, rate of nerve impulse transmission, concentration, and volume of local anesthetic will determine the rate of onset and extent of therapeutic effect. Anesthetic potency, as well as

TABLE 16-3 -- Comparable Anesthetic Doses for Peripheral Blocks and Local Infiltration (No Epinephrine Included)

onset and duration of action, depends on factors that include lipid solubility, protein binding, and ionization. In general, the "S" stereoisomer has less toxicity and greater duration than the "R" stereoisomer. Anesthetic metabolism and elimination are functions of the specific anesthetic's chemical structure.^[11]

Lidocaine was the first of the amino amide class of local anesthetics. It is metabolized by hepatic microsomal enzymes. Since its metabolites do not include paraaminobenzoic acid (PABA), allergic reactions are rare. Procaine is a synthetic amino ester local anesthetic. This class of anesthetic is hydrolyzed by cholinesterase to form paraaminobenzoic acid, which is responsible for allergic reactions seen with ester anesthetics. Because the esters are relatively unstable, they do not tolerate repeated autoclaving for sterilization.^[7] Although no specific studies have addressed temperature extremes experienced by supplies in wilderness settings, it is prudent to protect these medications from heat as much as is reasonably possible.

A local anesthetic may provide relief in a topical application before more invasive cleansing and debridement. TAC is a mixture of tetracaine 0.5%, adrenaline 1:2000, and cocaine 11.8% in saline, which may be soaked into a sterile bandage and placed directly over a wound. This combination may provide good analgesia and moderate vasoconstriction.^[38] Adverse effects to cocaine absorbed by this method have been reported. The local anesthetic EMLA is a eutectic mixture of 5% lidocaine and prilocaine. After this cream is applied to intact skin under a nonabsorbent dressing for at least 45 minutes, an invasive procedure such as IV needle insertion may be more easily

tolerated.

ANESTHETIC TOXICITY.

Blood level of anesthetic after tissue injection depends on absorption, dosage, metabolism, and elimination, with increased tissue vascularity and vasoactivity of the anesthetic having great effects. Infiltration into a highly vascular site, such as around an intercostal nerve, leads to more rapid escalation of blood level than does injection into less vascular subcutaneous tissues. Use of an anesthetic/epinephrine mixture leads to slower absorption but must be avoided when injecting distal extremities and digits, where epinephrine-induced vasoconstriction may lead to acute ischemic injury. Because of the possibility of unintentional direct intravascular injection, all local and regional anesthetic infiltrations should be made after negative aspiration for blood and in small aliquots between aspiration attempts.

As anesthetic toxicity levels are approached, common early symptoms include circumoral numbness, tinnitus, and cephalgia. CNS toxicity in the form of seizures occurs at lower anesthetic blood levels than does cardiotoxicity seen as ventricular arrhythmias and cardiovascular collapse. Lidocaine's CNS effects are actually paradoxical. At blood concentrations of 3 to 5 µg/ml, lidocaine is an anticonvulsant, whereas blood concentrations of 10 to 12 µg/ml are associated with seizures. Generally, cardiotoxicity is achieved at approximately 150% of the blood level concentrations required for anesthetic CNS toxicity. Bupivacaine has demonstrated increased cardiotoxicity out of proportion to its increased potency, relative to lidocaine.^[11]

Anesthetic allergy per se is uncommon, with perhaps 99% of all adverse anesthetic reactions actually related to pharmacologic toxicity of the anesthetic or to epinephrine mixed with the agent.^[11] Ester anesthetic allergies are related to PABA metabolites; therefore intolerance to PABA-containing sunscreens may indicate allergic tendency to ester anesthetics. Allergies to amide anesthetics in preservative-free vials are rare. There is no known evidence of cross-sensitivity between amide and ester anesthetic classes.

Anesthetic Infiltration Techniques and Nerve Blocks.

Soft tissue analgesia is accomplished with local injection of 1% lidocaine. Generally, the maximum injectable dose for lidocaine is 4 mg/kg. Take care to inject from the wound periphery toward the wound's center to decrease the chance of spreading bacteria or foreign matter to adjacent tissue.^[38] In larger wounds, injections proceed from an area previously anesthetized to lessen discomfort from subsequent injections.

Local anesthetic injection typically causes temporary pain resulting from the solution's pH. Buffered solutions are available or may be created by adding sodium bicarbonate (1 mEq/ml) to lidocaine or other anesthetic in a 1:10 ratio, bicarbonate to anesthetic. Tolerance to the injection is improved by gentle and slow injection, allowing prudence with the total dose of anesthetic. Adding epinephrine is not generally recommended for soft tissue, although it may provide useful hemostasis, especially in head and scalp lacerations. Avoid using epinephrine on nose tips, ear lobes, distal extremities, and

digits to avoid ischemic injury or even subsequent necrosis.

Many central and regional nerve blocks require special training, including a thorough knowledge of anatomy and management of potential complications, but several blocks can be appropriate in a wilderness setting if the physician is cautious and limits the amount of anesthetic injected. Make all infiltrations after aseptic preparation of the skin, whenever possible.

DIGITAL NERVE BLOCKS ([Figure 16-1](#)).

Anesthesia to the digits is easily accomplished with a low-volume field block to the medial and lateral aspects of the digit at the base of the respective phalanx. Approach the digital nerves from the dorsum of the hand or foot rather than from the palm or sole. The dorsal digital nerves and proper digital nerves course along the medial and lateral aspects of the digits roughly at the 10 and 2 o'clock

406

Figure 16-1 A, Site of digital nerve block. B, Digital nerve anatomy. (A courtesy Bryan L. Frank, MD.)

and 4 and 8 o'clock positions, respectively. From 3 to 5 ml of lidocaine 0.5% to 1.0% injected as a field block with a 25-gauge (or 27-gauge) needle to the medial and lateral aspects of the proximal digit gives a satisfactory digital block. *Do not use an epinephrine-containing anesthetic* because this could lead to circulatory compromise and possible necrosis of the digit.

WRIST BLOCKS ([Figure 16-2](#)).

The entire hand may be anesthetized by blocking the nerves at the wrist. The radial nerve supplies the cutaneous branches of the dorsum of the hand and thumb, and distally to the distal interphalangeal joints of the index, long, and radial aspect of the ring fingers. Median nerve sensory distribution includes the palmar surface of the hand, the ulnar aspect of the thumb, the palmar aspect of the index finger, and the long and radial portion of the ring finger. The median nerve innervation extends dorsally over the index, long, and ring fingers to the distal interphalangeal joint. The ulnar nerve gives sensation to the palmar and dorsal surfaces of the lateral hand, the fifth finger, and the ulnar half of the ring finger.^[5]

Using a 25-gauge needle, inject 2 to 4 ml of lidocaine 1% in the subcutaneous tissue overlying the radial artery. A superficial subcutaneous injection from this point and over the radial styloid anesthetizes cutaneous branches from the proximal forearm and

extending into the hand.^[42] Block the median nerve with 2 to 4 ml of lidocaine 1% just proximal to the palmar wrist crease between the tendons of the palmaris longus and the flexor carpi radialis muscles. Make the

Figure 16-2 Landmarks for wrist block. (Courtesy Bryan L. Frank, MD.)

injection deep to the volar fascia. If a paresthesia is elicited (resulting from contact with the nerve), withdraw the needle slightly before injection. Block the ulnar nerve with 2 to 4 ml of lidocaine 1% injected just lateral to the ulnar artery, which is radial to the flexor carpi ulnaris tendon at the level of the ulnar styloid.

ANKLE BLOCKS (Figure 16-3).

Anesthesia of the foot is easily accomplished with blocks of the sensory nerves at the ankle. Using a 25-gauge needle, block the deep peroneal nerve, providing sensation between the great and second toes, with 5 ml of lidocaine 1% between the tendons of the tibialis anterior and the extensor hallucis longus at the level of the medial and lateral malleoli. The needle may be passed to the bone just lateral to the dorsalis pedis artery. Inject the superficial peroneal nerve with 5 ml of lidocaine 1% with a superficial ring block between the injection of the deep peroneal nerve and the medial malleolus. This blocks sensation to the medial and dorsal aspects of the foot. Inject the posterior tibial nerve with 5 ml of lidocaine 1% just posterior to the medial malleolus, adjacent to the posterior tibial artery. Paresthesias are sought in these blocks and will increase the likelihood of success.^[28] Posterior tibial nerve distribution includes the heel and plantar foot surface. Follow paresthesias by a slight withdrawal of the needle before injection. Block the sural nerve, providing sensation to the posterolateral foot, with a similar volume of lidocaine 1% between the lateral malleolus and Achilles tendon, followed by a subcutaneous infiltration from this site and over the lateral malleolus.^[42]

TRIGGER POINT INJECTIONS.

Persons who suffer from neck and shoulder or lower back strain may benefit greatly from deactivation of myofascial trigger zones. The pain relief may be profound and enable an adventure to continue without disruption. Travell and Simons have extensively described primary and secondary painful points and their referral patterns. Myofascial pain may be intense and be referred to a large zone of the body.^[45] Successful deactivation of trigger zones may be accomplished with either dry needling

(acupuncture) or injection of lidocaine 1%. In the absence of anesthetic or acupuncture needles, trigger point deactivation may be accomplished with a 27-gauge needle.

Injection of a trigger zone is typically performed directly into the painful myofascial point and in a four-quadrant zone from the center of the trigger point, advancing 1 to 2 cm into the adjacent tissue at a 45- to 60-degree angle from the skin surface. Muscle twitches, or fasciculations, may accompany the injections though need not be sought. A volume of 1 to 2 ml of lidocaine 1% is usually ample for each trigger zone. There is no benefit to adding corticosteroids to the anesthetic. Using an acupuncture needle (or a 27- or 30-gauge needle) may deactivate the trigger zones nicely using a similar four-quadrant pecking of the myofascial zone, without injection of anesthetic. A 1- to 1 ½-inch needle may be used to peck briskly several times in each direction, also at a 45- to 60-degree angle from the center of the trigger zone. Depth of insertion is typically 1 to 2 cm. Soiled skin should be prepared similar as for an IM injection.

Figure 16-3 Landmarks for ankle block. (Courtesy Bryan L. Frank, MD.)

Intravenous Regional Anesthesia or Bier Blocks.

The Bier block may provide significant anesthesia to stabilize an arm or leg fracture for a physician unfamiliar with the anatomy and technique of a more sophisticated proximal nerve block. Because a tourniquet is necessary, a Bier block is generally not useful for longer than 60 to 90 minutes.

A vein of the hand or foot on the extremity to be blocked is cannulated with a 20- to 22-gauge IV catheter or butterfly, which is then capped and taped in place. The extremity is then raised above the level of the heart for 1 to 2 minutes to diminish the volume of

blood in the distal limb. If tolerated, wrap an Esmarch (rubber) bandage or elastic bandage from the hand or foot toward the proximal arm or leg to exsanguinate the limb. If a compression bandage is not tolerated, elevate the extremity for 5 to 10 minutes or apply an inflatable splint. Apply a tourniquet and hold the pressure at 50 to 100 mm Hg above systolic blood pressure. In the wilderness, a blood pressure cuff is effective, or a strap, rope, or tubing may be used. Place the limb horizontally for the injection, using 25 ml of lidocaine 1% for the upper extremity and 35 ml of lidocaine 1% for the lower

extremity. Slowly infuse the anesthetic through the previously inserted intravenous catheter or butterfly at a rate of approximately 0.5 ml per second. Take care to avoid extravasation of the anesthetic into the surrounding tissues.

Anesthesia will ensue over the first 10 to 15 minutes as the lidocaine diffuses from the intravascular space and binds to the soft tissue. Discontinue the injection if the tourniquet pressure is not maintained during injection to prevent anesthetic toxicity from an unrestricted IV bolus injection. The tourniquet should remain inflated for 60 to 90 minutes, when most of the anesthetic should be protein bound in the soft tissues. Then release the tourniquet all at once and the anesthetic effect will diminish within 5 to 10 minutes.

Other Pain Pharmaceuticals

Pharmaceutical agents other than narcotic analgesics and local anesthetics may offer significant relief and prevent or decrease the potential adverse effects of analgesics and anesthetics.

Ketamine.

Ketamine is a dissociative anesthetic agent that provides significant analgesia. Its mechanism of action is probably related to its agonist effects on the glutamate receptor of the *N*-methyl-D-aspartate (NMDA) subtype.^[53] NMDA may affect central or peripheral neuropathic pain transmission more than nociceptive transmission in tactile or thermal modalities.^[3] ^[26] Ketamine is believed to activate μ -opioid receptors responsible for analgesia and δ -opioid receptors for dysphoria.^[19] In wilderness settings where respiratory depression may be a significant concern, ketamine may provide significant analgesia and a dissociative state with tolerable respiratory depression and some loss of glossopharyngeal reflexes. Ketamine possesses sympathomimetic activity that may prove useful in injured persons with depressed cardiac function or shock and may also provide bronchodilation for victims with reactive airway disease. It is contraindicated with head injury because it increases intracranial pressure.^[25] Intracranial pressure increase results from augmented cerebral blood flow and direct cerebral vasodilatation. Cerebral metabolic oxygen requirements increase as well.^[4]

An IV dose of 0.2 to 0.4 mg/kg ketamine provides analgesia and 1 to 2 mg/kg IV or 2 to 4 mg/kg IM leads to profound analgesia and a dissociative state. A quiet and calm setting diminishes unpleasant dissociative experiences for the recipient.

Nonsteroidal Antiinflammatory Drugs.

NSAIDs are effective for mild to moderate pain and may provide ample clinical benefit without producing the respiratory depression seen with narcotic analgesics. The mechanism of action is most likely due to inhibition of a prostaglandin-mediated amplification of chemical and mechanical irritant effects on the sensory pathways. ^[33] NSAIDs undergo rapid absorption after oral or rectal administration, followed by hepatic metabolism and renal excretion of their conjugated metabolites. Injectable forms of

various NSAIDs have also been developed in recent years. This nonsteroidal class of medications includes chemically unrelated compounds grouped together by their therapeutic actions, represented by agents such as acetic acid, propionic acid, oxicam, and pyrazolone derivatives.

Adverse effects of NSAIDs include GI distress and bleeding, CNS disturbances (vertigo, drowsiness), and prolonged bleeding from platelet function inhibition. In certain circumstances, NSAID-induced immunosuppression increases a propensity to bacterial infection.

Antidepressants.

Wilderness travelers may be taking antidepressant medications for chronic pain or psychoemotional dysfunction. Continuation of these medications is important to avoid intensification of pain or psychoemotional liability. Chronic pain conditions that may benefit from antidepressants include migraine cephalgia, postherpetic neuralgia, and diabetic neuropathy. The tertiary amine tricyclic drugs (e.g., amitriptyline, imipramine, doxepin, and clomipramine) are commonly used for pain problems. Antidepressant medications are presumably effective for treating chronic pain problems by blocking presynaptic reuptake of serotonin and/or norepinephrine by the amine pump.^[2] These drugs are rapidly absorbed after oral administration, although this may be decreased by antimuscarinic effects. They are highly protein-bound and have half-lives of 1 to 4 days. They are generally oxidized by the hepatic microsomal system and conjugated with glucuronic acid. Elimination occurs via urine and feces.^[24]

Side effects may include dry mouth, urinary retention, constipation, and hyperactivity.^[18] Photosensitivity may place wilderness travelers at risk for sunburn, and orthostatic hypotension may lead to falls. Overdoses produce excessive sedation, anticholinergic effects on the cardiac conduction system, significant hypotension, respiratory depression, arrhythmias, and coma.

Anticonvulsants.

Of all the drugs classified as anticonvulsants, four are useful as adjuvant medications in

pain management: phenytoin, valproic acid, carbamazepine, and clonazepam. Their chemical structures bear little relationship to one another. Serum levels have not been clearly established as useful parameters in pain management. The mechanism of action of each of these drug classes is unique and varies from altering sodium, calcium, and potassium flux, to enhancing GABA activity or binding.^[24]

Side effects vary but may include nausea and vomiting and CNS effects, such as drowsiness, ataxia, and confusion. It is important to rule out drug effects as a factor in wilderness-related illnesses. These drugs are not recommended for acute pain

management in the wilderness.

Antihistamines.

Antihistamines may be useful adjuvants. Specifically, hydroxyzine provides additive analgesic effect in combination with narcotic analgesics while also lending antiemetic and sedative properties. Hydroxyzine may cause ataxia and disinhibition and on rare occasions is associated with convulsions when used in high doses.^[24] A dose of 50 to 100 mg IM may improve clinical pain management. Similarly, oral antihistamines, such as diphenhydramine 25 to 50 mg PO, may provide useful adjuvant effects.

Muscle Relaxants.

The term *muscle relaxants* refers to a diverse group of drugs with similar clinical effects but different pharmacologic properties. They are not true skeletal muscle relaxants in the sense of blocking neuromuscular transmission but act by depressing reflexes, generally in the CNS. They are indicated for the relief of muscle spasm related to acute, painful, musculoskeletal injuries. Side effects include decreased alertness, motor coordination, and physical dexterity.

Common centrally acting muscle relaxants include carisoprodol (Soma), 350 mg PO tid-qid; metaxalone (Skelaxin), 800 mg PO tid-qid; and methocarbamol (Robaxin), 1.5 g PO qid for the first 48 to 72 hours, then 1 g PO qid. The specific mechanism of action is unknown but appears to be related to centrally acting sedation. Cyclobenzaprine (Flexeril), 10 to 20 mg PO tid, is structurally related to the tricyclic antidepressant medications. Diazepam (Valium), 2 to 10 mg PO, IM, or IV, is a benzodiazepine that induces calm and anxiolysis via effects on the thalamus and hypothalamus.^[6]

Transcutaneous Electrical Nerve Stimulation

Shealy and Liss developed the transcutaneous electrical nerve stimulator as a trial for patients considering spinal cord electrical stimulation to relieve chronic pain.^[1] TENS units are so commonly used that wilderness physicians will probably encounter persons using these devices. The mechanism of action is believed to involve stimulation of large, myelinated A fibers, which block C fiber pain sensation from reaching the brain. This process is explained at least in part by the gate control theory of Melzack and Wall.^[37] Additionally, Pomeranz and others have shown the neurohumoral effects of electrical stimulation to include endorphins, enkephalins, serotonin, GABA, adrenocorticotrophic hormone (ACTH), and other modulators. High-intensity, low-frequency electrical stimulation elicits an endorphinergic response, whereas low-intensity, high-frequency electrical stimulation leads to spinal segmental analgesia, and monoamine-based presynaptic and postsynaptic inhibition of pain signals.^[44] Increased plasma and cerebrospinal fluid (CSF) levels of endorphins with high- or low-frequency electrical stimulation are sometimes seen. Conventional TENS units offer stimulation frequencies of 50 to 80 Hz, whereas acupuncture-like TENS devices use stimulation frequencies from less than 10 Hz to greater than 100 Hz.

Wilderness physicians familiar with TENS units may find them useful to treat acute traumatic pain, but more likely, a traveler will have a TENS unit. Most persons have developed personal preferences for TENS unit settings and skin electrode placement. Rigorous physical activity may cause difficulty maintaining electrode placement. Application to clean, dry skin is important. Preparing the skin with topical benzoin may significantly increase the duration of adhesiveness. Because benzoin is an iodine-based topical solution, avoid it in persons with sensitivity or allergy to iodine.

Complementary and Alternative Medicine Therapies

"Complementary and alternative" denote therapies and modalities that may not be supported by Western-designed prospective, randomized studies, that are not commonly taught in U.S. medical colleges, or that are not generally covered by traditional health insurance plans.^[14] ^[15] ^[48] Some may contribute significantly to wilderness pain management.

Acupuncture.

Acupuncture has developed over 3 to 5 millennia in Asia and has existed over the past several hundred years in the Western world. Conditions in which acupuncture developed are very similar to those found by wilderness travelers. The use of acupuncture by physicians to treat trauma and illness in wilderness settings has been described recently in medical literature.^[20] ^[22] Properly administered acupuncture should have a very low risk of morbidity and may be extremely effective in alleviating pain and even restoring function to an injured wilderness traveler ([Figures 16-4](#)).

Pomeranz and others have demonstrated endorphin, enkephalin, monamine, and ACTH release with acupuncture stimulation.^[44] Other effects, such as the gate theory and altered sympathetic activity,^[30] may apply as well. Clinically, improved microvascular circulation may lead to decreases in tissue edema, which in

Figure 16-4 Typical acupuncture needle placement for lateral ankle strain.
(Courtesy Bryan L. Frank, MD.)

Figure 16-5 Patient with auricular needles in place. (Courtesy Bryan L. Frank, MD.)

turn may diminish pain and aid in restoring function. The release of ACTH leads to increased circulating corticosteroids; decreased inflammation may contribute to decreased pain and improved healing.^[27]

Contemporary medical acupuncturists are typically trained in a variety of styles or traditions. Many physicians use a combined approach of acupuncture point selections based on neuroanatomy and those believed to have energetic effects in the body. Additionally, acupuncture microsystems are often used, in which the entire body is represented in a small area such as the ear, scalp, or hand. These microsystems are often quite beneficial for acute pain^[22] ([Figure 16-5](#)).

Sterile acupuncture needles are compact, lightweight, and easy to include in a day pack or first-aid kit. Integration of acupuncture into the biomedical care of wilderness trauma, pain, and illness may dramatically enhance patient comfort and facilitate extrication from a remote setting.

An energetic style of acupuncture that is especially useful for common trauma utilizes the tendinomuscular meridians (TMM) of the acupuncture energetic subsystems. The indications for activation of the TMM treatment include acute strains, sprains, abrasions, and hematomas. A needle is placed in the "Ting" point of one to three of the meridians involved in the lesion. This is followed by placing a needle in the "Gathering" point for the meridian(s), then by placement of needles approximately 1 cm around the area of induration, swelling, or bruising. All needles in this treatment are placed to only 2 to 3 mm depth and are left in place for 20 to 45 minutes.

For example, sprained ankles often respond to acupuncture. Commonly, a lateral ankle sprain involves both the gall bladder and bladder TMM zones. The Ting points for these meridians are at GB 44 and BL 67 on the lateral angles of the fourth and fifth toes, respectively. The Gathering point for these meridians is at SI 18, just below the zygoma in line with the lateral canthus. Local needles typically include four to six placed around the swelling or ecchymosis of the ankle sprain. Recovery from the sprain may proceed much more rapidly with this type of acupuncture input than with conventional therapies of rest, ice, compression, and elevation (RICE) alone. Failure to respond with 70% to 85% or greater decrease in pain over 24 to 48 hours may in fact alert the medical acupuncturist that an injury may be more serious than initially appreciated.

Most acupuncture treatment requires substantial training to be responsibly integrated with conventional Western therapies. National and international standards of training have been established for Western-trained physicians who desire to incorporate acupuncture into their traditional medical practices. The American Academy of Medical

Acupuncture (AAMA) represents physician acupuncturists whose training meets or exceeds standards established by the World Health Organization, the World Federation of Acupuncture and Moxibustion Societies, and the International Congress of Medical Acupuncture and Related Therapies (ICMART). Physicians interested in learning acupuncture may contact the AAMA at (323) 937-5514 for information on training programs designed specifically for physicians. The National Commission for Certification of Acupuncture and Oriental Medicine provides testing and resources primarily for nonphysician acupuncturists.^[21]

Herbal/Botanical Remedies (See [Chapter 50](#)).

The term *herb* is broadly defined as a nonwoody plant that dies down to the ground after flowering. The term *botanical* is a more general description of flora, although common interpretation includes any plant used for medicinal therapy, nutritional value, food seasoning, or dyeing another substance as an herb.^[13] As with acupuncture, the use of botanicals may be encountered in wilderness travels as a part of the indigenous culture and medical care. Botanicals are often prepared as infusions,

with the plant's soft portions placed in a pot and covered by boiling water to create a supernatant. Herbal decoctions are traditionally prepared in special earthen crocks, or in containers of stainless steel, ceramic, or enamel by contemporary practitioners, specifically avoiding aluminum and alloy metal pots. The herb is placed in the container and covered with cold water that is then boiled, covered, and simmered. Travelers may encounter an herbal remedy dispensed as a poultice, botanical liniment, ointment, or oil to be applied to the skin. Alternately, many modern herbalists utilize capsule forms of herbs for ease of administration. Combinations of several herbs are often more effective than a single herb, and common formulas have been recorded worldwide for centuries.^[29] Appropriate application or prescription of botanical products rarely leads to toxicity or adverse reactions, although such are possible if botanicals are used excessively or carelessly.

Certain botanical products used for pain include morphine, isolated from the opium poppy, and cocaine, from coca leaves (*Erythroxylon coca*). Often used as a seasoning or food, oregano (*Origanum vulgare*) has been beneficial for rheumatic pain.^[29] Sunflower (*Helianthus annuus*) is a source of phenylalanine, useful for general pain. Turmeric (*Curcuma longa*) contains curcumin, an antiinflammatory substance beneficial for rheumatoid arthritis, and ginger (*Zingiber officinale*) is beneficial for rheumatoid arthritis, osteoarthritis and fibromyalgia. Clove (*Syzygium aromaticum*) is endorsed by the German botanical resource, Commission E, topically for dental pain. Red peppers (*Capsicum* species) contain substance P-depleting capsaicin and also salicylates. Often taken as an infusion or decoction, kava kava (*Piper methysticum*) contains both dihydrokavain and dihydromethysticin, which have analgesic effectiveness similar to that of aspirin. Evening primrose (*Oenothera biennis*) is a great source of tryptophan and has been demonstrated to relieve pain associated with diabetic neuropathy. Lavender (*Lavandula* species) contains linalool and linalyl aldehyde, which appear to be

useful for pain of burns and other injuries in topical and aromatherapy form.^[13]

Willow (*Salix* species), used to treat pain since 500 BC, contains salicin and other salicylate compounds. The German Commission E has recognized willow as an effective pain reliever for headaches, arthritis, and many other pains.

Salicylate-containing plants include red peppers, wintergreen, and birch bark. Avoid all botanicals containing salicylates in persons who are sensitive or allergic to aspirin products. Further, children who have viral infections, such as a cold or influenza, should avoid these products because salicylates have been implicated in the development of Reye's syndrome.^[13]

Chamomile (*Matricaria chamomilla*) contains chamazulene, which is reportedly beneficial for abdominal pain related to GI spasm or colic; as an antihistaminic, it has mild calming or sedative properties. It is used in Europe to treat leg ulcers and may be beneficial for painful, irritated bites and stings.^[13] Plantain major (*Plantago major*) is also commonly used for bites and stings, poison ivy discomfort, and toothache, and has been used traditionally by Native Americans as a wound dressing. Aloe gel (*Aloe vera*) has been used since ancient times to treat burns and sunburn and to promote wound healing.

Especially useful for sprains and strains is the mountain daisy or arnica (*Arnica montana*), which is also endorsed by Commission E. Arnica was in *the U.S. Pharmacopoeia* in the early 1800s to 1960s and has long been used by Native Americans and others for relieving back pain and other myofascial pains and bruising. It is used topically or internally, often in homeopathic form. Comfrey (*Symphytum officinale*) has been used since ancient Greece for skin problems.^[13] It contains alloin, which is antiinflammatory, and is endorsed by Commission E to topically treat bruises, dislocations, and sprains. Comfrey has experienced a controversial safety record because oral ingestion of its pyrrolizidine alkaloids has been associated with hepatotoxicity and/or carcinogenicity.^[13] For this reason, only topical use of comfrey is recommended.

Magnet Therapy.

Magnetic therapy has been described for approximately 4000 years in the Hindu Vedas and the Chinese acupuncture classic, Huang Te Nei Ching. The application of magnetic stones, or *lodestones*, is said in ancient legends of Cleopatra and others to have decreased pain and preserved youth. Early Romans used the discharge of the electric eel to treat arthritis and gout.^[31]

Danish physicist Oerstad proved in 1820 that an electric current flowing through a wire had its own magnetic field. Modern medicine's most familiar use of magnetic energy is with magnetic resonance imaging (MRI). There are various theories about the effectiveness of permanent magnets for use in pain and healing. Lawrence^[31] reports increased blood circulation and increased macrophage activity and Lednev,^[32] Olney et al,^[39] and McLean et al^[36] have hypothesized effects on peripheral nerves, including blockage or modification of sensory neuron action potentials and enhanced

regeneration of peripheral nerves. [\[47\]](#)

Most permanent magnets marketed at this time for management of pain measure approximately 200 to 1200 gauss in strength. At this level, there is little if any risk in trying a magnet for pain reduction, assuming the patient is properly evaluated to provide other appropriate care. Many patients report significant pain reduction within hours, whereas others report relief after wearing the magnets for a week or more. In wilderness travel, it is reasonable to carry a few magnets because

412

they are usually lightweight, compact, and unbreakable. Magnets marketed for pain therapy range in size from a 2-inch circle to 6- by 12-inch rectangular pads. Most are only a few millimeters thick and are often flexible. These are becoming more readily available through multilevel marketing, television "infomercials," health food stores, and the Internet. Some people have experienced pain relief with simple, small magnets used to place notes and photographs on a refrigerator. Placement of the magnet should be directly over the area of pain, and it should be held in place with tape, clothing, or straps.

Chapter 17 - Emergency Airway Management

Anne E. Dickison

Emergencies involving the airway are among the most urgent conditions necessitating medical intervention. Airway management in the field is a combination of careful physical and scene assessment, recognition of risk, optimization of airway mechanics, and communication to bring the victim to definitive care.

Because the wilderness ability to provide an artificial airway or to assume control of respirations may be quite limited, optimally the victim can be an active participant in the remote-site rescue effort. The drive to breathe is one of the most powerful brainstem reflexes. Although they may be depressed, the autonomic reflexes to cough, gag, swallow, gasp, flare nostrils, open the vocal cords during inspiration, hyperventilate in response to hypoxemia or head injury, and recruit accessory muscles of respiration are generally preserved until the victim is near death. The wilderness rescuer must avoid any medications or interventions that might impair these reflexes.

Only a small minority of airway emergencies occur instantaneously, such as sudden complete airway obstruction by an aspirated foreign body ([Table 17-1](#)) or a crushed larynx from impact with a steering wheel. Certain other rapidly evolving life-threatening emergency situations have major immediate airway considerations, but if the underlying condition can be stabilized or relieved, the need to manage the airway becomes less pressing. Examples in this second category include suffocation, thoracic squeeze, near drowning, intoxication, or any circumstance in which absence of breathing (apnea) can be converted to spontaneous respiratory effort or an obstructed airway can be converted to a patent one.

Airway compromises that are anticipated to worsen with time fall into a third important category. Without timely and anticipatory intervention, an otherwise viable victim might die from a potentially preventable airway death. Examples in this third category include airway injury from inhalation burns; soft tissue trauma to the mouth, tongue, or neck; infections involving the pharyngeal or hypopharyngeal soft tissues; allergic reactions; and angioneurotic edema. Although there could be hours between onset of airway compromise and progression to end-stage respiratory failure, the more compromised

and distorted the airway becomes, the greater the skill (and luck) required to effectively intervene. In a multicasualty incident, the victim with airway compromise in evolution would be prioritized as first to be evacuated.

A fourth category of airway emergency involves the need to establish an artificial airway as a mechanism for providing sustained positive-pressure ventilation. The primary problem in this category is not airway anatomy or patency but rather a situation leading to alveolar hypoventilation. Examples of these circumstances include flail chest with pulmonary contusion; spinal cord injury; pulmonary aspiration resulting in noncompliant lungs or presence of particulate or chemical matter needing to be removed; or pulmonary edema from burns, altitude, or near drowning. In a multicasualty incident, this victim would be triaged as less immediate and, in all likelihood, resuscitative measures would not be initiated.

RECOGNITION OF AIRWAY OBSTRUCTION

The usual indicators for initiating cardiopulmonary resuscitation (CPR) are poor color and unresponsiveness to stimulation. Poor color can be anything from pallor, cyanosis, and mottling to perimortem or postmortem livedo reticularis and livor mortis. Although a very important diagnostic sign, the presence of poor color, even overt cyanosis, does not necessarily mean that the victim is compromised because of an airway emergency or that resuscitative measures should include airway intervention. Cyanosis can be present without airway compromise, and significant airway compromise can be present without cyanosis.

Cyanosis in the absence of airway compromise can result from hypothermia, anemia, hypovolemia, insufficient cardiac output, intrapulmonary or intracardiac shunts, or inadequate tissue perfusion. An allergic reaction with airway edema and vasodilation (causing flushed red skin) is one example of an airway emergency in the absence of cyanosis; unconsciousness (with associated upper airway obstruction) resulting from carbon monoxide poisoning is another.

If cyanosis is not a certain indicator of airway compromise, then what is? The two most important aspects of respiratory assessment are (1) the presence or absence of attempts to breathe; and (2) if attempts are being made, an appreciation of the degree of labor and posture adjustment required to support air exchange. The first observation assesses the integrity of the central nervous system, and the second the patency of airway corridors in combination with elasticity of the lungs and strength of the chest wall.

Labored respirations are typified by a rate that is forcefully rapid, irregular, or gasping. Unusual sounds

TABLE 17-1 -- Causes of Airway Obstruction

CAUSE	INTERVENTION
Aspiration of foreign body	Heimlich maneuver
	Removal by direct visualization and extraction
	Cricothyrotomy

Unconsciousness	Positioning
	Consider airway adjuncts
	Consider cricoid pressure
Apnea	Open airway
	Initiate rescue breathing
	Check for obstruction
	Consider airway adjuncts
Facial or neck trauma	Careful physical examination
	Remove debris in mouth
	Account for teeth
	Assess potential for swelling
	Positioning
	Secretion assistance
Allergic reactions	Remove from source of allergy
	Epinephrine if available
	Consider cool mist
	Consider topical or sprayed vasoconstrictors
	Consider inhaled β -agonists
	Consider airway adjuncts
Seizures	Pad environment
	Consider padded stick between side molars (no fingers)
	If possible, turn on side to facilitate gravity drainage of saliva or vomit

or noisy respirations could be present. Accessory muscles of the chest wall, shoulders, neck, and abdomen strain with the effort. If respiratory effort causes chest wall retractions, there may be an airway emergency in evolution.

Retractions result from mismatch between chest wall effort (when the rib cage expands) and ease of pulmonary air inflow. Pulmonary air inflow can be impeded by upper airway obstruction or by stiff lungs that do not readily expand. The pattern of retractions and the noises made in breathing can indicate which of these two possibilities is more dominant. The "restrictive" respiratory pattern for *stiff lungs* typically involves intercostal retractions, tachypnea, and the respiratory noises of rales (alveolar fine crackles) and "grunting" (the brief holding of breath at end-inspiration, then letting it go with an expulsive and audible quick exhalation).

In contrast, the "obstructive" respiratory pattern for *upper airway obstruction* exhibits greater use of neck and abdominal accessory muscles; comparatively greater supraclavicular, subcostal, and sternal retractions; and

TABLE 17-2 -- Description of Airway Sounds

SOUND	DESCRIPTION
Stridor	A sharp, high-pitched squeaky sound with vocal quality that emanates from the larynx and is usually more prominent on inspiration than expiration
Wheezing	A sustained whistling sound made by air passing through narrowed airways usually distal to the larynx, and generally more prominent in expiration than inspiration; the pitch is lower than stridor and higher than rhonchi
Rhonchi	Gurgling, congested, low-pitched rattling sounds in the chest caused by secretions in the large and medium-sized airways
Grunting	A staccato glottic noise heard in end-expiration only, with a lower pitch than that of stridor; usually found in association with restrictive lung disease or with thoracic or abdominal pain
Snoring	A characteristic low-pitched, very low-frequency inspiratory noise caused by periodically interrupted airflow through the soft tissues of the pharynx

fewer rales relative to the presence of wheezes, stridor, snoring, gurgles, or other abnormal respiratory noises ([Table 17-2](#) and [Table 17-3](#)). In the obstructed airway, expiration tends to be slowed or prolonged, and is not expulsive or accompanied by a "grunt," though it may be audibly wheezy.

Partial obstruction can be recognized by decreased volume exchange (decreased air entry by auscultation or decreased chest rise by inspection) or by increased transit time during inhalation or exhalation. In the normal breathing pattern, a pause occurs between exhalation and the next inspiration. During this resting pause, no respiratory muscles contract to move air. The duration of the pause depends on inspiratory time, expiratory time, and how rapidly a person must breathe to meet the body's obligate metabolic requirements to acquire oxygen and get rid of carbon dioxide. No pause between breaths is an ominous sign. This suggests that there exists a significant airway obstruction (prolonging the inspiratory and expiratory times) or that respiratory failure (to meet metabolic demands) is present or impending.

Any emergent respiratory problem could be "mixed" and have contributions from stiff lungs and from upper airway obstruction. Appreciating the relative contributions of obstruction vs. restriction is important for triage and for evaluating options for airway intervention.

TABLE 17-3 -- Sounds Associated with Airway Obstruction

SITE OF OBSTRUCTION	DISEASE EXAMPLE	SOUND TRANSMISSION
Nose	Upper respiratory infection, broken nose, sinusitis, allergic rhinitis	Dull, less resonant voice; blunting of consonants such as "m"
Nasopharynx	Adenoiditis, injured palate, bulbar palsy	Cannot raise soft palate well, so alteration of vowels, flattening of phonation, "cleft palate" enunciation
Tongue	Macroglossia, swollen tongue, airway burns	Vocal quality unchanged but enunciation is greatly affected, especially with "s," "j," "l," and "w"; snoring may be prominent, especially if the person is asleep or supine
Oropharynx	Tonsillitis, peritonsillar abscess, Ludwig's angina	"Hot potato" phonation; muffling of voice, coarse snoring with sleep
Hypopharynx	Epiglottitis, retropharyngeal abscess, supraglottitis, airway burns	Muffled voice, diminished volume of sound, facial grimacing with effort to speak or swallow, reluctance to vocalize or cry, occasional hoarseness, occasional snoring, rare stridor
Larynx	Croup, laryngomalacia, laryngeal injury/edema, vocal cord dysfunction, broken larynx, airway burns	Stridor common; hoarseness or raspiness on vocalization; wheezing, whistling, or vocal squeak may be present in exhalation; enunciation of consonants not altered, but vowels (especially "e" and "u") may lose their quality and identity
Trachea	Croup, tracheomalacia, airway burns	Hollow, brassy, barking cough that "carries"; wheezing may be prominent; quality of vocalization or resonance may be altered if additional upper airway pathology coincides (e.g., nasal stuffiness, laryngitis)
Large and medium airways	Asthma, aspirated objects, airway burns, near drowning	Wheezing is characteristic; cough often congested, with prominent rhonchi; quality of vocalization or resonance may be altered if additional upper airway pathology coincides (e.g., sinusitis, tonsillar hypertrophy, laryngeal inflammation)

HEAD POSITIONING

The most common causes of upper airway obstruction are a floppy tongue and lax pharyngeal muscles (deep sleep, unconsciousness, muscle weakness, cranial nerve dysfunction), or soft tissue enlargement from infection, edema, or hypertrophy. Because teeth play such an important role in preserving the size and patency of the oropharynx, edentulous persons (the young, elderly, poorly dentitioned, and recently traumatized) are most vulnerable to upper airway obstruction. Upper airway obstruction is almost always improved by optimal head positioning, mouth opening, clearing of nasal passages, and/or tongue manipulation.

Keeping open the mouth of an unconscious person is very important. With the interior of the mouth in view, one can visually gauge the position of the tongue and the presence of vomit, foreign debris, or pooling of secretions, and can hear the quality and regularity of respiratory noises, even at a distance. In the obtunded infant or small child, the site of upper airway obstruction is usually between the tip of the tongue and the hard palate in the front of the mouth. This is easily overcome by flattening the tongue down to the floor of the mouth using a finger, tongue blade, or other smooth object. In an obtunded adult, the site of upper airway obstruction from the tongue is more posterior, usually between the base of the tongue and the posterior oropharynx (back of the throat) ([Figure 17-1](#)). When the tongue is retrodisplaced, it causes the epiglottis to fold over and close off the tracheal introitus, which results in a secondary site of upper airway obstruction. Relief of both of these sources of obstruction will come from lifting the jaw upwards ([Figure 17-2](#)), "dislocating" the jaw hinge to simultaneously keep the mouth open and the jaw lifted ([Figure 17-3](#)), or by traction on the tongue itself.

The optimal head position for airway alignment and patency varies with age. However, no matter what the person's age, the most desirable posture is maintaining "neutral" (not flexion, not hyperextension) head position with the chin "proudly" jutting forward, nose in the "sniffing" position, mouth open, tongue resting on the

Figure 17-1 Tongue position in the unconscious adult. Note airway obstruction by the base of the tongue against the posterior pharyngeal wall with closure of the epiglottis over the

trachea.

Figure 17-2 Triple maneuver airway support: maintain axial alignment of the cervical spine, lift up on the angle of the mandible, and hold open the mouth. Located midway between the chin and the angle of the mandible, the facial artery pulse may be monitored at the same time.

Figure 17-3 Jaw thrust. (Courtesy University of Florida College of Medicine, Department of Anesthesiology.)

417

floor of the mouth, and angle of the mandible perpendicular to the ground ([Figure 17-4](#)). The least desirable head position in any age group is with the neck flexed and chin pointed towards the chest. Flexion also increases unfavorable stresses on a potentially unstable cervical spine. Extreme hyperextension of the head in any age group stresses ligaments, angulates the airway, and is to be avoided.

Head shape, relative head size, and curvature of the cervical spine change with age, so optimal head positioning and pillow support also change. Because of prominence of the cranial occiput in an infant, the baby's airway is best supported with a shoulder roll or built-up surface for the back. The child does best without a pillow or with a built-up cushion for the back and only a small pad for the occiput. The adult's airway is best supported in the sniffing position with a small pillow under the head, the chin pointed in the air, and a preserved natural lordosis of the cervical spine. Improvisationally, the sniffing position can be achieved with a soda can behind the neck and a folded T-shirt under the head (see [Figure 17-4](#)).

If the mechanism of injury or physical examination suggests a possibility for cervical spine injury, efforts to stabilize the neck and head should be undertaken, and

Figure 17-4 Sniffing position of adult attained by using an improvised pillow. The

line of the mandible should be perpendicular to the ground. (Photo from Anne E. Dickison, MD.)

Figure 17-5a A, Patient lying on side with airway/neck in good position and pressure points protected. Flexing the down-side leg stabilizes the torso. The pillow and axillary roll help maintain the spine in good alignment.

the victim should be spared neck flexion, hyperextension, or lateral rotation. Fortunately, the best head position for the airway is also good for the cervical spine. If a cervical spine immobilization method is utilized, the airway should be evaluated for obstruction both before and after application.

BODY POSITIONING

We are accustomed to seeing patients presented to us supine. However, the supine position may be neither desirable nor achievable. Because of gravity, some airways are better maintained in a side-lying or prone position. Nontraditional positioning for stabilization and transport may be necessary because of burns, vomiting, secretion management, or location of impaled objects. Principles of transport for patients in nonsupine positions have to do with preservation of good perfusion and mechanical alignment in all body parts under pressure, maintaining neck straightness, and assuring the ability of the rescuer to monitor airway patency.^{[1] [2] [3] [9]} In a nonsupine position, the same airway posture is sought: minimal torsion of the cervical spine, neck in a sniffing position, mouth open, and tongue on the floor of the mouth ([Figure 17-5](#) [Figure 17-5](#)).

418

Figure 17-5b B, Patient positioned semiprone to facilitate gravity drainage of secretions. A pillow under the head keeps the spine in relative alignment. With no pillow under the head, the width of the shoulder inclines the pharynx downward at a steeper angle.

NONINVASIVE AIRWAY MANEUVERS

If the upper airway is obstructed, there are four basic noninvasive airway opening maneuvers. The most simple is the *head tilt, chin lift*. The heel of one of the rescuer's hands is pressed down on the victim's forehead, and the fingers of the other hand are placed under the chin to lift it up. The intended result is the sniffing position ([Figure 17-6](#)). Problems arise if the mouth is closed or soft tissues are infolded because of the chin lift. In addition, downward pressure on the forehead tends to lift the eyebrows and open the eyelids, so measures may need to be taken to protect the eyes.

A second maneuver is the *jaw thrust* ([Figure 17-7, A](#)). Pressure is applied to the angle of the mandible to dislocate it upwards while forcefully opening the mouth. This is painful, and the conscious or semiconscious victim will object by clamping down or writhing.

A third maneuver is the *internal jaw lift* ([Figure 17-7, B](#)). The rescuer's thumb is inserted into the victim's mouth under the tongue, and the mandibular mentum (chin) is lifted, thus stretching out the soft tissues and opening the airway. This is the best maneuver for the unconscious victim with a shattered mandible. The internal jaw lift is dangerous to the rescuer if the victim is semiconscious and can bite.

A fourth noninvasive airway maneuver takes some practice but serves several purposes and is the best one if done correctly. In this two-handed *triple maneuver*, the

Figure 17-6 Head-tilt, chin-lift maneuver, mouth open. (Photo from Anne E. Dickison, MD.)

head is held between two hands to prevent lateral rotation and to maintain neck control. The fourth and fifth fingers are hooked behind the angle of the mandible to dislocate the jaw upwards, and the thumbs ensure that the mouth is maintained open (see [Figure 17-2](#)). The third finger may be positioned over the facial artery as it comes around the mandible so that the pulse can be monitored at the same time. For greatest stability, the rescuer's elbows should rest on the same surface upon which the victim is lying.

Figure 17-7 A, External jaw thrust. B, Internal jaw lift.

All noninvasive airway maneuvers except tongue traction and the internal jaw lift can be conjoined with rescue breathing or bag-valve-mask assisted ventilation.

RESCUE BREATHING AND FOREIGN BODY ASPIRATION

The principles of rescue breathing and response to foreign body aspiration are well presented by courses in basic life support (BLS), advanced cardiac life support (ACLS), advanced trauma life support (ATLS), neonatal advanced life support (NALS), and pediatric advanced life support (PALS).

CRICOID PRESSURE

Cricoid pressure, or the Sellick's maneuver, is a noninvasive maneuver intended to protect the airway from potential pulmonary aspiration of gastric contents. This maneuver has become a mainstay of airway management for any victim considered to have a "full stomach" and who is, or is about to become, neurologically depressed and unable to fully protect the airway. Full stomach conditions that place the obtunded victim at risk for passive regurgitation and pulmonary aspiration include obesity, pregnancy, intoxication, ascites, ulcer disease, gastroesophageal reflux, diabetes or other cause of delayed gastric emptying, increased intracranial pressure, bowel obstruction, and any form of major trauma.^{[1] [3] [9]} In general, infants and children are at greater risk for vomiting and aspiration, since they eat more often, vomit more readily when distressed, have a shorter distance between stomach and mouth, and are at greater risk for abdominal and head trauma (resulting from pediatric body proportions) than are adults. What time a victim last ate a meal is irrelevant to whether or not there is risk for vomiting, but knowing this information may forewarn the rescuer about what sort of stomach contents could appear during rescue and resuscitation.

Cricoid pressure may be applied any time during resuscitation when securing and protecting the airway with an endotracheal tube is not an option, or when intubation attempts have failed and the victim needs positive-pressure ventilation to stay alive. Positive-pressure breaths, whether from rescue breathing or bag-valve-mask resuscitation, follow the path of least resistance. By exerting occlusive pressure on the esophagus, properly applied cricoid pressure directs inflations into the lungs while helping to prevent abdominal distention, compromised diaphragmatic excursion, and increased risk for emesis and gastric rupture.

There are two major concerns about using cricoid pressure on a person with neck trauma. Theoretically, pressure on the anterior side of C6 (opposite the cricoid cartilage) could cause vertebral subluxation if ligaments were disrupted or lax between C5 and C7. Potentially a spinal cord lesion could be caused to progress from partial to complete. No known case of this complication has been reported.^[1]

Cricoid pressure should *not* be applied if there is a suspected laryngotracheal injury. Pressure may cause connective tissues "hanging on by a thread" to disrupt completely. Several cases of cricotracheal separation with total loss of airway patency and death have been reported under these circumstances.^[1] Laryngeal trauma is suspected when there is bruising over the anterior midneck; when the thyroid cartilage (Adam's apple) is

Figure 17-8 Schematic of cricoid pressure (Sellick's maneuver). The cricoid cartilage completely encircles the trachea and has a flat back side which may be pressed against the flat vertebral body across from it, thereby closing shut the esophagus in between. The shape of the cricoid cartilage is similar to that of a signet ring.

riding high, low, or askew; when crepitus is palpable over the larynx; when the victim is unable to vocalize or if the quality of the voice is hoarse and raspy; or when the traumatized person is unable to swallow. To help distinguish between vocal cord dysfunction (from an injured larynx) and other face and neck injuries that might impair speech or interfere with swallowing, the conscious person is asked to hum, and the unconscious victim is observed for alterations in the sound of a cough or moan.

To apply cricoid pressure, the rescuer forms a **V** between the thumb and index finger. Pressure of 10 to 15 mm Hg is applied, just enough to indent the tissues, but not enough to leave lasting fingernail impressions. Pressing down with the thumb exclusively leads to excessive force and poor control over lateral displacement of the cricoid ring, which in turn cause kinking and occlusion of the subglottic trachea. The **V** is correctly applied over the cricoid cartilage midneck 1 to 2 cm below the thyroid cartilage ([Figure 17-8](#)). A common error is to place the pressure directly on the thyroid cartilage or above the thyroid cartilage at the hyothyroid membrane. Since the soft-sided vocal cords lie just beneath the shield-shaped thyroid cartilage, pressure at this level or above will not preserve patency of the trachea while closing the esophagus. Only the cricoid cartilage completely surrounds the trachea and has a posterior firm flat edge against the esophagus. Pressure applied to any tracheal cartilage other than the cricoid "ring" will not work.

SUCTIONING

In the wilderness, one must remove secretions without the benefit of electricity, customary suction devices, or aesthetic and sterile protective barriers. A number of innovative products are on the market that the prehospital responder, extended care provider, or potential expedition medic might want to consider for the expedition first-aid kit (see [Chapter 69](#)).

Gloves and a face barrier (plastic square with a small one-way valve to place over the victim's face) can be tucked into an old 35-mm film container or one of the small pouches marketed specifically for this purpose. Alternatively, a plastic baggie with a slit in it for the mouth and nostrils can be placed over the victim's face for rescue breathing. Debris can be swept from the mouth with a finger wrapped in a T-shirt or other available cloth. The victim can be positioned so that gravity facilitates drainage of blood, vomit, saliva, and mucous; something absorbent or basinlike can be placed at the side of the mouth to catch drained effluvia.

Turkey basters can be included in an expedition first-aid kit not just for secretion management purposes but also for gentle wound irrigation and burn dressing or wet compress moisturizing. The rubber self-inflating bulbs marketed for infant nasal suctioning can also be used to suction out debris from the mouths and noses of adults.

If time permits and the supplies are available, a "mucous trap" suction device can be improvised from a jar with two holes poked in its lid and two tubes or straws duct-taped into the holes. One straw goes to the rescuer, who provides suction, and the other is directed towards whatever has accumulated in the airway. The jar serves to trap the removed secretions so that the rescuer is spared the distasteful experience of suctioning bodily fluids or foreign substances such as mud directly into his or her own mouth.

Secretion removal by gravity or suctioning is key to the management of epistaxis and for maintaining the airway of a victim with mandibular fractures (see [Chapter 23](#)).

AIRWAY EQUIPMENT

Stethoscope

A stethoscope is a useful addition to an expedition first-aid kit. However, auscultating breath sounds without a stethoscope is very easy. Either place the ear directly to the chest or isolate and amplify the breath sounds by listening through a hollow object, such as a cup, empty water bottle, or soda can, or through the cardboard center of a roll of toilet paper. The additional merit of a real stethoscope is that it can be disassembled to harvest compliant tubing that might be used improvisationally to substitute for nasopharyngeal airways, cricothyrotomy tubes or stents, straws for suction devices, chest tubes, restraining tethers, lymphatic constriction bands, or other medical devices not on hand.

Masks and One-Way Valves

The purpose of the one-way nonrebreathing flap-valve is to permit air to be pushed into the victim through

421

one aperture while exhaled air (and secretions) are exhausted through a separate route, thus helping minimize exposure to infectious substances.^[2] These one-way valves are small, lightweight, and inexpensive and would be easy to tuck into a small container along with gloves and a face barrier.

Face masks differ in shape, type of seal, transparency, and materials used for construction. The mask is composed of three parts: body, seal (or cushion), and universal connector. The mask body is usually domed to allow room for a wide range of chin, mouth, and nose sizes and is usually transparent or semitransparent to facilitate visualization of emesis or blood. The seal is the brim of the mask that comes into contact with the face. The two types of seals are the cushion type (often inflatable) and a soft rubber type that is an extension of the body of the mask molded to fit the contours of the face. The universal connector at the peak of the mask dome provides a 22-mm female adaptor that connects the mask to a one-way valve to go to the rescuer's mouth, the elbow of an Air-Mask-Bag-Unit (AMBU bag), or the breathing circuit of a ventilator.

Noncushioned masks are more difficult to use and demand a greater array of sizes. The cushioned masks are a far better choice for responding to out-of-hospital emergencies.

In general, the more generous the cushion, the greater its adaptability to a variety of facial sizes and shapes, and the less practice required to achieve and maintain a good seal between mask and face. On the other hand, the greater the volume of air involved in creating the cushion and the more flexible the materials of the cushion, the more vulnerable the cushion becomes to the effects of altitude and temperature. For a mask intended for use in the wilderness, the feature of a self-sealing nipple to permit adjustment of the volume and pressure of air within the cushion is strongly advised.

For maximum ease of use, a high-volume, low-pressure cushion (the softest, biggest one) should be kept well enough inflated so that there is an air-filled buffer and yet a smooth contact surface between the cushion and the various contours of the face. Despite optimal cushion inflation, however, some facial shapes provide special challenges. For example, a seal may be difficult to achieve on the bushy-bearded individual. If the beard cannot be rapidly modified, the rescuer could consider using petroleum jelly, hand lotion, bag balm, or K-Y jelly to try to slick down the beard and seal over areas where air could leak out. This maneuver has the disadvantage of making the rescuer's hands slick and the cushion of the mask slippery, so both of the rescuer's hands will be needed to maintain the mask fit. The rescuer also runs the risk of greasing up anything else handled during the resuscitation. Alternatively, a large, clear intravenous site dressing (e.g., Tegaderm 10 × 12 cm, 3M Health Care, St. Paul, Minn.) can be placed over the mouth and beard. The nostrils are left uncovered, and a slit the width of the mouth permits full mouth opening while sealing over the beard and improving the security of a rescuer's grip.^[4]

Another challenging facial contour is the prominently chinned, long-faced, and edentulous older individual. With the facial laxity that comes with age and without bordering teeth, the cheeks tend to cave in. Again, a two-handed mask technique is probably necessary. The thumbs press down on either side of the mask, and the fingers pull up on the jaw and bunch up as much of the cheek tissues as possible. A second pair of hands might be needed to bunch up the tissues around the entire lower perimeter of the mask. The stiffer the cushion, the harder it is to make this seal. Another maneuver to consider in this situation is to roll up two gauze or cloth packs to tuck into the mouth and distend the cheeks. The risks of this maneuver are dislodgement and possible aspiration of the packs, and retrograde displacement of the tongue despite a good jaw lift. If there is any choice in the matter, it is almost always easier to mask-ventilate an individual with dentures in place than one with dentures removed, so if intact and secure, dentures should be left in place during field resuscitation.

A third challenging facial contour is that of the average infant, any chubby-cheeked baby-toothed tonsil-abundant young child, or a moon-faced short-necked adult. The key to successful mask ventilation in these situations is to keep the victim's mouth open and the soft tissues from folding in on themselves from gravity and extrinsic compression. One approach is to mask-ventilate over a pacifier, oral airway, nasopharyngeal airway, or improvisational hollow object intended to hold the lips apart, the mouth open, and the tongue pressed down to the floor of the mouth and away from the back of the throat.

Several masks with one-way valves are specifically packaged and marketed for the adventurer or remote-site responder. Carrying cases for traveler's mask-and-valve

products can be impact- and puncture-resistant, colorful and readily identifiable, and usable for alternate purposes (e.g., catching water, corralling small objects, or transporting severed digits or avulsed teeth) and can display instructions for CPR or useful illustrations of airway anatomy.

To select the most widely adaptable "first-aid kit" mask-and-valve product, look for the following features: transparent and easily bendable mask body materials that retain little "memory" of residing in their carrying positions and do not become stiff, brittle, or nondeformable in cold temperatures; an inflatable cushion seal that can be adjusted for changes in temperature and altitude; a flexible high-volume low-pressure cushion seal able to conform to many different face sizes and

422

shapes; a mask span that can be used on both small and large victims; tough materials resistant to cracks and punctures; and a compact mask or carrying case that does not take up disproportionate space in the first-aid kit ([Figure 17-9](#)).

Oropharyngeal Airway

An oropharyngeal airway (OPA) holds the base of the tongue away from the posterior pharyngeal wall and keeps the mouth open and the lips apart. It may stimulate gagging or induce vomiting and is not well tolerated in the responsive or semiconscious victim. Improper or forceful insertion can cause soft tissue, palatal, or dental injury, as can subjecting the structures of the mouth to prolonged or intense pressures from biting down or holding the OPA in place with tethers.

An OPA should be wide enough to contact two or three teeth on both the maxilla and mandible, and should be rigid enough to withstand compression, yet compressible enough so that the biting teeth do not damage themselves. There are three parts to the OPA: a flanged end that protrudes from the lips and keeps the airway in sight; a flat straight surface that rides between the front teeth, and a semicircular posterior section that follows the curvature of the tongue to its base in the hypopharynx ([Figure 17-10, A](#)). An air channel in the interior or deep grooves along the sides allow for air passage. These characteristics should be mimicked with any improvisational OPA substitute.

If an oral airway does not conform to the size and shape of the victim's natural airway, upper airway obstruction may worsen. An overly large oral airway will either plug the tracheal introitus with its tip or will press down on and cause the epiglottis to fold over and occlude the glottis. Additionally, glottic stimulation can result in laryngospasm and a complete loss of airway. Too small an oral airway will miss the curvature of the tongue and will press down in the middle of it, worsening occlusion at the base of the tongue or causing the epiglottis to close over the glottis ([Figure 17-10, B](#)). Furthermore, an overly small oral airway can be swallowed entirely or partially swallowed and left hung up midneck between the larynx and the thoracic inlet.

Recently, Mallinckrodt (St. Louis, Missouri) introduced a cuffed oropharyngeal airway (COPA). The high-volume, low-pressure cuff at the distal end of the OPA is intended to passively lift the epiglottis and position the base of the tongue while it gently occludes the posterior pharynx. The proximal end of the COPA is fitted with a standard 15-mm male connector for easy adaptation to positive pressure ventilation. Insertion of the proper size is critical to successful seating of the cuff. Typically the COPA will be one size larger than a normal OPA. Compared with a standard OPA and the laryngeal mask airway (LMA), the COPA is more difficult to place correctly and requires a greater number of subsequent airway maneuvers to maintain its luminal patency.^[6]

Nasopharyngeal Airway

Compared with the OPA, the nasopharyngeal airway (NPA) is better tolerated in the awake or semiconscious person. Since it does not have to withstand the forces of biting teeth, the NPA can be more flexible and compliant. A flange outside the nostril prevents the NPA from slipping or being swallowed or aspirated. The flange can be improvised with a safety pin through the tube itself ([Figure 17-11](#)) or by securely duct-taping a circle of something to the outside of the nostril end of the tube. The gentle curvature of the NPA follows the superior surface of the hard palate, descends through the hidden nasopharynx and down the visible posterior oropharynx, and ends up in the hypopharynx behind the base of the tongue ([Figure 17-10, C](#)). An endotracheal tube can be shortened and softened in warm water to substitute for a commercial nasal trumpet. Any flexible tube of appropriate diameter and length can be used as an improvisational substitute for the NPA.

The key to successful and atraumatic insertion involves lubrication (saliva works well); an understanding of nasal anatomy; and steady, gentle pressure. If the NPA has a bevel, the flat edge of the bevel is oriented toward the nasal septum. The direction of insertion is straight back toward the occipital prominence of the skull. As the NPA passes through the turbinates, there will be mild resistance, but once the tip has entered the nasopharynx, there will be sensation of a "give." The tube should be visible in the oropharynx as it passes behind the tonsils, and the tip should come to rest behind the base of the tongue but above the vocal cords.

Complications of NPAs include failure to pass through the nose (usually resulting from a deviated septum), epistaxis, accidental avulsion of adenoidal tissue, mucosal tears or avulsion of a turbinate, submucosal tunneling (the tube tunnels out of sight behind the posterior pharyngeal wall), and creation of pressure sores. If the NPA or any nasal tube is left in place for more than several days, impedance to normal drainage may predispose the victim to sinusitis or otitis media.

Other Airway Adjuncts

Other commercial airway adjuncts used in prehospital circumstances include the esophageal-tracheal Combitube, the esophageal obturator airway (EOA), the esophageal-gastric tube airway (EGA), the pharyngotracheal lumen airway (PTLA), and the LMA. Successful insertion of these devices requires formal instruction and practice.

Their use in the wilderness setting is

423

appropriately limited to trained and experienced providers.

CRICOTHYROTOMY

If the upper airway is completely obstructed and obstruction cannot be relieved or bypassed, the only way to avoid death is to create an air passage directly into the trachea. The most accessible and least complicated access site is through the cricothyroid membrane. Even in experienced hands, the relatively high complication rates for emergent cricothyrotomies (10% to 40%)^[4] are still less than those for tracheostomies. Complications include bleeding, puncture of the posterior trachea and esophagus, creation of a false passage, inability to ventilate, aspiration, subcutaneous and mediastinal emphysema, vocal cord injury, and subsequent tracheal stenosis.

The cricothyrotomy hole may be made percutaneously with a trocar or needle or surgically with a knife blade. When the trachea is successfully entered, a gush of air will exit, often with a cough. If a syringe containing 1 ml of water or lidocaine is attached to the needle used for puncture, bubbles may be seen as the needle tip enters the trachea. Once the cricothyroid membrane is punctured, it is essential to maintain patency of the tract and identify the hole with a tube, stylet, obturator, tweezers, wire, or another temporary place marker. It is very easy to lose the tract and create a false passage while trying to instrument or cannulate the route.

Making a small (1- to 1.5-cm) vertical incision in the skin over the cricothyroid membrane facilitates the ease of the next step, puncture through the lower third of the dime-sized membrane. Vertical skin incisions have advantages over horizontal incisions because vertical incisions

Figure 17-12 Combination of catheter assemblies to allow connection of a needle cricothyrotomy to a 15/22-mm standard adaptor for AMBU ventilation. (Photo from Anne E. Dickison, MD.)

tend to be more controlled and better positioned in reference to landmarks. The needle/catheter is advanced in the midline of the neck at a 45-degree angle aiming toward the lower back ([Figure 17-10,D](#)). Once the needle or introducer aspirates air, the catheter is slid off the stylet and the stylet is withdrawn ([Figure 17-10, E](#)). Taking care not to kink a flexible catheter at the insertion site, the hub may be secured in place with tape or sutures or may be attached to a Luer-Lok syringe-adaptor mechanism. With anything other than a commercial cricothyrotomy set or endotracheal tube, provision of

positive-pressure ventilation requires the creative assembly of an adapter connecting the apparatus in the trachea to the female connector on an AMBU bag. [Figure 17-12](#) shows an example of the step-up series of connections needed for this type of extension.

If the catheter in the trachea is to be replaced by a stiffer or bigger cannula, a guidewire is inserted through the catheter several centimeters down the trachea, the catheter is withdrawn with the guidewire remaining, and a dilator is advanced over the guidewire, then withdrawn. Next, the intended cannula is threaded over the guidewire until it is seated with its flanges flush to the skin. The process of identifying a lumen with an introducer, marking the lumen with a guidewire, dilating the entry site, then placing the final apparatus over the guidewire is called the Seldinger technique, and the procedure of replacing a smaller tube with a larger one is termed a dilational cricothyrotomy.

A temporary cricothyrotomy trocar-and-tube can be fashioned from a tuberculin or 3-ml syringe that has been cut on the diagonal then forcefully inserted through the cricothyroid membrane ([Figure 17-13](#)). Since the improvised trocar point of the syringe is sharp and irregular, insertion is apt to be traumatic.

Figure 17-13 A tuberculin or 3-ml syringe can be cut on the diagonal to improvise a combination trocar-cricothyrotomy tube. Caution must be taken with insertion not to traumatize the posterior pharyngeal wall. (Photo from Anne E. Dickison, MD.)

Figure 17-14 Lifestat keychain emergency airway set. (Photo from Anne E. Dickison, MD.)

Figure 17-15 **A**, Wadhwa Emergency Airway Device. **B**, Wadhwa transtracheal catheter with removable stylet and Luer-lock connection for jet ventilation. **C**, Internal components of the Wadhwa Emergency Airway Device. Both the transtracheal catheter and the nasopharyngeal airway

Care must be taken to not lacerate the posterior tracheal wall or create a tracheoesophageal fistula.

Even with a universal adapter (15/22-mm) connection, without a jet ventilation device or cricothyrotomy tube of the proper diameter, curvature, and length, it is extremely difficult to positive-pressure ventilate a victim through a needle catheter or improvisational substitute. The victim has the best chances at survival if spontaneous respiratory effort can be preserved; it is easier for the victim to draw air in through a critically small opening than it is for a rescuer to generate the pressure needed to force air in through the same aperture. Pressures sufficient to make a chest rise can be generated by a rescuer blowing through the needle catheter, but such efforts rapidly lead to rescuer fatigue. Temporary transtracheal oxygenation and ventilation through a 12- or 14-gauge needle can be provided using a flow rate of 15 L/min or by jet ventilation (40 psi) at a slow intermittent rate of 6 breaths per minute and an inspiratory to expiratory ratio of 1:14.^[7] The very long expiratory time is necessary to allow passive expiration through a restrictive channel.

Packaged dilator cricothyrotomy sets, such as those manufactured by Melker, Arndt, and Corke Cranswick, contain a scalpel blade, syringe with an 18-gauge over-the-needle catheter and/or a thin introducer needle, guidewire, an appropriately-sized dilator, and a polyvinyl airway cannula. The Patil set (Cook Critical Care, Bloomington, Ind.), the Portex Minitrach II (Concord/Portex, Keene, N.H.), and the military version of the Melker set are sold without the guidewire and appeal to prehospital providers unfamiliar with the Seldinger technique. Pertrach (Pertrach, Inc., Long Beach, Calif.) is similar in concept except the guidewire and dilator are forged as a single unit so a finder catheter cannot be used, and the introducer must be peeled away. The Nu-Trake device (International Medical Devices, Inc., Northridge, Calif.) is complicated to use, has a rigid airway that risks trauma to the posterior trachea, and is difficult to secure.^[8]

In terms of expedition kit portability, three transtracheal puncture emergency airway devices deserve special mention. Lifestat (New Orleans, La.) manufactures a key chain emergency airway set that consists of a sharp-pointed metal trocar introducer that fits through a straight metal cannula that screws into a metal extension with a universal 15-mm male adaptor. Lightweight and less than 3 inches long, the three-component apparatus is attached to a separate and detachable keychain ([Figure 17-14](#)). Cook Critical Care offers a 6-Fr reinforced-catheter emergency transtracheal airway catheter (order number C-DTJV-6.0-7.5-BTT) with a molded Luer-Lok connection for jet ventilation or added assembly of a 15-mm adaptor for standard modes of positive-pressure ventilation. Cook Critical Care also offers the Wadhwa Emergency Airway Device (order number C-WEAD-100). This lightweight, impact-resistant assembly is 7.25 inches long and the diameter of a highlighter pen ([Figure 17-15](#)). It disassembles to yield a 12-Fr Teflon-coated cricothyrotomy catheter with removable

metal stylet (with a molded plastic Luer-Lok connection for oxygen or jet ventilation), plus a flexible nasopharyngeal airway adhered to a molded plastic flange. Both the cricothyrotomy catheter and the NPA screw into the Wadhwa case to provide a low-resistance extension and a 15-mm (male) connection for standard positive-pressure ventilation equipment.

Box 17-1. FUNDAMENTAL GOALS OF AIRWAY MANAGEMENT IN THE FIELD

The fundamental goals of airway management in the field are to

1. Promote conditions supporting airway patency
 - Optimal positioning
 - Facilitated removal of secretions or debris
 - Close observation for emesis, bleeding, seizures, or other intercurrent events leading to obstruction or aspiration
2. Avoid doing or administering anything that could further depress respirations, obstruct airway, or depress respiratory reflexes
3. Assess the potential for worsening
 - Plan the evacuation accordingly
 - Communicate the situation and concerns to others
 - Prepare for escalated intervention

SUMMARY

The conscious or semiconscious person with an airway emergency instinctively seeks an optimal posture for air exchange ([Box 17-1](#)). The unconscious person, unless deeply anesthetized, paralyzed, or profoundly hypoxic, continues effort to breathe until death is very near. If a victim shouts or cries out, the airway is intact and the lungs are filling. If a victim is breathing but obstructed, determination should be made as to why. If a victim is making no respiratory effort at all, a choice must be made about whether or not to initiate CPR.

Chapter 18 - Wilderness Trauma and Surgical Emergencies

Eric A. Toschlog
John A. Morris Jr.

PURPOSE

This chapter is written with the intent to provide physicians and health care practitioners with a concise, pragmatic approach to the management of trauma and surgical emergencies encountered in a wilderness environment. Our focus is directed primarily at the health care professionals responsible for the well-being of expedition members.

Wilderness expedition health care providers will have varied capabilities, experience, and resources, but it is the environment that will most influence patient outcome. Complex interventions in the field are frequently impractical. With ongoing debate concerning issues ranging from the value of field resuscitation for internal hemorrhage to the method (if any) of closure of animal bite wounds, it remains clear that identifying injuries, establishing an airway, and making expedient evacuation plans most strongly influence survival.^[22] ^[25] ^[71]

The key to successful management of wilderness emergencies is preparedness. Knowledge of the advanced trauma life support (ATLS) protocols provides a scaffold for preparation for wilderness travel. The simple, concise principles contained in ATLS concepts are well suited to the management of wilderness emergencies, where resources are scant and prompt response is essential to victim survival.

WILDERNESS TRAUMA EMERGENCIES

Overview

Management of wilderness trauma is based on military and civilian prehospital principles, including rapid assessment and diagnosis of injury, treatment, and, if necessary, evacuation. These principles and those promulgated by the Committee on Trauma of the American College of Surgeons (ACS) are formally taught in the ACS ATLS program. Any physician planning to be a medical officer on a wilderness expedition should be familiar with the material taught in the ATLS program. Optimally, the complete ATLS course should be successfully completed before assuming responsibility for the care of participants in a wilderness expedition.^{[1] [2] [3] [45]}

Background

Trauma remains the leading cause of death in the first four decades of life, and in terms of trauma-related expenditures and significant long-term disability, the societal cost is staggering. Epidemiologic data indicate that death from trauma occurs in a trimodal time distribution.^{[5] [95]} The first peak occurs within seconds to minutes and represents catastrophic injury. The second peak occurs within minutes to hours after injury. Injuries responsible for the second mortality peak are those associated with significant head injury, pneumothorax, and/or significant blood loss. This distribution emphasizes the concept of the "golden hour," the postinjury time interval when rapid and aggressive intervention may significantly influence mortality.

The medical literature is limited regarding the incidence of injury incurred during wilderness-related activities. It is estimated that greater than 10 million Americans participate in wilderness backpacking and camping activities annually. A study by Gentile et al^[33] documented the injury and evacuation patterns recorded by the National Outdoor Leadership School over a 5-year period. Injuries occurred at a rate of 2.3 per 1000 person-days of exposure, with orthopedic and soft tissue injuries most frequent. A recent study by Montalvo et al^[61] analyzed case incident report files from eight California National Park Service parks and found an injury incidence of 9.2 nonfatal events per 100,000 visits, with 78 fatalities reported in a 3-year period. Both studies document a low risk of injury but highlight the possible morbidity resulting from wilderness injury and the need for rapid, uniform intervention.

Establishing Priorities

There are three immediate priorities in managing wilderness trauma:

1. Control oneself. It is normal to feel anxious when confronted with an injured victim. However, anxiety must not be transmitted to the victim or other members of the expedition team. One must be in control of oneself to take control of the situation.
 2. Control the situation. The first priority in controlling the situation is ensuring the safety of the uninjured members of the party. Expedious evacuation of a victim requires that all expedition members function at maximal efficiency; even minor injuries to other members in the group can jeopardize physical strength, functional manpower, and the success of the evacuation. Although the physician member of the team may
-

430

not be the expedition leader, his or her position is automatically elevated during a medical crisis. However, this does not mean that the physician should dominate the evacuation process. Although the expedition leader must rely on the medical assessment provided by the physician, the leader is best prepared to plan the evacuation.

3. Obtain an overview of the situation. The victim's general condition should be evaluated. Is the victim in immediate distress from a condition that requires relatively simple management, such as airway control? Is the victim in such a precarious environmental situation that he or she needs to be moved before resuscitation? Scene security may be integral to the safety of the injured and caregiver. Is the victim properly protected from the elements, including sun, wind, cold, and water? Hypothermia remains one of the most important contributors to trauma-related coagulopathies. ^[92]

After the victim has been placed in the most stable and safe environment, the examining physician is ready to implement the ATLS-based five steps of wilderness trauma management:

1. Primary survey
2. Resuscitation
3. Secondary survey
4. Definitive plan
5. Packaging and transfer preparation

The purpose of the primary survey is to identify and begin initial management of life-threatening conditions by assessing the following (called the ABCDE of trauma care):

1. Airway maintenance and cervical spine stabilization
2. Breathing
3. Circulation, with control of significant external hemorrhage
4. Disability: Neurologic status

5. *Exposure/Environmental control*: Completely undress the victim with careful attention to the prevention of hypothermia

After the primary survey is performed, resuscitation efforts are initiated. The level of resuscitation depends on the equipment and expertise available. At a minimum, resuscitation consists of control of external hemorrhage. In the emergency department, resuscitation would also include the administration of oxygen and intravenous (IV) fluids.

The third step is the secondary survey, a head-to-toe evaluation of the trauma victim that uses inspection, percussion, and palpation techniques to evaluate each of the body's five regions: head and face, thorax, abdomen, skeleton, and skin. A history should be taken at the same time as performance of the secondary survey. The specifics of the mechanism of injury, if unknown to the physician or caregiver, may be of vital importance. Loss of consciousness, head injury, the height of a fall, or the species of attacking animal may influence treatment and evacuation plans, as well as contribute to the stability of the scene. The ATLS AMPLE method of rapid history-taking is discussed in further detail in the Secondary Survey section. After this survey, the examining physician should formulate a definitive plan. It is useful to record all observations on paper if the circumstances permit. Such data may prove to be of critical importance to evacuating or hospital personnel.

The first step in formulating a plan is to compile a list of the injuries present. The next step is to determine if any injury warrants evacuation. A determination needs to be made as to the route of evacuation: air, land, or water. Aeromedical evacuation is expensive and, depending on the environment, could pose a risk to both the victim and medical evacuation team. Aeromedical evacuation should be considered only for victims with potentially life- or limb-threatening injuries where the environment allows such a modality.

Packaging the victim for evacuation is the final step. The evacuation effort requires organization, coordination, and great effort on the part of the expedition team. Transfer protocol will be discussed within the respective injury sections.

Fluid Precautions in the Wilderness

A number of life-threatening viruses are transmitted through contact with bodily fluids. The Centers for Disease Control and Prevention (CDC) have established a set of standard precautions to be applied in all cases of contact with human body fluids:

1. Goggles
2. Gloves
3. Fluid-impervious gowns
4. Shoe covers and fluid-impervious leggings
5. Mask
6. Head covering

In the wilderness setting, the materials necessary for standard precautions are rarely

available. However, every victim in the wilderness must be assumed to carry a communicable disease. Every effort should be made to approximate universal precautions, particularly covering the hands and eyes.

Primary Survey

Persons injured in the wilderness should be assessed and their treatment priorities established based on their mechanism of injury, the vital signs, and the specific injuries incurred. Logical treatment priorities must be established in a critically injured victim, including the need for evacuation when the primary survey is complete. The victim's vital signs must be assessed quickly and efficiently, with restoration of life-preserving vital functions. This sequence constitutes the ABCDE of trauma care and is designed to identify and treat life-threatening conditions within the "golden hour."

431

Airway (see [Chapter 17](#)).

The upper airway should be assessed for patency. This rapid assessment should include inspection for signs of airway obstruction, including foreign bodies and signs of facial or tracheal fractures that may lead to airway obstruction. The chin lift (see [Figure 17-6](#)) or jaw thrust (see [Figure 17-3](#)) may be helpful in establishing an airway. If the victim is able to speak, the airway is likely not jeopardized, but this is not an absolute and frequent, repeated evaluation is mandatory. Additionally, a Glasgow Coma Scale (GCS) of 8 or less is indicative of the possibility of a precarious airway and requires establishment of a definitive airway.

Specific attention should be directed toward the possibility of cervical spine injury. The victim's head or neck should never be hyperextended, hyperflexed, or rotated to establish or maintain an airway. Approximately 10% of victims with head injuries or facial fractures have a concomitant cervical spine fracture. Such a fracture should be assumed to exist in any person with a significant injury above the level of the clavicle. If a situation requires removal of immobilizing devices, in-line *stabilization*, not *traction*, must be maintained. For a detailed discussion of airway management, please refer to [Chapter 17](#).

Breathing and Ventilation.

The victim's chest should be exposed and chest wall movement observed. Because oxygenation and carbon dioxide elimination require adequate function of the diaphragm, chest and abdominal musculature, and ribs, any trauma sustained by these structures may preclude adequate ventilation. Therefore establishment of an airway in the primary survey does not ensure ventilation.

Conditions that can lead to asymmetric chest wall movement include tension pneumothorax, open pneumothorax, and flail chest. Upon auscultation, absent or

asymmetric breath sounds may be produced by improper placement of an endotracheal tube, pneumothorax, or hemothorax.

Circulation.

Evaluation of circulation is divided into assessment of cardiac output and control of major external hemorrhage. Manometric blood pressure measurement is not easily performed in the field, although it may provide useful data. Important information regarding perfusion and oxygenation can be obtained rapidly by assessing the victim's level of consciousness, taking the victim's pulse, looking at skin color, and assessing capillary refill time.

The pulse should be assessed first. Although the following are only general estimates and carry some inaccuracy, approximations of systolic blood pressure can be used if a palpable pulse is present:

1. Radial artery—80 mm Hg
2. Femoral artery—70 mm Hg
3. Carotid artery—60 mm Hg

When circulating blood volume is reduced, cerebral perfusion pressure may be critically impaired, resulting in altered level of consciousness. Do not assume that altered level of consciousness is attributable to head injury. It must be noted that conscious victims may be in class III shock with impending death.

Skin color and capillary refill allow rapid initial estimation of peripheral perfusion. Pressure applied to the thumbnail or hypothenar eminence causes underlying tissue to blanch. In a normovolemic person, color returns to the nail bed within 2 seconds. In a hypovolemic, poorly oxygenated person, capillary refill requires more than 2 seconds.

If hypovolemia is suspected, on the basis of either absent pulses or prolonged capillary refill, the examiner should immediately assess the neck veins. Distended neck veins, although a nonspecific sign, may suggest tension pneumothorax or pericardial tamponade in the context of hypotension. Flat neck veins suggest hypovolemia and hemorrhagic shock.

Major hemorrhage can occur in five anatomic areas:

1. Chest
2. Abdomen
3. Retroperitoneum
4. Thigh
5. External environment

Exsanguinating external hemorrhage should be identified and controlled during the primary survey. Blood loss should be controlled by direct pressure on the wound. Tourniquets should not be used for control of external bleeding. Proper stabilization of a

femur fracture can minimize blood loss into the thigh. In the field, little can be done about significant intrathoracic or intraabdominal hemorrhage.

Disability and Neurologic Assessment.

The neurologic assessment of the injury victim conducted during the primary survey should be rapid and efficient. The victim's level of consciousness should be established. In addition, pupillary size and reactivity should be assessed. Level of consciousness should be assessed using the Glasgow Coma Scale ([Box 18-1](#)). It is critical that the neurologic assessment be repeated frequently, particularly if evacuation is delayed. Deterioration in mental status portends a poor prognosis, although a variety of conditions other than intracranial injury can affect mental status. Hypoxia, hypovolemia, and hypothermia should be expeditiously corrected.

Exposure and Environmental Control.

The victim should be fully undressed and exposed, if possible in a protected environment. Garments and gear should be removed by cutting them away, unless the garments can be dried and are essential for future protection from the environment. Wet clothing must be removed early to prevent hypothermia. It is mandatory to visualize the entire victim to document and assess injury. However, this step of the primary survey should be performed

with caution. First, it is imperative to cover the victim immediately after removal of clothing. Hypothermia and its effects on mental status, cardiovascular function, and coagulation is one of the most underappreciated entities in the care of the trauma victim. The possibility of hypothermia should be entertained in all environments, since it is most prevalent in trauma victims during warm summer months. Second, clothing and gear should not be pulled from the victim unless complete immobilization of injuries can be achieved. Expedition members may be wearing a variety of gear and clothing, including biking, skiing, or climbing helmets. Helmets should be removed with in-line stabilization of the cervical spine.

Shock

Shock is defined as cellular hypoxia secondary to inadequate circulation of blood. It was defined historically by John Collins Warren as "a momentary pause in the act of death." Nowhere is this adage more applicable than in the wilderness setting. Any physician who cares for trauma victims has witnessed an apparently "stable" victim rapidly

deteriorate and die. With only clinical acumen, the wilderness physician must be sufficiently astute to identify the subtle signs of shock.

The treatment of shock is resuscitation, which may be defined as any intervention that restores blood flow and cellular oxygenation. The power of the primary survey lies in the fact that it is essentially a form of resuscitation. Rapid identification of conditions leading to hypoperfusion facilitates their reversal. Although the majority of trauma victims exhibiting signs of shock in the wilderness have sustained acute blood loss, a simple entity such as a pneumothorax may be responsible for shock.

Hemorrhagic shock is classified according to the blood volume that has been lost. A central question in caring for victims of blood loss in the wilderness is the reliability of vital signs in quantifying degree of hemorrhage. Associated with each class of hemorrhage are clinical signs that allow a caregiver to quantify blood loss ([Table 18-1](#)). It is evident that assessing blood pressure alone is a poor way to predict impending deterioration. When hypotension can be measured, a normal individual has already lost 30% of his or her blood volume and salvage may be impossible. Resuscitation should be initiated at the first sign of shock, equating to class II hemorrhage, and evacuation planned accordingly.

Vascular Access

Vascular access must be obtained promptly. The standard method of obtaining access is by insertion of two large-bore (16-gauge or larger) catheters, preferably into peripheral veins of the upper extremity. Alternatives include using lower extremity veins and obtaining central venous access. If peripheral access cannot be secured, the femoral vein should be the next site attempted. Advantages of femoral vein access include ease of cannulation relative to jugular and subclavian access and fewer complications.^[93]

Depending on expertise, the internal jugular and subclavian veins may be accessed. Despite a higher incidence of complications compared with peripheral access, central access complication rates in trauma centers have been demonstrated to be less than 5% in most studies.^[93] If peripheral access is inadequate or unobtainable, it is clear that the next site attempted should be determined by the provider's level of confidence and expertise. Failure to obtain peripheral or central venous access mandates venous cutdown, which is most easily performed at the distal greater saphenous vein ([Figure 18-1](#)). Despite fewer complications than central access, cutdowns are more experience-dependent.

Children in the wilderness less than 6 years of age in whom venous access cannot be obtained should undergo intraosseous resuscitation. This is accomplished by introducing a needle through the periosteum of the tibia just inferior to the tibial tuberosity ([Figure 18-2](#)). Needles that are 18- to 20-gauge are preferable, but any needle strong enough to penetrate the periosteum without bending can be used.

Of the resuscitative therapies that potentially may be initiated in a well-prepared

TABLE 18-1 -- Classes of Hemorrhagic Shock

	CLASS I	CLASS II	CLASS III	CLASS IV
Blood loss (ml)	Up to 750	750–1500	1500–2000	>2000
Blood loss (% blood volume)	Up to 15%	15%–30%	30%–40%	>40%
Pulse rate	<100	>100	>120	>140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure (mm Hg)	Normal or increased	Decreased	Decreased	Decreased
Respiratory rate	14–20	20–30	30–40	>35
Urine output (ml/hr)	>30	20–30	5–15	Negligible
CNS/mental status	Slightly anxious	Mildly anxious	Anxious, confused	Confused, lethargic
Fluid replacement (3 : 1 rule)	Crystalloid	Crystalloid	Crystalloid and blood	Crystalloid and blood

Figure 18-1 Venous cutdown performed at the distal greater saphenous vein.

Figure 18-2 Intraosseous resuscitation performed by introducing needle through the periosteum of the tibia joint inferior to the tibial tuberosity.

deserves considerable attention. Fluid resuscitation in trauma has been a contentious topic, perhaps overly so, relative to fluid type and amounts used. A number of recent studies focusing on the prehospital administration of fluids in trauma victims not only rehashed the fluid composition debate but also called into question the efficacy of prehospital resuscitation.^[71] Although further prospective trials are needed relative to fluid type and prehospital use, an impressive compilation of data has been amassed looking at resuscitative fluids in the trauma victim. Past studies have not only compared colloids with crystalloids^[88] but have explored the use of blood and plasma substitutes, and hypertonic saline. An analysis of the details of such studies is beyond the scope of this chapter, but a summary of fluid recommendations is in order.

In small volumes, hypertonic saline has been shown to be an effective resuscitative fluid, and its efficacy in closed head injury is under evaluation. Currently, no improvement in survival has been demonstrated using hypertonic saline compared with crystalloid, and its use has been associated with hypokalemia, pulmonary edema, and dramatic increases in serum sodium and osmolarity.^[6] The significance of these reported complications in trained hands is questionable, and hypertonic fluids may have a future role in resuscitation. Further study is warranted in the use of hypertonic saline, but its use in the wilderness setting is not recommended at this time.

Artificial blood products, such as perfluorocarbons and diaspirin cross-linked hemoglobin, have been shown to be efficient resuscitative fluids in animal studies.^{[20] [77] [86]} However, they are expensive and not yet adequately studied in humans. Additional studies are needed concerning artificial blood products, since no benefit relative to crystalloid has yet been demonstrated in trauma victims. Their relatively experimental nature, cost, and lack of proven superiority over crystalloid preclude use in the wilderness setting at this time.

Based on the current literature, it is clear that both colloids (including hetastarches and albumin) and crystalloids are efficient volume expanders.^[79] Certainly, larger volumes of crystalloids than colloids are needed to achieve similar resuscitative endpoints, usually in a ratio of 3 to 1. However, no benefit in survival using colloids has been demonstrated, and recent studies indicate that their use in critically ill patients may increase mortality.^{[19] [68]} Additionally, no proven detriment, including increased extravascular lung water, impaired wound healing, or decreased tissue oxygen diffusion, has been proven with the use of large volumes of crystalloids. Crystalloids are safe, nonantigenic, easily stored and transported, effective, and inexpensive. Most experts in trauma care agree that crystalloid is preferable to colloid infusion in the prehospital, early resuscitative phase of trauma care. Accordingly, the resuscitative fluid recommended by ATLS protocol is normal saline.

Several animal studies and recent human clinical trials in trauma victims have found that treatment with IV fluids before control of hemorrhage resulted in increased mortality rates.^{[9] [56]} Although these data are compelling, they have been accumulated in victims with penetrating injuries and short prehospital times, and the definition of prehospital

resuscitation within these studies comprised widely varying volumes. Clearly, prehospital resuscitative protocols remain in evolution, and it is likely that current common practices will be altered in the future. However, application of these particular data to the wilderness setting at the current time is dangerous for a number of reasons. First, the leading cause of death in wilderness trauma is head injury. Many multiple trauma victims have a head injury, and it may be impossible to discern whether an intracranial lesion is present. Although under continued study, the current approach to management of head injury is aggressive maintenance of cerebral perfusion pressure to control intracranial pressure. Under-resuscitation in the context of an intracranial injury could be catastrophic. Second, the multisystem-injured victim frequently presents with associated orthopedic injuries. A victim with closed extremity fractures with significant contained hemorrhage benefits from fluid resuscitation. Third, a victim with significant external hemorrhage that can be controlled before evacuation benefits from intravascular repletion.

In summary, resuscitation with IV fluids should be initiated in the field, particularly in victims with head injury and unquantified multiple trauma. Victims should have vascular access secured and resuscitative fluids given in the form of normal saline as dictated by severity of injuries and hemodynamics.

Secondary Survey

The secondary survey is an extension of the primary survey and should not be undertaken until the primary survey is complete and the victim has been stabilized. Additionally, resuscitative regimens, if available, should have been initiated. The secondary survey is a head-to-toe assessment of the victim including history and physical examination. The face, neck, chest, abdomen, pelvis, extremities, and skin should be examined in sequence. A more detailed neurologic examination should be completed, including reassessment of the GCS. The neck should be examined independently of the thoracolumbar spinal cord. Examination of the pelvis should not include the traditional "rocking" to determine stability, since this may exacerbate existing comminution.

The detailed secondary survey should not delay evacuation packaging. As in the nonwilderness setting, it is imperative to repeat the primary survey as the victim's

condition warrants. Specific examinations will be discussed in the sections covering regional injuries.

History.

The victim's history should be assessed during the secondary survey. Knowledge of the mechanism of injury and any comorbid medical conditions or allergies may enhance

understanding the victim's physiologic state.

The ATLS "AMPLE" history is a useful and rapid mnemonic for this purpose:

Allergies

Medications currently used

Past medical history/Pregnancy

Last meal

Event or Environment related to the injury

Adjuncts.

Resuscitation should be initiated simultaneous with the primary survey. The degree of resuscitation depends on available resources, experience of the rescuer(s), and environmental conditions. Under optimal circumstances, resuscitation allows oxygenation, fluid administration, and cardiac and vital sign monitoring. As adjuncts to the secondary survey, it also includes placement of urinary and nasogastric (NG) catheters. This degree of resuscitation will be almost universally unavailable in the wilderness setting. Here, resuscitation may be limited to oral administration of warm, high-calorie fluids and maintenance of victim comfort and body temperature.

A nasogastric tube and indwelling urinary (Foley) catheter should be placed if available and appropriate. In a victim with depressed level of consciousness or nausea and vomiting, gastric decompression assists in protection against aspiration—which could prove catastrophic in a remote area. In addition, children can exhibit deterioration in hemodynamics secondary to massive gastric distention. Nasogastric tubes should be placed in persons who are endotracheally intubated in the field. The tube can be aspirated sequentially with a syringe or left open to gravity drainage. If there is suspicion of a facial fracture(s), an NG tube should not be placed through the nares.

A Foley catheter can assist in volume assessment and hemodynamic status determination in a critically injured victim. Hourly urine output typically does not decrease until the onset of class III hemorrhagic shock, with loss of 30% to 40% of blood volume. Contraindications to urinary catheter placement in the field are blood at the urethral meatus, high-riding prostate, scrotal hematoma, and personnel not experienced in placement.

PNEUMATIC ANTISHOCK GARMENT.

The pneumatic antishock garment (PASG) is a noninvasive device inflated around the lower extremities and abdomen to augment peripheral vascular resistance and increase blood pressure. It was widely instituted as a treatment for shock in the 1980s, largely

based on anecdotal data. Prospective data relevant to penetrating chest and abdominal trauma^[42] ^[57] and retrospective data in blunt trauma^[7] indicate an increase in mortality with its use. The PASG has theoretical benefits in the stabilization of hemodynamically unstable pelvic fractures, although no scientific evidence exists for this application.^[71] Further prospective studies in blunt trauma are needed, and use of the PASG is not indicated in the wilderness setting for blunt trauma at this time.

Injuries to the Head, Face, and Neck.

The secondary survey begins with examination of the entire head and scalp for evidence of skull or facial fractures, ocular trauma, lacerations, and contusions. The scalp is thoroughly palpated for tenderness, depressions, and lacerations. The bones of the face—including the zygomatic arch, maxilla, and mandible—are palpated for fractures. Detailed discussion of oral, facial, and eye injuries is presented in [Chapter 22](#) and [Chapter 23](#) . Elements of the GCS are repeated.

The wilderness eye is discussed in detail in [Chapter 22](#) , but general examination principles are as follows. Significant periorbital edema may preclude examination of the globe, and assessment should be carried out rapidly. The globe should be evaluated for visual acuity, pupillary size, conjunctival hemorrhage, lens dislocation, and entrapment. Persons with significant facial trauma have a high incidence of associated ocular or orbital injuries.^[75] Recent studies of ocular injuries in trauma victims have emphasized underappreciation of ocular and periocular signs indicative of significant underlying injury by many disciplines involved in the victim's care.^[70]

Head Injuries

Background.

Approximately 500,000 to 2 million cases of head injury occur in the United States yearly.^[34] Of these, approximately 10% die before reaching a hospital.^[5] Long-term disability and sequelae associated with head injury are significant, with more than 100,000 persons suffering varying degrees of permanent impairment. Because of the high-risk nature of traumatic brain injury (TBI) and the impact of initial management on disability and survival, clinical management objectives must address both immediate survival and long-term outcome. No standardized management guidelines for head injuries in a wilderness setting have been developed, and a wide range of clinical approaches are used in hospital settings.^[34] However, available literature suggests that morbidity and mortality can be reduced by means of a protocol that includes early airway control with optimization of ventilation,^[38] prompt cardiopulmonary resuscitation, and rapid evacuation to a trauma care facility.

In the wilderness setting, triage, resuscitation, and initial management of the head-injured victim must focus

on maintenance of ATLS protocol, attempts to prevent secondary brain injury, and expeditious evacuation to a neurosurgical center.

First and foremost, secure the airway. Multiple clinical and experimental studies have demonstrated the detrimental effects of hypoxia on the injured brain. A definitive airway should be established if any degree of compromise exists. Because of the high incidence of concomitant cervical spine injuries in this patient population, optimal immobilization is paramount in prevention of further devastating neurologic injury.

The focus must then be directed to prevention of secondary brain injury. The purpose of the wilderness head injury protocol is to allow individuals with widely varying levels of experience and expertise to identify signs of significant head injury, begin proper resuscitation in the context of prevention of secondary brain injury through airway maintenance and hemodynamic support, and evacuate appropriately.

Anatomy.

The scalp is comprised of five layers of tissue that cover the calvaria: skin, connective tissue, galea aponeurotica, loose areolar tissue, and periosteum of the skull. The galea is a fibrous tissue layer with important ramifications in closure of scalp wounds, discussed later in this chapter. Loose areolar tissue beneath the galea represents the site of accumulation of blood in scalp hematomas. A rich vascular network located between the dermis and the galea supplies the scalp. When lacerated, these vessels can be a significant source of hemorrhage, which may be of importance if evacuation is impossible or delayed.

The skull is composed of two groups of bones that form the face and cranium. Cranial bones are divided into the calvaria and base. The calvaria is composed of frontal, ethmoid, sphenoid, parietal, and occipital bones. The calvaria is especially thin in the temporal region, whereas the skull base is irregular with outcroppings, such as the anterior temporal fossa.

The covering of the brain within the skull is composed of three membranous layers: a thick and fibrous dura, a thinner arachnoid layer, and the innermost pia. In the wilderness environment, the layers have little clinical relevance, and their distinction—with the exception of defining a closed vs. open injury—bears little significance.

Pathophysiology of Traumatic Brain Injury.

TBI can be divided into primary and secondary injury. Primary injury is comprised of the physical or mechanical insult at the moment of impact, and the immediate and permanent damage to brain tissue and cranium. Little can be done in the wilderness setting relative to primary brain injury. Secondary injury is the biochemical and cellular

response to initial mechanical trauma and includes physiologic derangements that may exacerbate primary injury. Such physiologic alterations include hypoxia, hypotension, ischemia, and hypothermia. Elevated intracranial pressure (ICP) may cause and exacerbate secondary brain injury.

Many forms of head injury cause elevated ICP, the duration of which is significantly correlated with poor outcome. Thus elevated ICP is not only indicative of significant underlying pathology but also contributes negatively to the outcome. The Monro-Kellie doctrine states that the volume of intracranial contents must remain constant. If the normal compensatory response to increased volume, which consists of decreasing venous blood and cerebrospinal fluid (CSF) volume, is overcome, then small increases in volume cause exponential increases in ICP. The volume-pressure curve in [Figure 18-3](#) relates the small but critical time period between decompensation and brainstem herniation. With ICP elevation directly correlating with secondary brain injury, it is evident that the field provider must attempt to keep the head-injured victim in the flat portion of the curve, minimizing ICP.

The most important priority in minimizing secondary brain injury in the field is optimizing cerebral perfusion pressure (CPP). CPP is related to ICP and mean arterial pressure (MAP) as follows:

$$\text{CPP} = \text{MAP} - \text{ICP}$$

A CPP less than 70 mm Hg after head injury correlates with increased morbidity and mortality.^[5] ^[37] Cerebral blood flow (CBF) should be maintained at approximately 50 ml/100 g brain tissue/minute.^[54] At 5 ml/100 g/min, irreversible damage and potential cell death occur.^[5] Study data have shown a correlation between low CBF and poor outcome.^[54] At a MAP between 50 mm Hg and 160 mm Hg, cerebral autoregulation maintains

Figure 18-3 Critical time period between decomposition and brainstem herniation after traumatic brain injury.

CBF at relatively constant levels. Not only is autoregulation known to be disturbed in injured regions of the brain but also a precipitous fall in MAP can additionally impair autoregulatory function, decreasing CBF and exacerbating ischemia-induced secondary injury. Intuitively, it can be seen that the field provider has a means to combat rises in

ICP simply by optimizing the MAP through aggressive resuscitation.

Diagnosis.

There are three useful descriptions of head injury that may be applied to field recognition.

History.

The history, including the mechanism and timing, severity, and morphology of the injury, can assist in the decision-making process regarding resuscitation and evacuation.^[5] The mechanism may be identified as blunt or penetrating. The anatomic demarcation between blunt and penetrating injury is traditionally defined by the dura mater. Blunt injuries in the wilderness setting most often result from falls. Falling objects and assaults comprise the remainder of the majority of blunt injuries. Penetrating injuries are most commonly gunshot or arrow wounds.

Severity.

Severity of injury can be estimated by quantifying the GCS and the pupillary response. The generally accepted definition of coma is a GCS score of less than 8. With regard to the primary survey and the essential component of airway protection, it has been demonstrated that GCS score does not specifically correlate with need to intubate, and the airway may be acceptable below a score of 8. It is important to note the victim's *best* motor response, since it is most predictive of outcome. Any victim with a GCS score less than 15 who has sustained a head injury should be evacuated if possible. A low or declining GCS suggests increased ICP, which demands attention to optimizing MAP and consequently CPP. Abnormal or asymmetric pupillary responses relative to size or responsiveness also suggest intracranial mass lesion and elevated ICP.

Morphology.

Injury morphology may be difficult to assess in the wilderness setting and relies on level of suspicion and clinical signs and symptoms. Following attention to the primary survey, including airway and

TABLE 18-2 -- Interpretation of Pupillary Findings in Head-Injured Victims

PUPIL SIZE	LIGHT RESPONSE	INTERPRETATION
Unilaterally dilated	Sluggish or fixed	Third nerve compression secondary to tentorial herniation
Bilaterally dilated	Sluggish or fixed	Inadequate brain perfusion; bilateral third nerve palsy
Unilaterally dilated or equal	Cross-reactive (Marcus-Gunn)	Optic nerve injury

Bilaterally constricted	Difficult to determine; pontine lesion	Opiates
Bilaterally constricted	Preserved	Injured sympathetic pathway

immobilization, the physical examination of the secondary survey is imperative and can provide information as to the existence of TBI.

Injury Classification.

Intracranial injuries range from concussion to massive subdural hematoma. Subdural hematomas are more common than are epidural hematomas, comprising 20% to 30% of mass lesions. "Subdurals" result from torn bridging veins between the cerebral cortex and draining venous sinuses. Their prognosis is worse than that of "epidurals," although prompt recognition and drainage improve outcome. Epidural hematomas are most commonly located in the temporal region and result from injury to the middle meningeal artery, often associated with a fracture. They may present loss of consciousness followed by a lucid interval before rapid deterioration, although this sequence is frequently not observed. Hemorrhagic contusion is also quite frequent, constituting 35% of traumatic injuries; this lesion has the propensity to result in significant increases in ICP. *Diffuse axonal injury (DAI)* is the term used to describe a prolonged posttraumatic coma not resulting from a mass lesion or ischemic insult. Similar to hemorrhagic contusion, DAI may result in elevated ICP.

Physical Examination.

The physical examination should be done so that it does not delay evacuation. The GCS should be reassessed. The hallmark of TBI is altered level of consciousness. Physical signs that may denote underlying brain injury include significant scalp lacerations, contusions, scalp hematomas, facial trauma, and signs of skull fracture, including Battle's sign (see below) and periorbital ecchymosis (raccoon eyes). Hemotympanum and bleeding from the ears, or CSF rhinorrhea or otorrhea, also suggest skull fracture and underlying TBI.

The pupillary examination may provide valuable data in the assessment of underlying TBI. Temporal herniation may be heralded by a mild dilation of the pupil and a sluggish response to light. Further dilation of the pupil followed by ptosis, or paresis of the medial rectus or other ocular muscle, may indicate third cranial nerve compression by a mass lesion. [Table 18-2](#) relates pupillary examinations to possible underlying

brain lesions. Most dilated pupils are on the ipsilateral side of the mass lesion. With direct globe injury, traumatic mydriasis may result. Additionally, 5% to 10% of the population has congenital anisocoria. Neither direct trauma nor congenital anisocoria

should be assumed in a head-injured victim exhibiting mental status change in the wilderness.

After quantification of GCS score, pupillary examination, and examination of the head and face for signs of external trauma, a concise neurologic examination should be performed. The goal of the field neurologic examination is to identify motor or sensory focal deficits suggestive of intracranial injury. Sensory

Figure 18-4 Dermatome pattern, the skin area stimulated by spinal cord elements. Sensory deficits following general dermatome patterns.

deficits follow general dermatome patterns shown in [Figure 18-4](#). Unilateral hemiplegia may signify uncal herniation resulting from mass effect in the contralateral cortex because of compression of the corticospinal tract in the midbrain. Ipsilateral pupillary dilation associated with contralateral hemiplegia is a classic and ominous sign of tentorial herniation. Reflex changes in the absence of altered mental status are not indicative of TBI. With the exception of the performance of gag and corneal reflex evaluations, the brainstem cannot be evaluated in the wilderness environment. The "doll's eyes maneuver" should never be performed without complete radiologic evaluation of the cervical spine. Ice

water irrigation of the tympanic membrane intended to evoke nystagmus adds nothing to an evacuation decision and should not be performed outdoors.

Resuscitation.

Resources and circumstances permitting, resuscitation should be initiated as an adjunct to the primary survey. The primary focus for the head-injured victim, similar to any traumatized victim, is the airway. During the primary survey and performance of the ABCDE sequence, IV access should be established. If IV resuscitation is impossible, it is *not* advisable to administer fluids orally to the victim with head injury because of the likelihood of vomiting, airway compromise, and aspiration.

Individuals sustaining head trauma have a high incidence of concomitant injuries. Up to 32% of persons with severe head injury will have a long bone or pelvic fracture, 20% to 25% a chest injury, and 10% an abdominal injury. A victim who does not have a palpable femoral pulse or manifests other signs of hypotension in the context of suspected head injury must be assumed to have a nonneurogenic etiology of shock.

Resuscitation is critical in this setting for multiple reasons. First, management of a head injury should be secondary to other life-threatening injuries, which, if not addressed, may preclude survival. Second, as previously discussed, maintenance of MAP and thus CPP is critical in preventing secondary brain injury.

The type of resuscitative fluid administered is controversial. Previously, recommendations existed warning of the dangers of overhydration in head injury, to the extent of implementing fluid restriction. Fluid restriction has not been shown to reduce ICP or edema formation in the laboratory, and hypotonic solutions do not decrease cortical water content.^[87] The need for resuscitation and intravascular volume support is now well established. Possible resuscitative fluids now include primarily isotonic crystalloids, colloids, or hypertonic crystalloids. Hypotonic fluids are not appropriate in TBI because they can cause increased brain water and thus elevated ICP. Recent data from animal studies suggest that colloids offer no advantage over isotonic crystalloids, such as lactated Ringer's solution, in head injury in terms of augmenting CBF or preventing cerebral edema.^[98] As previously noted, no clear prospective trial has documented any advantage of colloid over crystalloid administration in the victim with multiple systemic injuries. Evidence is accumulating that hypertonic solutions, particularly hypertonic saline, may be beneficial in TBI.^[89] ^[94] However, an advantage has not been demonstrated in trauma victims overall, and expertise is necessary for their use. Thus the recommended resuscitative fluid for the head-injured victim in the wilderness setting is isotonic crystalloid. MAP should be optimized at 90 mm Hg based on cuff pressure or extrapolation from distal pulses.

Further Management.

Numerous adjuncts exist in the management of the head-injured victim, few of which are applicable in the wilderness setting. Once the primary and secondary surveys are complete, the airway is secured, resuscitation has been initiated, and spine immobilization has been achieved, the victim should be placed in a 30-degree head-up position. This position assists in control of ICP and thus CPP through augmentation of venous outflow. This maneuver should not be attempted if the spine cannot be adequately immobilized.

If endotracheal intubation is possible, ventilation should be optimized *without* hyperventilating the victim. Hyperventilation has been used aggressively in the past to promote hypocarbia-induced cerebral vasoconstriction, thereby increasing CBF. However, if P_{aCO_2} falls below 25 mm Hg, severe vasoconstriction ensues, effectively reducing CBF and promoting ischemia. Studies have demonstrated worse outcomes in victims with severe head injury who were hyperventilated.^[64] Because of the inability to measure or titrate this variable in the wilderness, ventilation should be controlled to approximate normal minute ventilation.

All bleeding from the scalp or face should be controlled with direct pressure. Scalp hematomas, regardless of size, should not be decompressed. Open wounds, particularly skull fractures, should be irrigated and covered with the most sterile dressing available. Fragments of displaced cranium overlying exposed brain tissue should not be replaced. If signs of skull fracture are present, immunization against tetanus and

broad-spectrum antibiotic prophylaxis are recommended.

Although diuretics have been widely utilized in the intensive care management of intracranial hypertension, no rationale exists for their use in the field. The wilderness trauma victim may have many injuries that are impossible to diagnose. In this setting, particularly in the presence of hemorrhagic shock, attempts to induce osmotic diuresis to decrease ICP may be life-threatening. Diuretics such as furosemide or mannitol may exacerbate hypotension and alkalosis and induce renal complications in the absence of physiologic monitoring.^[4]

Steroids have no role in head injury in the field or intensive care unit. Studies have documented no beneficial impact on ICP or survival. Attempts at brain preservation by slowing metabolic rate and oxygen consumption have no role in the wilderness setting. Barbiturates have been used for elevated ICP refractory to other measures but may induce hypotension, depress myocardial function, and depress the neurologic examination.^[4] Compared with minimizing ICP, they offer no proven benefit.^[37]

Approximately 15% of persons with severe head injury experience posttraumatic seizures. Phenytoin, if available, can be safely administered in the field, but

only after a witnessed seizure. Prophylactic administration has not been shown to decrease long-term seizure activity.

Skull Fracture.

Skull fracture in the wilderness mandates evacuation. Therapeutic options in the field are few, with intervention limited to identifying the injury and arranging rapid transport. Skull fractures may be open or closed, linear or stellate, and may occur in the vault or skull base. Basilar skull fractures often manifest signs that aid in the diagnosis, including periorbital ecchymosis (raccoon eyes), retroauricular ecchymosis (Battle's sign), CSF leaks, or eighth cranial nerve palsy. Skull fractures are associated with a high incidence of underlying intracranial injury. In an awake and alert victim with a skull fracture, the chance of brain injury is increased 400-fold.^[5]

Skull fractures with depression greater than the thickness of the skull may require elevation. No attempt at elevation should be made in the field. Any exposed brain surface should quickly be covered with the most sterile covering available, preferably moistened with crystalloid solution. Loose bone or brain fragments should not be manipulated. If a broad-spectrum antibiotic is available, it should be administered. After attention to the wound and stabilization of associated injuries, the victim should be rapidly evacuated.

Penetrating Head Injuries.

The majority of penetrating head injuries in the wilderness are gunshot wounds, although knives and arrows may penetrate the cranium. Such injuries are usually catastrophic. However, examples of survival exist in small caliber, low-velocity injuries and tangential wounds.^[55] As with closed head injury, management priorities consist of maintenance of airway, prevention of secondary brain injury, and rapid evacuation. If the cranium has been violated, the victim should receive antibiotics and tetanus immunization in the same manner as for open skull fracture. Some authors recommend 7 days of anticonvulsant therapy.^[55] In the rare instance that the projectile is embedded in the skull, no attempt at removal should be undertaken. If the length of the projectile makes immobilization or transport cumbersome, excess length may be removed, but only if this may be done easily and without displacement of the intracranial segment.

Evacuation.

Survival and outcome of head injury in the wilderness correlate directly with the rapidity of evacuation. Certain situations dictate immediate evacuation. Any person with evidence of an open or closed skull fracture should be evacuated. The incidence of TBI associated with skull fractures is variable but significant throughout the literature. Recent data predict that 30% to 90% of persons with raccoon eyes or Battle's sign will have an abnormal computed axial tomography (CAT) scan. ^[11] ^[18] Similarly, any person who sustains a penetrating injury should be evacuated.

The decision to evacuate victims who have sustained closed head injuries can be simplified by dividing the victims into three groups based on probability of injury.

The high-risk group is composed of persons with GCS score of 13 or less. Focal neurologic signs or evidence of decreasing level of consciousness requires evacuation. The low-risk group includes persons who have suffered a blow to the head but are asymptomatic, did not lose consciousness, and complain only of mild headache or dizziness. Data from recent studies suggest that persons who meet low-risk criteria (including GCS of 15, no loss of consciousness, minimal symptomatology, and unlikely mechanism) have a minimal chance of having significant TBI^[11] ^[18] and may be closely observed.

The group for which the evacuation decision is most difficult is the moderate-risk group. These persons have a history of brief loss of consciousness or change in consciousness at the time of injury, or a history of progressive headache, vomiting, or posttraumatic amnesia. If any of these signs is present in the face of concurrent systemic injury, the victim should be evacuated immediately. Studies associating clinical variables and abnormal computed tomography (CT) scans have demonstrated the significance of decreased GCS, symptoms, and loss of consciousness. If these signs are present in isolation and the evacuation can be completed in less than 12 hours, the evacuation should proceed. If the evacuation is impossible or will require longer than 12 hours, the victim should be closely observed for 4 to 6 hours. If the examination improves to normalcy during the observation period, it is reasonable to continue

observation.

Neck Injuries

Blunt Neck Injuries.

Injuries to the neck may be classified as blunt or penetrating. Significant blunt injuries include cervical spine injuries and laryngotracheal injuries. Seventy-five percent of injuries to the trachea are confined to the cervical region.^[69] Fracture of the larynx and disruption of the trachea usually require surgical intervention unavailable in the wilderness. The sooner laryngeal repair is accomplished, the better the outcome with respect to phonation.^[21] Victims present with a history of a significant blow to the anterior neck. Physical examination findings include difficulty with phonation, subcutaneous emphysema that may extend as far inferiorly as the abdominal wall, stridor, odynophagia, and, often, acute respiratory distress.

Treatment is focused on establishing and maintaining

441

an airway until evacuation can occur. Frequently, the airway will be in jeopardy, and because of the propensity for injuries of this type to result in significant and progressive edema, endotracheal or nasotracheal intubation is often necessitated. If these options are unavailable, airway maintenance techniques as described in the Primary Survey section should be used. In the event of intubation failure or lack of availability with impending hypoxic death, a surgical cricothyroidotomy may be necessitated. A recent study of prehospital cricothyroidotomy demonstrated that success rates were high regardless of medical specialty as long as previous training had been instituted.^[51] For further descriptions of airway management, refer to [Chapter 17](#).

BACKGROUND.

Vertebral column injury, with or without neurologic deficits, must be identified in any wilderness multiple trauma victim. Approximately 2.6% of victims of major trauma suffer acute injury of the spinal cord.^[16] Fifteen percent of victims sustaining an injury above the clavicles and 5% to 10% of persons with a significant head injury will have a cervical spine injury. Additionally, 55% of spinal injuries occur in the cervical region.^[55] In the wilderness setting, fractures or dislocations of the cervical spine are a result of falls from significant heights, or of high-velocity ski or vehicular injuries. Twenty-eight percent of persons with cervical spine fractures have fractures elsewhere in the spine.^[10]

ANATOMY.

The cervical spine consists of seven vertebrae. The anteriorly placed vertebral bodies form the weight-bearing structure of the column. The bodies are separated by

intervertebral disks and held in place anteriorly and posteriorly by longitudinal ligaments. The paraspinal muscles, facet joints, and interspinous ligaments contribute as a whole to the stability of the spine. The cervical spine, based on its anatomy, is more susceptible to injury than are the thoracic and lumbar spine. The cervical canal is wide from the foramen magnum to C2, with only 33% of the canal comprised by the spinal cord itself. The clinically relevant tracts in the spinal cord include the corticospinal tract, the spinothalamic tract, and the posterior columns.

CLASSIFICATION AND RECOGNITION.

Fractures of the cervical spine frequently result in neurologic deficit, with total loss of function below the level of injury.^[50] Resultant spinal cord injuries should be classified according to level, severity of neurologic deficit, and spinal cord syndrome. Fractures of the C1-C2 complex generally result from axial loading (a C1 ring fracture, or Jefferson's fracture) or an acute flexion injury (a C2 posterior element fracture, or hangman's fracture). Approximately 40% of atlas fractures have an associated fracture of the axis. The atlas fracture, if survived, is rarely associated with cord injury but is unstable and requires strict immobilization. Generally, a complete neurologic injury at this level is unsurvivable owing to paralysis of respiratory muscle function. One third of victims sustaining an upper cervical spine injury die at the scene. The most common mechanism of injury is flexion, and the most common level of injury at C5-C6. ^[10]

Fractures and dislocations may result in partial or complete neurologic injury distal to the fracture or in no neurologic injury at all. Partial injuries to the spinal cord result from typical patterns of injury. Because flexion injuries are the most common type of injury to the cervical spine, the anterior cord syndrome (see below) is the most commonly seen serious neurologic picture. A careful neurologic examination in the field to grade motor strength and to document sensory response to light touch and pinprick yields important information that should be documented and reported to the treating physician at the definitive care facility. The presence or absence of the Babinski's reflex should be noted, as well.

When appropriate resources are available, a rectal examination should be performed. Complete lack of tone and failure of the sphincter muscles to contract when pulling on the penis or clitoris (the bulbocavernosus reflex) indicate the presence of spinal cord injury.

When individuals with cervical spine fractures or dislocations are transported, the neck must be stabilized to prevent further injury to the spinal cord or nerve roots at the level of the fracture or dislocation. Approximately 28% of persons with cervical spine fractures have fractures elsewhere in the spine;^[10] therefore the entire spine must be protected during transport.

Occasionally, a pure flexion event can result in dislocation of one or both of the posterior facets without fracture or neurologic injury. The victim may complain only of neck pain and limitation of motion. If so, the victim should be transported with the neck rigidly immobilized. With this injury, posterior instability is present (since the interspinous

ligament is ruptured), and any further flexion stress could produce a spinal cord injury.

PHYSICAL EXAMINATION.

A thorough neurologic examination should be performed. Initial documentation of deficits and frequent repeat examinations are critical to follow-up care. The classification of injury in the field begins with determination of the level of injury. Knowledge of sensory dermatomal and motor myotomal patterns is invaluable (see [Figure 18-4](#)). The sensory level is the lowest dermatome with normal sensation and may differ on each side of the body. C1 to C4 are variable in their cutaneous distribution, and assessment should begin at C5. The examiner must not be confused by the occasional innervation of the pectoral skin by C1 to C4, known as the "cervical cape." Light touch and pinprick should be assessed.

442

Motor function should be assessed by the myotomal distribution listed in [Box 18-2](#). Each muscle should be graded on a six-point scale:

- 0—Total paralysis
- 1—Palpable or visible contraction
- 2—Full range of motion without gravity
- 3—Full range of motion against gravity
- 4—Full range of motion with decreased strength
- 5—Normal strength

Each muscle must be tested bilaterally and documented. The reflexes alluded to in the classification section must be tested, as well as anal sphincter tone.

SYNDROMES.

Central cord syndrome is characterized by a disproportionate loss of motor power between the upper and lower extremities, with greater strength retained in the lower extremities. Sensory loss is variable. The mechanism of injury usually involves a forward fall with facial impact and hyperextension of the spine.

Anterior cord syndrome is characterized by paraplegia and loss of pain and temperature sensation. It is the most common presenting syndrome caused by cervical spine injury

and carries a poor prognosis.

Brown-Séquard's syndrome results from hemisection of the cord. It consists of ipsilateral motor loss and position sense with contralateral sensory loss two levels below the level of injury. It is usually secondary to penetrating injury.

IMMOBILIZATION.

After identification of injury, the caregiver faces a critical decision with important ramifications—whether or not to immobilize.^[31] Victims who would as a matter of course be immobilized in an urban setting might not be appropriate candidates for immobilization in the wilderness. The decision to immobilize converts an otherwise ambulatory victim who can actively participate in his or her own evacuation to one requiring more involved evacuation procedures. The subsequent evacuation can be dangerous to the victim and rescuers and demands significant expense and resource utilization.

Risk criteria for cervical spine injury and the need for immobilization have been defined.^[40] ^[53] All criteria for the exclusion of immobilization must be satisfied. These include normal mental status without chemical influence; lack of distracting injury; normal neurologic examination; and a reliable neck examination without midline neck pain, deformity, or tenderness. [Figure 18-5](#) presents an evidence-based algorithm for determining need for immobilization. Although the need for immobilization poses hazards for the evacuation process, if criteria are met, immobilization takes precedent over ease of evacuation.^[58] A difficult balance must be struck in the wilderness between the likelihood of true injury and the danger to the expedition members and rescuers that may ensue when the victim is immobilized.

If a rigid litter is not available, the victim should be maintained on the flattest surface possible. A rigid cervical collar should be placed. All collars allow some degree of movement, particularly rotation. Soft collars offer the least immobilization.^[30] The Philadelphia collar

Figure 18-5 Clinical assessment of cervical spine stability. Failure of any criterion suggests need for immobilization.

has been shown to allow 44% of normal rotation and 66% of normal lateral bending. [55] To achieve 95% immobilization, a halo and vest are necessary. Any number of materials may be used to improvise an immobilizing device. Restriction of flexion, extension, and rotation must be achieved to the greatest degree possible. Optimal immobilization consists of a long spine board or litter, rigid collar, bolsters to the sides of the head, and tape or straps restricting movement ([Figure 18-6](#)).

TREATMENT.

The issue of pharmacotherapy for spinal cord injury is under continuous study. Currently, based on data accumulated by the National Acute Spinal Cord Injury Study Group, documented *blunt* spinal cord injury should be treated with a bolus of 30 mg/kg of methylprednisolone within 8 hours of injury followed by a continuous infusion of 5.4 mg/kg over the next 23 hours. [13] Steroids are not recommended in the field unless a victim clearly manifests a spinal cord injury in the absence of head injury.

Because little definitive treatment for cervical spine injury can be accomplished in the field, survival and outcome depend on speed of transport and maintenance of airway. This is particularly true considering the association of cervical spine injury with head injury and major systemic trauma. Transport all victims with proven or suspected cervical spine injury to a definitive care facility.

Penetrating Neck Injuries.

Similar to penetrating head injury, penetrating neck injury is usually due to gun or knife wounds. Most penetrating injuries do not confer

Figure 18-6 Proper spine immobilization.

bony instability; however, stability should not be assumed. Neurologic deficits, if present, can progress with further movement of an unstable spine. Projectiles should not be removed if embedded in the neck. Penetrating injuries to the neck may not directly injure the spine, but neurologic sequelae may result from blast effect. The same immobilization criteria should be implemented as when dealing with blunt injuries.

Penetrating injuries to the neck are classified according to anatomic zones of injury ([Figure 18-7](#)). Zone I injuries extend from the clavicles to the cricoid cartilage. Zone II injuries occur between the cricoid and the angle of the mandible. Zone III injuries occur superior to the angle of the mandible.

Historically, treatment has been based on penetration of the platysma muscle. In the wilderness setting, if the examiner is confident that platysmal penetration has not occurred, the victim may be observed and the wound considered a laceration. Much debate has occurred over management of platysmal penetration within respective topographic zones, with treatment arms consisting of surgical exploration vs. radiographic evaluation. In the wilderness setting, such considerations are not irrelevant. A penetrating injury violating the platysma muscle indicates the possibility of significant neurovascular, esophageal, and/or tracheal injuries, so the victim should be evacuated with close attention to the airway. If hemorrhage uncontrollable by direct pressure is present, careful insertion of a Foley catheter into the wound with balloon inflation may provide temporizing tamponade.^[21]

Injuries to the Thorax

Background.

The mortality from thoracic trauma is approximately 10%. Approximately 25% of all trauma

Figure 18-7 Zones in penetrating neck trauma.

deaths in the United States are attributable to chest injury.⁵ However, only 15% of persons with major thoracic trauma require thoracotomy. Early intervention can play a critical role in survival, and many deaths are preventable. Prompt identification of life-threatening injuries in the immediate postinjury period may facilitate proper, lifesaving intervention.

In the wilderness environment, blunt thoracic injuries usually result from falls or direct blows to the chest. Penetrating injuries result from gun, knife, or arrow wounds, or from impalement after a fall. Immediate, life-threatening thoracic injuries include airway obstruction, tension pneumothorax, flail chest, and cardiac tamponade. The hallmark of significant thoracic injury is hypoxia, which may sometimes be remedied in the field.

Pathophysiology.

Chest injuries often result in hypoxia, hypercarbia, and acidosis. The tissue hypoxia of thoracic trauma can be multifactorial. Inadequate delivery of oxygen can be from hemorrhagic shock, direct lung injury with ventilation-perfusion mismatch (pulmonary contusion, atelectasis, hematoma), and/or changes in normal intrathoracic pressure dynamics (tension or open pneumothorax). Hemodynamic instability and inadequate oxygen delivery may also result from cardiac tamponade or contusion.

Physical Examination.

Thorough physical examination begins with visualization and inspection of the chest. Exposure of the chest should be completed in the primary survey. The airway is assessed for patency and air exchange, and the pattern of breathing is noted. In the immediate postinjury period, most trauma victims are tachypneic, partly from pain and anxiety. Dyspnea, cyanosis, the use of accessory muscles of respiration, or intercostal muscular retraction are abnormal and may give clues to the underlying injury.

Chest wall movement during respiration should be symmetric. Paradoxical chest wall movement is associated with flail chest. The chest wall should be inspected for contusions and abrasions, which may herald underlying bony or visceral injury.

Distention of the external veins in a person who has just suffered thoracic trauma and is hypotensive or tachycardic (heart rate greater than 130 beats per minute) suggests impairment of venous return to the heart. This finding may be seen in situations of increased intrathoracic or intrapericardial pressure and is associated with tension pneumothorax and pericardial tamponade. In tension pneumothorax, deviation of the trachea is in a direction opposite the lesion. Significant sternal bruising may herald fracture or cardiac contusion.

The thorax should be palpated systematically for bony tenderness, starting at the distal

clavicles and working medially toward the sternum. The sternum is divided into the manubrium, gladiolus (body), and xiphoid cartilage. The manubrium is joined to the gladiolus by fibrocartilage, but mobility at this joint is minimal.

Each rib should be palpated individually. Ribs 1 to 7 are vertebrosteral; their costal cartilages join the sternum. Ribs 8 through 10 are vertebrochondral, with each costal cartilage commonly joining the cartilage of the rib above. Ribs 11 and 12, vertebral ribs, have no attachment to the sternum. Point tenderness over a rib can be associated with contusion or fracture. Displaced fractures can be palpated; occasionally, bone grating can be palpated during respiration.

Subcutaneous emphysema may extend up into the neck and down to the level of the inguinal ligaments. In the trauma situation, subcutaneous emphysema is invariably associated with pneumothorax.

Vocal fremitus describes palpation of vibrations transmitted through the chest wall. During speech, the victim's vocal cords emit vibrations in the bronchial air column that are conducted to the chest wall. Diminished vocal fremitus is associated with pneumothorax or hemothorax. To test for vocal fremitus, the examiner applies the palmar arch of the examining hand against the person's anterior chest wall. The person is asked to repeat "one, two, three" using the same pitch and intensity of voice with each repetition. If the vibrations are not well perceived, the patient is asked to lower the pitch of the voice. The chest should be symmetric, left to right.

Percussion is used to detect changes in the normal density of an organ. Percussion of the chest is performed by placing the examining fingertip on the chest wall and sequentially striking the fingertip with the tip of the finger of the other hand. In the trauma victim, dullness replacing resonance in the lower lung suggests hemothorax. Hyperresonance or tympany replacing resonance occurs only with a large pneumothorax or tension pneumothorax.

If a stethoscope is not available, primitive chest auscultation can be performed using a rolled piece of cardboard or paper. Any cylinder that can transmit sound through a column of air accentuates breath sounds when placed against the chest wall. The absence of sounds normally produced by the tracheobronchial air column indicates blockage in the airways or abnormal filtering of sound by fluid within the pleural cavity. In the trauma victim, this is invariably associated with pneumothorax or hemothorax.

Blunt Chest Trauma.

Blunt chest trauma in the wilderness is most often associated with either a direct blow or a deceleration injury. The mechanism usually relates to a fall from variable heights. Compression of the chest wall by moving or falling debris may also contribute to intrathoracic

injuries, as may be seen in traumatic asphyxia associated with burial in an avalanche or earthquake.

RIB FRACTURES.

Rib fractures range in severity from an isolated nondisplaced single fracture, which causes only minor discomfort, to a major flail segment, which can be associated with an underlying hemopneumothorax and pulmonary contusion. Rib fractures are characterized by painful respiration, most severe on inspiration. Victims often breathe in a characteristically rapid, shallow pattern. Point tenderness is palpated over the fracture, and displacement can occasionally be detected. Rib fractures are detected with a compression test, in which pressure is exerted on the sternum while the victim lies supine. This will elicit pain over the fracture site.

Isolated rib fractures are managed with oral analgesics and rest. Thoracic taping and splinting are not necessary or helpful. Multiple rib fractures are significant because of the potential seriousness of associated injuries and increased pain. However, this pain responds well to an intercostal nerve block. Victims with multiple rib fractures need to be evacuated as conditions permit. After administration of an intercostal block, a person may regain the ability to hike out of the wilderness.

The morbidity of rib fractures relates to decreased inspiratory tidal volume secondary to pain and splinting. In the wilderness setting, management must focus on pain control and pulmonary toilet. If oral analgesia is insufficient to control pain, an intercostal block is ideal. Depending on the anesthetic used, varying lengths of analgesia can be attained, perhaps allowing transient ambulation for evacuation. Deep breathing should be encouraged 10 times hourly to help prevent atelectasis.

COSTOCHONDRAL SEPARATION.

It is difficult to distinguish between a rib fracture and costochondral separation. With the latter, pain is more likely to be predominantly anterior over the costochondral junction. Pain increases with inspiration and worsens with direct palpation. Costochondral separation also responds to intercostal nerve block and oral and IV analgesics.

STERNAL FRACTURE.

A sternal fracture is usually associated with a direct blow to the anterior chest wall. The injury is characterized by severe, constant chest pain that worsens with direct palpation. Sternal instability is unusual and can be associated with a significant underlying visceral injury, including pulmonary or myocardial contusion. The victim should immediately be evacuated by litter or helicopter.

PNEUMOTHORAX.

Simple pneumothorax can occur from an injury that allows air to enter through the thoracic wall or, more frequently, from an injury to the lung that permits air to escape into the pleural space. Symptoms include tachypnea, dyspnea, resonant hemithorax, absence of breath sounds, and tactile fremitus. A person with chest pain after a blunt blow to the chest, particularly with accompanying rib fracture(s), should be suspected of having a pneumothorax.

Treatment of pneumothorax involves decompression of the pleural space. In the wilderness environment, tube thoracostomy is rarely possible. Fortunately, although victims with isolated pneumothorax may complain of chest pain or dyspnea, they are not completely disabled. With analgesia to control pain, ambulation facilitates evacuation. It may be easier and more prudent to set a slow pace with frequent rest periods than to perform an unnecessary litter evacuation.

If resources and expertise allow placement of a thoracostomy tube, it should be performed only when clinically indicated. Considering possible morbidity in a remote area, prophylactic decompression should never be undertaken. Suspicion of a pneumothorax alone on physical examination does not warrant a catheter or chest tube. When a high index of clinical suspicion is accompanied by incapacitating symptoms, such as shortness of breath, decompression should be considered. The key to saving a victim's life is the understanding that a condition exists that can rapidly progress from a nondisabling condition to a life-threatening condition. Once the diagnosis of pneumothorax is entertained, vigilant observation and a high index of clinical suspicion are necessary in the event of progression to a tension pneumothorax. Symptoms should be closely monitored and frequent repeat examinations should be performed.

TENSION PNEUMOTHORAX.

A tension pneumothorax develops when a one-way air leak follows lung rupture or chest wall penetration. Air is forced into the thoracic cavity with no means of escape, and pressure mounts within the hemithorax. With sufficient increases in intrathoracic pressure, the mediastinum is shifted to the contralateral side, which impedes venous return from both the superior and inferior vena cavae. Cardiac output is diminished and the victim soon exhibits signs and symptoms of shock. Victims with tension pneumothorax manifest distended neck veins and tracheal deviation away from the side of the lesion. There is unilateral absence of breath sounds, and the hemithorax is hyperresonant or tympanic. Respiratory distress, cyanosis, and frank cardiovascular collapse may occur.

Tension pneumothorax is life-threatening and frequently associated with additional serious injuries. It mandates rapid chest decompression, followed by evacuation to a medical facility.

Decompression is performed by inserting a needle or catheter into the chest and

converting the tension into an

446

open pneumothorax. Ideally, a 14-gauge catheter is inserted percutaneously over the second rib in the mid-clavicular or anterior axillary line ([Figure 18-8](#)). Once the rib is identified with the tip of the needle, the needle is marched over the anterior superior surface of the rib and inserted through the intercostal muscles and pleura into the thoracic cavity. As the pressure within the hemithorax is released, a distinct rush of air is heard. The plastic catheter is advanced over the tip of the needle, the needle withdrawn, and the catheter left in place to ensure continued decompression. The needle should not be reintroduced into the catheter because it may damage or sever the catheter. Because tension pneumothorax is commonly associated with severe injury, the victim should be evacuated to a medical facility as rapidly as possible. A rubber glove or a finger cot can be attached to the external catheter opening to create a unidirectional flutter valve that allows egress of air from the pleural space.

If resources are limited and treatment is needed, any number of devices can be used to decompress the chest. A

Figure 18-8 Needle decompression of tension pneumothorax. This procedure is performed only for tension pneumothorax in patients with hemodynamic instability.

sharp instrument and hollow tube, sterilized as well as possible, are all that is needed. Rapid cleansing of the skin surface is accomplished with antiseptic, alcohol, or water. A Heimlich valve kit is ideal for decompression and represents a valuable addition to the expedition first aid arsenal.

If resources permit placement of a thoracostomy tube, adequate anesthesia and expertise are required. The skin should be sterilized if possible, and local anesthesia should be infiltrated into the skin and periosteum of the rib. Insertion is most effectively accomplished through the fifth intercostal space at the anterior axillary line. A small incision is made and the subcutaneous tissue bluntly separated with a finger or clamp. A blunt instrument, preferably a clamp, is forcefully inserted into the pleural space closely adhering to the superior surface of the rib to avoid the inferiorly located intercostal neurovascular bundle. Having entered the pleural space, a tube (36 F or greater in size) is inserted apically and posteriorly.

The tube should then be secured with suture or tape and 10 to 20 cm H₂O suction or underwater seal applied. A tube open to the atmosphere can accomplish decompression. The end of the tube can be covered with a rubber glove, finger cot, or plastic bag; one-way flow evacuating the chest is the goal. It must be emphasized that this procedure is not without morbidity and should only be used by trained personnel under optimal conditions. Antibiotics with gram-positive coverage should be initiated if the pleural space is penetrated with an indwelling catheter or tube.

HEMOTHORAX.

Hemothorax is usually associated with multiple rib fractures resulting from a direct blow to the chest. The primary cause of a hemothorax is laceration of the lung, intercostal vessel, or internal mammary artery. The victim complains of chest pain, tenderness associated with rib fractures, inspiratory pain, and dyspnea. Vocal fremitus is absent, percussion may be flat or dull, and breath sounds are diminished or absent.

A chest tube may be placed if proper equipment is available and evacuation may be delayed. Needle aspiration of a hemothorax is unnecessary in the immediate postinjury period and may precipitate a pneumothorax. As in the case of pneumothorax, treatment is strictly based on clinical deterioration. Isolated hemothorax from blunt trauma leading to shock is unusual and commonly associated with other massive injuries.

FLAIL CHEST.

When a series of three or more ribs is fractured in both the anterior and posterior plane, a portion of the chest wall may be mechanically unstable. As negative intrathoracic pressure develops during inspiration, the unstable segment paradoxically moves inward and inhibits ventilation. A flail segment indicates a severe direct blow to the chest wall with associated multiple rib fractures and decreased tidal volumes, often with associated underlying pulmonary contusion. The contusion can be expected to progressively impair ventilation and oxygenation over the succeeding 48 hours. Victims will often tolerate a flail segment for the first 24 to 48 hours, after which they require mechanical ventilation.

Any victim with a flail segment should be rapidly evacuated. Because the victim is usually incapable of participating in evacuation, a litter should be prepared or aeromedical evacuation considered. Intercostal nerve block may assist in short-term management of pain and pulmonary toilet. Restrictive (to chest wall expansion during inhalation) external chest wall supports, including taping or extensive stabilization with sandbags, are contraindicated. These measures hinder chest wall movement, decrease vital capacity, and are less effective than intercostal nerve block in pain control. However, focal stabilization or cushioning of the flail segment only to control unnecessary motion and pain may provide minimal relief from the discomfort.

BLUNT CARDIAC INJURIES.

Blunt cardiac injuries leading to pericardial tamponade or cardiac contusion are rare. Pericardial tamponade is life-threatening. The pericardial sac is fibrous and expands little. A small amount of intrapericardial blood can severely restrict diastolic function. Blunt injury resulting in tamponade is usually from chamber rupture and rarely survivable, particularly in a remote setting.

The diagnosis of tamponade can be difficult, particularly in the wilderness. Beck's triad, which consists of distended neck veins, hypotension, and muffled heart sounds, is present in less than 33% of cases of tamponade and is particularly difficult to ascertain under nonoptimal conditions. Pulsus paradoxus, an increase in the normal physiologic decrease in blood pressure with inspiration, may be indicative of tamponade. Kussmaul's sign, or a rise in venous pressure with spontaneous inspiration, is possible to assess outdoors.

Once pericardial tamponade is diagnosed, immediate evacuation is required. Treatment consists of median sternotomy in a hospital operating room. The only temporizing measure pending evacuation is pericardiocentesis. This procedure can be lifesaving, particularly if a cardiac injury with a slow leak exists. However, its application in the wilderness setting should occur only if there is a high index of suspicion, coupled with shock and impending death unresponsive to resuscitative efforts. A long (approximately 15 cm) 16- to 18-gauge needle with an overlying catheter is introduced through the skin 1 to 2 cm below and to the left of the xiphoid. The needle is advanced at a 45-degree angle with the tip directed at the tip of the left scapula. When the pericardial sac is entered, aspiration with a syringe follows. The catheter is left in place and secured for possible repeat aspirations as the victim's condition warrants. Immediate evacuation should follow.

Cardiac contusion is a rare, nebulous condition resulting from a severe blow to the precordium. An overlying sternal contusion or fracture may be present. The diagnosis should be suspected in an isolated high-velocity blow to the precordium with unexplained evidence of increased venous pressure and hemodynamic instability. Chest pain is invariably present, usually resulting from musculoskeletal contusion. Morbidity results from ensuing arrhythmias. The diagnosis, if hemodynamically significant, is difficult to distinguish from blunt trauma-induced tamponade. Diagnosis can only be definitively made at autopsy. Electrocardiographic abnormalities after injury have correlated with subsequent arrhythmias.^[52] In the wilderness setting, any person who is unstable or symptomatic from an arrhythmia should be evacuated. If evacuation is not possible, it is noteworthy that fatal arrhythmia potential decreases significantly after 24 hours.

TRAUMATIC ASPHYXIA.

Traumatic asphyxia is a rare syndrome of craniocervical cyanosis, facial edema,

petechiae,

subconjunctival hemorrhage, and occasional hypoxemia-related neurologic symptoms that results from severe thoracic crush injury. In the wilderness environment, it is associated with land or mudslides, avalanches, or falling debris. Any significant blunt compressive force to the thorax can result in the syndrome. Children are particularly susceptible because of high compliance of the chest wall.^[16] Traumatic asphyxia is not a benign condition, as a result of a high incidence of serious associated injuries,^[67] and mortality in natural disasters is consequently high.^[32] A number of studies have documented the severity of associated injuries, with the syndrome useful as an indicator of potentially lethal injury.^[24] As documented in natural disasters, a significant crush injury component may accompany traumatic asphyxia.^[32] Crush injuries and rhabdomyolysis are discussed in the Extremity Injury section of this chapter.

The pathophysiology of traumatic asphyxia involves two elements. The crush injury results in acute increases in intrathoracic pressure and thus inferior and superior vena caval pressures. Venous flow is reversed in the veins of the head, which contain no valves. Venous hypertension leads to capillary rupture and the characteristic facial edema and petechiae. Recognition of the physical findings is imperative in diagnosing the syndrome and identifying concomitant injuries ([Figure 18-9](#)).

Treatment consists of carefully extracting and, if necessary, immobilizing the victim. Rapid extrication is the single most important factor in improving survival. Establishment and maintenance of an airway is critical because significant facial and laryngeal edema may rapidly develop. Associated injuries should then be addressed in the primary survey. Subsequent care is supportive, consisting of airway control, administration of oxygen, head elevation of 30 degrees, treatment of associated injuries, and possible evacuation.

Figure 18-9 Typical clinical facial appearance of traumatic asphyxia.

Mortality is low in civilian environments but higher in wilderness disaster settings. Mortality is due to pulmonary dysfunction and associated injuries. Morbidity is secondary to neurologic damage; however, the majority of neurologic sequelae clear within 24 to 48 hours. If the victim survives, long-term sequelae are rare.

Penetrating Chest Trauma.

Penetrating chest trauma above the nipple line is associated with hemopneumothorax and may also be associated with significant visceral injury. A victim with penetrating chest trauma below the nipple line often has intraabdominal penetration in addition to possible thoracic injury. Such a victim requires immediate rapid evacuation.

The open ("sucking") chest wound produces profound intrathoracic physiologic alterations. Normal chest expansion creates negative intrathoracic pressure, which pulls air into the trachea and allows the lungs to expand. When the diaphragm and chest wall relax, positive pressure creates expiration. If the chest wall sustains an injury approximately two-thirds the tracheal diameter, negative intrathoracic pressure for inspiration is lost, the ipsilateral lung collapses, and the loss of negative intrathoracic pressure affects the good lung. Consequently, it is important to rapidly reconstruct chest wall integrity. Initially, this is most easily done by placing a hand over the sucking chest wound. Field treatment includes placing a petrolatum gauze on top of the wound, covering it with a 4 × 4 gauze pad, and taping it on three sides ([Figure 18-10](#)). The untaped fourth side serves as a relief mechanism to prevent tension pneumothorax. Persons with sucking chest wounds should be rapidly evacuated to sophisticated medical care.

Injuries to the Abdomen

Intraabdominal injuries in the wilderness setting are unique because they are often difficult to recognize. *However, once recognized or suspected, all intraabdominal injuries require rapid resuscitation and immediate evacuation.*

Figure 18-10 Treatment of a sucking chest wound. Sealing the wound with a gel defibrillator pad works best because this pad adheres to wet or dry skin. Petrolatum gauze or Saran Wrap also works well. Note that one side is not sealed to allow egress of air.

The abdomen represents the most frequent site of life-threatening hemorrhagic shock; however, in the wilderness setting, few diagnostic and treatment options exist.

Blunt Abdominal Trauma.

Blunt intraabdominal injury is commonly associated with falls. Abdominal injuries are often associated with fractures or closed head injuries. Often the decision for evacuation is made on the basis of other injuries; however, the wilderness physician must be

attuned to the potential for intraabdominal hemorrhage as an occult injury.

ANATOMY.

For descriptive purposes, the abdomen may be divided into thoracic, true, and retroperitoneal compartments. The thoracic abdomen contains the liver, spleen, stomach, and diaphragm. The liver, spleen, and—more rarely—stomach may be injured by direct blows to the ribs or sternum. Twenty percent of persons with multiple left lower rib fractures have a ruptured spleen. A direct blow to the epigastrium may result in increased intraabdominal pressure with subsequent rupture of the liver or diaphragm. The true abdomen contains the small bowel, large bowel, and bladder. Isolated bowel injuries are rare in the wilderness setting. Blunt bladder or rectal injury usually occurs in conjunction with severe pelvic fracture and carries high mortality. The retroperitoneal abdomen contains the kidneys, ureters, pancreas, and great vessels. It is notoriously difficult to evaluate by physical examination. Life-threatening hemorrhage can occur into the true abdomen or the retroperitoneal space.

DIAGNOSIS.

Although much progress has been made in the last decade to evaluate for the presence of blunt intraabdominal injury, modalities such as CT, ultrasound, and diagnostic peritoneal lavage are irrelevant in the wilderness setting. The wilderness physician must have a high index of suspicion and perform a superlative history and physical examination.

PHYSICAL EXAMINATION.

The physician should look for signs of early shock: tachycardia, tachypnea, delayed capillary refill, weak or thready pulse, and cool or clammy skin. Physical examination of the abdomen begins with visualization and inspection. Contusions and abrasions may be the only harbingers of occult visceral injury. Periumbilical ecchymosis associated with abdominal hemorrhage (Cullen's sign) is virtually never present in a victim with acute abdominal trauma. Abdominal distention secondary to hemorrhage is a very late sign and never present before shock and cardiovascular collapse. Abdominal inspection should survey the flanks, lower chest, and back. Inspection of the back should follow palpation of the spine while the victim is supine. The victim should be very carefully logrolled if there is any suspicion of spinal injury.

Looking for muscle guarding, the examiner gently palpates the abdomen in all four quadrants. *Any* persistent guarding or tenderness after wilderness trauma mandates rapid evacuation. Percussion tenderness is an indicator of peritoneal irritation, also mandating evacuation. The presence or absence of bowel sounds has little prognostic significance. Bowel sounds may be present in the face of significant intraabdominal hemorrhage or, conversely, absent in victims when extraabdominal injuries induce ileus.

Referred pain to the left shoulder (Kerr's sign) strongly suggests the presence of a ruptured spleen. This pain is often exaggerated by placing the victim in Trendelenburg's

position, increasing the amount of left upper quadrant blood irritating the diaphragm. Pain from the retroperitoneal abdomen associated with injuries to the kidney or pancreas may be referred to the back. However, referred pain is usually a late finding and not helpful in the evaluation of acute trauma.

Gross hematuria that does not clear immediately or is coupled with an associated injury, such as pelvic fracture or abdominal or back pain, requires immediate evacuation. To minimize blood loss, the victim should be kept stationary and the evacuation team brought as close to the victim as possible.

In a wilderness setting, rectal and vaginal examination adds little to the evacuation decision when evaluating for abdominal trauma. The unstable pelvic fracture associated with rectal and vaginal injuries is usually the determinant for evacuation.

Penetrating Abdominal Trauma.

Penetrating intraabdominal injuries may result from gunshot, stab, or arrow wounds. The social context in which these injuries occur (accidental, intentional, or self-inflicted) makes little difference in the wilderness setting. Recrimination, guilt, and blame only interfere with the paramount goal of immediate evacuation.

GUNSHOT WOUNDS.

Low-caliber gunshot injuries often present with small entrance and no exit wounds. High-caliber, high-velocity gunshot injuries may have relatively innocuous entrance wounds but may be associated with large, disfiguring exit wounds and extensive internal injuries. No matter what the caliber or trajectory and no matter where the entrance and exit, all gunshot wounds from the nipple line to the inguinal ligament should be presumed to have penetrated the abdominal cavity and created an intraabdominal injury. These injuries mandate immediate surgical intervention. A victim of gunshot wounds to the head, neck, chest, abdomen, or groin should undergo immediate evacuation accompanied by the administration of a single-agent broad-spectrum antibiotic, such as an oral fluoroquinolone (e.g., ciprofloxacin, 750 mg po bid). Gunshot wounds (hunting injuries) are discussed in [Chapter 20](#).

SHOTGUN INJURIES.

Shotgun injuries to the torso are managed in the same manner as gunshot wounds. Shotgun injuries have potentially lower incidence of underlying visceral injury than gunshot wounds, but there is often extensive soft tissue damage requiring surgical debridement. The potential exists for delayed development of peritonitis from a single penetrating pellet to the viscera. Consequently, shotgun injuries should also be treated with emergency evacuation and a broad-spectrum antibiotic, as recommended above

for gunshot wounds.

Occasionally, a close-range shotgun blast results in a soft tissue defect large enough for the injured bowel to extrude through the wound. The injured bowel should not be placed back into the abdomen. Injured bowel displaced from the abdominal cavity conceptually should be treated as though it were an enterocutaneous fistula. Since evacuation is often delayed in the wilderness, it is better to have fecal contents outside, rather than inside, the peritoneal cavity. The exteriorized bowel should be kept moist and covered at all times. Uncovered bowel outside the peritoneal cavity rapidly desiccates and becomes nonviable, mandating later surgical resection. Exposed bowel should be covered with an abdominal pack or cloth moistened with sterile saline at best, or at worst with potable water. The dressing should be checked and remoistened at least every 2 hours.

STAB WOUNDS.

The penetrating object is usually a knife but may be as varied as a piton, ski pole, or tree limb. Any deep skin laceration from the nipple line to the groin should be considered to have damaged an intraabdominal organ. Whereas the odds of an abdominal gunshot wound injuring a visceral organ exceed 95%, the odds of a stab wound injuring a visceral organ are between 50% and 60%.

In certain urban hospitals, the high incidence of negative surgical explorations for stab wounds had led to a more selective approach toward patients with abdominal stab wounds.^[65] This approach uses local wound exploration, diagnostic peritoneal lavage, and frequent physical examination.

Although no data exist addressing the management of stab wounds in the wilderness environment, the following approach is practical and reasonable. If the wound extends into the subcutaneous tissue, the evacuation decision depends on local wound exploration. This procedure is simple to perform, even in the wilderness environment. The skin and subcutaneous tissue are infiltrated with local anesthetic, and the laceration is extended several centimeters to clearly visualize the underlying anterior fascia. It is helpful to use lidocaine (Xylocaine) 1% with epinephrine to minimize slight but annoying bleeding that can impair visualization. The wound should never be probed with any instruments, particularly if overlying the ribs.

Wound exploration is confined to the area from the costal margin to the inguinal ligament. Local wound exploration is contraindicated in wounds that extend above the costal margin, because it is possible for such exploration to communicate with a small pneumothorax, potentially exacerbating respiratory distress.

If thorough exploration of the wound shows no evidence of anterior fascial penetration, and if the victim demonstrates no evidence of peritoneal irritation, the wound can be closed with tape (Steri-Strips) or adhesive bandages, dressed, and the evacuation process delayed. Physical examination should be performed every few hours for the next 24 hours. If no peritoneal signs develop and the victim feels constitutionally strong, a remote expedition may resume with caution and an eye to evacuation should the

victim become ill.

In the wilderness environment, it is prudent to have a low threshold for evacuation because of technical difficulties in performing wound exploration—such as insufficient light and inadequate instruments. Persons who have been impaled by long objects, such as tree limbs or ski poles, should have the object left in place, and carefully shortened, if possible, to facilitate transport.

Pelvic Trauma

In the wilderness setting, fractures of the pelvis are generally associated with falls from significant heights, high-velocity ski accidents, or vehicular trauma.

Pelvic fractures can be lethal. With opening of the pelvic ring, there may be hemorrhage from the posterior pelvic venous complex and occasionally branches of the internal iliac artery. For hemodynamically unstable victims with severe pelvic fracture, resuscitative efforts should be instituted. Additionally, simple techniques to reduce any increased pelvic volume through the application of sheets or slings may slow bleeding.

The key factor in initial management of pelvic fractures is identification of posterior injury to the pelvic ring. Posterior ring fractures or dislocations are associated with a greater incidence of significant hemorrhage, neurologic injury, and mortality than are other pelvic fractures. The diagnosis of a posterior ring fracture is based on instability of the pelvis associated with posterior pain, swelling, ecchymosis, and motion. Persons with posterior ring fractures must be immediately evacuated on backboards, with care taken to minimize leg and torso motion.

The flank, scrotum, and perianal area should be inspected for blood at the urethral meatus, swelling or bruising, or a laceration in the perineum, vagina, rectum, or buttocks suggestive of an open pelvic fracture. The pelvis should be examined carefully once, without any aggressive rocking motion. The first indication of mechanical disruption is leg length discrepancy or rotational deformity in the absence of an obvious leg fracture

or hip location. For more information on pelvic fracture, see [Chapter 21](#).

Extremity Trauma

The majority of wilderness-related extremity injuries involve fractures and sprains, which are discussed in [Chapter 21](#). This section focuses on the general field management of significant extremity vascular injury, traumatic amputation, and recognition and treatment of rhabdomyolysis.

Vascular Injuries.

Injury to the major vessels supplying the limbs can occur with penetrating or blunt trauma. Fractures can produce injury to the vessels by direct laceration (rarely) or by stretching, which produces intimal flaps. Penetrating injuries can be devastating if transection of a vessel occurs. Significant vascular injuries, from both penetrating and blunt causes, can result in multiple vessel injury subtypes, each of which may be limb-threatening. Injury subtypes include laceration, transection, contusion with spasm, thrombosis, or aneurysm formation (true and false), external compression, and arteriovenous fistula. An accurate history, expeditious physical examination, and swift evacuation are the keys to life and limb salvage.

HISTORY.

A complete history of the time and mechanism of injury is invaluable in planning further management. Although no absolute ischemia time has been established, a goal of less than 6 hours to reperfusion is prudent.^[30] The amount of blood present at the scene should be quantified. A history of bright pulsatile blood that abates is suggestive of arterial injury. Thirty-three percent of victims with arterial injuries have intact distal pulses.

PHYSICAL EXAMINATION.

Vascular examination in the field can be highly variable. Hypovolemia, hypothermia, and hostile conditions make an accurate examination challenging. Skin color and extremity warmth should be assessed first. Distal pallor and asymmetric hypothermia are suggestive of a vascular injury. Pulses should be palpated. In the upper extremity, the axillary, brachial, radial, and ulnar arteries should be assessed. In the lower extremity, the femoral, popliteal, posterior tibial, and dorsalis pedis pulses should be assessed. Location and direction of the wound should be determined, hemorrhage quantified, and the presence of hematomas or a palpable thrill noted.

A good neurologic examination that quantifies motor and sensory deficits is critical. Because of the high metabolic demands of peripheral nerves, disruption of oxygen delivery makes neuronal cells highly susceptible to ischemic death. Conversely, skeletal muscle is relatively resistant to ischemia. Loss of sensation or limb paralysis is an alarming sign of impending anoxic necrosis.

TREATMENT OF VASCULAR INJURIES.

Significant hemorrhage should be identified and controlled in the primary survey. All hemorrhage should be controlled with direct pressure at the site of injury. Tourniquets should be applied only when direct pressure fails to control bleeding. Tourniquets should be released every 5 to 10 minutes to prevent further ischemia.

Hematomas should never be explored or manually expressed. Attempts to clamp or

ligate vessels are not recommended. Frequent repeat neurovascular examinations are mandatory.

Once bleeding is controlled and the wound is covered with a sterile but noncompressive dressing, completion of the primary survey, identification and stabilization of associated injuries, and appropriate resuscitation with normal saline should follow. The extremity should be splinted to prevent further movement. The need for evacuation depends directly on the results of the physical examination. Examination results can be grouped into "hard signs," indicative of ischemia or continued hemorrhage, and "soft signs" that are suggestive but not indicative of ischemia ([Box 18-3](#) and [Box 18-4](#)).

All victims with hard signs should be evacuated emergently. Based on current data, an isolated soft sign may warrant observation alone, depending on the remoteness of the expedition and the risks of evacuation. The data for observation of soft signs has emerged from hospital settings and must be applied with great caution in the wilderness. If soft signs are present, clinical suspicion is high, and evacuation can be accomplished

safely, the victim should be transported and observed in a medical facility.

Traumatic Amputation.

In the wilderness environment, amputation victims require immediate evacuation. Hemorrhage is controlled during the primary survey with direct pressure, and resuscitation is instituted. Tourniquets are rarely required. The victim should be kept warm and calm. Reassurance and analgesics should be administered. Amputations should only be completed if minimal tissue bridges exist and it is clear that the neurovascular supply has been interrupted.

Amputation of a mangled extremity, defined as an extremity with high-grade open fracture and soft tissue injury, should not be carried out in the wilderness except in the case of uncontrollable hemorrhage threatening the life of the victim, and then only by experienced surgical personnel. All other severely injured extremities should be wrapped in available sterile materials, splinted, and kept moist.

Amputated extremities should be cooled if possible, optimally in a plastic bag in ice or ice water. Avoid placing the extremity in direct contact with ice. Without cooling, the amputated extremity remains viable for only 4 to 6 hours; with cooling, viability may extend to 18 hours. The amputated extremity should accompany the victim throughout the course of the evacuation.

Crush Injuries and Rhabdomyolysis.

Rhabdomyolysis is a potentially fatal syndrome that results from lysis of skeletal muscle cells. In its fulminant form, rhabdomyolysis can affect multiple organ systems. Compartment syndrome, renal failure, and cardiac arrest represent the major complications.

Any condition resulting in significant acute or subacute striated muscle damage can precipitate rhabdomyolysis. Crush injuries of the extremities and pelvis,

revascularization of ischemic tissue, ischemic extremities, animal bite and snakebite,^[17] frostbite,^[23] and traumatic asphyxia^[32] can all result in rhabdomyolysis in a wilderness setting. Crush injuries are frequently a result of avalanches, falls from heights, or rock slides.

The pathophysiology of rhabdomyolysis remains controversial. The exact mechanism of muscle injury appears not to be simple direct force or isolated ischemia and is probably multifactorial.^[32] The common cellular derangement is interference of the normal function of muscle cell membrane sodium-potassium adenosine triphosphatase (ATPase) with intracellular calcium influx and cell death.^[74] After cell death, multiple intracellular constituents, including myoglobin, creatine kinase, potassium, calcium, and phosphate, are released into the systemic circulation.

The metabolic derangements of rhabdomyolysis depend directly on the release of intracellular muscle constituents. Myoglobinemia, hypercalcemia, hyperphosphatemia, hyperkalemia, hyperuricemia, metabolic acidosis, coagulation defects, and contracted intravascular volume result.

The clinical presentation of rhabdomyolysis may include muscle weakness, malaise, fever, tachycardia, abdominal pain, nausea and vomiting, or encephalopathy. Symptoms may mimic those of persons with spinal cord injury.^[9] The danger of the syndrome lies in the cardiovascular effects of electrolyte disturbances and renal failure^[66] secondary to changes in renal perfusion and direct toxicity of myoglobin to tubular cells.

Successful treatment relies on prompt diagnosis based on clinical signs and urinalysis, aggressive hydration, and forced diuresis. Myoglobin turns urine tea-colored, which is an important indicator of significant muscle death and need for aggressive treatment.

Normal saline should be administered intravenously at 1 to 2 L/hr to achieve a urine output of 100 to 300 ml/hr. Victims who are trapped in rubble should have resuscitation initiated before extrication, if possible. The addition of agents to alkalinize the urine and promote diuresis have been shown to improve clearance of myoglobin but not to alter survival. Additionally, diuretics may be detrimental in multisystem trauma victims who are hypovolemic. All victims demonstrating myoglobinuria should be evacuated.

Injuries to the Skin and Wilderness Wound Management

The goals of wilderness wound management are to minimize wound complications and promote healing. Treatment should begin with an approach to the victim as a trauma patient. Within the context of the primary survey, hemorrhage should be controlled. Then, the victim should be examined and the wound inspected. Steps to minimize infection should be undertaken, incorporating anesthesia, assessment of need for tetanus immunization and antibiotics, irrigation, and debridement. After attempts to minimize infection, a definitive plan should be established, including the need for evacuation ([Box 18-5](#)).

**Box 18-5. GUIDELINES FOR
WILDERNESS WOUND MANAGEMENT**

1. Identify and stabilize associated traumatic injuries
2. Control hemorrhage
3. Examine wound
4. Minimize infection
 - a. Tetanus immunization as indicated
 - b. Antibiotics for high-risk wounds
 - c. Irrigation
 - d. Debridement
5. Implement definitive care

453

Wound Morphology.

Major lacerations are often the most obvious sign of trauma; however, injuries to the integument are rarely life-threatening. Contusions, abrasions, and lacerations should force the examiner to focus on areas of potential occult injury. Contusions often overlie extremity fractures or, when present on the torso, suggest the potential for underlying visceral injury. Extremity lacerations may be associated with fractures or may extend into the joint space.

The four basic types of skin injuries are lacerations, crush injuries, stretch injuries, and puncture wounds. Lacerations rarely require closure in the wilderness environment. Commonly, multiple wound morphologies are present in the same injury, and an array of wound presentations are possible.

Crush injuries may be associated with significant tissue necrosis, impaired healing, increased rates of infection, and underlying muscle damage with subsequent rhabdomyolysis. Fortunately, they are rare in the wilderness.

Stretch injuries produce a split in the skin but, more important, may be associated with underlying nerve or tendon damage.

Puncture wounds often appear innocuous but have a high propensity for infection. Animal bite wounds, discussed in detail in [Chapter 41](#) [Chapter 42](#) [Chapter 43](#) [Chapter 44](#) can manifest any of these wound morphologies alone or in combination.

Primary Survey.

Many skin and soft tissue wounds encountered in the wilderness setting accompany significant injuries. Therefore the wound must never distract the physician from associated life-threatening injuries. The ATLS primary survey should be performed in the usual fashion.

Control of Hemorrhage.

The vast majority of bleeding will be controlled with direct pressure, applying the most sterile covering available. Applying pressure over major arterial pressure points is discouraged, as is the use of tourniquets. In the event of bleeding not controlled by direct pressure, tourniquets may be applied with the knowledge that limb sacrifice is possible. If applied, tourniquets should be released every 5 to 10 minutes if possible to transiently restore perfusion and to assess if they are still necessary. Clamping bleeding vessels is not advised, since this may cause unnecessary neurovascular injury.

Physical Examination.

Wound inspection and physical examination are critical in any setting. This phase of treatment may need to be abbreviated and should not delay packaging and evacuation. Although it is important to assess the extent of injury, including tissue loss and underlying musculoskeletal and neurovascular injury, aggressive wound exploration may worsen existing injuries.

Detailed knowledge of regional anatomy is useful. The detailed neurovascular examination should be documented before anesthesia and definitive care, including assessment of pulses and regional perfusion. The neurologic examination should quantify sensory and motor function, with particular attention to functional assessment of muscle groups traversing the injured region. Two point discrimination should be assessed in wounds involving the hands or fingers. Wounds over joints and tendons should be put through full range of motion.

Anesthesia.

Pain management in the wilderness is discussed in [Chapter 16](#). Administration of anesthesia occurs before mechanical wound cleansing and definitive care. The three methods of anesthetic administration briefly discussed here are topical, local, and regional.

Topical anesthesia was originally introduced for mucosal lacerations but has been shown to be effective for skin wounds. TAC (sterile tetracaine 0.5%, adrenalin 1:2000, and cocaine 11.8% in saline) has been used with success as a topical anesthetic. Complications have included seizure and death.^[90] An alternative preparation consisting of lidocaine, adrenalin, and tetracaine (LAT) has been shown to be as effective as TAC without the associated complications.^[29] Topical anesthetics may be soaked into a

sterile gauze and placed on the wound surface for 7 to 10 minutes. Disadvantages of topical anesthetic include potential for a slightly increased risk of infection and less versatility than locally injected lidocaine.

Local anesthesia is the standard method for achieving soft tissue analgesia. Typically, 1% lidocaine without epinephrine is used. In adults, the maximum injectable dose of lidocaine is 300 to 400 mg subcutaneously. Lidocaine should not be injected directly from within the wound to the periphery because this increases the chance of introducing bacteria deeper into the soft tissue.^[60] The injection should proceed from the periphery of the wound, with each successive needle stick entering the skin through a previously anesthetized area.

Local anesthesia can be administered with relatively little discomfort using a 25-gauge needle and a 1-ml tuberculin syringe. Although using a small syringe increases the time to anesthetize a larger wound, this method minimizes both the anesthetic dose and the distortion of soft tissue planes, facilitating tissue repair. Pain associated with administration of local anesthesia is due to the acidity and stretching of nerve endings within the dermis and subcutaneous tissue. Burning sensation associated with lidocaine injection is directly proportional to the rate of administration. Warming the local anesthetic,^[44] buffering the solution with sodium bicarbonate to a concentration of 1%, and administering anesthetic slowly in small doses all minimize pain.

Regional anesthesia, defined as sensory nerve blockade proximal to the wound, is an excellent mode of anesthetizing wounds of the upper and lower extremities. Two types are regional nerve block and Bier block. Regional nerve blocks require skill and a detailed knowledge of regional anatomy. They are not suitable for the first-time user in the wilderness environment.

The Bier block is easier to administer and is preferred in the wilderness setting. It involves injection of local anesthetic into a cannulated hand or foot vein, with concurrent control of venous outflow using a tourniquet.

Irrigation.

Once the wound is anesthetized, irrigation, debridement, and closure can proceed. Irrigation removes dirt, debris, foreign bodies, and bacteria from the wound. Irrigation has been extensively studied in traumatic wounds and clearly results in a decreased incidence of infection, reducing infection rates as much as twentyfold when proper technique is used.

The type of irrigation fluid and the technique utilized will be resource-dependent in the wilderness setting. The cleanest fluid available should be used. Wilderness fresh water sources that are not grossly contaminated can be boiled or filtered.^[31] Any concentration of sterile crystalloid solution can be used, although normal saline remains the most

readily available, economical, and cost-effective irrigant. Recent data suggest that tap water may be as effective as normal saline.^[62]

The amount of irrigation necessary is difficult to quantify. Some authors use 60 ml of irrigant per centimeter wound length as a guide,^[44] but in the wilderness setting where precision is more difficult to attain, irrigation should be continued in amounts and time intervals sufficient to remove visible debris from the wound.

Many bactericidal and bacteriostatic irrigants, including commercial soaps, ethyl alcohol, iodine solutions, and hydrogen peroxide, are available in wilderness first-aid kits. Many of these agents have been shown to result in significant microcellular destruction of tissues^[14] and, when used in high concentrations, may impair wound healing. They offer no advantage over copious irrigation with sterile water or crystalloid. Although addition of antibiotics to irrigant solutions is an attractive concept, they are costly, difficult to store, and offer no advantage over irrigation with sterile water alone.

The method of wound irrigation, as well as the pressures used, have been studied extensively. The goals of irrigation are to remove bacteria, assist in the mechanical debridement of necrotic tissue, and remove foreign bodies that can impair subsequent wound healing. Optimal irrigation pressures are 5 to 8 psi, delivered through a syringe with a 16- to 20-gauge needle.

In summary, irrigation consisting of normal saline or sterilized potable water should be delivered in a continuous fashion by the most sterile implement available at a pressure sufficient to dislodge debris but not overtly damage tissue.

Debridement.

Like irrigation, debridement has been shown to decrease the incidence of wound infection. Additionally, debridement has the potential to improve long-term cosmesis. Debridement should be carried out sharply. Scrubbing the wound with abrasive materials does not improve infection rates and may cause damage to healthy tissue. Similarly, soaking the wound has never been shown to improve outcome. Hair removal should be undertaken only if it impairs visualization and inspection of the wound,^[90] or if tape is to be used as a method of temporary closure.

The goal of debridement in the wilderness should be to remove grossly contaminated or devitalized tissue and to remove foreign bodies and bacteria embedded in such tissue. The extent of tissue removal should be based on the experience and training of the caregiver.

Tetanus Prophylaxis.

The spores of *Clostridium tetani* are ubiquitous in the environment, in such places as soil, animal teeth, and saliva. Any animal bite that penetrates the skin can be responsible for a tetanus infection. The majority of cases of tetanus infection in the United States follow failure to attain adequate immunization.^[76] This fact accentuates the

preventable nature of tetanus infections and the essential role of proper immunization. If available in the wilderness setting, tetanus prophylaxis should be administered as outlined in [Table 18-3](#).

Definitive Care of Lacerations.

"Definitive" care may have many definitions, depending on the setting. The planned approach to management of wounds in the wilderness is determined by a combination of morphology of the wound, infection risk factors, available resources, level of expertise, and type of expedition.

Major lacerations or those associated with significant injury should be evacuated. If wound management cannot acceptably minimize infection risk factors, the victim should be evacuated. In general, wounds that can be closed or managed open and that do not impose excessive infection risk factors and do not immobilize the expedition member or group can be treated definitively in the wilderness. The wound must not impair physical ability in a way that the victim risks further injury or jeopardizes group safety.

WOUND CLOSURE.

Lacerations can be closed if they are small to intermediate in size; have minimal infection risk factors; are on well-vascularized regions, such the scalp and face; are less than 6 hours old; and have no anatomic contraindications.

TABLE 18-3 -- Tetanus Prophylaxis

HISTORY OF IMMUNIZATION (DOSES)	CLEAN MINOR WOUNDS		MAJOR DIRTY WOUNDS	
	TOXOID*	TIG†	TOXOID	TIG
Unknown	Yes	No	Yes	Yes
None to one	Yes	No	Yes	Yes
Two	Yes	No	Yes	No (unless wound older than 24 hours)
Three or more				
Last booster within 5 years	No	No	No	No
Last booster within 10 years	No	No	Yes	Yes
Last booster more than 10 years ago	Yes	No	Yes	Yes

*Toxoid: Adult: 0.5 ml dT intramuscularly (IM).
Child less than 5 years old: 0.5 ml DPT IM.
Child older than 5 years: 0.5 ml DT IM.
†Tetanus immune globulin (TIG): 250 to 500 units IM in limb contralateral to toxoid.

Closure may be accomplished with suture, staples, tape and similar bandages, or adhesives. Tape, and—less frequently—adhesives, are viable alternatives to sutures. Healing and cosmetic outcome depend directly on dermal apposition, which is the goal of any closure method.

Advantages of sutures include meticulous closure and high wound tensile strength. The primary disadvantage is the skill necessary to place them. The suture selected is dictated by morphology of the wound. To simplify selection in the wilderness environment, absorbable sutures, such as chromic gut and polyglactin (Vicryl), should be used to close deep layers and for subcuticular closures. Nonabsorbable suture, such as nylon (Ethilon) and polypropylene (Prolene), should be used on the skin. Silk is reactive, has poor tensile strength, and should be avoided. *No wound should be sutured by an individual who is inexperienced in basic surgical technique.* Additionally, no wound incurred in the wilderness is truly risk-free regarding infection. In general, the safest management strategy for lacerations in the wilderness setting is open management or closure with nonsuture alternatives.

Surgical staples are easily placed, are nonreactive, have lower infection rates than sutures, and minimize time of closure.^[90] They should be avoided on areas of cosmetic importance, such as the face.

Tapes and adhesives offer a preferable alternative to sutures. Tape and adhesive strips (e.g., Steri-Strips) are easily applied and require little technical ability. If a wound is appropriate for closure, tape offers a rapid, safe, painless, and inexpensive alternative to sutures and staples.^[27] The only requirement of tape use is conformity to principles of dermal apposition. Disadvantages of tape include need for adhesive solutions, such as benzoin; low tensile strength; and lack of applicability over any region of tension.^[90] A critical limiting factor in wilderness use of tape closure is the need for the wound to remain dry.

Tissue adhesives in wound closure have been studied for 20 years.^[26] Recently, use of octylcyanoacrylate and similar synthetic agents have been shown to be equal in strength and cosmesis compared with sutures at 1 year.^[78] Advantages of adhesives include ease of application, safety, patient comfort, and low cost.^[91] Similar to tape, immediate tensile strength is poor and dehiscence is more likely compared with sutures.^[90] If closure is possible and other means are unavailable or impractical, adhesives may be used.

SCALP LACERATIONS.

The extent and severity of scalp lacerations are often initially obscured by surrounding hair that is matted with blood. Hydrogen peroxide and water effectively remove blood from hair, although hydrogen peroxide should not be used to irrigate the wound. Interestingly, and most likely owing to the vascularity of the scalp, irrigation did not alter outcome in clean lacerations in one study.^[41]

Hair surrounding the laceration is removed only if absolutely necessary to clean the wound using a safety razor. Hair removal should be limited to the immediate area of the laceration, since the surrounding hair can later be twisted into strands and used to approximate the wound edges if necessary. Once wound margins have been identified, anesthetic should be applied.

The key to examination of the scalp is determining the integrity of the galea. Significant degloving injury or galeal laceration may mandate evacuation. The scalp is highly vascularized. An extensive scalp laceration bleeds freely, and if it follows a fall or direct blow to the head, may be associated with an underlying skull fracture. Superficial scalp lacerations often bleed freely and may require pressure dressings to achieve hemostasis.

Minor scalp lacerations can be effectively treated in the wilderness setting, after following the aforementioned infection-minimizing steps. Of note, debridement of scalp wounds should be kept to a minimum because it may be difficult to mobilize wound edges to cover the resulting soft tissue defect. In addition, cosmesis is not a significant concern on the hair-covered scalp. Acceptable closure of a minor scalp laceration can be performed using strands of hair to approximate wound edges. This method minimizes shaving.

FACIAL LACERATIONS.

Facial lacerations are relatively simple to manage because they rarely damage underlying structures and are well vascularized. If suspicion exists regarding damage to cranial nerves or the parotid duct, the wound should be managed in an open fashion. Debridement should be limited to obviously necrotic tissue. Because of vascularity of the face, infection is rare, and most wounds can be closed. For small wounds, tape is a useful closure technique.

TORSO LACERATIONS.

Torso lacerations require evaluation for fascial penetration. Anterior fascial penetration in the torso converts the wound from a skin wound to one requiring management of underlying chest or abdominal structures. Tissue debridement may be more aggressive over the torso, since surrounding tissue planes can be mobilized for closure. Adipose

tissue should not be approximated with suture, and subdermal dead space should be obliterated with deep, nonadipose approximating sutures.

Hand Injuries.

Severe contusions to the hand commonly occur with crush or rope injuries. The hand should be carefully protected if marked swelling and pain with motion are present. If no joint instability or fracture is identified, a bulky hand dressing should be applied with the wrist dorsiflexed 10 degrees, the thumb abducted, and the metacarpophalangeal joints flexed 90 degrees, known as the position of function. Cotton wadding or bandages can be placed in the palm and between the fingers, and an elastic bandage can be used as an overwrap. A volar splint allows this position to be maintained until definitive care is reached.

Lacerations of the finger flexor or extensor tendons occur with accidents involving knives or other sharp objects. A flexor tendon laceration, partial or complete, can be a serious problem if not repaired early. The open wound should be cleansed and loosely taped closed if no infection risk factors are present, and the finger should be splinted in slight flexion at the interphalangeal joints and in 90 degrees of flexion at the metacarpophalangeal joint. To achieve optimal results, this injury should be managed by a hand surgeon within the first 3 to 5 days.

For an extensor tendon, the open wound should be cleansed and taped closed, and a splint should be applied with the metacarpophalangeal joint in slight flexion and the interphalangeal joint extended. The victim should be seen by an orthopedic surgeon within 7 days.

The nerves most commonly injured by laceration include the superficial radial nerve at the wrist, ulnar nerve at the elbow or wrist, and median nerve at the wrist. Digital nerves are commonly lacerated in accidents with knives. In general, the wound should be cleansed and taped loosely and a splint should be applied to the wrist and hand. The victim should see a hand surgeon within 7 days.

Puncture Wounds.

Puncture wounds carry significant infection risk where organic contamination is frequent. Significant puncture wounds to the torso should be treated according to the guidelines outlined in the section on penetrating trauma to the chest and abdomen. Puncture wounds to the extremities should be unroofed if they are proximal to the wrist or ankle. The unroofed wound should be irrigated as previously described and then packed open with sterile gauze. Delayed primary closure with tape can occur at 48 to 96 hours. Puncture wounds to the hands and feet should not be explored in the absence of detailed knowledge of anatomy. If this expertise is not available, the wound should be cleaned and the victim started on antibiotics, such as cephalexin (Keflex), 500 mg po q6h.

If the skin is punctured with a fishhook, the skin surrounding the entry point should be

cleansed with soap and water. Fishhook removal techniques are discussed in [Chapter 20](#).

Antibiotic Use and Infectious Complications.

The use of prophylactic antibiotics for wounds incurred in the wilderness is not recommended. Antibiotic treatment usually begins after the injury has occurred and therefore is never truly "prophylactic." The use of antibiotics in lacerations and bite wounds should be confined to victims with significant infection-risk factors, such as animal bites, heavily contaminated wounds, or comorbid medical conditions. This includes high-risk wounds, such as puncture wounds and those occurring on the hands. Debridement and irrigation are far more important than antibiotics in eliminating infection and remain the mainstay of risk reduction in any wound incurred in the wilderness.

If antibiotics are indicated, selection should be tailored by available resources and coverage of likely contaminating organisms. Many single-agent broad-spectrum oral antibiotics are available. If any sign of infection develops in a wound—closed or open—including pain, discharge, erythema, edema, or fever, antibiotics should be administered. In an infected closed wound, the adhesive or sutures should be removed and the wound irrigated. Wet-to-dry dressings with

normal saline should be started and the wound closely observed. Elevation and splinting may assist in relieving pain.

Management of Animal Attacks and Bite Wounds.

See [Chapter 41](#), [Chapter 42](#), [Chapter 43](#), [Chapter 44](#).

WILDERNESS SURGICAL EMERGENCIES

The Acute Abdomen

In the wilderness, the critical distinction between the surgical and nonsurgical abdomen determines whether the victim should be evacuated. A myriad of nonsurgical conditions mimic a surgical abdomen. It has been extensively reported that the bite of the black widow spider (*Latrodectus mactans*) can induce abdominal pain indistinguishable from a surgical acute abdomen,^[49] and mushroom ingestion can cause severe gastroenteritis.^[82] Pain, anorexia, nausea, vomiting, and fever are characteristic manifestations of an acute abdominal disorder. Tenderness and guarding are the hallmarks of peritoneal irritation and suggest that surgery is needed.

TABLE 18-4 -- Differential Diagnostic Features of Abdominal Pain

DISEASE	LOCATION OF PAIN AND PRIOR ATTACKS	MODE OF ONSET AND TYPE OF PAIN	ASSOCIATED GASTRO-INTESTINAL SYMPTOMS	PHYSICAL EXAMINATION
Acute appendicitis	Periumbilical or localized generally to right lower abdominal quadrant	Insidious to acute and persistent	Anorexia common; nausea and vomiting in some	Low-grade fever; epigastric tenderness initially; later, right lower quadrant
Intestinal obstruction	Diffuse	Sudden onset; crampy	Vomiting common	Abdominal distention; high-pitched rushes
Perforated duodenal ulcer	Epigastric; history of ulcer in many	Abrupt onset; steady	Anorexia; nausea and vomiting	Epigastric tenderness; involuntary guarding
Diverticulitis	Left lower quadrant; history of previous attacks	Gradual onset; steady or crampy	Diarrhea common	Fever common; mass and tenderness in left lower quadrant

Acute cholecystitis	Epigastric or right upper quadrant; may be referred to right shoulder	Insidious to acute	Anorexia; nausea and vomiting	Right upper quadrant pain
Renal colic	Costovertebral or along course of ureter	Sudden; severe and sharp	Frequently nausea and vomiting	Flank tenderness
Acute pancreatitis	Epigastric penetrating to back	Acute; persistent, dull, severe	Anorexia; nausea and vomiting common	Epigastric tenderness
Acute salpingitis	Bilateral adnexal; later, may be generalized	Gradually becomes worse	Nausea and vomiting may be present	Cervical motion elicits tenderness; mass if tuboovarian abscess is present
Ectopic pregnancy	Unilateral early; may have shoulder pain after rupture	Sudden or intermittently vague to sharp	Frequently none	Adnexal mass; tenderness

The approach to someone with abdominal pain begins with a detailed history that includes the person's age, gender, systemic symptoms, and past medical history. This information provides a framework for more detailed questioning about the character of the pain, its mode and time of onset, severity, and precipitating and palliating factors.

In persons 15 to 40 years of age, females are more likely to have abdominal pain, but males have a higher incidence of surgical disease. Common genitourinary causes for abdominal pain in men include epididymitis, renal colic, urinary retention, and testicular torsion. Common causes in women include pelvic inflammatory disease (PID), urinary tract infection, dysmenorrhea, ruptured ovarian cyst, and ectopic pregnancy.

Pain is the hallmark of a surgical abdomen ([Table 18-4](#)). It can be characterized by mode and time of onset, severity, localization, and precipitating factors. The onset of abdominal pain can be explosive, rapid, or gradual. The person who is suddenly seized with explosive, agonizing pain is most likely to have rupture of a hollow viscus into the free peritoneal cavity. Colic of

renal or biliary origin may also be sudden in onset but seldom causes pain severe enough to prostrate the victim. If someone has rapid onset of pain that quickly worsens, acute pancreatitis, mesenteric thrombosis, or small bowel strangulation should be suspected. The person with gradual onset of pain is likely to have peritoneal inflammation, such as that accompanying appendicitis or diverticulitis.

Severity of the pain may be characterized as excruciating, severe, dull, or colicky. Excruciating pain unresponsive to narcotics suggests an acute vascular lesion, such as rupture of an abdominal aneurysm or intestinal infarction. Both conditions are unusual in the wilderness environment. Severe pain readily controlled by medication is characteristic of peritonitis from a ruptured viscus or acute pancreatitis. Dull, vague, and poorly localized pain suggests an inflammatory process and is a common initial presentation of appendicitis.

Colicky pain characterized as cramps and rushes is suggestive of gastroenteritis. The pain from mechanical small bowel obstruction is also colicky but has a rhythmic pattern, with pain-free intervals alternating with severe colic. The peristaltic rushes associated with gastroenteritis are not necessarily coordinated with colicky pain.

Physical examination of the abdomen is initiated by inspection. Valuable clues to the underlying condition that may be obtained in this manner include stigmata of cirrhosis, distention, hyperperistalsis, or incarcerated herniae. The victim may not be able lie still, which is indicative of renal or biliary colic. Persons lying perfectly still frequently have peritoneal inflammation. Auscultation is helpful if the classic "rushes and tinkles" of small bowel obstruction are present. Palpation in the wilderness setting is most helpful in documenting the presence or absence of peritoneal signs. Shake or percussive tenderness, particularly in the context of fever, nausea, and or vomiting, indicates a need for evacuation. Rectal and vaginal examinations should be performed, if practical.

General Field Treatment Principles.

When evaluating someone with a possible emergent surgical condition in the wilderness, correctly identifying the etiology of a given condition is less important than identifying peritoneal inflammation and the need for operation.

When dealing with a surgical abdomen or other condition requiring evacuation, adjuncts to definitive hospital treatment can be initiated in the field.

Dehydration and intravascular volume depletion accompany many surgical conditions, particularly when the disease process has progressed and evacuation is delayed. Initiation of crystalloid resuscitation in the field is intuitively beneficial for persons who have developed or have the potential to develop septic or hypovolemic shock. Dehydration is common in the wilderness, and frank hypovolemia can result from vomiting associated with gastroenteritis, appendicitis, renal colic, and small bowel

obstruction. Perforated viscus, pancreatitis, cholecystitis, small bowel obstruction, PID, and necrotizing soft tissue infections all may feature volume depletion. The goal in the wilderness setting is to recognize the signs of hypovolemia and initiate resuscitation to decrease eventual perioperative morbidity.

Nasogastric tube decompression of the stomach can prove beneficial in alleviating emesis secondary to abdominal pain or obstruction. Large-bore catheters are best and can be easily aspirated with a syringe. Placement should be confirmed by aspiration of gastric contents or auscultation of gastric air after insufflation of the stomach.

Foley catheters are becoming increasingly more available in wilderness first-aid kits. Recording urine output provides an effective estimate of intravascular volume status. Foley catheter placement should never hinder the possibility of ambulatory evacuation.

Appendicitis.

Acute appendicitis is the most common cause of a surgical abdomen in persons under the age of 30 years. Acute appendicitis is really more than one single disease entity. In terms of physical signs and symptoms, appendicitis proceeds from inflammation to obstruction to ischemia to perforation, all within approximately 36 hours. Symptoms reflect the stage of the disease. Unfortunately, the time frame for the progression of clinical events is highly variable.

Differential diagnosis of appendicitis includes gastroenteritis and mesenteric adenitis, the most common inflammatory disorders in adults. The first symptom of gastroenteritis is typically vomiting, which precedes the onset of pain and is often associated with diarrhea; it is rarely associated with localizing signs or muscular spasm. Bowel sounds are usually hyperactive. A rectal examination rarely shows abnormalities in gastroenteritis but frequently does so in adults with appendicitis.

Mesenteric adenitis is often preceded by an upper respiratory infection and is associated with vague abdominal discomfort that often begins in the right lower quadrant. Abdominal examination reveals only mild right lower quadrant tenderness that is often not well localized.

The incidence of PID in young women with abdominal pain confounds the diagnosis of appendicitis. Some clinicians have documented a relationship between menses and onset of pain. If abdominal pain occurs within 7 days of menses, the incidence of PID is twice that of appendicitis. If onset of pain occurs greater than 8 days from menses, appendicitis is twice as likely as PID. This history with a pelvic examination may enable the examiner to differentiate between the two entities.

Acute appendicitis mandates evacuation because untreated perforation retains significant mortality. Broad-spectrum antibiotics (if IV capability, cefotetan [Cefotan] 2 g

IV q12h, or as an alternate, piperacillin/tazobactam [Zosyn] 4.5 g IV q8h; if only oral antibiotic capabilities, a fluoroquinolone, such as ciprofloxacin [Cipro] 750 mg po bid) should be initiated, attempting coverage against gram-negative and anaerobic organisms. Intravenous crystalloid resuscitation should be initiated, particularly if the victim is older or perforation is suspected, and the victim should be placed at bowel rest.

Acute Cholecystitis and Biliary Colic.

Biliary colic refers to pain induced by obstruction of the cystic duct, usually by gallstones. The label of this condition as "colic" is a misnomer, since the pain is usually constant. The condition is rarely seen before adulthood and is several times more common in women than in men. A sufferer often relates a past history of gallstones and previous episodes of similar pain, which is described as constant right upper quadrant and/or epigastric pain, radiating to the right scapula and back. Onset ranges from insidious to acute and frequently follows a meal. The episode usually lasts 15 minutes to 1 hour and then abates.^[63] If pain is severe, nausea and vomiting may be present (60% to 70%).

Acute cholecystitis is an infection of the gallbladder secondary to cystic duct obstruction, usually from gallstones. In the wilderness setting, it is useful to think of these interrelated conditions as a continuum of one unified disease process. Both biliary colic and cholecystitis present with right upper quadrant pain; however, biliary colic has the potential to be self-limiting and may not require evacuation. Not all persons with biliary colic develop cholecystitis, and signs of infection should be excluded.

Cholecystitis symptoms typically escalate in severity. Pain that persists more than 1 to 2 hours is suspicious for cholecystitis, particularly when accompanied by fever, more significant nausea and vomiting, and right upper quadrant rebound tenderness. Recent studies have shown that fever may be an unreliable predictor of severity of infection.^[36] Acute cholecystitis mandates hospitalization, and evacuation plans should be instituted. The disease can progress to gangrenous changes in the gallbladder wall, leading to perforation and death if untreated.

The definitive treatment of cholecystitis is cholecystectomy. In the field, IV antibiotics (ampicillin/sulbactam [Unasyn] 3 g IV q6h or PO alternative ciprofloxacin [Cipro] 750 mg po bid) should be given, directed at common biliary organisms, including *Escherichia coli*, *Klebsiella*, *Bacteroides*, *Enterobacter*, *Streptococcus*, and *Proteus* species. Oral antibiotics with optimal bioavailability should be initiated in the absence of parenteral forms, ensuring the broadest spectrum of coverage available. As with most abdominal infections, IV hydration should be started in the field. If significant nausea and vomiting are present, nasogastric decompression may improve comfort and prevent aspiration.

Peptic Ulcer Disease.

The incidence of peptic ulcer disease (PUD) is decreasing in the United States. With the advent of treatment of *Helicobacter pylori* infections and the variety of acid-reducing agents available, it is less often a disease seen by surgeons. The exception is perforation of gastric or duodenal ulcer, which should be considered in the differential

diagnosis of acute abdomen in the wilderness. Victims frequently relate a history of PUD and need for medication. This history, in combination with acute onset of unrelenting epigastric pain radiating to the back, is suspicious for perforation of an ulcer.

The physical examination greatly assists in the differentiation between simple ulcer disease symptoms and perforation. Pain may be severe. Gastric secretions are caustic to the peritoneum, and as a result, the abdomen frequently displays a rigid, boardlike character with associated diffuse peritoneal signs.

History and examination consistent with gastric or duodenal perforation mandates evacuation. Dehydration may be significant. IV resuscitation should be started and the victim placed on bowel rest. Antibiotics are not indicated.

Diverticulitis.

Diverticulitis is localized infection of a colonic diverticulum. Impacted material in the diverticulum, usually feces, leads to a localized inflammatory process that can lead to abscess formation and perforation. Diverticulitis presents over a wide range of severity, ranging from mild, localized infection to intraabdominal catastrophe. It is more common in middle age; one third of the population over the age of 45 have diverticula, 20% of which will develop diverticulitis.^[86]

Victims often relate a history of previous attacks. Pain is typically described as gradual in onset and localized in the left lower quadrant of the abdomen, although right-sided diverticulitis can occur. Diarrhea and fever are frequently associated complaints. Examination findings range from mild left lower quadrant abdominal tenderness to frank peritonitis, depending on the severity of the underlying infection.

Treatment in the wilderness setting consists of hydration, bowel rest, antibiotics, and evacuation. If evacuation is impossible or significantly delayed, oral broad-spectrum antibiotics may be effective. Mild cases of diverticulitis are frequently treated on an outpatient basis with oral antibiotics,^[80] such as broad-spectrum fluoroquinolones, such as cefotetan 2 g IV q12h, or an alternative oral fluoroquinolone such as ciprofloxacin 750 mg po bid. Antibiotic therapy is directed primarily

at gram-negative aerobic and anaerobic bacteria, and single-agent therapy covering these organisms has been demonstrated to be as effective as multiple-agent regimens.^[48] Because of unpredictability of response to antibiotic treatment, evacuation is indicated.

Mechanical Small Bowel Obstruction.

Small bowel obstruction is a true emergency in the wilderness. When the obstruction is

complete, expedient surgery is the only treatment. Small bowel obstruction in the United States is almost invariably the result of adhesions from previous laparotomy or incarceration of abdominal hernias, and the history often makes the diagnosis. Victims complain of sudden onset of diffuse, crampy abdominal pain associated with vomiting and obstipation. With progression of the process to strangulation and infarction of bowel, fever and tachycardia develop.

Late physical examination findings reveal a distended, tympanitic abdomen. Although variable, high-pitched tinkling bowel sounds suggest obstruction. A thorough inspection for hernias should be performed.

Progression of examination findings to frank peritonitis is alarming and suggests ischemic bowel. The adage, "Don't let the sun set on a small bowel obstruction," is sound advice in the wilderness setting. All persons suspected of having a small bowel obstruction should be evacuated immediately. In the interim, the stomach should be decompressed with a nasogastric tube to relieve vomiting and abdominal distention, and aggressive IV hydration should be started.

Incarcerated Abdominal Wall Hernias.

Abdominal wall hernias are common; groin herniorrhaphy is the most common major general surgical operation performed in the United States.^[59] Hernias can become incarcerated or strangulated, which constitutes a surgical emergency. Seventy-five percent of hernias occur in the groin^[83]; the majority of incarcerated hernias presenting in the wilderness setting will be inguinal hernias. Other common hernias with the capacity for incarceration are incisional and umbilical hernias.

Many people live with bulging asymptomatic hernias. Others manually reduce symptomatic hernias. New painful hernias or known hernias that can no longer be reduced elicit concern. The pain of inguinal hernias is usually intermittent. A description of constant pain is suspicious for incarceration. Associated symptoms of fever, tachycardia, nausea, and vomiting are indicative of possible incarceration or strangulation.

On physical examination, a mass should be sought along the course of the spermatic cord. Masses may present from the external inguinal ring to the scrotum. The differential diagnosis for painful inguinal or scrotal masses includes lymphadenopathy, testicular torsion, and epididymitis. Associated tenderness of the spermatic cord may be present. A painful mass at the umbilicus or previous incision site, or below the inguinal ring, indicates possible incarcerated umbilical, incisional, or femoral hernia, respectively.

Bowel within an incarcerated hernia sac can become gangrenous in as little as 4 to 5 hours;^[59] therefore it is important to attempt to identify time of incarceration. The decision to evacuate is determined by the presence of contraindications to manual reduction (see below), which are essentially physical signs that progression to strangulation may be occurring.

Femoral hernias should not be reduced. The danger is en masse reduction of compromised or gangrenous bowel. Contraindications to reduction include associated signs of toxicity, such as fever, tachycardia, or evidence of bowel obstruction in association with a painful irreducible mass. If the hernia itself is exquisitely tender to palpation and the overlying skin is erythematous and warm, the hernia should not be reduced. Victims with incarcerated hernias with signs of systemic or local toxicity should be evacuated. Similarly, victims with irreducible hernias—which require emergent surgery—should be evacuated.

A newly incarcerated hernia without contraindications to reduction may be reduced by personnel experienced in such techniques. Gentle pressure is exerted on the hernia mass toward the inguinal ring, optimally with the victim flat and hips elevated. Analgesia and sedation may aid in reduction. Gangrenous bowel can rarely be reduced by this method.^[90] If successful, the victim should be closely observed for signs of recurrence or abdominal pain.

Urologic Emergencies

Renal colic describes a symptom complex resulting from acute obstruction of the urinary tract secondary to calculus formation. The goal of the wilderness physician is to recognize the symptom complex and institute treatment. After obstruction of the urinary tract, the pain crescendo of renal colic begins in the flank. The pain progresses anteriorly over the abdomen and radiates to the groin and testes in men and the labia in women. Because the autonomic nervous system transmits visceral pain, many abdominal complaints may manifest. Nausea and vomiting are common. With severe colic, the victim writhes in pain and is unable to find a comfortable position.

Physical findings are less revealing than is the review of systems. Tenderness to deep palpation of the region of obstruction or percussion of the flank is present. Diagnosis in the wilderness is assisted by the presence of gross hematuria.

Management is directed primarily at pain control. Although almost universally deployed, forced diuresis may reduce ureteral peristalsis. Thus forced oral fluids or aggressive IV hydration are of questionable benefit.^[97] The majority of calculi pass spontaneously in 4 to

6 hours. The goal of management is to control pain until passage of the stone has occurred. A number of pharmacologic approaches may be used. Nonsteroidal antiinflammatory drugs, such as ibuprofen and ketorolac, have been shown to be effective in the management of renal colic.^[97] Narcotic analgesics are most effective given parenterally; however, agents such as meperidine, codeine, and hydromorphone (Dilaudid) may be given orally. For symptoms uncontrolled by antiinflammatory agents, narcotics may be added. Antiinflammatory agents and analgesics can be combined. An

antiemetic may be added to relieve nausea. When administering pain medication in the field, particular attention should be given to airway maintenance and induced nausea and vomiting.

Any person whose symptom complex cannot be controlled must be evacuated. Additional indications for evacuation include calculus anuria and evidence of obstruction-induced infection.

Urinary Retention.

Urinary retention is an unpleasant and painful experience that requires immediate medical, and often surgical, intervention.^[12] The etiology of urinary retention ranges from prostatism^[46] in men to atonic bladder in women. In general, causes have been broadly divided into four groups: obstructive, neurologic, pharmacologic, and psychogenic.^[96] Twenty-five percent of men reaching 80 years of age will experience acute retention,^[12] which has been shown to increase prostate surgery perioperative mortality.^[73] Acute urinary retention can lead to incapacitating symptoms in the wilderness; prompt recognition and intervention are necessary.

Principal symptoms are bladder distention and pain that may mimic acute abdomen, overflow incontinence, dribbling, and hesitancy. Physical examination findings include prostatic enlargement in men and lower midline abdominal tenderness and distention. If painful distention of the bladder is present, decompression should be undertaken.

Bladder decompression should be initially attempted with a standard Foley catheter. In men with prostatic hypertrophy, passage of the catheter may be challenging, and a large catheter or catheter coudé should be used if a standard Foley catheter cannot be passed. Instrumentation of the urethra with hemostats or dilators is dangerous and should not be attempted in the field.

If multiple attempts are unsuccessful and symptoms are severe, needle decompression is indicated. The skin of the suprapubic region should be anesthetized, if possible. The distended bladder is palpated to guide aspiration. A 22-gauge needle attached to a syringe is introduced through the skin of the lower abdomen two finger breadths above the pubic symphysis and directed at the anus. The needle is advanced with simultaneous aspiration of the syringe until free-flowing urine is visualized. Palpation of the bladder in combination with adherence to this technique should lead to successful decompression.

Complications related to decompression can occur.^[81] Drainage of greater than 300 ml/hr can induce mucosal hemorrhage. In addition, 10% of victims develop post-obstructive diuresis that may lead to dehydration, in which case crystalloid repletion should be undertaken. Finally, it must be recognized that the situation has been temporized and that retention will recur. Treatment may need to be continued or repeated. Drainage of the bladder acutely relieves symptoms and may allow ambulatory evacuation, but the underlying etiology must be addressed in a medical facility.

The Acute Scrotum.

Acute onset of scrotal pain and swelling requires immediate attention. Etiologies are multiple, but incarcerated hernia and testicular torsion are the most clinically significant in the field. Although any one aspect of the history and physical examination may not be diagnostic, when taken as a whole, they frequently suggest the etiology of the scrotal pathology.^[47]

Testicular torsion can occur at any age, but it is more likely near puberty. The likelihood of testicular salvage is inversely proportional to elapsed time from torsion; this is a true surgical emergency. Acute onset of severe testicular pain is the hallmark. Mild to moderate pain is more suggestive of a torsed testicular appendage or epididymitis. It has been stated that victims who can ambulate with minimal pain are less likely to have a torsed testicle. In addition, nausea and vomiting may accompany torsion, whereas fever, dysuria, and frequency are associated with epididymitis.

Physical examination reveals a firm-to-hard testis frequently associated with bluish discoloration at the superior pole (blue dot sign).^[47] Scrotal skin may be edematous and discolored. Unilateral scrotal swelling without skin changes is more indicative of a hernia or hydrocele. In testicular torsion, the affected testis is often larger than the unaffected side. Testicular torsion can be somewhat differentiated from acute epididymitis by Prehn's sign,^[85] which is relief of pain accomplished by elevation of the testicle. Because torsion twists the spermatic cord and elevates the testicle, pain is not relieved by elevation (negative Prehn's sign). Conversely, pain is relieved in epididymitis with elevation (positive Prehn's sign). This maneuver has low sensitivity in distinguishing the two conditions but is helpful in conjunction with other findings.^[85]

Treatment consists of surgical detorsion, which should be accomplished within 12 hours of torsion.^[47] Manual detorsion is not the treatment of choice; however, remoteness of the wilderness environment may mandate manual attempts. Studies of manual detorsion are scant and the cohorts small.^[39]

If manual detorsion is necessitated, the victim should be placed supine. If the left testis is affected, the right hand of the examiner should grip the testis between thumb and forefinger to elevate the testis toward the inguinal ring. A counterclockwise (epididymis turning medially) rotation should be used. If successful, the testis will descend to its normal position and relief will be felt by all. The right testis is grasped with the left hand and rotated counterclockwise.

The surgical treatment of testicular torsion includes pexis of the testis to prevent recurrent torsion. Thus, although detorsion may temporize an acute situation in the field, all victims must be evacuated for proper follow-up.

Prostatitis.

Fifty percent of men will experience prostatic symptoms in their adult life.^[74] A number of forms of prostatitis have been defined, including viral, bacterial (5%), nonbacterial (65%), and chronic forms, as well as prostatodynia.^[76] The acute bacterial form may potentially lead to severe infection.

Bacterial prostatitis is an infection of the prostate caused primarily by gram-negative bacteria, with 80% attributable to *Escherichia coli*. It is an acute, febrile illness characterized by perineal pain radiating to the low back, chills, malaise, and voiding symptoms, such as urgency, frequency, and dysuria. Urinary retention is not uncommon, and cystitis frequently accompanies the infection. On rectal examination, the prostate gland is usually boggy, warm, and tender. Enlargement is variable.

In an ideal situation, treatment is individualized to the cause, which may be difficult to discern in the wilderness. The infection may respond to an oral antibiotic. Ciprofloxacin (750 mg po bid), ampicillin (500 mg po qid), or trimethoprim (80 mg with sulfamethoxazole 400 mg po bid) is an effective regimen. Penetration of prostatic secretions has been shown to be best achieved by trimethoprim/sulfamethoxazole (TMP/SMX). The chosen antibiotic should be administered for 30 days. If retention is present, catheterization or suprapubic aspiration should be undertaken.

Acute bacterial prostatitis can escalate in severity to systemic toxicity. Persons who have evidence of systemic toxicity unresponsive to a trial of oral or parenteral antibiotic therapy should be evacuated.

Urinary Tract Infection

Urinary tract infections (UTIs) are extremely common and include episodes of acute cystitis and pyelonephritis occurring in otherwise healthy individuals. These infections predominate in women; approximately 25% to 35% of women age 20 to 40 report having had a UTI.^[43] Conversely, men between the ages of 15 and 50 rarely develop a UTI.

Despite the striking difference in prevalence, symptoms are similar between men and women. The symptoms may represent urethritis, cystitis, or an upper urinary tract infection; the distinction is often difficult. Common symptoms include frequency, urgency, dysuria, suprapubic pain, flank pain, and hematuria. Flank pain with tenderness to percussion suggests pyelonephritis. On urinalysis, pyuria is nearly invariably present and hematuria may assist in the diagnosis. Definitive diagnosis is based on significant bacteriuria. The leukocyte esterase test has a screening sensitivity of 75% to 96% and a specificity of 94% to 98% in detecting greater than 10 leukocytes per high-power field.^[43]

Treatment in the wilderness setting for both men and women should be directed at the most common causative agents, although 50% to 70% of cases resolve spontaneously

if untreated. Causative bacteria include *Escherichia coli* (70% to 95%); *Staphylococcus* species (5% to 20%); and, less frequently, *Klebsiella*, *Proteus*, and enterococci. Fortunately, oral antibiotics are highly effective. Although resistant *Escherichia coli* strains are being reported, TMP/SMX (Bactrim DS) is an excellent first-line drug. Alternative regimens include nitrofurantoin, a fluoroquinolone, or a third-generation cephalosporin. A 3-day course of therapy has been shown to be more effective than single-dose therapy.^[43] For pyelonephritis, similar antibiotics in a 10- to 14-day course is acceptable initial treatment. Evacuation should be reserved for systemic toxicity unresponsive to oral antibiotics.

Gynecologic Emergencies

See [Chapter 75](#) .

Skin and Soft Tissue Infections

Poor hygiene, superficial skin wounds, blisters, dermatologically significant plants, and insect bites contribute to disruption of the skin barrier. Most often seen are superficial pyodermas that do not extend beyond the level of the skin. These include erysipelas, impetigo, folliculitis, furunculosis, and carbunculosis. The majority of superficial skin infections are self-limited. However, with less than optimal hygiene and limited resources, skin infections may progress to deep soft tissue infections.

Cellulitis.

Cellulitis is acute infection of the skin involving subcutaneous tissue. The superficial form of cellulitis, erysipelas, is identified by well-demarcated, warm, and erythematous plaques with raised borders. The face, scalp, hands, and lower extremities are most often affected. Cellulitis is frequently preceded by a superficial wound.

In the wilderness setting, there are ongoing infection risk factors. Members of expeditions may be physically stressed and nutritionally depleted. High altitude is associated with immunosuppression. *Clostridia* species and other pathogens are ubiquitous in the soil, and

proper initial wound care may be suboptimal. Under such conditions, cellulitis can progress to abscess formation and tissue necrosis, leading to septicemia. Wounds that develop erythematous, warm, and boggy margins should be treated with antibiotics and closely observed. The margins of erythema should be marked to gauge progression.

Treatment consists of proper wound hygiene and antibiotic therapy. Local wound measures include elevation, application of moist heat every 4 to 6 hours, and immobilization. Antibiotic therapy is directed at common causative pathogens. Group A

streptococci and *Staphylococcus aureus* are most commonly implicated. If complications occur and the cellulitis appears to be progressing, a mixed infection is likely.

Because Gram's stain and culture-directed therapy are not possible, the most broad-spectrum antibiotic available should be administered. Parenteral antibiotics are indicated for serious or mixed infections. Penicillin G (1 to 2 million units every 2 to 3 hours) is recommended, with first-generation cephalosporins as an alternative. Because oral antibiotics may be the only available therapy, they should be initiated early in the field. Suggested agents include erythromycin (for the penicillin-allergic victim); cephalexin; a macrolide, such as clarithromycin; or a fluoroquinolone, such as ciprofloxacin or levofloxacin.

Lymphangitis.

Acute lymphangitis is an infectious process involving subcutaneous lymphatic channels. Its recognition in the wilderness setting is important relative to its propensity to follow puncture wounds, hand wounds, infected blisters, and animal bite wounds. Clinical presentation involves linear erythematous streaks that originate in the lymphatic drainage basin of the wound and "point" to the draining nodal group. Causative agents are similar to those common for cellulitis, with the addition of *Pasteurella multocida* from animal bite wounds.

Treatment consists of antibiotics, warm moist soaks every 4 to 6 hours, and immobilization and elevation of the extremity. Optimal treatment consists of parenteral antibiotics, but as with cellulitis, oral agents should be initiated if parenteral drugs are not available. Broad-spectrum agents with good oral bioavailability and gram-positive coverage are recommended.^[84]

Abscess Formation.

When untreated, many superficial skin infections convert to abscesses. Development of a raised, fluctuant mass with overlying warmth and erythema should raise suspicion that surgical drainage is necessary. Frequently, the lesion will "point" when purulent fluid has amassed below the dermis and rupture is impending. Warm soaks and observation are recommended by some clinicians, particularly if the presence of drainable pus is uncertain. However, the definitive treatment is drainage. Antibiotics are recommended if significant associated cellulitis is present, but penetration may be poor.

Local anesthesia should be administered before incision. The lesion should be incised in line with tissue planes over the point of maximum fluctuance. The value of cruciate incisions over linear incisions is debatable; the important feature is assurance of adequate drainage to prevent recurrence. If drainage is undertaken, the incision must be large enough to adequately drain the cavity. All purulent material should be evacuated and the cavity copiously irrigated with saline or water.

Packing is unnecessary if adequate continued drainage is ensured. The wound should

be covered with a sterile dressing, changed 2 to 3 times per day with concurrent irrigation, and closely observed for reaccumulation of purulence.

Necrotizing Infections.

Necrotizing skin and soft tissue infections are life-threatening conditions caused by virulent, toxin-producing bacteria. Depth of tissue involvement is variable and may involve skin, fascia, or muscle. The etiology of necrotizing infections is related to breaks in normal cutaneous defenses associated with some form of injury. Although rare, such infections are of importance to the wilderness physician because of the array of documented inciting injuries and the reduction in mortality possible if diagnosis and treatment are rapid.^[28] Necrotizing infections have developed after innocuous-appearing injuries, including simple scratches, insect bites, ankle sprains, and sore throats.^[35]

The incidence of necrotizing soft tissue infections is unknown, and there is no age or gender predilection. They most commonly occur on the extremities, abdominal wall, and perineum, within 1 week of the inciting event. Common pathogens include streptococcal species, *Staphylococcus*, *Vibrio* species, *Clostridia*, *Pseudomonas*, *Aeromonas*, *Enterobacter*, and fungi. Many infections become polymicrobial.

The clinical manifestations can be subtle. An area of cellulitis is commonly the first indication of infection. Pain is often excruciating, and fever is usually present. The infection then progresses to spreading erythema, induration, blue-black discoloration, and blister formation. Necrosis of skin, subcutaneous fat, muscle, and/or fascia follows, depending on the organism involved. Necrotic tissue exudes a foul-smelling, watery "dishwater" fluid. Subcutaneous emphysema may be present, particularly with clostridial infections, although enteric organisms may also produce air in tissues.

Unfortunately, treatment is limited in the wilderness environment. Debridement of infected tissue should be carried out to the greatest degree humanely possible, but further debridement in a hospital setting is invariably necessary. The extent of debridement necessitated is often striking.

After debridement, parenteral antibiotics are necessary. Vancomycin and gentamicin are appropriate first-line agents. The most broad-spectrum oral antibiotic available should be initiated, and the victim expeditiously evacuated. Time is of the essence because the infection can only be halted by aggressive surgical intervention.

Chapter 19 - Wilderness Improvisation

Eric A. Weiss
Howard J. Donner

At the heart of wilderness medicine is improvisation, a creative amalgam of formal medical science and commonsense problem solving. Defined as "to fabricate out of what is conveniently at hand," improvisation encompasses many variations, is governed by few absolute rights and wrongs, and is limited more often by imagination than by personnel or equipment.

GENERAL GUIDELINES

When you work with an improvised system, you should test your creation on a noninjured person ("work out the bugs") before applying it to a victim. Include materials that lend themselves to improvisation in the wilderness survival kit to enhance efficiency. Creativity is needed when searching for improvisational materials. The victim's gear can provide needed items (e.g., backpacks can be dismantled to obtain foam pads and straps). When possible, practice constructing improvised systems before they are required in an actual rescue.

IMPROVISED AIRWAY MANAGEMENT

Airway obstruction in the semiconscious or unconscious victim is usually caused by relaxation of the oropharyngeal muscles, which allows the tongue to slide back and obstruct the airway. If only one rescuer is present, maintaining a patent airway with the jaw thrust or chin lift technique precludes further first-aid management. You can improvise a nasal trumpet type

Figure 19-1 Safety pinning tongue to open airway. (From Auerbach PS, Donner HJ, Weiss EA: *Field guide to wilderness medicine*, St Louis, 1999, Mosby.)

of airway from a Foley catheter, radiator hose, solar shower hose, siphon tubing, or inflation hose from a kayak flotation bag or sport pouch.

Establish a temporary airway by attaching the anterior aspect of the victim's tongue to the lower lip with two safety pins ([Figure 19-1](#)). An alternative to puncturing the lower lip is to pass a string through the safety pins and hold traction on the tongue by securing the other end to the victim's shirt button or jacket zipper.

Surgical Airway (Cricothyroidotomy)

Cricothyroidotomy—the establishment of an opening in the cricothyroid membrane—is indicated to relieve life-threatening upper airway obstruction when a victim cannot be ventilated effectively from the mouth or nose, and endotracheal intubation is not feasible. This may occur in a victim with severe laryngeal edema, or with trauma to the face and upper larynx. Cricothyroidotomy may also be useful when the person's upper airway is obstructed by a foreign body that cannot be extracted by a Heimlich maneuver or direct laryngoscopy.

In the wilderness, you can perform cricothyroidotomy by cutting a hole in the thin cricothyroid membrane and then placing a hollow object into the trachea to allow for ventilation ([Box 19-1](#)). Locate the cricothyroid membrane by palpating the victim's neck, beginning at the top. The first and largest prominence felt is the thyroid cartilage ("Adam's apple"), whereas the second (below the thyroid cartilage) is the cricoid cartilage.

Figure 19-2 A, Cut plastic drip chamber at halfway point. **B**, Insert spike from drip chamber into the cricothyroid membrane. **C**, Bag-valve device will fit over the chamber for ventilation.

The small space between these two, noted by a small depression, is the cricothyroid membrane ([Figure 19-4](#)). With the victim lying on his or her back, cleanse the neck around the cricothyroid membrane with an antiseptic if one is readily available. Put on protective gloves. Make a vertical 1-inch incision through the skin with a knife over the membrane (go a little bit above and below the membrane) while using the fingers of your other hand to pry the skin edges apart. Anticipate bleeding from the wound. After the skin is cut apart, puncture the membrane by stabbing it with your knife or other sharp penetrating object ([Figure 19-5.A](#)). Stabilize the larynx between the fingers of one hand, and insert the improvised cricothyroidotomy tube through the membrane with your other hand ([Figure 19-5.B](#)). Secure the object in place with tape.

Box 19-1. IMPROVISED CRICOTHYROIDOTOMY TUBES

1. IV administration set drip chamber: Cut the plastic drip chamber of a macro drip (15 drops/ml) IV administration set at its halfway point with a knife or scissors. Remove the end protector from the piercing spike and insert the spike through the cricothyroid membrane. The plastic drip chamber is nearly the same size as a 15-mm endotracheal tube adapter and fits snugly in the valve fitting of a bag-valve device ([Figure 19-2](#)).
2. Syringe barrel: Cut the barrel of a 1- or 3-ml syringe with the plunger removed at a 45-degree angle at its midpoint to create an improvised cricothyroid airway device. The proximal phalange of the syringe barrel helps secure the device to the neck and prevents it from being aspirated ([Figure 19-3](#)).
3. Any small hollow object: Examples include a small flashlight or penlight casing, pen casing, small pill bottle, and large-bore needle or IV catheter. Several commercial devices are small and lightweight enough to be included in the first-aid kit.

Figure 19-3 Improved cricothyroid airway device can be created by cutting barrel of syringe at 45-degree angle at its midway point. (From Auerbach PS, Donner HJ, Weiss EA: *Field guide to wilderness medicine*, St Louis, 1999, Mosby.)

Figure 19-4 Cricothyroid membrane is found in the depression between the Adam's apple (thyroid cartilage) and the cricoid cartilage. (From Auerbach PS, Donner HJ, Weiss EA: *Field guide to wilderness medicine*, St Louis, 1999, Mosby.)

Complications associated with this procedure include hemorrhage at the insertion site, subcutaneous or mediastinal emphysema resulting from faulty placement of the tube into the subcutaneous tissues rather than into the trachea, and perforation through the posterior

Figure 19-5 Cricothyroidotomy. **A**, Locate cricothyroid membrane and make a vertical 1-inch incision through the skin. **B**, Insert pointed end of improvised cricothyrotomy tube through the membrane. (From Auerbach PS, Donner HJ, Weiss EA: *Field guide to wilderness medicine*, St Louis, 1999, Mosby.)

wall of the trachea with placement of the tube in the esophagus.

Improved Barrier For Mouth-To-Mouth Rescue Breathing

A glove can be modified and used as a barrier shield for performing rescue breathing. Cut the middle finger of the glove at its halfway point and insert it into the victim's mouth. Stretch the glove across the victim's mouth and nose and blow into the glove as you would to inflate a balloon. After each breath, remove the part of the glove covering

the nose to allow the victim to exhale. The slit creates a one-way valve, preventing backflow of the victim's saliva ([Figure 19-6](#)).

EAR, NOSE, AND THROAT EMERGENCIES

Epistaxis is a common problem in travelers. The reduced humidity in airplanes, cold climates, and high-altitude environments can produce drying and erosion of the nasal mucosa. Other etiologic factors include facial

469

Figure 19-6 Improvised cardiopulmonary resuscitation (CPR) barrier is created using a latex or nitrile glove. Make a slit in the middle finger of the glove.

trauma, infections, and inflammatory rhinitis. Although most cases of epistaxis are minor, some present life-threatening emergencies.^[32]

Anterior epistaxis from one side of the nasal cavity occurs in 90% of cases.^[7] If pinching the nostrils against the septum for a full 10 minutes does not control the bleeding, nasal packing may be needed. Soak a piece of cotton or gauze with a vasoconstrictor, such as oxymetazoline (Afrin) nasal spray, and insert it into the nose, leaving it in place for 5 to 10 minutes. Vaseline-impregnated gauze

Figure 19-7 Anterior epistaxis from one side of the nasal cavity can be treated using nasal packing soaked in a vasoconstrictor. Vaseline-impregnated gauze or strips of nonadherent dressing can be packed in the nose so that both ends of the gauze remain outside the nasal cavity.

or strips of a nonadherent dressing can then be packed into the nose so that both ends of the gauze remain outside the nasal cavity ([Figure 19-7](#)). This prevents the victim from inadvertently aspirating the nasal packing.^[32]

Complete packing of the nasal cavity of an adult victim requires a minimum of 1 m (3 feet) of packing to fill the nasal cavity and tamponade the bleeding site.^[7] Expandable packing material, such as Weimert Epistaxis Packing or the Rhino Rocket, is available commercially. A tampon or balloon tip from a Foley catheter can also be used as improvised packing.^[32]

Anterior nasal packing blocks sinus drainage and predisposes to sinusitis. Prophylactic antibiotics are usually recommended until the pack is removed in 48 hours.^[32]

If the bleeding site is located posteriorly, use a 14- to 16-Fr Foley catheter with a 30-ml balloon to tamponade the site.^[10] Prelubricate the catheter with either Vaseline or a water-based lubricant, then insert it through the nasal cavity into the posterior pharynx. Inflate the balloon with 10 to 15 ml of water and gently withdraw it back into the posterior nasopharynx until resistance is met. Secure the catheter firmly to the victim's forehead with several strips of tape. Pack the anterior nose in front of the catheter balloon as described earlier.

Esophageal foreign bodies may cause significant morbidity. Respiratory compromise caused by tracheal compression or by aspiration of secretions can occur. Mediastinitis, pleural effusion, pneumothorax, and abscess may be seen with perforations of the esophagus

Figure 19-8 Packing the back of the nose. Insert a Foley catheter into the nose and gently pass it back until it enters the back of the throat. After the tip of the catheter is in the victim's throat, carefully inflate the balloon with 10 to 12 ml of air or water from a syringe. Inflation should be done slowly and should be stopped if painful. After the balloon is inflated, gently pull the catheter back out until resistance is met.

from sharp objects or pressure necrosis caused by large objects.^[20]

The use of a Foley balloon-tipped catheter can be a safe method for removing blunt esophageal foreign bodies.^{[4] [5] [12]} Success rates of 98% have been cited.^[4] Associated complications include laryngospasm, epistaxis, pain, esophageal perforation, and tracheal aspiration of the dislodged foreign body.^[20] Sharp, ragged foreign bodies or an uncooperative victim precludes use of this technique ([Figure 19-8](#)).^[28]

Lubricate a 12- to 16-Fr Foley catheter and place it orally into the esophagus while the victim is seated. After placing the victim in Trendelenburg's position, pass the catheter beyond the foreign body and inflate the balloon with water. Withdraw the catheter with steady traction until the foreign body can be removed from the hypopharynx or expelled by coughing. Take care to avoid lodging the foreign body in the nasopharynx. Any significant impedance to withdrawal should terminate the attempt.^[28] Use of this technique is recommended only in extreme wilderness settings or when endoscopy is not available.

IMPROVISED PLEURAL DECOMPRESSION OF A TENSION PNEUMOTHORAX

Signs and symptoms of a tension pneumothorax include distended neck veins, tracheal deviation away from the side of the pneumothorax, unilateral absent breath sounds, hyperresonant hemithorax to percussion, subcutaneous emphysema, respiratory distress, cyanosis, and cardiovascular collapse. Tension pneumothorax mandates rapid pleural decompression if the victim appears to be dying. Possible complications of pleural decompression include infection; profound bleeding from puncture of the heart, lung, or a major blood vessel; or even laceration of the liver or spleen.

Technique

Swab the entire chest with povidone-iodine or another antiseptic. If sterile gloves are available, put them on after washing your hands. If local anesthesia is available, infiltrate the puncture site down to the rib and over its upper border.

Insert a large-bore intravenous (IV) catheter, needle, or any pointed, sharp object that is available into the chest just above the third rib in the midclavicular line (midway between the top of the shoulder and the nipple in a line with the nipple approximates this location) ([Box 19-2](#)). If you hit the rib, move the needle or knife upward slightly until it passes over the top of the rib, thus avoiding the intercostal blood vessels that course along the lower edge of every rib. The chest wall is 1 ½ to 2 ½ inches thick, depending on the individual's muscularity and the amount of fat present. A gush of air signals that you have entered the pleural space; do not push the penetrating object further. Releasing the tension converts the tension pneumothorax into an open pneumothorax.

Box 19-2. IMPROVISED PLEURAL DECOMPRESSION DEVICES

1. Large-bore (12- or 14-gauge) IV catheter or needle
2. Endotracheal tube
3. Foley catheter with a rigid support ("stylet"), such as a clothes hanger, placed into the lumen
4. Section of a tent pole
5. Hose from a hydration pouch

Figure 19-9 A, Finger of glove is attached to needle or catheter to create flutter valve. **B**, Flutter valve allows air to escape. **C**, Flutter valve collapses to prevent air entry. (From Auerbach PS, Donner HJ, Weiss EA: *Field guide to wilderness medicine*, St Louis, 1999, Mosby.)

Leave the needle or catheter in place and place the cut-out finger portion of a rubber glove with a tiny slit cut into the end over the external opening to create a unidirectional flutter valve that allows continuous egress of air from the pleural space ([Figure 19-9](#)). To create a one-way flutter valve, cut a finger portion of a latex glove off at the proximal end of the finger and insert the needle or catheter into the open end of the glove finger and through the tip as shown (see [Figure 19-9, A](#)). The cut-out-finger portion of the glove creates a unidirectional flutter valve that allows egress of air from the pleural space during expiration but collapses to prevent air entry on inspiration (see [Figure 19-9, B and C](#)).

OPEN ("SUCKING") CHEST WOUND

Penetrating trauma to the chest can produce a chest wound that allows air to be sucked into the pleura on inspiration. Place a piece of plastic food wrap, aluminum foil, or one side of a plastic sandwich bag on top of the wound and tape it on three sides. The untaped fourth side serves as a relief valve to prevent formation of a tension pneumothorax.

IMPROVISED SPLINTING AND TRACTION*

Cervical Spine Injuries

Because of its mobility, the cervical spine is the spinal column area most commonly injured in trauma. Any obvious or suspected cervical spine injury demands full spinal immobilization with use of both a rigid or semirigid cervical collar and long board immobilization. Historically, dogma about cervical spine injuries has specified a "splint 'em as they lie" approach. Transporting a victim who is not in anatomic position is arduous in the backcountry. It is uncomfortable for the victim, difficult for the rescuers, and increases the risk of further injury. In general, gentle axial traction back to anatomic position is indicated unless (1) return to anatomic position significantly increase pain or focal neurologic deficit or (2) movement of the head and neck results in any noticeable mechanical resistance. ^[17]

All cervical spine injuries (or suspected injuries) deserve full long board immobilization. Movement of the pelvis and hips laterally is potentially more dangerous than anterior-posterior movement; therefore it is appropriate during extended transport to allow gentle flexion at the hip with immobilization in that position if the victim is more comfortable. Soft pads behind the knees and the small of the back also add to the victim's comfort during a long transport. ^[9]

Cervical Collars.

Cervical collars are always adjuncts to full spinal immobilization and never used alone. The improvised cervical collar is used in conjunction with manual cervical spine stabilization followed by complete immobilization of the victim on a spine board. A properly applied and fitted collar is a primary defense

*Specific aspects of fracture care are covered in detail in other chapters. This chapter focuses on improvised *systems*, not on definitive orthopedic *management*. Improvised systems rarely provide the same degree of protection as commercial systems. Good judgment is needed.

against axial loading of the cervical spine, particularly in an evacuation that involves tilting the victim's body uphill or downhill. Improvised cervical collars have had a bad reputation, and textbooks continue to depict them made from a simple cravat wrapped around the neck. This type of system is no more effective than the soft cervical collars often used by urban plaintiffs trying to impress a jury.

An improvised cervical collar works effectively *only* if it has the following features:

1. It is rigid or semirigid.
2. It fits properly (many improvised designs are too small).
3. It does not choke the victim.
4. It allows the victim's mouth to open if vomiting occurs.

The following are improvisational approaches to cervical collars.

CLOSED-CELL FOAM SYSTEM.

The best closed-cell foam systems incorporate a full-size or three-quarter-length pad folded longitudinally into thirds and applied by being centered over the back of the victim's neck and wrapped forward. The pad is crossed under the chin, contoured underneath opposite axillae, and secured. If the pad is not long enough, you can tape or tie on extensions. This system also works well with blankets, beach towels, or even a rolled plastic tarp. Avoid small flexible cervical collars that do not optimally extend the chin-to-chest distance.

PADDED HIP BELT.

A padded hip belt or fanny pack removed from a large internal or external frame backpack can sometimes be modified to work perfectly. Wider is usually better. Take up excess circumference by overlapping the belt, and secure the excess material with duct tape ([Figure 19-10](#)).

CLOTHING.

Bulky clothing, such as a fiberpile or fleece jacket, can be rolled and then wrapped around the victim's neck to make a cervical collar. The extended sleeves can be used to secure the collar. Prewrapping a wide elasticized (Ace) wrap around the jacket compresses the material to make it more rigid and supportive.

MALLEABLE ALUMINUM SPLINT.

A well-padded, aluminum splint (e.g., SAM splint) can be adjusted to fit almost any size neck ([Figure 19-11](#)).

Improvised Spinal Immobilization.

As noted, the improvised cervical collar is only an adjunct to full spinal immobilization. Two immobilization systems are (1) short board immobilization, which is useful for short-duration transport (that is, getting the victim out of immediate danger) or when

used in conjunction

Figure 19-10 Inverted pack used as spine board. (From Auerbach PS, Donner HJ, Weiss EA: *Field guide to wilderness medicine*, St Louis, 1999, Mosby.)

with a long board; and (2) long board immobilization, used for definitive immobilization during extensive transport.

Use all of these systems in conjunction with a rigid or semirigid cervical collar, as described previously. Improvised lateral "towel rolls" are often added to these systems for additional head and neck support. These rolls can be improvised from small sections of Ensolite. Alternatively, a U-shaped head support or "horse collar" can be made from any rolled garment, blanket, tarp, or tent fly; this is placed over the victim's head in an inverted U and used with the improvised cervical collar and spine board. Hiking socks or stuff bags filled with dirt, sand, or gravel also work well for this purpose. Stuff bags filled with snow for support should *never* be used because the snow can melt during transport and allow excessive head and neck motion. However, snow-filled stuff bags can act as temporary support while more definitive systems are being constructed.

IMPROVISED SHORT BOARD IMMOBILIZATION

Internal frame pack and snow shovel system.

Some internal frame backpacks can be easily modified by inserting a snow shovel through the centerline attachment points (the shovel handgrip may need to be removed first). The victim's head is taped to the lightly padded shovel ([Figure 19-12](#)); in this context the shovel blade serves as a head bed. This system incorporates the remainder of the pack suspension as designed (that is, shoulder and sternum straps with hip belt) and works well with other long board designs, such as the continuous loop system (see Continuous Loop System section).

Figure 19-11 Malleable aluminum splint cervical collar. **A**, Place a vertical bend in the malleable aluminum splint approximately 6 inches from one end to form a vertical pillar. Then, add bilateral flares to make the splint comfortable for the victim where it rides against the lower mandible. **B**, Place the anterior pillar securely beneath the victim's chin and wrap the remaining length of the splint around the victim's neck. **C**, Side view of cervical collar fashioned from SAM splint. **D**, Frontal view. The end is angled inferiorly to provide an adequate chin-to-chest distance.

474

Figure 19-12 Head immobilized on a padded shovel.

Figure 19-13 Short board using an inverted pack system. The backpack waistbelt can be seen encircling the head.

Inverted pack system.

An efficient short board can be made using an inverted internal or external frame backpack. The padded hip belt provides a head bed, and the frame is used as a short board in conjunction with a rigid or semirigid cervical collar ([Figure 19-13](#)).

Turn the pack upside down, and lash the victim's shoulders and torso to the pack. Fasten the waist belt around the victim's head, as in the top section of a Kendrick extrication device. The hip belt is typically too large, but you can eliminate excess circumference with bilateral Ensolite rolls. Unlike the snow shovel system, this system requires that the victim be lashed to the splint.

Snowshoe system.

A snowshoe can be made into a fairly reliable short spine board ([Figure 19-14](#)). Pad the snowshoe and rig it for attachment to the victim as shown.^[19]

IMPROVISED LONG BOARD IMMOBILIZATION

Continuous loop system.

For the continuous loop system (also known as the daisy chain, cocoon wrap, or mummy litter), the following items are needed:

1. A long climbing or rescue rope
2. A large tarp
3. Sleeping pads (Ensolite or Therm-a-Rest)
4. Stiffeners (such as skis, poles, snowshoes, canoe paddles, or tree branches)

Lay the rope out with even **U**-shaped loops as shown in [Figure 19-15, A](#) . The midsection should be slightly wider to conform to the victim's width. Tie a small loop at the foot end of the rope and place a tarp on the laid rope. On top of the tarp, lay foam pads the full length of the system (the pads can be overlapped to add length). Then lay stiffeners on top of the pads in the same axis as the victim ([Figure 19-15, B](#)). Add multiple foam pads on top of the stiffeners followed optionally with a sleeping bag ([Figure 19-15, C](#)). Place the victim on the pads. To form the daisy chain, bring a single loop through the pretied loop, pulling loops toward the center, and feeding through the loops brought up from the opposite side. It is important to take up rope slack continuously. When the victim's armpits are reached, bring a loop over each shoulder and tie it off (or clip it off with a carabiner) ([Figure 19-15, D](#)).

One excellent modification involves adding an inverted internal frame backpack. This can be incorporated with the padding and secured with the head end of the rope. The pack adds rigidity and padding, and the padded hip belt serves as a very efficient head and neck immobilizer (see [Figure 19-10](#) and [Figure 19-13](#)).

Backpack frame litters.

Functional litters can be constructed from external frame backpacks. Traditionally two frames are used, but three or four frames (as illustrated in [Figure 19-16](#)) make for a larger, more stable litter. Cable ties or fiberglass strapping tape simplifies this fabrication. These litters can be reinforced with ice axes or ski poles.

Kayak system.

Properly modified, the kayak makes an ideal rigid long board improvised litter. First, remove the seat along with sections of the upper deck if necessary. A serrated river knife (or camp saw) makes this improvisation much easier. Open deck canoes can be

used almost as is once the flotation material has been removed.

Canoe system.

Many rivers have railroad tracks that run parallel to the river canyon. The tracks can be used to slide a canoe by placing the boat perpendicular to the tracks and pulling on both bow and stern lines.

475

Figure 19-14 Improvised snowshoe short board. A well-padded snowshoe is prerigged with webbing and attached to the victim as shown. This system can also be used in conjunction with long board systems, such as the continuous loop system.

Figure 19-15a Continuous loop, or "mummy," litter made with a climbing rope. **A**, Rope is laid out with even U-shaped loops. **B**, Stiffeners such as skis and poles are placed underneath the victim to add structural rigidity. It is important to pad between the stiffeners and the victim. **C**, A sleeping bag may be used in addition to the foam pads.

476

Figure 19-15 D, Loop of rope is brought over each shoulder and tied off (see text).

Figure 19-16 Backpack frame litter.

Figure 19-17 Improvised head bed.

Improvised head bed.

A malleable aluminum splint can be formed as shown to create a head bed to assist in securing the immobilized head of an injured victim. Tape this head bed to a commercial or improvised backboard ([Figure 19-17](#)).

Traction

Why are improvised traction systems so crucial? Traction can be lifesaving in certain situations.^[6] The importance of femoral traction in urban emergency medicine is generally accepted. In the backcountry environment, traction is essential for two fundamental reasons: (1) the general inability to provide IV volume expansion and (2) prolonged transport time to definitive care.

The primary purpose of backcountry femoral traction is to *limit blood loss into the thigh*. For a constant surface area, the volume of a sphere is greater than the volume of a cylinder. Pulling (via traction) the thigh compartment back into its natural cylindrical shape limits blood loss into the soft tissue. Although the main objective is to control hemorrhage and prevent shock, enhanced comfort for the victim and decreased potential for neurovascular damage are important secondary benefits. Properly applied, improvised femoral traction can save lives in the backcountry, particularly on extended transports where IV fluids are not available.

General Principles of Traction.

The potential variety of traction designs is unlimited, but five key design principles should be considered when evaluating any femoral traction system:

1. Does the splint provide inline traction? Or does the splint incorrectly pull the victim's leg off to the side or needlessly plantar flex the ankle?
2. Is the splint comfortable? Be sure to ask the victim.
3. Does the splint compromise neurologic or vascular function? Constantly check distal neurovascular function.
4. Is the splint durable, or will it break when subjected to backcountry stresses? As stated earlier, it might help to try the traction design on an uninjured person and then knock the device around a bit to determine its strength.
5. Is the splint cumbersome? Many reasonable splint designs become so bulky and

awkward that litter transport, technical rescue, or helicopter evacuation is impossible. For example, a full-length ski splint is not compatible with evacuation in a small helicopter.

Femoral Traction Systems.

Every femoral traction system has six components:

1. Ankle hitch
2. Rigid support that is longer than the leg
3. Traction mechanism
4. Proximal anchor
5. Method for securing the splint to the leg
6. Additional padding

ANKLE HITCH.

Various techniques are used to anchor the distal extremity to the splint. Many work well, but some are impossible to recall in an emergency. Choose an easy-to-remember technique and practice it. It is best to leave the shoe on the victim's foot and apply the hitch over it. Cut out the toe section of the shoe to periodically check the circulation.

Single runner system.

Loop a long piece of webbing, shoelace, belt, or rope over itself, bringing one end through the middle to create a stirrup. After rotating it away from the person by 180 degrees, slip the hitch over the shoe and ankle.

Double runner system.

In this very straightforward technique, lay two short webbing loops ("runners") over and under the ankle as shown ([Figure 19-18, A](#)). Pass the long loop sides through the short loop on both sides ([Figure 19-18, B](#)) and adjust as needed ([Figure 19-18, C](#)). One advantage of this system is that it is infinitely adjustable, enabling the rescuer to center the pull from any direction. As always, proper padding is essential, especially for long transports. The victim's boot can distribute pressure over the foot and ankle but will obscure visualization and palpation of the foot. A reasonable compromise is to leave the boot on and cut out the toe section for observation.

S-configuration hitch.

This type of hitch is preferred if the victim also has a foot or ankle injury because traction is pulled from the victim's calf instead of the ankle. Lay a long piece of webbing or other similar material over the upper part of the ankle (lower calf) in an S-shaped configuration. Wrap both ends of the webbing behind the ankle and up through the loop on the other side. Pull the ends down on either side of the arch of the foot to tighten the

hitch and tie an overhand knot ([Figure 19-19](#)).

Victim's boot system.

Another efficient system uses the victim's own boot as the hitch. Cut two holes into the side walls of the boot just above the midsole and in line with the ankle joint. Thread a piece of nylon webbing or cravat through to complete the ankle hitch ([Figure 19-20](#)). Cutting away the toe may be necessary for neurovascular assessment.

Buck's traction.

For extended transport, Buck's traction can be improvised using a closed-cell foam pad ([Figure 19-21](#)). Wrap the pad around the lower leg as shown and loop a stirrup below the foot from medial calf to lateral calf. Fasten this assembly with a second cravat wrapped circumferentially around the calf over the closed-cell foam (duct tape or nylon webbing can be used instead of cravats). This system greatly increases the surface area over which the stirrup is applied and decreases the potential for neurovascular complications and dermal ischemia. In addition, improvised Buck's traction has been used to manage backcountry hip fractures. However, recent literature indicates that this technique may have little benefit.^[4] If Buck's traction is used for a hip injury, use smaller amounts of traction (roughly 5 pounds or less).

RIGID SUPPORT.

The rigid support can be fabricated as a unilateral support (similar to the Sager traction splint or Kendrick traction device) or as a bilateral support, such as the Thomas half ring or Hare traction splint. Unilateral supports tend to be easier to apply than bilateral supports. The following are some ideas for rigid support.

Double ski pole or canoe paddle system.

This is fashioned like a Thomas half ring, with the interlocked pole straps slipped under the proximal thigh to form the ischial support. Some mountain guides carry a prefabricated drilled ski pole section or aluminum bar that can be used to stabilize the distal end of this system ([Figures 19-22](#)).

Figure 19-18 Double runner ankle hitch. **A** and **B**, Two webbing loops (runners) are laid over and under the ankle. **C**, Completed double runner ankle hitch. The beauty of this system is

its infinite adjustability. The traction can be easily centered from any angle, ensuring in-line traction.

Figure 19-19 S-configuration hitch for traction splinting.

479

Figure 19-20 Traction using cut boot and cravat.

Figure 19-21 Buck's traction. Duct tape stirrups are added to a small foam pad that is wrapped around the leg. The entire unit is wrapped with an Ace bandage. This system helps distribute the force of the traction over a large surface area.

Figure 19-22 Double ski pole system with prefabricated cross-bar and webbing belt traction. A prefabricated drilled ski section is used to attach the ends of two ski poles. Traction is applied with a webbing belt and sliding buckle.

Figure 19-23 Single ski pole system. An adjustable telescoping ski pole is used as the rigid support. A stirrup is attached to a carabiner placed over the end of the pole. Traction is applied by elongating the ski pole while another rescuer provides manual traction on the victim's leg. Additional padding and securing follow (not shown).

Figure 19-24 Prefabricated drilled tent pole section and bent tent stake. The ski pole section is used to stabilize the end of a double ski pole traction system. This can be improvised on site if necessary. The bent tent stake serves as a distal traction anchor if a tent pole is used as the rigid support.

Figure 19-25 A Prusik knot made from a small-diameter cord is used as an adjustable distal traction anchor. Although two wraps are shown in the illustration, an additional wrap adds further security when applied to a smooth surface, such as a kayak paddle.

Figure 19-26 Two Prusik wraps are shown. Three or four wraps provide additional friction and security. If the Prusik knot slips, it can be easily taped in place.

Single ski pole or canoe-kayak paddle.

Use a single ski pole or paddle either between the legs, which is ideal for bilateral femur fractures, or lateral to the injured leg. The ultimate rigid support is an adjustable telescoping ski pole used laterally. Adjust the pole to the appropriate length for each victim, making the splint compact for litter work or helicopter evacuation ([Figure 19-23](#)).

Tent poles.

This system uses conventional sectioned tent poles. Fit the poles together to create the ideal length rigid support. Because of their flexibility, tent poles must be well secured to the leg to prevent them from flexing out of position. Place a blanket pin or bent tent stake ([Figure 19-24](#)) in the end of the pole to provide an anchor for the traction system. Alternately, use a Prusik knot ([Figure 19-25](#)) to secure the system to the end of the tent pole ([Figure 19-26](#)).

Miscellaneous.

Any suitable object, such as a canoe or kayak paddle (see [Figure 19-26](#)), two ice axes taped together at the handles, or a straight branch can be used to make a rigid support. Although skis immediately come to mind as suitable rigid components, they are too cumbersome to work effectively. Because of their length, skis may extend far beyond the victim's feet or require placement into the axillae, which is unnecessary and inhibits mobility (e.g., sitting up during transport). Premanufactured canvas pockets, available from the National Ski Patrol System, provide a ski tip and tail attachment grommet for use with the ski system.

TRACTION MECHANISM.

The first modern popularized improvised traction mechanism was the Boy Scout-style Spanish windlass. Although these systems work and look good in the movies, they can be awkward to apply

481

Figure 19-27 Tent pole traction with trucker's hitch. A bent tent stake is placed into the end of the tent pole as the distal traction anchor. A simple trucker's hitch is used to provide traction.

and are often not durable. The windlass can unspin if it is inadvertently jarred and can apply rotational forces to the leg.

The amount of traction required is primarily a function of comfort. A general rule is to use 10% of body weight or about 10 to 15 pounds for the average victim. After the traction is applied, always recheck distal neurovascular function (circulation, sensation,

movement).

Cam lock or Fastex-like slider.

This simple, effective system uses straps that have a Fastex-like slider. Such straps are often used as waist belts or to hold items to packs. Alternately, a cam lock with nylon webbing can be used. Attach the belt to the distal portion of the rigid support and then to the ankle hitch. Traction is easily applied by cinching the nylon webbing (see [Figure 19-22](#)).

Trucker's hitch.

A windlass can be easily fashioned using small-diameter line (parachute cord) and a standard trucker's hitch for additional mechanical advantage ([Figure 19-27](#)).

Prusik knot.

Almost any system can be rigged with a Prusik knot (see [Figure 19-25](#)). Prusiks are ideal for providing traction from rigid supports with few tie-on points (such as a canoe paddle shaft or a tent pole). The Prusik knot can be used to apply the traction (by sliding the knot distally) or simply as an attachment point for one of the traction mechanisms already mentioned.

Litter traction.

If no rigid support is available and a rigid litter such as a Stokes is being used, apply traction from the rigid bar at the foot end of the litter. If this system is used, ensure that the victim is immobilized

Figure 19-28 Proximal anchor using cam lock belt. The belt is applied as shown. A ski pole is used laterally as the rigid support. Duct tape is useful for securing components. Padding is helpful but is not always necessary if the victim is wearing pants.

Figure 19-29 Life jacket proximal anchor. An inverted life jacket worn like a diaper forms a well-padded proximal anchor. A kayak paddle is rigged to the life jacket's side adjustment strap.

on the litter with adequate countertraction, such as inguinal straps.

PROXIMAL ANCHOR.

The simplest proximal anchor uses a single proximal thigh strap, which can be made from a piece of climbing webbing or a prefabricated strap, belt, or cam lock ([Figure 19-28](#)). A cloth cravat can be used in a pinch. On the river a life jacket can be used ([Figure 19-29](#)). When climbing, a climbing harness is ideal.

SECURING AND PADDING.

Check all potential pressure points to ensure that they are adequately padded. An excellent padding system can be made by first covering the upper and lower leg with a folded length of Ensolite ([Figure 19-30](#)). This is preferred over a circumferential

482

Figure 19-30 Folding Ensolite padding often provides better visualization of the extremity than does a circumferential wrap.

wrap because the folded system allows you to see the extremity. The victim is more comfortable if femoral traction is applied with the knee in slight flexion (padding placed beneath the knee during transport). Secure the splint firmly to the leg. Almost any straplike object will work, but a 4- to 6-inch Ace bandage wrapped circumferentially provides a comfortable and secure union. Finally, strap or tie the ankles or feet together to give the system additional stability. Tying the ankles together also prevents the injured leg from excess external rotation and jarring during transport.

Extremity Splints

Splint all fractures before the victim is moved unless his or her life is in immediate danger. In general, make sure the splint incorporates the joints above and below the fracture. If possible, the splint should be fashioned on the uninjured extremity and then transferred to the injured one.

On ski trips, skis and poles can be used as improvised splints. On white-water trips, canoe and kayak paddles can be used in a similar manner. Airbags used as flotation for kayaks and canoes can be converted into pneumatic splints for arm and ankle injuries. The minicell or ethafoam pillars found in most kayaks can be removed and carved into pieces to provide upper and lower extremity splints. A life jacket can be molded into a

cylinder splint for knee immobilization or into a pillow splint for the ankle.

The flexible aluminum stays found in internal frame packs can be molded into upper extremity splints. Other improvised splinting material includes sticks or tree limbs, rolled-up magazines, books or newspapers, ice axes, tent poles, and dirt-filled garbage bags or fanny packs.

Ideally a splint should immobilize the fractured

Figure 19-31 Tripod splint for unreduced anterior shoulder dislocation. This splint holds the arm in abduction when adduction is not possible. Additional padding should be added where necessary and the splint secured to the arm with an elastic wrap or other bandaging material.

bone in a functional position. In general, "functional position" means that the legs should be straight or slightly bent at the knee, the ankle and elbow bent at 90 degrees, the wrists straight, and the fingers flexed in a curve as if the person were attempting to hold a can of soda or a baseball.

Splints can be secured in place with strips of clothing, belts, pieces of rope or webbing, pack straps, gauze bandages, or elastic bandage wraps.

Padded aluminum can be molded into various configurations to splint extremity injuries ([Figure 19-31](#) , [Figure 19-32](#) , [Figure 19-33](#) , [Figure 19-34](#) , [Figure 19-35](#) , [Figure 19-36](#)).

Functional Splints

Although most splints are designed to completely immobilize an injured extremity, in the backcountry a splint may need to allow for a limited range of motion so the victim can facilitate his or her own rescue. Many functional splints can be quickly improvised using nothing more than a closed-cell foam sleeping pad and some tape or elastic wrap. With the advent of inflatable sleeping pads (e.g., Therm-a-Rest), foam pads are not as ubiquitous as they once were in the backcountry. However, many of these splints can be made using a partially inflated Therm-a-Rest. Once applied, these pads can be inflated to provide the necessary support, fit, and comfort ([Figure 19-37](#)).

Figure 19-32 Humerus splint. Used in conjunction with a sling and swath, this splint adds extra support and protection for a fractured humerus.

Figure 19-33 Forearm splint. These splints are used for the treatment of wrist or forearm fractures. The sugar-tong splint (A) prevents pronation and supination and has the advantage of greater security and protection than the volar splint (B) because of its anterior-posterior construction.

Figure 19-34 Lower leg and/or ankle splint. A sugar-tong splint can be used to immobilize fractures of the tibia, fibula, or ankle.

Figure 19-35 Posterior arm splint. This splint is cut from of a 5- to 9-gallon plastic fuel or water can (jerry can). When used with appropriate padding, this forms an excellent splint for injured or

fractured elbows.

Figure 19-36 Webbing sling. An 8-foot length of 1-inch tubular or flat webbing is used to form a functional arm sling. A Crazy Creek Chair can be used to improvise both upper and lower extremity splints. Its inherent integral strapping system precludes the need for additional straps or tape.

Functional Shoulder Immobilizer (Shoulder Spica Wrap).

After a dislocated shoulder is reduced, standard treatment is to completely immobilize the arm with a sling and swath. This, however, prevents the victim from using the extremity to facilitate evacuation. A

Figure 19-37 Functional knee and lower leg immobilizer. Wrap a sleeping pad around the lower leg from the midthigh to the foot. Fold the pad so that the top of the leg is not included in the splint. This provides better visualization of the extremity and leaves room for swelling. A full-length pad forms a very bulky splint and may need to be trimmed before rolling. Because of the conical shape of the lower extremity and the effects of gravity, foam pad lower extremity splints tend to work their way inferiorly when the victim ambulates. A simple solution is to use "duct tape suspenders" to keep the splint from migrating downward.

more functional system can be made using a 6-inch elastic wrap. This method allows the victim limited function (e.g., ski poling or kayak paddling) while still preventing complete abduction of the arm.

Triangular Bandage

One of the most ubiquitous components of first-aid kits and one of the easiest to replace through improvisation is the triangular bandage. The need to carry this bulky item, which is commonly used to construct a sling and swath bandage for shoulder and arm immobilization, can be eliminated by carrying two or three safety pins. Pinning the shirt sleeve of the injured arm to the chest portion of the shirt effectively immobilizes the extremity against the body ([Figure 19-38, B](#)).

If the victim is wearing a short-sleeved shirt, the bottom of the shirt can be folded up and over the arm to create a pouch. This can be pinned to the sleeve and chest section of the shirt to secure the arm ([Figure 19-38, A](#)).

Triangular bandages are also used for securing splints and constructing pressure wraps. Common items, such as socks, shirts, belts, pack straps, webbing, shoe laces, fanny packs, and underwear, can easily be substituted.

485

Figure 19-38 Techniques for pinning the arm to the shirt as an improvised sling. **A**, With a short-sleeved shirt the bottom of the shirt is folded up over the injured arm and secured to the sleeve and upper shirt. **B**, With a long-sleeved shirt or jacket the sleeved arm is simply pinned to the chest portion of the garment.

IMPROVISED WOUND MANAGEMENT

The same principles that govern wound management in the emergency department apply in the wilderness. The main problem faced in the wilderness is access to adequate supplies. In deciding to close a wound primarily or pack it open, take into account the mechanism of injury, age of the wound, site of the wound, degree of contamination, and ability to effectively clean the wound.

Wound Irrigation

The primary determinants of infection are bacterial counts and amount of devitalized tissue remaining in the wound.^[15] Ridding a wound of bacteria and other particulate matter requires more than soaking and gentle washing with a disinfectant.^[18] Irrigating the wound with a forceful stream is the most effective method of reducing bacterial counts and removing debris and contaminants.^[21] ^[27] The cleansing capacity of the stream depends on the hydraulic pressure under which the fluid is delivered.^[14] ^[26] Irrigation is best accomplished by attaching an 18- or 19-gauge catheter to a 35-ml syringe or a 22-gauge needle to a 12-ml syringe. This creates hydraulic pressure in the range of 7 to 8 lb/in² and 13 lb/in², respectively.^[14] ^[23] ^[26] The solution is directed into the wound from a distance of 1 to 2 inches at an angle perpendicular to the wound surface and as close to the wound as possible. The amount of irrigation fluid varies with the size and contamination of the wound, but should average no less than 250 ml.^[14] Remember, "The solution to pollution is dilution."

**Box 19-3. RECOMMENDED
TECHNIQUE FOR WOUND IRRIGATION**

1. Fill a sandwich or garbage bag with disinfected water.
2. Disinfect the water with iodine tablets, iodine solution, or povidone-iodine or by boiling it.
3. Normal saline can be made by adding 2 teaspoons of salt (9 g) per liter of water.
4. Seal the bag.
5. Puncture the bottom of the bag with an 18-gauge needle, safety pin, fork prong, or knife tip.
6. Squeeze the top of the bag forcefully while holding it just above the wound, directing the stream into the wound.
7. Use caution to ensure that none of the irrigation fluid splashes into your eyes.

Which irrigation solution is best for open wounds? Those who subscribe to the dogma that nothing should enter a wound that could not be instilled safely into the eye believe that normal saline is the best solution.^[8] ^[16] In a study of 531 patients with traumatic wounds, there was no significant variation in infection rates among sutured wounds irrigated with normal saline, 1% povidone-iodine, or pluronic F-68 (Shur-Cleans).^[11]

Tap water was recently found to be as effective for irrigating wounds as sterile saline. In fact, the infection rate was significantly lower after irrigation with tap water, and no infections resulted from the bacteria cultured from the tap water.^[2]

Improvised wound irrigation requires only a container that can be punctured to hold the water, such as a sandwich or garbage bag, and a safety pin or 18-gauge needle ([Box 19-3](#)).

Wound Closure

Before a wound is closed, remove all foreign material and grossly devitalized tissue. You can accomplish debridement

using scissors, a knife, or any other sharp object. Close wounds with sutures, staples, tape, pins, or glue. Although suturing is still the most widely used technique, stapling and gluing are ideal methods for closing wounds in the wilderness.

Box 19-4. WOUND TAPING TECHNIQUE

1. Obtain hemostasis and dry the wound edges.
2. Apply benzoin or cyanoacrylate glue to the skin adjacent to the wound. Benzoin should be left to dry until it becomes tacky, but the tape should be applied to the glue while the glue is still wet.
3. Tape should be cut to ¼-inch or ½-inch widths, depending on the size of the laceration, and to a length that allows for 2 to 3 cm of overlap on each side of the wound.
4. Secure one half of the tape to one side of the wound. Oppose the opposite wound edge with a finger while the tape is secured to the other side.
5. Wound tapes should have gaps of 2 to 3 mm between them to allow for serous drainage.
6. Cross-stays of tape can be placed perpendicular over the tape ends to prevent them from peeling off.
7. Additional glue can be applied to the tape edges every 24 hours to reinforce adhesion.

Clinical studies of the use of staples to close traumatic lacerations have found various advantages of stapling over suturing: wound tensile strength is greater, there is less inflammation, the time required for closure is shorter, and fewer instruments are needed.^[24] Most important, the cosmetic outcome is not compromised.^[13] Staplers are lightweight, presterilized, and easy to use.

Wound Taping.

Skin tapes are useful for shallow, non-gaping wounds and have several advantages over suturing, including reduced need for anesthesia, ease of application, decreased incidence of wound infection, and availability. Any strong tape can be used to improvise skin tape strips, but duct tape works especially well ([Box 19-4](#)). Puncturing holes in the tape before application helps prevent exudate from building up under the tape.

Wipe the skin with a solvent such as acetone first to remove oil and sweat. Then apply benzoin to the skin before the tape to augment adhesion. Wound taping does not work well over joints or on hairy skin surfaces unless the hair is first removed.

Hair-Tying a Scalp Laceration.

If you are faced with a bleeding scalp laceration and the injured person has a healthy head of hair, you can tie the wound closed using the victim's own hair and a piece of suture (0-silk

Figure 19-39 Scalp laceration closed using dental floss. (From Auerbach PS, Donner HJ, Weiss EA: *Field guide to wilderness medicine*, St Louis, 1999, Mosby.)

works best), dental floss, sewing thread or thin string. Take the material and lay it on top of and parallel to the wound. Twirl a few strands of hair on each side of the wound and then cross them over the wound in opposite directions so that the force pulls the wound edges together. Have an assistant tie the strands of hair together with the material while you hold the wound closed with the strands of hair. A square knot works best ([Figure 19-39](#)). Repeat this technique as many times as necessary, along the length of the wound, to close the laceration.

Gluing.

The concept of gluing wounds is not new; the U.S. Army used a quick-sealing glue to treat battlefield wounds in Vietnam, and Histoacryl (butyl-2-cyanoacrylate) tissue adhesive has been used in Europe and Canada for sutureless skin closure for more than a decade.^[31]

The U.S. Food and Drug Administration (FDA) has recently approved a topical skin adhesive to repair skin lacerations. Dermabond (2-octyl cyanoacrylate) is packaged in a small single-use applicator and costs about \$30 per tube. Tissue glue is ideal for

backcountry use because it precludes the need for topical anesthesia, is

487

easy to use, reduces the risk of needle stick injury, and takes up much less room than a conventional suture kit. When applied to the skin surface, tissue glue provides strong tissue support and peels off in 4 to 5 days without leaving evidence of its presence.^[23] It provides a faster and less painful method for closing lacerations than does suturing and has yielded similar cosmetic results in children with facial lacerations ([Box 19-5](#)).^[22] Tissue glue evokes a mild acute inflammatory reaction with no tissue necrosis.^[30]

Box 19-5. TECHNIQUE FOR GLUING LACERATIONS

1. Irrigate the wound with copious amounts of disinfected water.
2. Control any bleeding with direct pressure. Place a gauze pad moistened with oxymetazoline (Afrin) nasal spray into the wound to help control bleeding.
3. Once hemostasis is obtained, approximate the wound edges using fingers or forceps.
4. Paint the tissue glue over the apposed wound edges using a very light brushing motion of the applicator tip. Avoid excess pressure of the applicator on the tissue because this could separate the skin edges, forcing glue into the wound. Apply multiple thin layers (at least three), allowing the glue to dry between each application (about 2 minutes).
5. Glue can be removed from unwanted surfaces with acetone, or loosened from skin with petrolatum jelly.

Dermabond has 4 times the three-dimensional breaking strength of Histoacryl and forms a more flexible bond, thus providing a stronger and longer bond than its European counterpart. Petroleum-based ointments and salves, including antibiotic ointments, should not be used on the wound after gluing, since these substances can weaken the

polymerized film and cause wound dehiscence.

Tissue glue has also been used successfully to treat superficial painful fissures of the fingertips ("polar hands"), which commonly occur in cold climates and at high elevations.^[9]

RING REMOVAL

Remove rings quickly from injured fingers and after any trauma to the hands. Progressive swelling may cause rings to act as tourniquets. If a ring cannot be removed with soap or lubricating jelly, the string wrap technique can be used. Pass a 20-inch length of fine string, dental floss, umbilical tape, or thick suture between the ring and the finger. Pull the string so that

Figure 19-40 String technique for removing a ring from a swollen finger.

most of it is on the distal side of the digit and then wrap it around the swollen finger from proximal to distal, beginning next to the ring and continuing past the proximal interphalangeal joint. Place successive loops of the wrap close enough together to prevent any swollen skin from bulging between the strands. Remove the ring by unwinding the proximal end of the string and forcing the ring over the distal string. If the string is not long enough, the technique may require repeated wraps ([Figure 19-40](#)).

IMPROVISATIONAL TOOLKIT

Some people, convinced they could whittle a SwanGanz catheter from a tree branch, enter the wilderness with nothing more than a Swiss Army knife. However, a little foresight and preparation make improvisation much easier. Efficiency translates into speedy preparation and assembly, which ultimately results in better care. The following section lists items that facilitate improvisation in the field.

488

Knife

The knife can be a fairly simple model, but it should have an awl for drilling holes into skis, poles, sticks, and so on. The awl on a Swiss Army knife works quite well for this purpose. This allows you to create well-fitted components during improvisation (e.g., a drilled cross-bar attached to ski tips for an improvised rescue toboggan).

Tape

Carry some form of strong, sticky, waterproof tape. (This item *cannot* be improvised.) Use either cloth adhesive tape (already in the medical kit) or duct tape. Duct tape is ideal for almost all tasks, even being useful on skin when needed (e.g., to close wounds, treat blisters, or tape an ankle). Some persons may be sensitive to the adhesive. Fiberglass strapping tape has greater tensile strength and is ideal for joining rigid components, such as taping two ice axes together. However, it is less sticky than duct tape and not as useful for patching torn items. Extra tape can be carried by wrapping lengths of it around pieces of gear.

Plastic Cable Ties

Lightweight cable ties can be used to bind almost anything together (for example, binding pack frames together for improvised litters or ski poles together for improvised carriers). They are also perfect for repairing many items in the backcountry.

Parachute Cord

Parachute cord has hundreds of uses in the backcountry. It can be used for trucker's hitch traction and for tying complex splints together. Parachute cord is light; carry a

good supply.

Safety Pins

Safety pins have various uses ([Box 19-6](#)).

Wire

Braided picture-hanging wire works well because it is supple and ties like line. Its strength makes it superior for repairing and improvising components under an extreme load, such as fabricating improvised rescue sleds or repairing broken or detached ski bindings.

Bolts and Wing Nuts

Bolts and wing nuts make the job of constructing an improvised rescue sled much easier (see Improvised Rescue Sled or Toboggan section). Bolts are useful only if holes can be created to put them through. Therefore a knife with an awl is needed for drilling holes through skis, poles, and so on.

Prefabricated Cross-Bar

The prefabricated cross-bar can be used for double ski pole traction splint systems. A cross-bar is easily fabricated from a branch or short section of a ski pole, but carrying a prefabricated device, such as a 6-inch predrilled ski pole section, saves time (see [Figure 19-22](#)).

Box 19-6. USES OF A SAFETY PIN

Using two safety pins to pin the anterior aspect of the tongue to the lower lip to establish an airway in an unconscious victim whose airway is obstructed

Replacing the lost screw in a pair of eyeglasses to prevent the lens from falling out

Improvising glasses: Draw two circles in a piece of duct tape where your eyes would fit. Use the pin to make holes in the circles, then tape this to your face. The pinholes will partially correct myopic vision and protect the eyes from ultraviolet radiation. Slits can also be used for improvised sunglasses.

Neurosensory skin testing

Puncturing plastic bags for irrigation of wounds

Removing embedded foreign bodies from the skin

Draining an abscess or blister

Relieving a subungual hematoma

As a fishhook

As a finger splint (mallet finger)

As a sewing needle, using dental floss as thread

Holding gaping wounds together

Replacing a broken clothing zipper

Holding gloves or mittens to a coat sleeve

Unclogging jets in a camping stove

Replacing a broken clothing zipper
Holding gloves or mittens to a coat sleeve

Unclogging jets in a camping stove

Pinning triage notes to multiple victims

Removing a corneal foreign body (with ophthalmic anesthetic)

In a sling and swath for shoulder or arm injuries

To fix a ski binding

To extract the clot from a thrombosed hemorrhoid

To pin a strap or shirt tightly around the chest for rib fracture support

Tick removal

Ensolite (Closed-Cell Foam) Pads

Since the introduction of Therm-a-Rest types of inflatable pads, closed-cell foam has become increasingly scarce; however, closed-cell foam (Ensolite) is still the ultimate padding for almost any improvised splint or rescue device. The uses for closed-cell foam are virtually unlimited. Even die-hard Therm-a-Rest fans should carry a small amount of closed-cell foam, which is lightweight and doubles as a comfortable seat cushion. Furthermore, unlike inflatable pads, Ensolite will not puncture and deflate.

Therm-a-Rest pads also have their place, being useful for padding for long bone splints and immobilizers (e.g., an improvised universal knee immobilizer). An inflatable pad can also be used to cushion pelvic fractures. First, wrap the deflated pad around the pelvis.

Then secure the pad with tape and inflate it, creating an improvised substitute for military antishock trousers (MAST device).

Fluorescent Surveyor's Tape

Surveyor's tape can be used much like Hansel and Gretel's bread crumbs to help relocate a route into or out of a rescue scene. It is also ideal for marking shelters in deep snow and can serve as a wind sock during helicopter operations on improvised landing zones. Surveyor's tape is not biodegradable, so it should always be removed

from the site after the rescue is completed.

Space Blanket or Lightweight Tarp

For improvising hasty shelters in times of emergency, some form of tarp is essential. In the snow a slit trench shelter can be built in a matter of minutes using a tarp. Otherwise, the complex and time-consuming construction of improvised structures such as snow caves, igloos, or tree branch shelters might be necessary. Typically, little time or help is available for this task during emergencies. In addition, tarps are essential for "hypothermia wraps" when managing injured persons in cold or wet conditions. The only advantage of a space blanket over other tarps is its small size, which means there is a good chance it was packed for the trip.

IMPROVISED EYEGLASSES

Exposure of unprotected eyes to ultraviolet radiation at high altitudes may produce photokeratitis (snow blindness). Symptoms are delayed, and the victim is often unaware that an eye injury is developing. When sunglasses are lost at 4267 m (14,000 feet) in the snow, photokeratitis can develop in 20 minutes. You can improvise sunglasses from duct tape, cardboard, or other light-impermeable material that can be cut. Cardboard glasses with narrow eye slits can be taped over the eyes for protection.

Slits can also be cut into a piece of duct tape that has been folded over on itself with the sticky sides opposing. After a triangular wedge is removed for the nose, apply another piece of tape to secure the glasses to the head.

Pinhole tape glasses can improve vision in a myopic person whose corrective lenses have been lost. With myopia, parallel light rays from distant objects focus in front of the retina. The pinhole directs entering light to the center of the cornea, where refraction (bending of the light) is unnecessary. Light remains in focus regardless of the refractive error of the eye ([Figure 19-41](#)). Pinhole glasses decrease both illumination and field of vision, so puncture a piece of duct tape or cardboard repeatedly with a safety pin, needle, fork, or other sharp object until enough light can enter to focus on distant objects. Secure the device to the face.

Figure 19-41 Pinhole in cardboard to improve vision in person with myopia.

IMPROVISED TRANSPORT

Carries

Two-Hand Seat.

Two carriers stand side by side. Each carrier grasps the other carrier's wrists with opposite hands (for example, right to left). The victim sits on the rescuers' joined forearms. The carriers each maintain one free hand to place behind the back of the victim for support (support hands can be joined). This system places great stress on the carriers' forearms and wrists.

Four-Hand Seat.

Two carriers stand side by side. Each carrier grasps his or her own right forearm with the left hand, palms facing down. Each carrier then grasps the forearm of the other with his or her free hand to form a square "forearm" seat. With the forearm seat, the victim must support himself or herself with a hand around the rescuers' backs.

*Both the two-hand seat and the four-hand seat are useful only for very short carries over gentle terrain.

490

Figure 19-42 Ski pole seat. **A**, Ski poles are anchored by the packs. **B**, The victim is supported by the rescuers.

Ski Pole or Ice Ax Carry.

Two carriers with backpacks stand side by side with four ski poles or joined ice ax shafts, resting between them and the base of the pack straps ([Figure 19-42](#)). The ski poles or ice ax shafts can be joined with cable ties, adhesive tape, duct tape, wire, or

cord. Because the rescuers must walk side by side, this technique requires wide-open, gentle terrain. The victim sits on the padded poles or shaft with his or her arms over the carriers' shoulders.

Split-Coil Seat ("Tragsitz").

The split-coil seat transport uses a coiled climbing rope to join the rescuer and victim together in a piggyback fashion ([Figure 19-43](#)). The victim must be able to support himself or herself to avoid falling back, or must be tied in.

Two-Rescuer Split-Coil Seat.

The two-rescuer split-coil seat is essentially the same as the split-coil Tragsitz transport, except that two rescuers split the coil over their shoulders. The victim sits on the low point of the rope between the rescuers ([Figure 19-44](#)). Each rescuer maintains a free hand to help support the victim.

Backpack Carry.

A large backpack is modified by cutting leg holes at the base. The victim sits in it like a baby carrier. Some large internal frame packs incorporate a sleeping bag compartment in the lower portion of the pack that includes a compression panel. With this style of pack, the victim can sit on the suspended panel and place his or her legs through the unzipped lower section without damaging the pack, or the victim can simply sit on the internal sleeping bag compression panel without the need to cut holes.

Nylon Webbing Carry.

Nylon webbing can be used to attach the victim to the rescuer like a backpack ([Figure 19-45](#)). At least 4.6 to 6.1 m (15 to 20 feet) of nylon webbing is needed to construct this transport. The center of the webbing is placed behind the victim and brought forward under the armpits. The webbing is then crossed and brought over the rescuer's shoulders, then down around the victim's thighs. The webbing is finally brought forward and tied around the rescuer's waist. Additional padding is needed for this system, especially around the posterior thighs of the victim.

Three-Person Wheelbarrow Carry.

This system is extremely efficient and can be used for prolonged periods on relatively rough terrain. The victim places his or her arms over two rescuers' shoulders (the rescuers stand side by side). The victim's legs are then placed over a third rescuer's shoulders. This system equalizes the weight of the victim very efficiently.

Litters (Nonrigid)

Many nonrigid litter systems have been developed over the years. These systems are

best suited for transporting non-critically injured victims over moderate terrain. They should *never* be used for trauma victims with potential spine injuries.

Blanket Litter.

A simple nonrigid litter can be fabricated from two rigid poles, branches, or skis and a large blanket or tarp. The blanket or tarp is wrapped around the skis or poles as many times as possible and the poles are carried. The blanket or tarp should not be simply draped over the poles. For easier carrying, the poles can be rigged to the base of backpacks. Large external frame packs work best, but internal frame packs can be rigged to do the job. Alternatively, a padded harness to support the litter can be made from a single piece of webbing, in a design similar to a nylon webbing carry.

Tree Pole Litter.

The tree pole litter is similar to the blanket litter described previously. In the tree pole litter,

491

Figure 19-43 Split-coil seat. **A**, Rope coil is split. **B**, Victim climbs through rope. **C**, Rescuer hoists the sitting victim.

instead of a blanket or a tarp, the side poles are laced together with webbing or rope and then padded. Again, the poles may be fitted through pack frames to aid carrying. To give this litter more stability and to add tension to the lacing, the rescuer should fabricate a rectangle with rigid cross-bars at both ends before lacing.

Parka Litter.

Two or more parkas can be used to form a litter ([Figure 19-46](#)). Skis or branches are slipped through the sleeves of heavy parkas, and the parkas are zipped shut with the sleeves inside. Ski edges should be taped first to prevent them from tearing through the parkas.

Internal Frame Pack Litter.

The internal frame pack litter is constructed from two to three full-size internal frame backpacks, which must have lateral compression straps (day packs are suboptimal). Slide poles or skis through the compression straps; the packs then act as a support surface for the victim.

Life Jacket Litter.

Life jackets can be placed over paddles or oars to create a makeshift nonrigid litter.

Rope Litter.

On mountaineering trips the classic rope litter can be used, but this system offers little back support and should never be used for victims with suspected spine injuries. The rope is uncoiled and staked onto the ground with 16 180-degree bends (eight on each side of the rope center). The rope bends should approximate the size of the finished litter. The free rope ends are then used to clove hitch off each bend (leaving 2 inches of bend to the outside of each clove hitch). The

Figure 19-44 Two-rescuer split-coil seat. Balance could be improved by using a longer coil to carry the victim lower.

Figure 19-45 Webbing carry. Webbing crisscrosses in front of the victim's chest before passing over the shoulders of the rescuer.

Figure 19-46 Parka litter. On the right the sleeves are zipped inside to reinforce the litter.

493

Figure 19-47 Rope litter.

leftover rope is threaded through the loops at the outside of each clove hitch. This gives the rescuers a continuous handhold and protects the bends from slipping through the clove hitches. The rope ends are then tied off ([Figure 19-47](#)). The litter is padded with packs, Therm-a-Rest pads, or foam pads. This improvised litter is somewhat ungainly and requires six or more rescuers for an evacuation of any distance. A rope litter can be tied to poles or skis to add lateral stability if needed.

Improvised Rescue Sled or Toboggan

A sled or toboggan can be constructed from one or more pairs of skis and poles that are lashed, wired, or screwed together. Many designs are possible. Improvised rescue sleds may be clumsy and often bog down hopelessly in deep snow. Nonetheless, they can be useful for transporting a victim over short distances (to a more sheltered camp or to a more appropriate landing zone). They have sometimes been used for more extensive transports, but they do not perform as well as commercial rescue sleds.

To build an improvised rescue sled/toboggan, the rescuer needs a pair of skis (preferably the victim's) and two pairs of ski poles; three 2-foot-long sticks (or ski pole sections); 24.4 m (80 feet) of nylon cord; and extra lengths of rope for sled hauling.

The skis are placed 0.6 m (2 feet) apart. The first stick is used as the front cross-bar and is lashed to the ski tips. Alternately, holes can be drilled into the stick and ski tips with an awl, and bolts can be used to fasten them together. The middle stick is lashed to the bindings. One pair of ski poles is placed over the cross-bars (baskets over the ski tips) and lashed down. The second set of poles is lashed to the middle stick with baskets facing back toward the tails. A third rear stick is placed on the tails of the skis and lashed to the poles. The lashings are not wrapped around the skis; the cross-bar simply sits on the tails of the skis under the weight of the victim. Nylon cord is then woven back and forth across the horizontal ski poles. The hauling ropes are passed through the baskets on the front of the sled. The ropes are then brought around the

middle cross-bar and back to the front cross-bar. This rigging system reverses the direction of pull on the front cross-bar, making it less likely to slip off the ski tips.^[29]

Another sled design incorporates a predrilled snow shovel incorporated into the front of the sled. A rigid backpack frame can also be used to reinforce the sled. This requires drilling holes into the ski tips and carrying a predrilled shovel. This system holds the skis in a wedge position and may offer slightly greater durability.^[25]

A FINAL NOTE

Under certain conditions, improvised systems are entirely *suboptimal* and may not meet standard of care criteria. It would, for example, be ill advised to fabricate a litter for transporting a victim with a suspected spine injury when professional rescue is only a few miles away. An improvised litter system might be entirely appropriate, however, if the injured person is 40 miles out and needs transport to a sheltered camp or potential helicopter landing zone. The context of the situation should be considered. At times, persons are obligated to do whatever they can, and a resourceful approach to problem solving combined with a little ingenuity could save a victim's life.

Chapter 20 - Hunting and Other Weapons Injuries

Edward J. Otten

Even as Nimrod the mighty hunter before the Lord.
Genesis 10:9

Anthropologists have many theories concerning the origins and importance of hunting in the evolution of the human species. The physical attributes of bipedal locomotion, binocular vision, and an opposable thumb all make humans more efficient hunters. Whether these exist because humans have an innate compulsion to hunt or whether humans are hunters because of these traits is debatable. There is no debate, however, that human social evolution, language, the use of tools, and domestication of animals are directly related to more efficient hunting. In a survival situation, and in some ways with regard to evolution, hunter-gatherer animals have a distinct advantage over strictly vegetarian animals because of the relative food value of meat over plants. Hunters tend to be males. Approximately three fourths of all calories in modern hunter-gatherer groups are derived from plants, and this portion of the food is usually supplied by the women in the group. Even in Eskimo tribes where plants make up little of the diet, the women do most of the fishing while the men hunt.

Hominids were at a disadvantage, even in groups, when hunting large animals or driving off other predators from their kills until they began using stones, long bones, and sticks to enhance their relatively weak teeth and claws. Implements for hunting and skinning animals were the earliest tools found by anthropologists. Human cultural evolution followed closely the technologic changes in weapons, although sports, business, and war had replaced the need for hunting in most cultures even by the time Nimrod walked the earth. Bows and arrows, slings, spear throwers, nets, harpoons, traps, and firearms were designed to extend the reach and increase the lethality of the human hand. Unfortunately, humans discovered that they could kill each other with these weapons. Since the discovery of gunpowder, the development of weapons technology has surpassed all other forms of human endeavor, including medicine and transportation.^[6]

[7]

HUNTING IN THE UNITED STATES

Only a few cultures still depend on hunting as their primary food-gathering method. Examples are the Mbuti tribe, Andaman Islanders, and Eskimos. Many cultures, however, use hunting to supplement agriculture, plant gathering, or raising livestock. Most hunting in the United States is done for sport or pleasure, although in some areas of the country hunting and trapping are still the primary source of income for a few people. The total number of hunters and trappers is unknown. Many participate illegally and are not licensed. Throughout the United States, 30 million hunting licenses were sold in 1988. Although hunting seasons are regulated and relatively short, hunters spent 16 million visitor-days in the national forests.

The North American Association of Hunter Safety Coordinators, a division of the New York State Office of Wildlife Management, reported 860 fatal hunting injuries during the 4-year period 1983–1986, with a total of 6992 injuries from firearms. Interestingly, 34% of the total injuries and 89% of the handgun injuries were self-inflicted. Shotguns accounted for 106 of the fatalities and 906 of the total injuries, whereas rifles accounted for 79 fatalities and 465 injuries. Hunting injuries are only a small portion of the total number of unintentional firearm deaths in California from 1977 to 1983, only eight were the result of hunting accidents.* Hunting injury data may be inaccurate for a number of reasons. Many minor nonfatal injuries may go unreported, and most states do not differentiate accidental firearm hunting deaths from deaths that occur during any other activity. Also, automobile and all-terrain vehicle accidents that occur while hunting, or gunshot wounds inflicted while "cleaning a gun" at home, could be considered nonhunting injuries.

Types of Injuries Encountered

Most injuries to hunters are the same types of injury seen in backpackers, fishermen, and climbers. Frostbite, sprains, burns, and fractures occur with the same frequency in hunters as in others who visit wilderness areas.

A common type of injury in hunters that is not associated with weapons is the tree stand injury. Tree stands are platforms designed to hold hunters several feet off the ground so that they can more easily kill large game. Whether homemade or of commercial design, the platforms generally are small and attached to the trunks of trees, with some method, usually a ladder or steps, for

*References [8] [10] [22] [29] [36] [40]

Figure 20-1 The wrong way to use a tree stand. This hunter is not wearing a safety harness, is drinking alcohol, and is pulling his firearm into the tree stand with the muzzle pointing upward.

climbing the tree ([Figure 20-1](#) and [Figure 20-2](#)). Hunters often fall asleep in the platforms and fall off, or fall while climbing up or down trees. At least half of these injuries could be prevented if all hunters wore tree stand safety harnesses. Although most of the injuries are similar to those seen with any type of fall, occasionally a hunter drops a firearm, which discharges, or falls on an arrow or rifle, causing an additional weapons injury ([Figure 20-3](#)). Over 10 years, injuries of this type in Georgia accounted for 36% of reported hunting injuries and 20% of hunting fatalities.^{[35] [37]}

Injuries that are unique to hunters are those caused by their weapons. Most hunting is done with firearms. Shotguns and rifles are more commonly used, although handguns are increasing in popularity. Other types of weapon include the bow or crossbow and arrow. These are popular because an extended hunting season is allowed in several states if this type of "primitive" weapon is used. The rationale is that these weapons are less dangerous to innocent bystanders at long range compared with rifles and shotguns, and that more skill is needed to hunt with this type of weapon.

Other weapons are used for hunting but are less likely to be encountered. For example, spears, harpoons,

Figure 20-2 A commercially produced tree stand can be used to climb the tree and obviates the need for a ladder or steps, which are the cause of many falls.

and nets are used by some hunters in the Arctic, Australia, and Africa. Trap injuries may be included in the definition of hunting injuries. Most traps are designed to catch and hold small game. Injuries usually occur when a trapper triggers a spring-loaded trap prematurely. Crush injuries and puncture wounds to the hands are most common.

Hikers occasionally tread on unmarked traps, and domestic animals such as dogs are accidentally caught in poachers' traps. Another problem with traps occurs when an animal (wild or domestic) is caught in a trap and attacks the trapper while being released. Many knife lacerations occur when hunters clean game. Lack of familiarity with the process or techniques for field dressing and cleaning game is the likely cause. Failing to wear protective gloves; using the wrong type of knife; working with bloody, slippery material; and having cold hands all contribute to accidents.

Arrow Injuries.

Modern arrows are usually made from aluminum, graphite, or fiberglass, although many beginners still use inexpensive wooden arrows. A number of types of arrowhead are in use,

497

Figure 20-3 The correct way to bring a firearm into the tree stand, with the muzzle pointing down and the hunter wearing a safety harness at all times.

such as field points and target points, but most injuries are due to broadheads. These come in a variety of sizes and shapes and are designed to inflict injury by lacerating tissue and blood vessels, thereby causing bleeding and shock. Unlike firearms, which are designed to kill quickly by tearing tissue and transferring large amounts of energy, arrows usually kill more slowly with less tissue damage ([Figure 20-4](#)).^[4] ^[19] Arrows are propelled by a conventional bow, which may be straight, recurved, or compound, or by a crossbow. The force used to propel the arrow is usually measured in "draw weight," which is the number of foot-pounds necessary to draw a 28-inch arrow to its full length. The higher the pound draw, the more powerful the bow and the deeper the penetration the same type of arrow will have. Arrows have a much shorter range than bullets and must be more accurately placed to kill the animal quickly; therefore most shots are taken under 50 m (164 feet). Because brush and tree branches can easily deflect an arrow, most shots are taken with a clear field of view. For these reasons, target identification is usually not a problem and a bow hunter is less likely to shoot another hunter. Most arrow injuries occur when hunters fire illegally at night in heavy brush and are not

Figure 20-4 Types of arrows. *Top*, Aluminum shaft arrow with hunting broadhead. *Middle (left to right)*, Four field points of various weights: two types of broadheads and small game blunt hunting head with spring claws to prevent arrow loss from burrowing into the ground. *Bottom*, Fiberglass shaft for interchangeable heads.

sure of their target. Another common injury occurs when a hunter runs after a wounded animal and falls on an arrow that was to be used for a second shot or falls out of a tree stand onto an arrow. A loaded cross-bow is similar to a loaded gun. Hunters have been accidentally shot when dropping the weapon or snagging the trigger on a branch or fence. Hunting arrowheads are quite sharp; injuries commonly occur when a hunter is sharpening the blade of the arrow or returning an arrow to the quiver.

Injuries from Firearms.

Firearms discharge a projectile by using air, modern fast-burning powders, or old-fashioned black powder. Air guns use a spring or carbon dioxide cartridge to push the projectile from the barrel. Although air guns are quite accurate at short distances, the projectiles cannot usually penetrate skin from distances greater than 100 m (328 feet). Air guns are commonly used by children, who cannot legally obtain or use other types of firearms. Well-meaning parents buy them as toys, erroneously believing them to be safe. The wounds they cause can be lethal, especially from the spring-propelled guns, which can send out lead pellets at sufficiently high velocities to penetrate bone. Black powder weapons use a solid propellant that is ignited with a spark from flint striking steel or a percussion cap. When ignited, the propellant is rapidly converted to a gas that expands and pushes a lead ball out of the barrel of the weapon. These weapons are quite accurate and are used to hunt large game, such as deer and elk. The injuries from black powder weapons are similar to those from modern weapons and are discussed below. The same precautions should be used when hunting with or shooting any type of firearm, whether the propellant is air or gunpowder.^{[24] [28] [39]}

The powder (propellant) in weapons that use modern gunpowder is encased in a brass or aluminum shell for rifles and handguns and in a plastic or paper shell for shotguns. Shells are open on one end for the actual projectiles to be inserted, and in the case of shotgun

shells, plastic or cotton wadding is used to keep the projectiles from moving around inside the shells. The powder is detonated from the opposite end by an explosive primer that is in either the rim of the shell, as with the .22 caliber long rifle cartridge, or the middle of the shell, as with the 12-gauge shotgun shell or 30/30 rifle cartridge. Detonation occurs when the firing pin on the weapon strikes the primer, igniting the powder. Upon detonation the powder produces a rapidly expanding gas that pushes the projectile (and wadding) out of the barrel of the weapon. Not all of the powder is burned,

so that in case of close-proximity wounds, powder stippling may appear on clothing or skin. With contact wounds the escaping gases may cause bursting of the skin and a stellate laceration near the point of entrance. The projectile may vary in size and shape from 1 mm in circumference and a few milligrams in weight to 2 cm in circumference and 100 g in weight. The projectiles are usually made of lead or steel and may be covered with a copper jacket. They are usually single when shot from a rifle or pistol and multiple when fired from a shotgun, although some hunters prefer large single (deer slug) rounds fired from shotguns.

Hundreds of types of bullets or rounds are available for firearms. They may be factory loaded or hand loaded, which adds the variables of propellant amount and type. Small arms are classified according to caliber, which is expressed in fractions of an inch; for example, .22 caliber means the diameter of the bullet is 0.22 inch; .45 caliber is 0.45 inch; and so forth. The caliber may be expressed in metric measurement; for example, a 9 mm bullet is 9 mm in diameter, which also happens to be 0.357 inch. This system can be made more complicated when considering the amount of powder used, the year the bullet was adopted, or the name of the person who first introduced the round. Examples of these types are .45/70 (70 grains of powder), .30-06 (adopted in 1906), and .35 Whelen (the man who developed the round). Shotgun terminology is a little less complicated, based on the number of lead balls, the diameter of the barrel, and how many lead balls it takes to make a pound. For example, a 12-gauge shotgun has a barrel that is the same diameter as a lead ball that weighs 1/12 pound, a 20-gauge, 1/20 pound. The higher the gauge, the smaller the barrel and the smaller the round. The only exception is the .410 shotgun, which is caliber .410 or 0.410 inch in diameter. The recent introduction of the term "magnum" refers more to the type and amount of powder than to the size of the bullet used ([Figure 20-5](#) and [Figure 20-6](#)).

The type and severity of wounds inflicted by a firearm depend on several factors. The most often quoted factor, but the least important, is the amount of energy the bullet (projectile) has when leaving the firearm. The kinetic energy formula, $KE = \frac{1}{2} MV^2$, can be applied to any moving object or to calculate the

Figure 20-5 Examples of hunting bullets. *Left to right*, .50 caliber black powder lead bullet, .22 caliber lead bullet, .22 caliber long rifle lead bullet, .44 magnum semijacketed hollowpoint bullet, .44 magnum shot-shell, .223 caliber (5.56 mm) full metal jacket bullet, .22/250 caliber semijacketed soft point bullet, .30/30 caliber soft point flat nose bullet, .270 caliber pointed soft point bullet, and .30-06 caliber round nose soft point bullet.

Figure 20-6 Examples of shotgun rounds. *Left to right*, 12-gauge slug round, empty 12-gauge plastic round, plastic 12-gauge wadding, and number six shotgun pellets.

muzzle energy for a particular type of firearm. Energy increases much more as a function of the velocity of the bullet than as a function of the mass. For this reason, most firearms are classified according to muzzle velocity. The higher the velocity of the bullet, the greater the energy and the greater the potential for injury. Firearms with muzzle velocities greater than 2500 feet/sec are considered high velocity, 1500 to 2500 feet/sec medium velocity, and less than 1500 feet/sec low velocity ([Table 20-1](#)). Bullets cause damage to tissue by crushing. The energy of a bullet may be transmitted to the tissue in part or in total depending on the surface area the bullet presents to the tissue. Bullets that strike at an angle, yaw, mushroom, or fragment present more surface area than do bullets that stay in one axis and maintain one shape. Hunting bullets are designed to manipulate shape and composition to maximize surface area. By the Geneva Convention, military bullets must have a full metal jacket and be less than .50 caliber. This is designed

TABLE 20-1 -- Comparison of Bullet Caliber, Weight, Velocity, and Muzzle Energy

CALIBER	WEIGHT (g)	MUZZLE VELOCITY (feet/sec)	MUZZLE ENERGY (foot-pounds)
.22	40	1080	90
.223	55	3250	1280
.44 magnum	180	1600	1045
.30/60	150	2750	2500

to minimize surface area. However, most military rounds travel at such high velocities (greater than 2700 feet/sec) that fragmentation reliably occurs even with full metal jackets. Fragmentation may also occur when a bullet strikes bone and sends splinters in several directions. The bone fragments cause injuries within the body similar to those from bullet fragments and may even exit the body to injure bystanders. Another phenomenon is temporary cavitation, which occurs at all velocities to some degree but becomes a factor only at high velocities. A permanent cavity occurs when a bullet or fragment crushes tissue. The bullet also creates a radial dispersion wave as a result of acceleration of tissue away from its path, which creates a temporary cavity. This wave is well tolerated by most elastic tissue, such as muscle, bowel, and lung; however, inelastic tissues, such as liver or brain, do not tolerate it and may be severely damaged by the temporary cavity. In high-velocity bullet wounds the temporary cavity may be

several times larger than the permanent cavity. The total effect of high energy, fragmentation, mushrooming, yaw, and temporary cavity formation injures tissue. Although the kinetic energy formula cannot be denied, the other factors are probably more important to injury production. The type of tissue struck is the most important factor. As can be seen from [Table 20-1](#), the .22 caliber long rifle bullet has a low mass and velocity and thus a low muzzle energy, yet more fatalities have occurred from this round than from any other. It is very inexpensive, can be fired from a number of rifles and handguns, is commonly used to hunt game, and is not thought of as particularly dangerous by inexperienced hunters. For these reasons, most people are shot by this round. The bullet is highly lethal when striking the brain, the heart, or a major blood vessel.

Other rare problems associated with firearms are explosions that occur within the firearm itself. These can cause burns or fragment types of injuries. When firearms are loaded with excessive amounts of powder or the wrong powder is used in reloading bullets, the resultant detonation may cause the frame or cylinder of the firearm to explode. The burning powder or fragments of metal can cause injuries to the shooter. These injuries usually occur to the face and hands; penetrating eye injuries are also common. Obstruction of the barrel of the firearm by snow, mud, or other foreign material may cause a similar explosion.

Trap Injuries.

Traps are designed to either kill animals or to capture them alive and uninjured. The latter type poses no risk to humans unless they should happen upon a trap and attempt to free the animal or otherwise approach the trap. The trapped animal will often bite or claw anyone within range. Leg hold traps designed to kill or injure an animal may occasionally cause problems for unwary hikers or campers. These traps have a spring-loaded jaw that closes when triggered by touching a trigger plate usually only involving 1 to 2 pounds of pressure. Most injuries involve the foot, but any area of the body that can fit between the jaws can potentially be injured. The jaws can be released by compressing the spring controlling the jaws ([Figure 20-7](#)). Very large traps used to trap poachers or to catch large animals, such as tigers or bears, cannot easily be released without help. These traps may also be attached to large weights, such as logs or concrete blocks, to prevent escape. Fortunately, most of these large traps are now collector's items and not used in the field. Nonconventional traps, such as snares, deadfalls, and pit traps, may rarely be encountered, but the mechanisms and types of injuries are quite variable. Trap guns are illegal in most areas of the world; injuries are similar to gunshot wounds.

Unexploded Ordnance.

There are many areas in the world where unexploded ordnance can be found. This may include aerial bombs, rockets, artillery and mortar shells, grenades, and mines. Any area of the planet where a war has been fought in this century has potential for harboring these items. Crews excavating streets in urban areas of England, France, and Germany often uncover unexploded ordnance from World War I or World War II. Many areas of the United States that have been used for bombing or artillery ranges are

adjacent to wilderness regions and, although they are usually well marked as impact areas, still pose a risk for the unwary traveler. Many areas of the shallow ocean accessible to scuba divers have sunken munition transports and warships that contain massive amounts of unexploded bombs, shells, and torpedoes. Another problem that has arisen is the use of mines and booby traps to protect marijuana and opium fields and illegal drug laboratories throughout the world.

Currently, unexploded land mines represent a significant health problem in Southeast Asia, the Balkans, Central America, Egypt, Iran, and Afghanistan. The International Red Cross estimates that someone is killed

or injured by a land mine every 22 minutes. The average number of mines deployed per square mile in Bosnia is 152, in Iran 142, in Croatia 92, and in Egypt 59. There are a total of 23 million mines in Egypt alone. Land mines may be commercially manufactured or produced locally from available materials ([Figure 20-8](#)). Commercial, currently produced United States land mines have a limited active life and self-destruct after their active life has expired. Unfortunately, this is not true of older types of mines or mines produced by other countries. Locally produced mines have no standard size, shape, or detonation pattern and may be very difficult to detect and defuse. These types of land mines are used extensively in El Salvador, Malaysia, and Guatemala. Land mines have two primary functions, the first of which is to cause casualties; these are so-called antipersonnel mines. These may be blast or fragmentation type; the fragmentation type may be either directional or nondirectional ([Figure 20-9](#)). These may cause lethal or nonlethal injuries in several persons. Wounded soldiers require more care than killed soldiers do, and the tactical effect may be the same. The

501

Figure 20-8 An example of an antipersonnel mine manufactured by the Soviet Union.

Figure 20-9 Above, A directional type mine used against unarmored vehicles or personnel. Below, An improvised mine, or booby trap, manufactured from a hand grenade and materials at hand.

second primary function is to destroy vehicles, such as tanks, so these mines are usually much larger. All mines have three basic components: (1) a triggering device, (2) a detonator, and (3) a main explosive charge. The triggering device differs, depending on the type of mine. Blast mines usually involve pressure types of triggers and occasionally are command detonated, especially for antitank purposes. Many antitank mines will not explode unless a pressure of 300 to 400 pounds is applied. The M14 blast antipersonnel mine needs only 20 to 30 pounds of pressure to trigger the detonation. Fragmentation mines are usually triggered by trip wires or similar "touch" devices. The M18A1 fragmentation mine, or "claymore" mine, is designed to be command detonated by an electronic trigger. Booby traps other than land mines may be mechanical, chemical, or explosive. During the Vietnam War, venomous snakes were used, as well as the notorious sharpened bamboo spikes known as "punji" traps. The distribution of mines usually entails spreading them on the surface of the ground; by air along roads, railways, and defensive positions; or hiding them by burying or camouflage along trails or suspected routes of approach.

Injuries from land mines depend on several factors: type of mine (blast or fragmentation), position on the ground, method of detonation, whether it explodes above the ground, position of the victim, environment, and type of soil. Four general patterns of injuries occur with land mines. Pattern A injuries occur with small blast mines, such as the U.S. M14 and the Chinese Type 72. These injuries usually involve only the leg below the knee. Complete or partial foot amputations are most common, and trunk or head injuries are rare. Pattern B injuries are caused by larger blast mines, such as the Russian PMN. These mines contain 4 to 6 times as much high explosive material, and the cone of explosion is much larger. The injuries seen with this type of land mine usually involve massive soft tissue injuries to both legs below and above the knee and commonly the pelvis, abdomen, and chest. Pattern C injuries are generally caused by Russian PFM-1, or "butterfly," mines. These mines are usually distributed by air, and the

wings are designed to help spread the mines. They are triggered by pressure applied to the wings; handling the mine commonly does this. Most of the injuries involve amputation of the hand at the wrist, but often the head, neck, and chest are injured also. Unfortunately, the loss of one or both eyes is not uncommon with this mine. Pattern D injuries are caused by fragmentation mines. These may be bounding mines, such as the U.S. M16 or the Russian OZM, or directional mines, such as the U.S. M18A1 or the Russian MON. They are designed to spread metallic fragments over a wide area at the height of a person's waist. The fragments lose their energy much faster than a bullet projectile but at close range can be devastating. The lethal range is usually 25 to 50 m (82 to 164 feet), with casualties occurring out to 200 m (656 feet). The injuries are quite similar to gunshot wounds and are often multiple. Large, unexploded artillery shells or bombs may cause a combination of blast and fragment injuries but

on a larger scale, sometimes involving scores of victims.

The treatment of these injuries can be very complex and involve vascular, orthopedic, soft tissue, abdominal, and craniofacial procedures. The wounds are usually highly contaminated with soil, clothing, and fragments, so massive debridement is necessary. Rarely, unexploded ordnance may be imbedded in soft tissues and body cavities and must be removed in the operating room, possibly endangering the lives of medical personnel. Most victims who survive never completely regain normal function, especially if the initial treatment was delayed or inadequate. Postsurgical infection of mine injuries is common and greatly increases morbidity and mortality. Initial treatment involves airway control, treating tension pneumothorax, and controlling hemorrhage. Tourniquets are often necessary to control the bleeding from amputated limbs. Splinting the injured extremity and covering the wound to prevent further contamination is necessary. Initial debridement must be done carefully; removal of fragments may cause bleeding to recur. Penetrating injuries of the pelvis and abdomen usually require laparotomy, and soft tissue injuries may require multiple reconstructive procedures. Broad-spectrum antibiotics and tetanus prophylaxis are appropriate in all cases and fluid resuscitation usually indicated with extremity injuries.

Blast injuries without fragmentation may cause tympanic membrane rupture, blast lung resulting from alveolar rupture, and intestinal rupture, although the latter is more common with underwater mine explosions. The mechanism is production of an overpressure wave that travels through tissue of various density and causes tear injuries at membrane interfaces. These injuries must be suspected in any victim involved in a blast, whether from a land mine or other explosive device. Scuba divers and swimmers who are involved in underwater explosions may have more serious injuries because of the increased speed of sound in a liquid medium. This can cause more severe tearing of membranes at the fluid-air interface and additional trauma secondary to a "water hammer" effect and spalling. The position of the victim and the number of shock waves caused by reflection of the blast wave off of walls and ground may increase the amount of damage. Victims in contact with solid objects, such as the hull of a ship or vehicle, may have increased injuries because of increased velocity of

the blast wave through solids. Burns and translational injuries, whereby the victim is thrown by the blast and has injuries similar to a fall or motor vehicle crash, also occur.

Generally speaking, the closer the victim is to the blast, the greater the injury. The tympanic membrane will rupture at overpressures of 5 psi. This causes acute hearing loss, pain, and tinnitus. Blast lung is caused by the overpressure wave passing through the chest wall and may involve one or both lungs. Chest pain, dyspnea, and hemoptysis may present immediately or be delayed up to 48 hours. Chest x-ray may show patchy or diffuse infiltrates, pneumothorax, subcutaneous air, and/or hemothorax. Implosion of air into the vascular system may cause air embolism and sudden death. Abdominal injuries in air blast are uncommon but in water blast may present as abdominal pain, nausea, vomiting, and tenesmus. Sigmoid and transverse colon injuries are most often seen, followed by small bowel and solid organ (such as liver and spleen) injuries from the "water hammer" effect. Abdominal injuries may have a delayed (up to several days) presentation. The key to therapy is to be suspicious of occult injuries in any victim of a blast, whatever the cause. Most injuries will present within the first hour; however, because injuries may be delayed in presentation, observation and close follow-up are critical. Treatment is generally supportive for ear and lung injuries and operative for abdominal injuries.*

Treatment of Hunting Injuries

The treatment of hunting injuries involves standard principles and priorities of trauma care. Airway, breathing, circulation, bleeding control, immobilization of the spine and fractured extremities, wound care, and stabilization of the victim for transport should be performed in an expedient manner. The victim should always be disarmed to prevent accidental injury to the rescuer or further injury to the victim. Removing the firearm or arrow from the vicinity of patient care is usually sufficient, but ideally the firearm should be made safe by removal of the ammunition and opening of the firing chamber. Arrows should be placed in a quiver, or the points may be wrapped in cloth to prevent injury.

The management of common traumatic injuries and illnesses, such as hypothermia and mountain sickness, is no different except for one important point: *always disarm the victim*. A victim with a charged weapon and a head injury or change in mental status for any reason presents an immediate danger to a well-meaning rescuer. If the person attempting to offer aid to an injured hunter is not familiar with weapons, it is usually best to move the weapon several feet from the victim and point it in a direction where an accidental discharge will do the least harm.

Arrow Injuries.

Lacerations from razor-sharp hunting points are not unusual and can be treated like any similar laceration. The wound should be irrigated, any foreign material removed, and the laceration closed primarily. Victims pierced by an arrow should be stabilized, and the arrow should be left in place during transport, if possible. Attempts to remove the arrow by

pulling it out or pushing it through the wound may cause significantly more injury and should be avoided. It is acceptable to cut off the shaft of the arrow and leave 3 or 4 inches protruding from the wound to make transport easier if this can be accomplished with a minimum of arrow movement. A large pair of paramedic types of shears can usually cut through an arrow shaft if it is stabilized during cutting. The portion of the arrow that remains in the wound should then be fixed with gauze pads or cloth and tape. A similar approach should be used for spears and knives. The victim should be transferred as quickly as possible to an operating room, where the arrow can be removed under controlled conditions. Radiographs are helpful to identify associated anatomic structures before removal is attempted in the operating room ([Figure 20-10](#)).

Gunshot Wounds.

Emergency department care of the gunshot wound includes securing the airway, placing two intravenous lines in unaffected extremities, performing cardiac monitoring, and providing oxygen therapy. The patient with a neck wound and expanding hematoma should be endotracheally intubated as soon as possible. If endotracheal intubation is not possible, a needle cricothyrotomy followed by a tube cricothyrotomy should be performed. Relief of tension pneumothorax with a needle or tube thoracostomy or occlusion of a sucking chest wound should be done immediately. Any external bleeding should be controlled by direct pressure. A radiograph should be obtained of the involved area, and where there is a presumed entrance wound without an exit wound, multiple x-ray studies may be needed to find the location of the bullet. On rare occasion, bullets have been observed to embolize from the chest area via the aorta to the lower extremity arteries or to the heart via the vena cava. A type

Figure 20-10 Arrow wound to the left side of the neck near the mandible. The shape of the wound resembles the blades of the broad-head as shown in [Figure 20-4](#) .

and crossmatch and basic trauma laboratory tests should be performed. Tetanus toxoid and immunoglobulin should be administered as indicated by the victim's history. Broad-spectrum antibiotics should be administered to cover the wide range of pathogens associated with gunshot wounds, especially with complex wounds to the abdomen and extremities. Victims in shock should be taken to the operating room immediately. If this is not possible, type O-negative or type-specific blood should be transfused. Autotransfusion, when available, can be an ideal way to replace lost blood in the victim in shock. Military antishock trousers or pneumatic antishock garments have not been shown to be beneficial in the treatment of shock secondary to penetrating

trauma. Emergency thoracotomy is indicated for victims who have lost vital signs shortly before reaching the emergency department or while in the emergency department. Injuries to the heart or great vessels can be occluded with Foley catheter balloons, pericardial tamponade can be relieved, and the aorta can be cross-clamped. Hypothermia is commonly unrecognized in the trauma victim and may lead to coagulopathy, cardiac arrhythmias, or electrolyte disturbances. Rectal temperatures should be obtained and only warmed fluids and blood given to the victim.

Many myths associated with the management of gunshot wounds should be repudiated. The size or caliber of a bullet cannot easily be determined from the size of the wound; skin is quite elastic and stretches before being torn by a blunt bullet. The path of the bullet cannot be determined by connecting the entrance and exit wounds, since bullets may bounce and only a fragment may exit. The exit wound may be larger or smaller than the entrance wound, and the point of entrance or exit is not easily determined by looking at the wound. Wounds from high-velocity bullets are similar to other types of wounds, and standard rules of debridement should be followed. Wide debridement of normal-appearing tissue is unnecessary and should not be done. In general, victims of gunshot wounds should be evacuated quickly and stabilized if possible. Most victims (80%) of gunshot wounds to the chest who survive the first 30 minutes can be treated with a thoracostomy tube and observation. All gunshot wounds to the abdomen should be explored in the operating room. Radiographs should be used to identify bullets, bullet fragments, and bony injuries. Extremity wounds can be treated conservatively unless signs of vascular injury are present. Experience in combat has shown that vascular injuries do best when identified and treated immediately. Obviously, major bony injuries and nerve injuries eventually need operative therapy, but immediate intervention is rarely necessary. Most important, the underlying injury cannot be determined by examination of the external wound.

Vascular injuries may not be identified during the initial examination; therefore noninvasive, portable, Doppler ultrasound studies can be extremely valuable in the emergency department. Contrast angiography should be performed on any victim with a suspected vascular injury. The removal of the bullet or bullet fragment is not necessary unless the bullet is intravascular, intraarticular, or in contact with nervous tissue, such as the spinal cord or a peripheral nerve. Bullets found during exploratory laparotomy or wound debridement should be removed, but it is unnecessary to explore soft tissue, such as muscle or fat, solely to remove a bullet. Shotgun pellets that have minimal penetration can be removed from the skin with a forceps. Often the plastic or cloth wadding is found in superficial shotgun wounds and should be removed. Shotgun blasts may produce large soft tissue defects that need extensive debridement and either skin grafting or surgical flap rotation to maximize coverage. Patients with powder burns should have as much of the powder residue removed as possible with a brush under local anesthesia. The powder will tattoo the skin if it is not removed,

Figure 20-11 A, Close-range 12-gauge shotgun wound to the right side of the upper chest. The large central wound was caused by the plastic wadding, and the pellets have struck at an angle toward the shoulder. The patient was turning to the right when shot. The external appearance of the wound indicates a massive injury to the chest. **B**, Chest radiograph of the patient in **A**. No pellets have penetrated the chest, and there was no pneumothorax, pulmonary contusion, or vascular injury. The injury was totally superficial, and the patient was admitted for observation and local wound care.

and the deep burns may need dermabrasion or surgical debridement ([Fig. 20-11](#)).^{[12] [27] [38]}

Retained lead bullets and shotgun pellets for the most part are not hazardous; however, when they are within joint spaces or the gastrointestinal tract, significant amounts of lead can be absorbed and toxicity can occur.^[33]

Prevention of Hunting Injuries

Most state fish and wildlife agencies have recognized that hunters are at risk for injuries and have tried to develop programs to minimize morbidity and mortality. National organizations such as the Boy Scouts of America and the National Rifle Association have been teaching firearm and hunting safety for decades. The Hunter Education Association and the North American Association of Hunter Safety Coordinators (NAAHSC) have attempted to identify high-risk groups and situations by collecting data on both fatal and nonfatal hunting-related injuries. NAAHSC-approved Hunter Safety Programs are available in every state, and all states except Alaska, Massachusetts, and South Carolina require the course before issuing a license to hunt. These courses are roughly 12 hours long and cover hunter responsibility, firearms and ammunition, bow hunting, personal safety, game care, and wildlife identification. They stress respect for the wilderness and a rational approach to game management. All hunters, potential hunters, and persons going into hunting areas should take one of these courses. Approximately 650,000 hunters complete a hunter safety course annually. Since the first course given in Kentucky in 1946, more than 18 million hunters have been certified.

Most injuries could probably be prevented by following a few simple rules. Nonhunters should be aware of hunting seasons and designated hunting areas and wear international orange clothing articles while in hunting areas. Hunters should always be sure of their target before shooting, use safety harnesses in tree stands, and use appropriate technique and tools for cleaning game. Tree stands should be well constructed. Hunters should never consume alcohol or mind-altering drugs that might interfere with their judgment. Eye protection in the form of safety glasses should be worn while hunting or target shooting to prevent injuries from ricocheting fragments and shotgun pellets. High-frequency hearing loss is common in hunters because of the loud report of the firearm. Although earplugs and headsets can protect the hunter, they are

impractical for most hunting and are used mainly for target shooting. Some hunters use a single ear plug for the ear closest to the muzzle of the firearm. This protects the ear most likely to be injured but still allows the hunter to hear approaching game and other hunters. Bow hunters should always use wrist and finger protection to prevent injuries from the arrow

505

fletching and the bowstring. All arrows should be carried in a quiver until ready for use. The arrow broadhead should always be pointed away from the hunter. These few steps would probably eliminate most hunting injuries.^[30] ^[31]

FISHING INJURIES

Sport fishing is associated with a large number of relatively minor injuries compared with hunting. The usual problems associated with outdoor recreation are common among fishermen: sunburn, frostbite, hypothermia, near drowning, sprains, fractures, motion sickness, and heat illness. Lacerations are relatively more common because of the use of knives to cut bait and fishing lines and to clean fish. These lacerations are often contaminated with a variety of marine and freshwater pathogens that may increase the incidence of wound infection. Thorough debridement of the wound and copious irrigation with sterile saline solution are the best initial methods to prevent infection (see [Chapter 60](#) [Chapter 61](#) [Chapter 62](#)).

Fishhook Injuries

Fishhooks are designed to penetrate the skin of fish easily and to hold fast while the fish is played and landed. To perform this dual role, they are extremely sharp at the tip, have a barb just proximal to the tip, and are curved so that the more force applied to the hook, the deeper it penetrates. Fishhooks may be single or in clusters of two, three, or four to increase the chance of catching the fish. Some state fishing laws limit the number of hooks allowed on a single line when fishing for certain game fish to make it more sporting. Unfortunately, the increased number of hooks on a lure or line also increases the chance of catching a fisherman. The most common fishhook punctures occur when fish are removed from hooks. The combination of sharp hooks, slippery fish, and an inexperienced fisherman leads to puncture wounds or embedded fishhooks. Many fishermen use commercial fishhook removers or large Kelly forceps to remove hooks. Some fishing guides simply cut the hook with a side-cutting pliers; they believe the remaining segment of hook will eventually oxidize in the victim and disintegrate. Often, fishhooks are stepped on with a bare foot or fishermen catch themselves or another person on the backcast.

Fishhooks can penetrate skin, muscle, and bone. They may pierce the eye or the penis. Care must be taken in removing a fishhook so that further damage to underlying structures is avoided. The first step is to remove the portion of the hook that is embedded from any attached lines, fish, bait, or lure. This is best done with a sharp side-cutting pliers. A bolt cutter may be needed for large, hardened hooks. A number of techniques are used for removing embedded fishhooks, but

Figure 20-12 A to D, Removal of a fishhook that has penetrated a fingertip. **E**, "Press-and-yank" method of fishhook removal.

all involve a certain amount of movement of the hook, which causes increased pain. A local anesthetic should be infiltrated around the puncture site to minimize pain and movement of the patient. The first method can be used if the hook is not deeply embedded. Pressure is applied along the curve of the hook while the hook is pulled away from the point. Because the barb is on the inside of the curve of the hook, this enlarges the entrance hole enough to allow the barb and point to pass through. Sometimes a string looped through the curve of the hook facilitates the process. If the hook is deeply embedded, pressure can be applied along the curve of the hook until the point and barb penetrate the skin at another place, and then the barb can be cut off and the remainder of the hook backed out ([Figure 20-12](#)). Fishhooks embedded in the eye should be left in place, the eye covered with a metal patch or cup, and the victim referred to an ophthalmologist for further care. Rarely, hooks become embedded in bone or cartilage; this victim must be taken to the operating room to have the hook removed via a surgical incision.

Fishing Spear Injuries

Fishing spears, like fishhooks, are designed to penetrate and hold fish. They may be jabbed or thrown or propelled by rubber straps or carbon dioxide cartridges. The more force used to propel the spear, the deeper penetration into tissue. Although arrows are designed to cause bleeding and bullets to cause crushing, fishing spears are designed to hold the fish until it drowns or is otherwise dispatched. Spears may penetrate the human chest or abdominal cavity, skull, or any other anatomic area. Some bleeding may occur, especially if major blood vessels are struck. The victim should be removed from the water as soon as possible and immediate attention given to airway, breathing, and bleeding control. The spear should be stabilized in place, and the victim immediately transported to a medical facility. Penetrating neck and chest injuries may require endotracheal

Figure 20-13 A, Male patient with a multipronged fishing spear through the foot. He

said he saw something move and he speared it. **B**, Same patient with the spear being cut off in the emergency department with a bolt cutter. The patient was taken to the operating room to have the remainder of the spear removed.

intubation and tube thoracostomy. If a spear is embedded in the cheek and interfering with the victim's airway, cutting it off with a bolt cutter and removing it through the mouth is permitted. Spears in all other locations should be left in place, although they may be cut off to facilitate transportation or improve the victim's comfort ([Figure 20-13](#)).

Chapter 21 - Orthopedics

Thomas J. Ellis
Marc F. Swiontkowski

SKELETAL SYSTEM INJURIES

In the wilderness, initial management of a person with a musculoskeletal injury must consider the cause of the injury; the direction of force in relation to the individual or limb so the victim can be checked for injuries to adjacent bones and joints; the time of the injury, because the length of time to treatment may determine prognosis; and the environment where the accident has occurred, including cold, wind, or heat exposure, especially with open wounds that communicate with fractures.

Once the victim's condition is stabilized, examine the skeletal system closely beginning with the spine, moving to the pelvis, and ending with the extremities.

SPINAL INJURIES

Cervical Spine

In the wilderness, cervical spine fractures or dislocations result from falls off significant heights or high-velocity ski or vehicular injuries. Because head and cervical spine injuries are highly associated, individuals with significant head injuries are considered to have a cervical spine injury, especially if unconscious. Ideally, a person with a suspected cervical spine injury is placed on a backboard, with neck immobilization, and evacuated.

Neurologic deficit often results from cervical spine fracture. Fracture of the C1-2 complex results from axial loading (a C1 ring fracture—Jefferson's fracture) or an acute flexion injury (a C2 posterior element fracture—hangman's fracture). Complete neurologic injury at this level is fatal because of paralysis of the respiratory muscles, so surviving victims generally have partial deficits or are neurologically intact. Axial cervical spine fractures may result from flexion (most common), extension, rotational forces, or a combination of these, and most commonly occur at C5-6.^[3]

Fractures and dislocations may result in neurologic insult distal to the bony injury. Because flexion injuries are the most common cervical spine injuries, the neurologic deficit is generally an anterior cord syndrome. The victim suffers complete motor and sensory loss but retains proprioception. The field examination aims to grade motor strength, document sensory response to light touch and pinprick, and note the presence or absence of Babinski's reflex.

When appropriate supplies are available, do a rectal examination. Complete lack of tone and failure of the sphincter muscles to contract when pulling on the penis or clitoris (the bulbocavernosus reflex) indicate spinal cord injury.

When transporting an individual with a cervical spine fracture or dislocation, stabilize the neck to prevent further injury. Because 28% of persons with cervical spine fractures also have other spinal fractures, protect the entire spine.^[3] A pure flexion event may dislocate one or both posterior facets, producing neck pain and limitation of motion. Because the interspinous ligament is ruptured, transport this victim with the neck rigidly immobilized to accommodate the posterior instability.

Thoracolumbar Spine

Thoracolumbar spine fractures occur most frequently at the thoracolumbar junction.

Because the thoracic spine is well splinted by the thoracic cage, when an axial or flexion load is applied, the ribs diminish forces on the thoracic vertebral bodies and transmit the force to the upper lumbar levels. In the wilderness, falls from significant heights or high-velocity sporting vehicular trauma produce these fractures ([Figure 21-1](#)). Thoracolumbar spine fracture is frequently associated with major hindfoot fractures (particularly of the calcaneus). With these mechanisms of injury and unilateral or bilateral calcaneus fracture, assume there is a spine fracture and transport the victim with spine precautions.

Perform a careful neurologic examination as part of the secondary survey, paying close attention to the dermatomal response to light touch and pinprick, motor function, and the presence or absence of cord level reflexes. With significant head injury, assume a spinal injury is present. Logroll the victim, maintaining perfect spinal alignment, and carefully place him or her on a backboard, or use the scoop stretcher (see [Chapter 26](#)). Because significant fluctuations in sympathetic tone may occur, monitor blood pressure and body temperature, taking appropriate steps to cool or warm the victim.

PELVIC INJURIES

Pelvic fractures generally occur in a fall from significant height, high-velocity ski accident, or vehicular trauma. The direction of force is directly related to the fracture and influences definitive management.^{[9] [11]} Penna and Tile^{[5] [11]} divide pelvic fractures into anteroposterior (AP) compression injuries, lateral compression (LC) injuries, and vertical shear (VS) injuries. In

508

Figure 21-1 Wedge compression fracture from axial or flexion loading at the thoracolumbar junction.

addition, there are simple, nondisplaced inferior or superior ramus fractures and avulsion fractures. On clinical examination, these latter fractures are generally seen as an area of tenderness but no instability.

The key factor in pelvic fracture is identification of posterior injury to the pelvic ring, which is associated with significant hemorrhage, neurologic injury, and mortality. Posterior ring fractures are revealed by instability of the pelvis associated with posterior pain, swelling, ecchymosis, and motion. Immediately evacuate this victim on a backboard, taking care to minimize leg and torso motion. Bleeding associated with a pelvic injury is from cancellous bone at fracture sites, retroperitoneal lumbar venous plexus injury, or, rarely, pelvic arterial injuries.

LC injuries are usually stable, with impaction of the posterior structures but seldom any complications. AP compression injuries demonstrate anterior instability, palpable ramus fractures, or pubic symphysis gapping. These fractures are often accompanied by bladder, prostatic, or urethral injury. Transport the victim on a backboard with the feet internally rotated to help reduce the anterior pelvic diastasis. With severe injury and hemodynamic instability, medical antishock trousers (MAST) provide stability and decrease intrapelvic blood loss. Keep them inflated until transfer to a definitive care

center. If MAST are not available, tie a garment securely around the pelvis. Because vertical shear injuries are both rotationally and vertically unstable, definitive care is directed toward providing posterior stability, as it is for those few lateral compression injuries with unstable posterior fractures. In an AP injury, symphyseal widening exceeding 2.5 cm indicates injury to the anterior capsular structures of the sacroiliac joint, requiring stabilization with internal or external fixation.

EXTREMITY INJURIES

Physical Examination

Physical examination addresses circulatory, nerve, skeletal, and joint function.

Circulatory Function.

Penetrating or blunt trauma can injure the major vessels supplying the limbs. Fractures can produce injury by direct laceration (rarely) or by stretching, which produces intimal flap tears that can occlude distal flow or lead to platelet aggregation and delayed occlusion. Thus circulatory function examination is done before and after the victim's arrival at the definitive care center. Assess the color and warmth of the skin or distal extremity; pallor and asymmetric regional hypothermia may indicate vascular injury. In the upper extremity, palpate the brachial, radial, and ulnar arteries, using hand-held, battery-powered sound Doppler units if available. If blood loss, hypothermia, or obesity makes these pulses difficult to assess, evaluate temperature and color. Any suspected major arterial injury mandates immediate evacuation after appropriate splinting.

Nerve Function.

Nerve function may be impossible to assess in an unconscious or uncooperative person. If possible, establish nerve function to the distal extremity after the victim's condition is stabilized. Then compare these initial findings periodically with repeat examinations during transport, noting any deterioration.

Carefully document the results of light touch and pinprick tests. For spinal and pelvic injuries, assess the dermatomal distribution of spinal nerves, and evaluate muscle function by observing active function and grading the strength of each group against resistance.

Skeletal Function.

The long bones of the lower extremity serve as the major structural supports for locomotion, whereas those of the upper extremity stabilize the soft tissues, enabling positioning of the hand in space. A visible angular deformity reveals a fracture; palpable crepitus confirms the diagnosis. Perform appropriate splinting after aligning the limb with axial traction. Other than noting the degree and orientation of the limb's position when the victim is found, do not delay aligning and splinting fractures. Distinguishing joint injuries and intraarticular or very proximal or distal fractures must wait for the definitive

care facility. Similarly, distinguishing wrist or ankle ligamentous injury from a fracture is not required for initial treatment.

Joint Function.

Muscle forces act across joints to improve the position of the lower limbs for ambulation and the hand for handling objects. Each joint has a certain minimum function to allow for stability and a normal range of motion. Making the diagnosis of a joint injury in the field allows appropriate splinting and prevents further damage during transport.

Begin palpation of long bones distally and proceed across all joints. Apply a splint if there is palpable crepitus, swelling, deformity, or a block to motion. If the victim can cooperate, take each joint through an active range of motion to quickly locate the injury. When this is not possible, evaluate passive motion of each joint after palpation for crepitus and swelling.

Reduce any dislocations after completing the neurocirculatory examination. This generally relieves the victim's discomfort considerably. Next, evaluate stability by careful, controlled motion. Joints with associated fractures or interposed soft tissues are frequently unstable after reduction. Take great care in applying splints to prevent redislocation. Report details of the reduction maneuver, including orientation of the pull, amount of force involved, amount of sedation, and residual instability of the joint, to the definitive care physician.

Splinting Techniques (see also [Chapter 19](#))

With suspected cervical or thoracolumbar spine trauma, transport the victim on a hard surface. Backboards or scoop stretchers (see [Chapter 26](#)) are most effective, but improvisation with any hard piece of wood, fiberglass, or straight tree limbs lashed together may be needed. If cervical spine injury is suspected, place a roll of clothes or a water bottle as high as the victim's mid face on either side of the head to prevent rotational movement. Apply tape from the supporting stretcher across the objects and the victim's forehead to add stability. Transport victims with a suspected major pelvic injury in similar fashion, stabilizing the lower extremities.

For shoulder fractures or dislocations, use a commercially available sling or improvised triangular bandage to take the weight of the arm off the injured structures. Whenever possible, splint the upper extremity in the position of function. It may be difficult to place an injured elbow in 90 degrees of flexion and neutral pronation-supination.

Securely fix the limb to the splint with tape or elastic bandages. Air splints, when inflated, can adequately splint the upper extremity in this position. These splints are lightweight and compact but should be used with caution under conditions such as heat and rapid increase in altitude in which they might expand and compress the limb. Splints

may also be made from plaster or fiberglass, which can be applied over cotton softroll. Lightweight fiberglass splints, such as Orthoglass (Smith and Nephew), are easy to use and effective in

Figure 21-2 Improvisation of an ankle wrap to be used for traction.

the initial management of these injuries. These splints are prepacked and can be applied with either cold or warm water. The warmer the water, the faster the fiberglass sets and the greater the exothermic reaction. Avoid hot water because it may generate an excessively exothermic reaction and possibly burn the skin. Immerse the fiberglass in the water, gently squeeze out the excess, and apply the splint. An elasticized bandage helps hold the splint where desired until the fiberglass is hard. Wooden or metal splints, custom made or improvised, also work.

Splints are used to immobilize the limb securely in functional position until definitive care is reached. Apply hand splints with the metacarpophalangeal (MCP) joints flexed 90 degrees and the interphalangeal (IP) joints extended. This position places the collateral ligaments at maximum length and prevents later joint contracture. Position the lower extremity for transport with the hip and knee extended and the ankle in neutral position. With hip or femur fractures or dislocations, apply traction whenever possible, improvising when necessary ([Figure 21-2](#)). Usually, a Thomas splint with a Spanish windlass is available. The ring of the splint rests against the victim's ischium and pubis, and traction is applied through the windlass, stabilizing the

joint or fracture fragments. The Kendrick traction device is lightweight and packaged for easy transportation. If commercial splints are unavailable, strap the injured leg to the noninjured leg, placing a tree limb or walking stick between them. If possible, transport the victim on a backboard.

For the lower leg, air splints provide adequate immobilization of tibia-fibula fractures or ankle fractures and dislocations. Splints made from plaster or fiberglass may be applied over cotton padding with elasticized wraps. Custom-made or improvised metal splints can be stabilized with elastic bandages or tape. Hold the ankle in neutral and apply the splint firmly. Transport victims with unstable lower extremity fracture or dislocation in the recumbent position with the limb elevated.

Open Fractures

Recognizing an open fracture is imperative; without prompt surgical treatment, the incidence of osteomyelitis is high. In an open fracture, the fractured bone communicates with a break in the skin. Consider all lacerations near a fracture as open. With subcutaneous bones (tibia), open fractures are easily identified, but with other bones (humerus, femur, pelvis) that have more surrounding soft tissue, identification is more difficult because the fractured bone end usually retracts once it punctures the skin and is then covered by soft tissue. Most open fractures persistently ooze blood from the laceration, which may facilitate diagnosis. Fat globules may be extruding from the wound.

General care of an open fracture outdoors depends on evacuation time. Open fractures require prompt operative irrigation, debridement, and stabilization. If evacuation can be completed within 8 hours, realign the fracture, give a broad-spectrum antibiotic, and splint the extremity. If the fractured ends of the bones are sticking out of the skin, try to realign the fracture and reduce the bone ends under the skin. If bone ends extrude through the skin, cover the exposed bone with a povidone-iodine solution-soaked gauze sponge, splint the extremity, and arrange for prompt evacuation. If evacuation time exceeds 8 hours, attempt irrigations, limited debridement, and stabilization with a splint in the field. Antibiotic options are listed in [Box 21-1](#) .

Amputation

In the wilderness, the amputation victim requires immediate evacuation. Control hemorrhage using direct pressure; tourniquets are virtually never indicated. Without cooling, an amputated part remains viable for only 4 to 6 hours; with cooling, viability may be extended to 18 hours. Cleanse the amputated part with saline or water, wrap it in a moistened sterile gauze or towel, place it in a plastic bag, and transport it in an ice-water mixture. Do not use dry ice. Keep the amputated part with the victim throughout evacuation.

Box 21-1. ANTIBIOTIC OPTIONS

INTRAVENOUS

Cefazolin (Ancef) 1 g q8h and gentamicin (5 mg/kg) q24h or ticarcillin (Timentin) 3.1 g q8h

INTRAMUSCULAR

Ceftriaxone (Rocephin) 1 g q24h

Oral ciprofloxacin 750 mg BID and cephalexin (Keflex) 500 mg QID

WATER EXPOSURE

Ciprofloxacin 400 mg IV/750 mg po BID or sulfamethoxazole (Bactrim) DS 1 po BID and cefazolin (Ancef) 1 gm IV q8h/cephalexin (Keflex) 500 mg po q6h

DIRT OR BARNYARD

Add penicillin 20 million units IV qd/500 mg po q6h

PENICILLIN ALLERGIC

Use clindamycin 900 mg IV q8h or 450 mg po q6h in place of penicillins and cephalexin (Keflex)

ALTERNATIVES

Erythromycin 500 mg q6h or

cephalexin (Keflex)

ALTERNATIVES

Erythromycin 500 mg q6h or
amoxicillin 500 mg po q8h

Compartment Syndrome

A compartment syndrome begins when locally increased tissue pressure reduces arterial blood flow to a muscle compartment. When local blood flow is unable to meet metabolic demands of the tissue, ischemia ensues. In the wilderness, compartment syndromes most frequently occur in association with fractures or severe contusions. This syndrome can occur when the victim has been lying for some time across a limb so that the body weight occludes the arterial supply. Elevated local tissue pressure (compartment pressure within 10–20 mm Hg of diastolic arterial blood pressure) can occur with acute hemorrhage or after revascularization of an ischemic extremity. Hypotension can lower the risk of a compartment syndrome.

The lower leg and forearm are the most common sites for a compartment syndrome because of the tight fascia in these regions, but it also occurs in the thigh, hand, foot, and gluteal regions. The conscious victim complains of severe pain out of proportion to the injury. The muscle compartment feels extremely tight, and applied pressure increases the pain. There is decreased sensation to light touch and pinprick stimuli in the areas supplied by the nerves traversing the compartment. Stretching muscles within the compartment produces severe pain. The most reliable signs of a compartment syndrome are pain, tight compartments, hypesthesia, and pain on passive stretch. Pulselessness,

pallor, and slow capillary refill may not be observed, even with a severe compartment syndrome.

Emergency evacuation is required. The victim must be definitively treated in the first 6 to 8 hours after onset to optimize return of function to the involved limb. Emergency fasciotomy, the treatment of choice, relieves the pressure. Limited fasciotomies can be performed in the field by an experienced surgeon if evacuation will require more than 8 hours.

RICE Principle

The general principle in the acute management of all extremity injuries is rest, ice, compression, and elevation (RICE). For unstable fractures, immobilization is also indicated. Avoid heat for the first 72 hours after injury. Premade chemical cold packs work well, but cold packs made from ice or snow suffice. If ice is used, mix some water

in a bag with the ice to more evenly distribute the cold. Wrap the cold pack to the injured area with an elasticized bandage. Place a thin piece of fabric between the cold pack and the victim's skin to prevent burning of the skin. Apply the ice to the elevated (above the level of the heart) extremity for 30 to 45 minutes every 2 hours, or, if cold packs are unavailable, immerse the extremity intermittently in a cold mountain stream. A compressive dressing also helps decrease swelling, but should not be used if compartment syndrome is possible. In this situation, keep the limb at the level of the heart and avoid compressive dressings.

UPPER EXTREMITY FRACTURES

Clavicle

Fracture of the clavicle usually occurs in the middle or lateral thirds of the bone and is associated with a direct blow or with a fall onto the lateral shoulder. Clavicle fractures are common with snow skiing. The victim complains of shoulder pain, which may be poorly localized. Arm or shoulder motion exacerbates the pain. To localize the problem, gently palpate the clavicle to identify the area of maximum tenderness. The presence of crepitus at the clavicle confirms the diagnosis. Although rare, a clavicle fracture can be associated with a pneumothorax because the cupula of the lung is punctured; therefore auscultate the chest for breath sounds. Shortness of breath and deep pain on inspiration increase suspicion for a pneumothorax. Clavicle fracture may also accompany injury to the brachial plexus and axillary artery or subclavian vessels. Perform a thorough neurocirculatory examination of the affected extremity and examine the skin carefully. Approximately 3% to 5% of clavicle fractures may be open because of the bone's subcutaneous location. Evacuate the victim if there is a significant open wound, suspected pneumothorax, or nerve or vascular injury. Field treatment

Figure 21-3 To control pain, a fractured humerus should be stabilized manually until a splint can be applied.

for a clavicle fracture consists of a figure-eight bandage or sling and judicious use of analgesics.

Humerus

Fracture of the humeral shaft may result from a direct blow or torsional force on the arm. This fracture frequently occurs with a fall, rope accident, or skiing accident. Fractures of the midshaft and junction of the middle and distal third of the humeral shaft violate the spiral groove path of the radial nerve. If there is arm pain with deformity and crepitus, stabilize the arm, and carefully check the sensory and motor function of the radial nerve as part of the overall neurocirculatory examination ([Figure 21-3](#)). Evaluate radial nerve function by checking sensation in the dorsal thumb web space and MCP extension with the proximal and distal IP joints flexed. When fracture of the humeral shaft is suspected, firmly apply an appropriate coaptation splint made of plaster, fiberglass, or wood with an

elastic bandage on the medial and lateral sides of the humerus. Use a sling for comfort. Acute reduction of the fracture is not routinely required.

Fracture of the proximal humerus is often difficult to differentiate from shoulder dislocation in the acute phase. The mechanism is frequently a high-velocity fall onto an abducted, externally rotated arm, or a direct blow to the anterior shoulder. The victim complains of severe pain around the shoulder with palpation or any arm motion. Palpable crepitus confirms the diagnosis. This fracture does not routinely require acute reduction; application of an arm sling is appropriate field management.

Fracture-dislocation of the proximal humerus can also occur, with most dislocations being anterior. Anterior or posterior fullness, with crepitus on the injured side compared with the uninjured side, suggests the diagnosis. This is a more severe injury, so perform a very careful neurocirculatory examination. Any significant nerve or vascular injury should prompt evacuation to a definitive care center. If the injury is identified and definitive care

Figure 21-4 Nursemaid's elbow most commonly occurs when a longitudinal pull is applied to the upper extremity. Usually the forearm is pronated. There is a partial tear in the orbicular ligament, allowing it to subluxate into the radiocapitellar joint. (From Rockwood CA Jr, Wilkins KE, King RE, editors: *Fractures in children*, ed 3, Philadelphia, 1991, JB Lippincott.)

is more than 1 to 2 hours away, attempt reduction. Using available sedation, stabilize the trunk while applying firm longitudinal traction in line with the arm. Have an assistant apply anterior pressure to the humeral head to ease it back into the glenoid joint space. Avoid any maneuver that compresses the brachial plexus (i.e., a foot in the axilla for countertraction).

Fracture of the distal humerus is more frequently extraarticular in children and intraarticular in adults. Children generally sustain supracondylar fractures after falls from heights. Extension-type injuries are much more common than flexion-type, and they most commonly occur in children ages 4 to 8 years. Deformity, swelling, pain, and crepitus are present, and the diagnosis is fairly obvious. Perform a careful neurocirculatory examination, then focus the motor examination on flexion of the thumb and distal IP joint of the index finger, because injury to the anterior interosseus nerve is frequently associated. If the radial pulse is absent, try to flex or extend the elbow while palpating the radial pulse. If the pulse improves, splint the limb in that position for transport. If the pulse does not improve and definitive care is more than 1 hour away, perform a reduction. After available sedation is given, extend the supinated elbow with

gentle longitudinal traction. Reduce the fracture by flexing the elbow while maintaining longitudinal traction, then splint the elbow in 90 degrees of flexion. Evacuation should be performed promptly.

For the adult with pain, crepitus, deformity, and swelling after a fall, perform the neurocirculatory examination, then apply a splint with the elbow at 45 or 90 degrees of flexion, depending on the victim's comfort. Do not attempt reduction without radiographic confirmation because crepitus is more often associated with a fracture than with a dislocation. Evacuate the victim promptly if there is an open fracture or neurocirculatory deficit.

Subluxation of the radial head in children (nursemaid's elbow) occurs when a longitudinal pull is applied to the upper extremity ([Figure 21-4](#)). The orbicular ligament partially tears, allowing a portion of it to slip over the radial head. An audible snap may be heard at the time of the injury. The initial pain from the injury subsides rapidly, and the child does not seem distressed, but refuses to use the extremity. Any attempt to supinate the forearm brings about a cry of pain and distress. If a definitive care center is nearby, splint the injury and arrange for evacuation. Otherwise, if the history and examination are consistent with the diagnosis, attempt a reduction. First supinate the slightly flexed forearm; if this fails to produce the characteristic snapping sensation of reduction, maximally flex the elbow in supination until the snapping sensation occurs ([Figure 21-5](#)). If the reduction is successful, the child is usually content and playing within 5 to 10 minutes, and no immobilization of the joint is indicated. If the reduction is unsuccessful, the child continues

513

Figure 21-5 Reduction of nursemaid's elbow injury. *Left*, the forearm is supinated. *Right*, the elbow is then hyperflexed. The rescuer's thumb is placed laterally over the radial head to feel the characteristic snapping as the ligament is reduced. (From Rockwood CA Jr, Willkins KE, King RE, editors: *Fractures in children*, ed 3, Philadelphia, 1991, JB Lippincott.)

to avoid using the involved arm and should be evacuated for definitive care.

Radius

Radial shaft fracture is commonly associated with a motor vehicle or industrial accident but may occur with a fall involving angular or axial loading of the forearm. A radial shaft fracture may be associated with dislocation of the distal radioulnar joint (Galeazzi's

fracture), so examine the wrist for tenderness, swelling, and deformity. The victim generally complains of pain, and deformity and crepitus are noted over the radial shaft after a fall or direct blow, with any arm motion exacerbating the pain. When both the radius and ulna are fractured, forearm instability is marked. Always examine the joint above (elbow) and the joint below (wrist) for tenderness, crepitus, and deformity. Once a fracture of the radius or both bones of the forearm is identified, splint the wrist, forearm, and elbow in the position of function.

Fractures of the radial head generally occur in young to middle-aged adults who fall onto outstretched hands. The victim complains of pain about the elbow, with loss of full extension, and pain at the radial head on the lateral side of the elbow with gentle pressure and rotation of the forearm. Fracture of the radial head frequently produces an elbow hemarthrosis, which is identifiable by fullness posterior to the radial head and anterior to the tip of the olecranon. A fluid wave can be ballotted. If equipment is available and you are confident of the diagnosis, aspirate the hemarthrosis and instill 5 ml of lidocaine. Gently move the elbow through a range of motion and then place it in a posterior splint in 90 degrees of flexion with the forearm supinated. On a prolonged expedition when definitive care cannot be reached, remove the splint after 5 days and have the victim perform intermittent range of motion exercises (both flexion/extension and pronation/supination), reapplying the splint for comfort. With more comminuted radial head fractures, attempts at motion produce pain and crepitus and motion remains restricted. These injuries require operative treatment. With nondisplaced or minimally displaced radial head fractures, early motion prevents permanent loss of motion, although most individuals lose some extension and pronation/supination. Splint the arm in supination to prevent contracture of the intraosseus ligament and loss of supination.

Fracture of the distal metaphyseal radius is generally associated with a fall onto the outstretched hand of an older osteoporotic individual. In the wilderness, these fractures occur in younger adults with falls from significant heights onto outstretched hands. Intraarticular distal radius fracture often accompanies fracture of the ulnar styloid. Pain, deformity, and crepitus are obvious. Perform a distal neurocirculatory examination, focusing on the sensory function of the median nerve. When there is neurocirculatory compromise, and definitive care is more than 1 to 2 hours away, perform a gentle reduction. Place one hand on the forearm to provide countertraction and the other around the wrist of the involved extremity. Dorsiflex the wrist and apply longitudinal traction as the wrist is returned to a neutral position. Apply a splint that immobilizes the wrist and elbow. Distal radius and ulna fractures occur most commonly in girls ages 11 to 13 years and in boys ages 13 to 15. These fractures are not usually comminuted but can be difficult to reduce ([Figure 21-6](#)). In cases involving an open fracture, significant distal neurologic deficit, or abnormal circulatory examination, splinting and evacuation should be prompt. Keep the limb elevated above the heart during transport.

Ulna

Ulna shaft fracture is most often associated with fracture of the radial shaft at the same level. When isolated, it usually occurs as a result of a direct blow, the so-called *nightstick fracture*. Fracture of the ulnar shaft can be associated with dislocation of the radial head (Monteggia's lesion), so assess elbow function carefully. In the wilderness,

the most frequent mechanism of injury is bracing a fall or collision with the forearm. Pain, localized swelling, and crepitus are present. Apply a long-arm splint in the position of function. An open fracture is an indication for prompt evacuation.

Fracture of the proximal ulna (olecranon) results from a fall onto the posterior elbow, or avulsion with

514

Figure 21-6 Technique for reduction of a complete fracture of the forearm. **A**, Initial fracture position. **B**, Hyperextend fracture to 100 degrees to disengage the fracture ends. **C**, Push with the thumb on the distal fragment to achieve reduction. (*B and C modified from Levinthal DH: Surg Gynecol Obstet 790, 1933. A to C from Green N, Swiontkowski MF: Skeletal trauma in children, vol 3, ed 2, Philadelphia, 1998, WB Saunders.*)

violent asymmetric contraction of the triceps muscle. The victim may be unable to extend the elbow actively against gravity if the triceps is dissociated from the forearm with a complete olecranon fracture. On initial examination, the victim has pain, significant swelling, and a palpable gap in the olecranon. With severe trauma, olecranon fracture may be associated with an intraarticular fracture of the distal humerus, which can only be diagnosed radiographically. Do a complete distal neurocirculatory examination, examine the shoulder and wrist, then apply a splint in the position of function and comfort. An open fracture, absent pulse, severe swelling, or neurologic deficit should prompt immediate evacuation.

Wrist

Wrist fractures occur with significant rotational forces or high axial loading forces, as occur in falls onto the

Figure 21-7 The scaphoid (navicular) bone sits in the "anatomic snuffbox" of the

radial aspect of the wrist

hand. The victim first complains of pain and later wrist swelling. Hand use or forearm rotation produces significant pain. Many carpal bone fractures are associated with wrist dislocation. Reduction of dislocations is described later.

Carpal bone fractures cannot be diagnosed without radiographs. Scaphoid (navicular) fracture is the most common fracture and is suspected when the patient's area of maximum tenderness is in the "anatomic snuffbox" ([Figure 21-7](#)). If appropriate splinting materials are available, apply a thumb spica splint, immobilizing both the radius and the entire thumb. With fracture of the hook of the hamate bone, the victim complains of pain at the base of the hypothenar eminence. This injury occurs when the hand is used to apply significant force to an object with a handle on it, such as an ax or hammer, and great resistance is met. A short-arm splint suffices for this injury, and for other suspected carpal injuries, until definitive treatment is obtained. With open fractures or those accompanied by median nerve dysfunction, promptly evacuate the victim.

Metacarpals

Fracture of the metacarpal base or shaft occurs with crush injuries or with axial loads when rocks or other immovable objects are struck. Fractures at the base of the digit metacarpals are suspected when tenderness, crepitus and, occasionally, deformity are present. Manage these with a short-arm splint.

Fractures of the metacarpal necks also occur by the same mechanism and usually involve the fifth and fourth metacarpals. These fractures occur at the base of the knuckles and can be associated with significant flexion deformity. Up to 40 degrees of flexion in the

fifth and fourth digits can be accepted without compromising hand function, so these fractures rarely require reduction. Rotational deformity of the metacarpal is poorly tolerated and should be anticipated with suspected metacarpal fractures. With the MCP and the IP joints flexed 90 degrees, the fingernails should be parallel to one another and perpendicular to the orientation of the palm. The terminal portions of the digit should point to the scaphoid tubercle.

When malalignment or significant shortening with a suspected shaft fracture is noted, reduce the fracture with longitudinal traction on the involved digit. Immobilize a fractured metacarpal shaft or neck by applying an aluminum splint (or stick) to the volar surface and taping the involved digit to the adjacent digit, with the MCP joint at 90 degrees. This is the point of maximum length of the collateral ligaments. Immobilizing the joint in this position prevents contractures that can lead to subsequent loss of motion.

Fracture of the base of the thumb metacarpal often occurs with an axial force directed

against a partially flexed thumb metacarpal. If the fracture extends into the joint, it often requires operative fixation. If this fracture is suspected, immobilize the thumb and wrist in a thumb spica splint. An open metacarpal fracture needs cleansing, debridement, and presumptive antibiotic therapy for 48 hours or until definitive care is obtained.

Phalanges

Fractures of the digital phalanges occur with crush injuries or when the digits are caught in ropes or within equipment being used to haul objects. Angular or rotational deformity and crepitus make these fractures obvious. Without radiographs, an intraarticular fracture with subluxation or dislocation is difficult to differentiate from an IP joint dislocation. Angular deformities in these fractures can be reduced using a pencil or thin stick placed in the web space as a fulcrum to assist in reduction. Reduce a fracture of the shaft of a phalanx by applying traction and correcting the deformity. Immobilize the fractures by taping the injured digit to the neighboring uninjured digit or to a volar splint. Cleanse nail-bed fractures or crushes with soap, apply a sterile dressing, and apply a protective volar splint to prevent further injury.

UPPER EXTREMITY DISLOCATIONS AND SPRAINS

Sternoclavicular Joint

Traumatic dislocation of the sternoclavicular joint generally requires tremendous force, either direct or indirect, applied to the shoulder, and consequently it is rare. Anterior dislocation is most common, with the medial head of the clavicle going anterior to the manubrium of the sternum. The victim complains of pain around the sternum and frequently has difficulty taking a deep breath. When the dislocation is posterior, significant pressure may be placed on the esophagus and superior vena cava. The victim may complain of difficulty swallowing and have engorgement of the veins of the face and upper extremities, representing superior vena cava obstruction syndrome. A step-off between the sternum and the medial head of the clavicle (compared with the uninjured side) confirms this diagnosis.

Unreduced anterior dislocation does not produce neurocirculatory compromise and is treated with a sling. It is usually unstable after reduction. Attempt reduction of a posterior dislocation as soon as possible if any neurocirculatory compromise is present. Place the victim supine with a large roll of clothing or other firm object between the scapulae. Apply traction to the arm against countertraction in an abducted and slightly extended position. You may need to manually manipulate the medial end of the clavicle to dislodge the clavicle from behind the manubrium ([Figure 21-8](#)). If this fails, apply sharp, firm pressure posteriorly to both shoulders. Repeat this maneuver several times, placing a larger object between the scapulae if reduction attempts are initially unsuccessful. Alternatively, seat the victim and place your knee between the shoulders, then pull back on both shoulders. If the victim remains in extremis, grasp the midshaft clavicle with a towel clip or pliers and forcefully pull it out of the thoracic cavity. Once reduced, the injury is usually stable. This type of dislocation requires evacuation.

Acromioclavicular Joint

The acromioclavicular joint is injured by a blow on top of the shoulder ([Figure 21-9](#)). Because using the hand increases pain, place the arm on the affected side in a sling. As long as the individual can tolerate the discomfort associated with such an injury, evacuation is not necessary.

Glenohumeral Joint

The head of the humerus at the shoulder joint is generally dislocated anteriorly and inferiorly. The usual mechanism of injury is a blow to the arm in the abducted and externally rotated position. This frequently occurs in skiing as the individual crosses his

or her ski tips or goes forward on a mogul and lands face first with the arms in this position.

Recurrent dislocations and dislocations in younger patients may be easier to reduce than first-time dislocations in older patients. Do a thorough motor, sensory, and circulatory examination of the involved extremity. Carefully assess axillary and musculocutaneous nerves because they are the nerves most commonly injured with an anterior dislocation. Do serial examinations of distal pulses, capillary refill, and forearm compartments.

The preferred method of reduction is linear traction along the axial line of the extremity while stabilizing

516

Figure 21-8 Technique for closed reduction of the sternoclavicular joint. **A**, The patient is positioned supine with a sandbag placed between the two shoulders. Traction is then applied to the arm against countertraction in an abducted and slightly extended position. In anterior dislocation, direct pressure over the medial end of the clavicle may reduce the joint. **B**, In posterior dislocation, in addition to the traction it may be necessary to manipulate the medial end of the clavicle with the fingers to dislodge the clavicle from behind the manubrium. **C**, In a stubborn posterior dislocation, it may be necessary to sterilely prepare the medial end of the clavicle and use a towel clip to grasp around the medial clavicle to lift it back into position. (From Rockwood CA Jr, Green DP, Bucholz RW, editors: *Rockwood and Green's fractures in adults*, ed 3, Philadelphia, 1991, JB Lippincott.)

the torso with a blanket or rope ([Figure 21-10](#)). Narcotic or benzodiazepine premedication can be extremely helpful, but avoid this in a multiply-injured victim if you are concerned about altering mentation or adversely affecting blood pressure. You may tie a sheet, belt, webbed strapping, or avalanche cord around your waist and the victim's bent forearm, so that you (standing or kneeling) can lean back to apply traction, keeping your hands free to guide the head of the humerus back into position ([Figure 21-11](#)). Place padding in the armpit and bend of the elbow to prevent pressure injury to sensitive nerves beneath the skin. In the Milch technique, place the patient prone or sitting upright. Place your right hand in the axilla for a dislocated right shoulder and hold the victim's hand with your left. Gently abduct the victim's arm and apply pressure to

517

Figure 21-10 Traction and countertraction for dislocated shoulder reduction.

Figure 21-11 Pulling on the hanging arm to relocate a dislocated humerus. (From Auerbach PS: *Medicine for the outdoors: the essential guide to emergency medical procedures and first aid*, ed 3, New York, 1999, The Lyons Press.)

Figure 21-12 Milch technique of closed reduction of anterior glenohumeral dislocation with the patient prone. The arm can be manipulated in the same manner with the patient supine. (Redrawn from Lacey T II, Crawford HB: *J Bone Joint Surg* 34A:108, 1952. In Browner BD et al: *Skeletal trauma*, vol 2, ed 2, Philadelphia, WB Saunders, 1998.)

the humeral head. When the arm is fully abducted, rotate it externally and apply gentle traction to reduce the humeral head. This slow process can be highly successful in the acute setting because it usually does not require analgesics or muscle relaxants ([Figure 21-12](#)).^[6] The success of this maneuver decreases as the time after dislocation increases.

Scapular manipulation is also minimally traumatic and highly successful. ² Place the victim prone and apply 5 to 15 pounds of traction on the arm. Once relaxation is obtained, raise the inferior angle of the scapula and rotate it toward the spine; rotate the superior aspect away from the spine (Figure 21-13 (Figure Not Available)). This can also be done with the victim in the standing position ([Figure 21-14](#)). If the victim is standing, it may help to pull the arm forward, as well as down. This technique generally requires excellent relaxation, but can be highly successful.

An alternative method is to have the victim lie prone so that the injured arm dangles free. Place a thick pad under the injured shoulder. Attach a 10 to 20 lb (4.5 to 9 kg) weight to the wrist or forearm (do not have the victim attempt to hold the weight) and allow it to exert steady traction on the arm, using gravity to relocate the humeral head (Figure 21-15 (Figure Not Available)). A standing victim can bend forward at the waist as you pull steadily downward on the arm to simulate the gravity effect. Use gentle side-to-side motion at the wrist to assist with the reduction ([Figure 21-16](#)). Avoid the Hippocratic maneuver (Figure 21-17 (Figure Not Available)) of placing a foot in the axilla of the injured limb to achieve countertraction because of increased pressure on the structures within the axillary sheath.

Figure 21-13 (Figure Not Available) Scapular manipulation technique for closed reduction of anterior glenohumeral dislocation. (Redrawn from Anderson D, Zvirbulis R, Ciullo J: *Clin Orthop* 164:181, 1982. In Browner BD et al: *Skeletal trauma*, vol 2, ed 2, Philadelphia, 1998, WB Saunders.)

Posterior dislocation of the glenohumeral joint makes up less than 5% of shoulder dislocations. It may occur with adduction and axial loading of the shoulder, a direct blow to the anterior aspect of the shoulder, or as a result of marked internal rotation accompanying a grand mal seizure. Frequently, the dislocation is associated with either a humeral head impaction injury or a glenoid fracture. The victim complains of significant pain and loss of shoulder motion. Generally, external rotation is completely lost. On palpation of the shoulder, you can usually detect posterior fullness not found on the uninjured side. This dislocation can be more difficult to reduce than an anterior dislocation, so excellent analgesia is generally required. Flex the arm forward, rotate it internally, and adduct it to disengage the head from the posterior glenoid rim. Occasionally, lateral traction on the humeral shaft is also required. With longitudinal traction and anterior pressure on the humeral head from behind, reduction is achieved.

If the reduction maneuver is successful, place the arm in a sling until definitive care is reached. If possible, hold a posterior dislocation in neutral or slight external rotation. Because of the significant incidence of fractures with these injuries, radiologic examination is required to make the diagnosis, and evacuation is mandated.

Figure 21-14 Repositioning a dislocated shoulder. Attached to the victim's forearm with a strap, rope, or sheet, the rescuer uses his body weight to apply traction, leaving his hands free to manipulate the victim's arm. A second rescuer applies countertraction, or the victim can be held motionless by fixing the chest sheet to a tree or ground stake. (From Auerbach PS: *Medicine for the outdoors: the essential guide to emergency medical procedures and first aid*, ed 3, New York, 1999, The Lyons Press.)

(From Auerbach PS: *Medicine for the outdoors: the essential guide to emergency medical procedures and first aid*, ed 3, New York, 1999, The Lyons Press.)

Figure 21-17 (Figure Not Available) Hippocratic technique of closed reduction of anterior glenohumeral dislocation. The foot is placed against the proximal humerus, and longitudinal traction is applied to the upper extremity. (Redrawn from Rockwood CA, Green CP, editors: *Fractures in adults*, vol 1, Philadelphia, 1984, JB Lippincott. In Browner BD et al: *Skeletal trauma*, vol 2, ed 2, Philadelphia, 1991, WB Saunders.)

Elbow

Dislocation of the elbow occurs with hyperextension or axial load from a fall onto the outstretched hand. It is generally posterior and lateral. The diagnosis is obvious, with posterior deformity at the elbow and foreshortening of the forearm. After carefully assessing distal sensory, motor, and circulatory status, perform reduction. With countertraction on the upper arm, apply linear traction with the elbow slightly flexed and the forearm in the original degree of pronation and supination. Downward pressure on the proximal forearm to disengage the coronoid from the olecranon fossa may be helpful. Avoid hyperextension. Adequate analgesia can be extremely helpful. An

alternative method is to place the patient prone over a log or makeshift platform and apply gentle downward traction on the wrist for a few minutes. As the olecranon begins to slip distally, lift up gently on the arm. No assistant is needed, and if the maneuver is done gently, no anesthesia is required ([Figure 21-18](#)). A modification of this maneuver is to hang only the forearm over the platform and apply gentle downward traction via the wrist. Guide the reduction

Figure 21-18 Parvin's method of closed reduction of an elbow dislocation. The patient lies prone on a stretcher, and the physician applies gentle downward traction on the wrist for a few minutes. As the olecranon begins to slip distally, the physician lifts up gently on the arm. No assistant is required, and if the maneuver is done gently, no anesthesia is required. (Redrawn from Parvin RW: *Closed reduction of common shoulder and elbow dislocations without anesthesia*, Arch Surg 75:972, 1957. In Rockwood CA Jr, Green DP, Bucholz RW, editors: *Rockwood and Green's Fractures in adults*, ed 3, Philadelphia, 1991, JB Lippincott.)

of the olecranon with the opposite hand (Figure 21-19 (Figure Not Available)). Reduction provides nearly complete relief of pain and restoration of normal surface anatomy. Apply a posterior splint with the elbow in 90 degrees of flexion and the forearm in neutral position, using a sling for comfort. If reduction is not successful after three attempts or if a nerve injury is suspected, apply a splint to the arm as it lies and initiate evacuation.

Wrist

Wrist dislocations, which are frequently associated with carpal fractures, are generally produced by a fall onto the outstretched hand. A wrist dislocation may be difficult to differentiate clinically from a fracture of the distal radius. However, in either case, perform a reduction maneuver after careful assessment of distal neurocirculatory function, emphasizing median nerve function. The reduction maneuver is similar to that for a distal radius fracture. Use one hand to stabilize the forearm and the other to grasp the hand. First, dorsiflex the wrist if the dislocation is dorsal (most common) or volarflex it if the dislocation is volar, then apply longitudinal traction. In general, significant dorsiflexion is required to obtain reduction, and premedication can be

Figure 21-19 (Figure Not Available) In Meyn and Quigley's method of reduction, only the forearm hangs from the side of the stretcher. As gentle downward traction is applied on the wrist, the physician guides reduction of the olecranon with the opposite hand. (Redrawn from Meyn MA, Quigley TB: *Reduction of posterior dislocation of the elbow by traction on the dangling arm*, Clin Orthop 103:106, 1974. In Rockwood CA Jr, Green DP, Bucholz RW, editors: *Rockwood and Green's Fractures in adults*, ed 3, Philadelphia, 1991, JB Lippincott.)

extremely helpful. If reduction is unsuccessful after three attempts or if there is median nerve dysfunction, initiate evacuation. Apply a short-arm splint if reduction is successful, and elevate the arm above the level of the heart until definitive care is procured. Consider pain and tenderness about the wrist with no significant deformity an intercarpal ligamentous disruption or a carpal fracture and apply a short arm splint.

Metacarpophalangeal Joint

MCP joint dislocation is rare, being produced by a crush injury or when the hand is caught in a rope. This dislocation may be dorsal or volar, with dorsal dislocation being most common. Clinically, the joint is hyperextended and the phalanx shortened. Most dorsal dislocations are easily reduced. First, hyperextend the proximal phalanx 90 degrees on the metacarpal, then push the base of the proximal phalanx into flexion, maintaining contact at all times with the metacarpal head to prevent entrapment of the volar plate in the joint ([Figure 21-20](#)). Avoid straight longitudinal traction because it may turn a simple dislocation into a complex dislocation (see below). Flex the wrist and IP joints to relax the flexor tendons, and the joint usually reduces easily with a palpable and audible clunk. Apply a dorsal-volar splint, with the joint held at 90 degrees of flexion. Irreducible or complex dislocations also occur when the volar plate is interposed in the joint. Clinically, the joint is only slightly hyperextended and the volar skin is puckered over the joint. These dislocations are most common in the index, thumb, and little finger. A single attempt at reduction using the technique just described is indicated, but these dislocations usually require open

Figure 21-20 The single most important element preventing reduction in a complex MCP dislocation is interposition of the volar plate within the joint space, and it must be extricated surgically. (From Rockwood CA Jr, Green DP, Bucholz RW, editors: *Rockwood and Green's Fractures in adults*, ed 3, Philadelphia, 1991, JB Lippincott.)

reduction. If reduction of an MCP joint dislocation is unsuccessful, splint the joint in the position of comfort and obtain definitive treatment as soon as possible.

The thumb MCP joint is most commonly injured. Dislocations are reduced as already described. Injury to the ulnar collateral ligament of this joint (skier's or gameskeeper's thumb) results from a valgus stress, as may occur when an individual falls holding an object in the first web space. The victim complains of tenderness over the ulnar aspect of the MCP joint. There may be instability to radial stress with the joint held in 30 degrees of flexion, an indication for surgical repair. In the field, apply a thumb spica splint and seek definitive care within 10 days. If splinting material is not available, tape

the thumb until definitive care can be obtained ([Figure 21-21](#)).

Proximal Interphalangeal Joint

Proximal interphalangeal (PIP) joint dislocations may be dorsal, volar, or rotatory, with dorsal dislocation by far the most common. Dorsal dislocation occurs with hyperextension, and the volar plate is always ruptured. It can be associated with fracture of the volar lip of the middle phalanx, creating instability after reduction. Perform reduction as described for dorsal MCP dislocation. Avoid straight longitudinal traction to prevent entrapment of the volar plate into the joint. After reduction, tape the finger to an adjacent finger to avoid hyperextension and allow early motion ([Figure 21-22](#)). As with MCP dislocation, a complex dislocation can occur, but it is rare. This is difficult to reduce closed and often requires open reduction.

Volar dislocations are rare. For this injury to occur, the central slip must be disrupted, and the potential for a boutonniere deformity is present. Reduce the digit by flexion of the PIP joint, pushing the base of the middle phalanx dorsally. Treat the PIP joint like a rupture of the central slip, with the PIP joint splinted in extension. Leave the distal interphalangeal (DIP) and MCP joints free to allow motion.

Figure 21-21 Taping the thumb for immobilization. **A**, The buddy-taping method. **B**, A thumb-lock; if possible, padding should be placed between the thumb and forefinger. (From Auerbach PS: *Medicine for the outdoors: the essential guide to emergency medical procedures and first aid*, ed 3, New York, 1999, The Lyons Press.)

522

Figure 21-22 Buddy-taping method to immobilize a finger. (From Auerbach PS: *Medicine for the outdoors: the essential guide to emergency medical procedures and first aid*, ed 3, New York, 1999, The Lyons Press.)

Figure 21-23 Rotary subluxation of the PIP joint. The condyle of the head of the proximal phalanx is button-holed between the lateral band and central slip, both of which remain intact. (From Rockwood CA Jr, Green DP, Bucholz RW, editors: *Rockwood and Green's Fractures in adults*, ed 3, Philadelphia, 1991, JB Lippincott.)

Rotatory subluxation of the PIP joint is also rare ([Figure 21-23](#)), occurring after a twisting injury. The condyle of the head of the proximal phalanx is buttonholed between the lateral band and the central slip, both of which remain intact. This injury can be difficult to reduce. With both the MCP and PIP joints flexed, apply gentle traction to the finger. This relaxes the volarly displaced lateral band and allows the band to be disengaged and slip dorsally when a gentle rotary and traction force is applied. You can achieve further relaxation of the lateral band by dorsiflexion of the wrist. After reduction, buddy tape the finger and begin early motion. With any dislocation of the PIP joint, seek definitive care promptly to ensure adequate reduction of the injury.

"Jammed" fingers may be just as debilitating and painful as dislocated digits. With these injuries, stress the involved joint both radially and ulnarly to ensure collateral ligament integrity. If the joint is stable, the finger can be buddy taped to an adjacent digit and immediate care is not indicated. If the finger is unstable, seek definitive care.

Figure 21-24 The three types of injury that cause a mallet finger of tendon origin. *Top*, The extensor tendon fibers over the distal joint are stretched without complete division of the tendon. Although there is some drop of the distal phalanx, the patient retains weak active extension. *Center*, The extensor tendon is ruptured from its insertion on the distal phalanx. There is usually a 40- to 45-degree flexion deformity, and the patient has loss of active extension at the distal joint. *Bottom*, A small fragment of the distal phalanx is avulsed with the extensor tendon. This injury has the same clinical findings as that shown in the center drawing. (From Rockwood CA Jr, Green DP, Bucholz RW, editors: *Rockwood and Green's Fractures in adults*, ed 3, Philadelphia, 1991, JB Lippincott.)

Distal Interphalangeal Joint

The DIP joint is less frequently injured than the PIP joint. Pure dislocations are rare and are usually dorsal and associated with an open wound. The reduction maneuver is similar to that used for dorsal PIP joint dislocation, and the injury is stable after reduction. More commonly, a mallet-finger injury occurs when the extensor tendon is taut, as when striking an object with the finger extended. The basic injury is incompetence of the extensor tendon at its insertion into the distal phalanx. The three types of mallet injuries are shown in [Figure 21-24](#) . Individuals with this injury lack full extension of the DIP joint when the MCP and PIP joints are kept in extension. Holding

these joints in extension isolates the extensor tendon by neutralizing the intrinsic muscles. If an extension lag is noted, splint the joint in slight extension for 6 to 8 weeks, leaving the PIP and DIP joints free ([Figure 21-25](#)). Obtain a radiograph within the first 10 days to ensure that the joint is reduced.

Occasionally, the flexor digitorum profundus (FDP) tendon is avulsed from its insertion on the distal phalanx.

523

Figure 21-25 Mallet finger can be treated by immobilizing the DIP joint with a dorsal padded aluminum splint **(A)**, a volar unpadded aluminum splint **(B)**, a Stack splint **(C)**, a modified Stack splint **(D)**, or an Abouana splint **(E)**. Note that each of these splints uses a three-point fixation principle. (From Rockwood CA Jr, Green DP, Bucholz RW, editors: *Rockwood and Green's Fractures in adults*, ed 3, Philadelphia, 1991, JB Lippincott.)

This occurs with forced hyperextension of the DIP joint while the FDP is maximally contracted. The ring finger is most commonly injured. The diagnosis is made by demonstrating inability to flex the DIP joint with the PIP joint held in extension. Pain and local tenderness are more common over the PIP joint, where the retracted end of the tendon usually lies. Splint the digit in flexion, and seek care within 7 days from a surgeon specializing in the upper extremities.

LOWER EXTREMITY INJURIES

Femur and Patella

In general, healthy, active individuals sustain fractures of the proximal femur only in falls from significant heights or from high-velocity injuries sustained during water or snow skiing. These fractures occur in the femoral neck or intertrochanteric region. When the head and spinal cord are uninjured, the victim complains of pain within the proximal thigh. In all but the thinnest individuals, there is little local reaction in terms of swelling or deformity around the hip region to aid in diagnosis. Any movement of the affected limb produces significant pain. In many cases, the affected limb is noticeably shortened and externally rotated. Following a careful sensory, motor, and circulatory examination, realign the limb and apply a Kendrick, Thomas, or REEL splint, if available. An improvised traction splint can be fabricated (see [Chapter 19](#)). If none is available, transport the victim on a backboard, with the limbs strapped together or tied to a board with a tree limb placed between them. Fracture of the femoral neck is associated with a significant risk of posttraumatic femoral head necrosis. Without a radiograph, this fracture is impossible to distinguish from an intertrochanteric hip fracture. Because there is evidence that emergency treatment of a fracture of the femoral neck decreases the risk of posttraumatic avascular necrosis,^[10] arrange rapid evacuation of any victim in whom this injury is suspected.

Fracture of the femoral shaft occurs by similar mechanisms. Crepitus and maximum deformity are noted in the midportion of the thigh. After neurocirculatory examination, place the limb in traction or protect it as noted previously. Correct any gross deformity of the shaft with gentle traction, and repeat the neurocirculatory examination. This fracture may be an open injury, so split the victim's pants to complete the examination. Discovery of an open wound should prompt rapid evacuation.

Fracture of the distal end of the femur is frequently intraarticular and occurs with high-velocity loading when the knee is flexed. With axial loading on the femur, the patella becomes the driving wedge and the femoral condyles suffer direct impact, producing either a patella fracture or a fracture of the femoral condyles or distal metaphysis. With a patella fracture, the injury may be obvious on deep palpation. This is often an open injury because there is very little soft tissue overlying this sesamoid bone. Instability of the distal femur with crepitus indicates a supracondylar femur fracture, not a patella fracture. The definitive diagnosis is made radiographically. After initial neurocirculatory examination, realign the limb to avoid compression of the popliteal artery and vein. Apply a posterior splint to the realigned limb for transportation. As with all fractures, open wounds in the region of the fracture, or an

abnormal nerve or vascular examination should prompt immediate evacuation.

Tibia and Fibula

The tibial plateau is the broad intraarticular surface of the upper tibia that articulates with the distal femur. This area can be fractured with a fall or leap from a height. Frequently, angulatory moments across the knee are associated. A valgus moment produces a fracture of the lateral tibial plateau, whereas a varus moment produces a medial plateau fracture. Pain, swelling, and deformity are obvious on initial examination. With a tibial plateau fracture, significant hemarthrosis develops quickly. Because of anatomic tethering of the popliteal artery by the fascia of the soleus complex, arterial injury may result from this fracture, especially when associated with a knee dislocation. Assess distal pulses and capillary refill at 1-hour intervals, keeping in mind the possibility of a compartment syndrome. After initial examination, carefully realign the limb and apply a posterior splint for transportation.

Tibial shaft fractures are associated with fibular shaft fractures in 90% of cases. These fractures result from high-impact trauma. Before the development of higher, anatomically conforming ski boots, these fractures were the most common ski injuries. The injury was sustained when the body rotated around a fixed foot (occurring with a ski caught against a rock or tree stump), which produced a torsional, spiral fracture of the tibia and fibula.

Tibial shaft fracture is the most common type of open fracture in the wilderness setting. When this injury is suspected, inspect the entire limb for distal sensory, motor, and circulatory function before realignment. Apply a posterior splint for transport. Take great care in serially examining the limb for the possibility of a compartment syndrome because this is the most common anatomic location for this problem.

Ankle

The intraarticular distal tibia, medial malleolus, and distal fibula, or any combination of these, may be involved in an ankle fracture, which is generally produced by large torsional moments about a fixed foot. With the distal tibia, axial loading from a fall or jump may also be involved. Note if there is significant pain and swelling as the shoe is removed. Palpation along the medial and lateral malleoli confirms the clinical suspicion. After the shoe is removed to inspect the skin for open wounds, perform a neurocirculatory examination.

If there is a rotational deformity in the ankle, realign the ankle with gentle traction before applying a posterior splint with the ankle in neutral position. During transport, elevate the limb above the level of the heart.

Tarsal Bones

The calcaneus and talus are usually fractured during falls or jumps from significant heights when the victim lands on his or her feet. With a calcaneus fracture, significant heel pain, deformity, and crepitus are immediately evident after the boot is removed. A talus fracture may be impossible to differentiate from an ankle fracture on clinical grounds. An ankle fracture is tender at the malleolus level, whereas with a talar fracture, the tenderness is located distal to the malleoli. Talus fracture occurs when the foot is forced into maximum dorsiflexion. Knowing the point of the foot's impact with the ground is helpful in differentiating a talus fracture from an ankle fracture. Talus fracture may be associated with subtalar or ankle joint dislocation, but this deformity is more severe. Arrange for emergency evacuation because these injuries are very difficult to reduce closed, and pressure on the skin from the displaced talar body can produce significant skin slough. Fractures of the other tarsal bones are exceedingly rare but can be defined by localizing the tenderness to a specific site. Apply a short-leg splint with extra padding and elevate the limb during transportation. If a talus fracture is suspected, expedite evacuation because posttraumatic avascular necrosis of the talar body is a common complication.

Metatarsal Bones

Fractures at the base of the metatarsals often accompany midfoot dislocation (Lisfranc's dislocation). These injuries occur across the entire midfoot joint and are commonly associated with fractures at the bases of the second and fifth metatarsals. The mechanism usually occurs with axial loading of the foot in maximum plantar flexion as a result of vehicular trauma, most frequently snowmobiling. The victim complains of midfoot pain and swelling; on removing the shoe, crepitus and tenderness are noted at the base of the metatarsals (especially the first, second, and fifth metatarsals) and plantar ecchymosis may be present. Overall foot alignment is maintained, but stressing the midfoot by stabilizing the heel and placing force across the forefoot in the varus and valgus directions reveals instability. Place the foot in a well-padded posterior splint and elevate it whenever possible. Do not allow the victim to ambulate. Swelling associated with this injury can produce a compartment syndrome.

Metatarsal shaft fracture occurs with a crush injury or a fall or jump from moderate height. Midshaft metatarsal fractures also occur as "fatigue," or so-called "march" fractures, which often occur with prolonged hiking or running with poor preconditioning. Pain and localized tenderness are the hallmarks of this diagnosis. The dull pain at the midshaft of a metatarsal (often the second or fifth) may be converted to more severe pain with associated crepitus by a jump from a log or a

rock. You can temporarily manage these fractures with a stiff-soled boot or orthotic insert. If there is fracture instability or extreme pain, apply a short-leg splint and allow no

further weight bearing.

Phalanx

Toe phalanges are fractured by crush injuries and can be prevented by the use of steel-toed or hard-toed boots. A great-toe phalanx fracture can be a significant problem because force is placed on this digit during the toe-off phase of gait. Manage phalanx fractures by buddy taping the toe to an adjacent uninjured digit with cotton placed between the toes. Displaced intraarticular fracture of the proximal phalanx of the great toe may need operative fixation. Stiff-soled boots minimize discomfort during weight bearing.

LOWER EXTREMITY DISLOCATIONS AND SPRAINS

Hip

Posterior hip dislocation is produced by axial loading of the femur with the hip flexed and adducted.^[7] It generally occurs in vehicular trauma but can follow a fall or sledding or skiing accident. With posterior dislocation, the victim complains of severe pain about the hip and the affected limb appears shortened, flexed, internally rotated, and adducted. Any hip motion increases the pain. It is not clinically possible to determine if there is an associated acetabular or femoral neck fracture. With the rare anterior dislocation, the limb is externally rotated and slightly flexed and abducted. This

Figure 21-26 (Figure Not Available) The Allis technique for reduction of a hip dislocation. The surgeon's position must provide a mechanical advantage for the application of traction. **A**, Internal and external rotation is gently alternated, perhaps with lateral traction by an assistant on the proximal thigh. **B**, In-line traction with hip flexed. **C**, Adduction is often a helpful adjunct to in-line traction. (**A to C**, redrawn from DeLee JC. In Rockwood CA Jr, Green DP: *Fractures*, vol 2, ed 2, Philadelphia, 1985, JB Lippincott. In Browner BD et al: *Skeletal trauma*, vol 2, ed 2, Philadelphia, 1998, WB Saunders.)

type of dislocation is generally produced by wide abduction of the hip caused by significant force.

Place the victim in a supine position to do a complete survey of all organ systems. Carefully examine the distal limb for associated fractures, and perform a thorough sensory and motor examination. The peroneal division of the sciatic nerve is most susceptible to injury with a posterior dislocation. Hip dislocations are an orthopedic emergency because time to reduction is directly linked to the incidence of avascular necrosis of the femoral head. Immediate transfer to a definitive care center is desirable because hip radiographs may reveal an associated femoral neck fracture that could become displaced if closed reduction is attempted. However, if it will be more than 6 hours before the victim can be evacuated to a definitive care center, attempt closed reduction. With the Allis technique (Figure 21-26 (Figure Not Available)), position the victim supine on the ground or a stretcher. Stand above the victim and pull in-line traction on the extremity while an assistant applies counter traction to the iliac wings. With anterior dislocation, apply traction with the leg slightly abducted and externally rotated and the hip gently extended. Reduce posterior dislocations by flexing the hip 60 to 90 degrees. Internal rotation and adduction of the hip will facilitate the reduction. Successful reduction is usually indicated by an audible "clunk" and restoration of limb alignment. As with any reduction maneuver, adequate analgesia and a slow, progressive increase in traction force are helpful. The Stimson gravity technique (Figure 21-27 (Figure Not Available)) may not be as practical in the wilderness. Position the

patient prone on a makeshift platform. With a posterior dislocation,

Figure 21-27 (Figure Not Available) The Stimson gravity reduction technique. This method has limited application in patients with multiple injuries. (Redrawn from DeLee JC. In Rockwood CA Jr, Green DP: *Fractures*, vol 2, ed 2, Philadelphia, 1985, JB Lippincott, 1985. In Browner BD et al: *Skeletal trauma*, vol 2, ed 2, Philadelphia, 1991, WB Saunders.)

the hip and knee are flexed 90 degrees. Apply longitudinal traction in addition to adduction and internal rotation. The reduction maneuver is actually the same for both techniques, with one performed with the victim supine and the other with the victim prone.

Knee

Knee dislocation is obvious because of the amount of deformity. The tibia may be dislocated in five directions: anterior, posterior, lateral, medial, and rotatory. The most common directions are anterior and posterior. This represents a true emergency because 5% to 40% of knee dislocations have associated vascular injuries.^{[1] [3] [4] [8] [12]} In a large series, Green and Allen^[4] reported an above-knee amputation rate of 86% for vascular injuries associated with knee dislocations that were not repaired within 8 hours of injury. The vascular injury occurs because of tethering of the popliteal vessels along the posterior border of the tibia by the soleus fascia. A knee dislocation is a high-velocity injury usually produced by vehicular trauma or a fall. When this injury is suspected, do a careful screening neurocirculatory examination. Intact distal pulses do not definitively rule out an arterial injury. Intimal flap tears can produce delayed thromboses of the popliteal artery. In addition, injury to the peroneal nerve can occur.

Many knee dislocations spontaneously reduce and may lead the examiner to underestimation of the seriousness of the injury. Instability in extension to either varus or valgus stress indicates disruption of at least one of the cruciate ligaments and should alert you to the potential for a knee dislocation.

After initial examination, reduce the persistent dislocation. Anterior dislocation is reduced with traction on the leg and gentle elevation of the distal femur. Posterior dislocation is reduced with traction in extension and anterior elevation of the tibia. Posterolateral rotatory dislocation can be very difficult to reduce and usually requires open reduction. It occurs when the medial femoral condyle buttonholes through the medial capsule. A transverse furrow on the medial aspect of the knee is pathognomonic for this injury. For transport, apply a posterior splint to the limb and move the victim on a backboard. Be vigilant to the possibility of an arterial lesion or emerging compartment syndrome. Emergency evacuation is advised because of the risk of amputation related to vascular injury.

Isolated ligament or meniscal injuries can also occur. Anterior cruciate ligament (ACL) injury happens with a hyperextension or twisting injury to the knee, often associated with

an audible "pop" and rapid onset of swelling and pain. On examination, the victim has both a pivot shift and increased laxity on a Lachman's test. Meniscal injuries also occur with a twisting mechanism. These injuries show a slower onset of swelling (24 to 48 hours), with pain to palpation over the joint line. The victims may complain of the knee catching, locking, or giving way, especially with twisting motions. Medial collateral ligament (MCL) injury occurs with a valgus stress to the knee. The victim complains of tenderness along the medial aspect of the proximal tibia and sometimes over the medial femoral condyle. Valgus stress with the knee in 30 degrees of flexion is painful. With a partial or complete tear, laxity will be

527

present. It is difficult to determine if a concomitant meniscal injury is present acutely because both injuries can be painful over the joint line. Instability to valgus stress in full extension indicates injury to the MCL and at least one of the cruciate ligaments. Wrap the knee with an elasticized bandage to contain the swelling, and place in an immobilizer if instability is present. Transport the victim to a definitive care center.

Frequently, the patellofemoral joint is dislocated. Because of the increased femorotibial angle in females, this injury is far more common in women. Generalized ligamentous laxity may predispose to this problem. Dislocation of the kneecap may result from a twisting injury or asymmetric quadriceps contraction during a fall. These mechanisms routinely occur with hiking, climbing, and skiing accidents. The patella winds up lateral to the articular surface of the distal femur. Although neurovascular injuries rarely occur in association with a dislocated patella, conduct a screening examination.

The patella can often be reduced by simply straightening the knee. If this is not successful, apply gentle pressure to the patella to push it back up onto the distal femoral articular groove. Apply a knee splint with the joint in extension; weight bearing is allowed. Keep the knee in extension until definitive care can be obtained. A radiograph is ultimately required to rule out osteochondral fractures, which are frequently associated with this injury.

Ankle

Ankle dislocations are almost always accompanied by fractures of both malleoli. These dislocations generally occur with falls onto uneven surfaces or with twisting injuries of moderate velocity. Carefully examine the area about the ankle for open injuries and conduct a neurocirculatory examination to obtain a baseline status. Then align the ankle joint by grasping the posterior heel, applying traction with the knee bent (to relax the gastrocnemius-soleus complex), and bringing the foot into alignment with the distal tibia. After this maneuver, reexamine the foot, dress any wounds, and apply a posterior splint. During transport, elevate the limb above the level of the heart.

The most common musculoskeletal injury occurring in the wilderness setting is an ankle sprain. Ligament sprain, or tearing of the fibers, is separated into three grades. Grade 1

injury is partial disruption of some of the ligament fibers, represented grossly by mild intersubstance hemorrhage. Grade 2 injury is complete disruption of a portion of the ligament fibers. The main substance of the ligament remains intact, and the injury is characterized by moderate hemorrhage with grossly visible torn ligament fibers. Grade 3 injury is complete disruption of the ligament fibers, which can result in instability of the related joint.

The medial ligament complex consists of the deltoid ligament, which runs from the medial malleolus to the talus ([Figure 21-28](#)). The ligament complex on the lateral side is much more complex and consists of three separate ligaments named for their origins and insertions: the calcaneofibular ligament, the anterior talofibular ligament, and the posterior talofibular ligament (see [Figure 21-28](#)). The lateral ligament complex is the most frequent site of an inversion injury. When such an injury occurs, remove the shoe and sock and conduct a screening neurocirculatory examination. Palpate each ligament individually for tenderness, and then evaluate the ankle for instability with the anterior drawer test. This test is performed by stabilizing the tibia with one hand and grasping the posterior heel to pull the foot forward with the other hand. If the talus slides forward within the ankle mortis (using the uninjured side as a comparison), the injury represents a grade 3 injury. Place the foot and ankle into a posterior splint or air splint. If possible, keep the victim from bearing weight on the limb. If this examination does not reveal instability and is thus indicative of a grade 1 or 2 sprain, apply an elasticized bandage or ankle taping (see [Chapter 19](#)). All injuries should be acutely treated following the RICE principle. Commercially available stirrup air splints also aid in ambulatory management of these injuries.

A more serious ankle sprain is the high ankle sprain, which affects the anterior inferior tibiofibular ligament (portion of the syndesmotic ligament) and occurs in up to 10% of ankle sprains. The victim complains of pain to palpation over the distal tibiofibular joint and also with dorsiflexion and external rotation of the foot relative to the tibia. Compression of the fibula and tibia in the proximal half of the calf produces pain over the syndesmosis. Unlike stable lateral ankle sprains, these injuries take 4 to 6 weeks to resolve. Treat initially with a short leg splint or walking boot. Failure to recognize this injury will produce prolonged disability.

In the field, tape the ankle both to decrease pain and to limit swelling ([Figure 21-29](#) ; see also [Chapter 19](#)). During taping, keep the victim's ankle perpendicular to the tibial shaft. This makes walking easier, because the ankle is not plantar flexed, and it helps prevent development of an Achilles tendon contracture. If available, an Aircast ankle brace provides additional ankle support and can be used with a shoe or boot.

A fracture of the lateral process of the talus may be confused with a lateral ankle sprain, so radiographs are generally needed to rule out this injury. Inversion injuries are also infrequently associated with fractures at the insertion of the peroneus brevis tendon. You can identify this injury by the point tenderness at the base of the fifth metatarsal, but a radiograph is required for definitive diagnosis. Early management is the same as for an ankle sprain.

Figure 21-28 Ligament complexes of the ankle.

Figure 21-29 Taping a sprained ankle. **A**, Strips of adhesive tape are placed perpendicular to each other to **(B)** lock the ankle with a tight weave. **C**, The tape edges are covered to prevent peeling. Hindfoot

The subtalar joint may infrequently be dislocated in a significant fall or jump when an individual lands off balance or on an uneven surface. The calcaneus may be dislocated medially or laterally relative to the talus, the latter being slightly more common. Assess the position of the heel relative to the ankle. With either dislocation, attempt a reduction if it will be more than 3 hours until the victim will reach a definitive care center.

Medial dislocation is reduced more easily than is lateral dislocation, in which the posterior tibial tendon frequently becomes displaced onto the lateral neck of the talus, blocking the reduction. The maneuver is the same for both: grasp the heel with the knee flexed (relaxing the gastrocnemius-soleus complex), accentuate the deformity, apply linear traction, and bring the heel over to the ankle joint. This maneuver is generally successful for medial dislocation, but lateral dislocation, especially when associated with open wounds, often requires open treatment. After reduction is attempted, apply a posterior splint and elevate the limb above the heart. Even if the reduction is successful, do not allow the victim to bear weight until definitive care is obtained.

Midfoot

Midfoot fracture dislocation (Lisfranc's injury) is described in the metatarsal fracture section.

Metatarsophalangeal and Interphalangeal Joints

Metatarsophalangeal (MTP) joint dislocations of the toes are relatively uncommon but can occur when a moderate axial force is directed at the great toe. Crush

injuries and rock-climbing accidents while the victim is wearing flexible-soled shoes can produce this injury; wearing boots with reinforced toe boxes of adequate depth generally prevents it. Injuries of this type at the great toe may be associated with fractures of the metatarsal or phalanx. The dislocation is generally dorsal. Because these may be open injuries, inspect the foot carefully. Reduce the joint in a manner similar to that used for dorsal PIP joint dislocation of the hand. MTP dislocation of the great toe can occasionally require open reduction if the head of the metatarsal buttonholes through the sesamoid-short flexor complex.

The lesser MTP joints are generally dislocated laterally or medially. The most common mechanism for this injury is striking unshod toes on immovable objects. Relocate the toes by applying linear traction with the victim supine and using the weight of the foot as countertraction. Similar mechanisms produce dislocations of the IP joints, which are also reduced by applying linear traction with gentle manipulation. Once reduced, tape the injured toe to the adjacent toe for 1 to 3 weeks and have the victim wear a protective boot with a stiff sole and deep toe box.

OVERUSE SYNDROMES

Plantar Fasciitis

Plantar fasciitis is inflammation of the fascia (tough connective tissue) on the sole of the foot. An individual with plantar fasciitis complains of insidious onset of pain at the origin of the plantar fascia, which is located at the most anterior aspect of the heel pad. Any activities that stretch the plantar fascia elicit pain. The pain is worse when first getting up in the morning or after resting, and is accentuated when the ankle and great toe are dorsiflexed (i.e., during push-off). Conservative treatment consists of (1) heel cord stretching 20 minutes twice a day, (2) antiinflammatory medications, and (3) wearing an orthotic that cups the heel, has a soft spot under the tender area, and supports the arch. It may take several weeks for symptoms to improve, but conservative therapy is successful in 90% of cases. An ankle-foot splint worn at night may also help because it holds the foot in a neutral position, keeping the plantar fascia slightly stretched. The orthosis also provides significant pain relief if used while walking. In severe cases, taping the arch can provide pain relief ([Figure 21-30](#)). A thin layer of benzoin or spray tape adhesive is applied to the bottom of the foot. Fix an anchor strip of $\frac{3}{4}$ -inch adhesive tape in a U-shape around the heel from just under the malleoli (prominences of the ankles) up to just behind the level of the "knuckles" of the toes ([Figure 21-30, A](#)). Next, lay fairly tight cross-strips of $\frac{1}{2}$ -inch tape across the bottom of the foot, with their ends torn to lay on the anchor strip ([Figure 21-30, B](#)). This creates a "sling" of tape under

Figure 21-30 Taping for arch support. **A**, Fix an anchor strip under the heel. **B**, Attach strips across the bottom of the foot. **C**, Lock the crosspieces. (From Auerbach PS: *Medicine for the outdoors: the essential guide to emergency medical procedures and first aid*, ed 3, New York, 1999, The Lyons Press.)

the foot for the support. Finally, apply another U-shaped piece of tape around the heel that crosses under the center of the arch and locks down the crosspieces ([Figure 21-30, C](#)).

Carpal Tunnel Syndrome

Carpal tunnel syndrome (CTS) occurs when the median nerve is compressed within the carpal tunnel. The carpal tunnel is located on the palmar side of the wrist and is formed by the transverse carpal ligament volarly and the carpal bones dorsally. The FDP and superficialis tendons to the second through fifth digits, the long thumb flexor, and the median nerve pass through this canal. Individuals complain of pain and paresthesias

along the palmar aspect of the radial digits. They also complain of frequently dropping objects. Symptoms are worse at night and aggravated with prolonged wrist extension or flexion. Phalen's sign, which is numbness and tingling in the median nerve distribution after sustained wrist flexion, is suggestive of CTS. Thenar muscle atrophy is only seen in severe cases. Consider other causes, such as more proximal sites of nerve compression (especially the cervical spine), dialysis, pregnancy, or acute and chronic trauma. Treatment consists of wrist splinting in slight extension (especially at night), activity modification, and antiinflammatory medications.

Tibial Fatigue Fractures

Tibial fatigue fractures can also occur in individuals who suddenly increase their activity. Victims complain of pain with weight bearing, swelling, tenderness to palpation, and increased warmth at the fracture site. The most common site in the tibia is the proximal two thirds of the tibial diaphysis. Fracture of the distal third of the fibula can also occur. Treatment consists of activity reduction, protective weight bearing, and avoiding activities that produce pain. Failure to decrease activity level completes fracture of the tibia. As the pain subsides, the activity level can be increased. Two to three months may be required for resolution of symptoms.

EVACUATION DECISION

The issues surrounding the decision to evacuate an orthopedically injured individual vary depending on the goals and support of the expedition. A group of 25 climbers in the Himalayas with physician support and a field hospital at base camp will have very different criteria for evacuating an injured person than will a family of four spending a week hiking in the Rockies. In all cases, party leaders should have a plan for contacting evacuation support teams if a serious injury occurs.

Musculoskeletal injuries that warrant immediate evacuation to a definitive care center are listed in [Box 21-2](#). These include any suspected cervical, thoracic, or lumbar spine injuries. A victim who has a suspected pelvic injury with posterior instability, significant suspected blood loss, or injury to the sacral plexus should receive emergency evacuation on a backboard. Any open fracture requires definitive debridement and care within 8 hours to prevent development of deep infection and should prompt emergency evacuation. Victims with suspected compartment syndromes must be evacuated on an emergency basis. Joint dislocations involving the hip or knee warrant immediate evacuation because of the associated risk of vascular injury or posttraumatic avascular necrosis of the femoral head. Lacerations involving a tendon or nerve warrant urgent evacuation to a center where an upper-extremity surgeon is available. In all but the most serious wilderness expeditions, arrangements should be made to evacuate the victim when the treating individuals are not reasonably sure of the injury with which they are dealing or its appropriate management.

**Box 21-2. INDICATIONS FOR
EMERGENT EVACUATION**

Suspected spine injury

Suspected pelvic injury

Open fracture

Suspected compartment syndrome

Hip or knee dislocation

Vascular compromise to an extremity

Laceration with tendon or nerve injury

Uncertainty of severity of injury

Chapter 22 - The Eye in the Wilderness

Frank K. Butler Jr.

In the practice of ophthalmology, where the diagnosis often rests primarily on what is seen with a slit lamp, any locale that does not afford ready access to this modality could be considered wilderness. Another aspect of wilderness medicine practice is unfavorable environmental conditions, such as extremes of temperature or exposure to hypoxic or hyperbaric stress. Remote locations often make determining the urgency with which a victim should be referred for specialty care one of the most challenging aspects of treating medical disorders in the wilderness.

This chapter considers several commonly encountered types of eye disorders: periocular trauma; chemical injury to the eye; sudden vision loss in a white, quiet eye; acute orbital and periorbital inflammation; and the acute red eye. A diagnostic and therapeutic approach to these disorders suitable for the wilderness environment is presented. Finally, eye problems that are encountered in diving and altitude exposures are discussed.

PRELIMINARY PLANNING

Pertinent ocular items in a preliminary medical survey include contact lens wear; previous episodes of nontraumatic iritis; previous episodes of herpetic keratitis; and a history of corneal transplantation, retinal detachment, radial keratotomy, or other ocular surgery. A positive response to these questions may alert the health care professional to specific ocular problems that may be encountered on the proposed trip. In addition, a basic wilderness eye kit (described below) should be assembled and taken on the trip.

THE WILDERNESS EYE KIT

[Box 22-1](#) contains the suggested items for a basic wilderness ocular emergency kit. A topical fluoroquinolone, such as ciprofloxacin or ofloxacin, is the antibiotic eye drop of choice. These medications are preferred for treatment of bacterial keratitis in a wilderness setting. Topical tetracaine and fluorescein strips are important for diagnosis. Topical prednisolone is an excellent ocular antiinflammatory medication. The choice of an oral antibiotic is based on the efficacy of the proposed antibiotic in treating preseptal cellulitis, orbital cellulitis, and penetrating trauma to the globe. The fluoroquinolone family of antibiotics offers several good choices for these indications. Trovafloxacin (500 mg tablets) is a systemic fluoroquinolone with excellent coverage against gram-positive, gram-negative, and anaerobic bacteria.^{[29] [80]} It also offers the convenience of once-daily dosing, but currently there have been a number of unpublished reports of hepatotoxicity with trovafloxacin that may limit the usefulness of this medication.^[57] Levofloxacin (500 mg tablets) is another systemic fluoroquinolone with very good activity against a wide variety of gram-positive and gram-negative organisms but less anaerobic coverage than trovafloxacin.^[57] Ciprofloxacin has been shown to have excellent ocular penetration when given orally^[40] but is less efficacious against gram-positive organisms than is levofloxacin. Weighing these factors, levofloxacin is my current recommendation for the preferred oral antibiotic. Bacitracin is an antibiotic ointment suitable for use in patching corneal abrasions. Ophthalmic ointments are best applied by using downward pressure on the lower lid to pull it away from the eye and then applying a 1-cm ribbon of ointment to the conjunctiva of the lower lid. When released, the lid returns to its normal position and normal blinking distributes the ointment over the corneal surface. Oral prednisone has three possible treatment uses in the wilderness—refractory iritis, giant cell arteritis, and orbital pseudotumor. Topical scopolamine (0.25%) is used to reduce ciliary muscle spasm, which causes much of the discomfort associated with iritis and corneal abrasion. Scopolamine, however, has the disadvantage of dilating the pupil (making the eye very sensitive to bright light) and preventing accommodation (making reading very difficult) for 5 to 7 days. Artificial tears are used to treat ocular surface drying and to flush conjunctival foreign bodies from the eye. Diclofenac 0.1% drops have been shown to decrease corneal sensitivity, especially when multiple drops are used.^{[68] [78] [79]} They have been found helpful in reducing the discomfort associated with traumatic corneal abrasion^[31] and excimer laser refractive surgery.^{[20] [81] [82]} In the unlikely event of angle-closure glaucoma in a wilderness setting, 2% pilocarpine may be used. The medications in [Box 22-1](#) are listed in my recommended priority order. In the spirit of making do in the wilderness, all of the disorders mentioned in this chapter can be managed with only the medications mentioned above, but alternative therapies are also discussed.

**Box 22-1. THE WILDERNESS EYE
EMERGENCY KIT**

MEDICATIONS

Ciprofloxacin or ofloxacin 0.3% drops

Tetracaine 0.5% drops

Prednisolone 1% drops

Levofloxacin 500 mg tabs

Bacitracin ointment

Prednisone 20 mg tabs

Artificial tears

Scopolamine 0.25% drops

Diclofenac 0.1% drops

Pilocarpine 2% drops

MISCELLANEOUS

Penlight with blue filter

Fluorescein strips

Cotton-tipped applicators

Metal eye shield

Eye patches (gauze)

Tape (1 inch, plastic or nylon)

Near vision card

Eye patches (gauze)

Tape (1 inch, plastic or nylon)

Near vision card

Wound closure strips ($\frac{1}{4}$ inch)

Magnifying glass

VISUAL ACUITY MEASUREMENT IN THE WILDERNESS

Evaluation of visual acuity is an essential element of the eye examination. Serial measurements of visual acuity are used to monitor an individual's progress while being treated for an eye disorder. Lack of an eye chart does not preclude the ability to obtain some quantitative measure of visual acuity. A near vision card can be used for this purpose. It should be held the prescribed distance—usually 14 inches—from the eye. If a near card is not available, the ability to read print in a book is a useful alternative measure. If glasses have been lost, use a piece of paper with a pinhole created by the tip of a pen or pencil to help compensate for the lost refractive correction. Remember that individuals 40 years of age and older may need a pinhole or reading correction to help them focus on a near target. Although a marked decrease in visual acuity can be an important warning of a significant ocular disorder, visual acuity cannot always be considered a reliable indicator of the severity of disease. A corneal abrasion victim may initially have worse visual acuity than a person with a retinal detachment or corneal ulcer, despite the fact that the latter two entities are much more serious disorders.

GENERAL THERAPEUTIC APPROACH

The recommendations made in this chapter are not necessarily the preferred management of the disorders mentioned when one is not in the wilderness setting. Of special interest is the recommendation for a nonophthalmologist to use a topical steroid in the management of several of the disorders discussed. The use of topical ocular steroids is generally best undertaken by ophthalmologists for two reasons: first, steroids are usually indicated only for relatively serious ocular disorders, which should be followed by an ophthalmologist when possible. Second, topical steroid use may result in elevated intraocular pressure, cataracts, and exacerbation of certain eye infections. All of the disorders for which steroids are recommended below should be referred to an ophthalmologist for follow-up as soon as possible upon return from the wilderness. Caution should be exercised in prescribing a topical steroid for longer than 3 days. Although cataracts are typically associated with long-term steroid use, a significant rise in intraocular pressure may occur within just a few days after initiation of topical steroid therapy. ^[23]

The requirement for expedited evacuation is one of the questions that must be answered when treating an eye disease in the wilderness. In the sections below, the need for evacuation may be considered nonurgent unless an *emergent* (as soon as possible) or *expedited* evacuation (as soon as is deemed reasonable given the resources required to accomplish the evacuation) is specified in the recommendations for treatment.

ACUTE PERIOCCULAR INFLAMMATION

Causes of acute periocular inflammation are listed in [Box 22-2](#). Preseptal cellulitis means that the infectious process is confined to the tissues anterior to the orbital septum. Preseptal cellulitis therefore presents as erythema and edema of the eyelids without restricted ocular motility, proptosis, pupillary change, or decrease in visual acuity. However, some of these findings may be difficult to appreciate in the presence of marked lid edema. Historical clues include antecedent periocular trauma or insect bite or sting. In the past, this disorder has been treated very aggressively because of the high incidence of *Haemophilus influenzae* infection, especially in pediatric patients, with subsequent septicemia and meningitis. The advent of *H. influenzae type B* vaccine has changed the microbiology of this disorder and may dictate changes in treatment strategies in the future.^[15] Persons who present with this disorder may be treated with levofloxacin 500 mg once a day and should have an expedited evacuation. Alternative antibiotic choices include ciprofloxacin 750 mg twice a day, dicloxacillin 500 mg every 6 hours, or cephalexin 500 mg 4 times a day.

Dacryocystitis (infection of the lacrimal sac) may mimic the findings of preseptal cellulitis, but erythema, edema, and tenderness are localized to the area inferior to the medial aspect of the eye, over the nasolacrimal sac and duct. The presence of this condition generally indicates obstruction in the opening between the lacrimal sac and the nasal cavity. Surgical intervention to restore the patency of this opening is usually undertaken after the acute infection is treated. The most common pathogens in acute dacryocystitis are *Staphylococcus aureus*, *Streptococcus* species, and (in children) *H. influenzae*.^[52] Treatment should be initiated with

levofloxacin 500 mg once a day and warm compresses. Alternative antibiotic choices include ciprofloxacin 750 mg twice a day or amoxicillin/clavulanate 875 mg/125 mg every 8 hours. Worsening of the condition after 24 to 48 hours should be managed with an expedited evacuation.

**Box 22-2. DIFFERENTIAL DIAGNOSIS
OF ACUTE PERIOCCULAR
INFLAMMATION**

Preseptal cellulitis

Orbital cellulitis

Dacryocystitis

Orbital pseudotumor

Insect envenomation

Periocular insect envenomation is a preseptal cellulitis look-alike. Although secondary infection may follow envenomation, the envenomation itself may produce significant erythema and edema. Diagnostic clues include a history of insect bite or a periocular papular lesion at the site of the envenomation. Ice or cool compresses may be used to treat the envenomation, with levofloxacin 500 mg once a day, dicloxacillin 500 mg every 6 hours, or cephalexin 500 mg 4 times a day added if secondary infection is suspected.

The term *orbital cellulitis* means that the infection has spread to or originated in the tissues posterior to the orbital septum. This may be manifest as diplopia or restriction in ocular motility as the extraocular muscles are affected, proptosis as edema in the orbit pushes the globe forward, decreased vision as the optic nerve is affected, or pupillary change if innervation of the pupil is affected. Fever is suggestive of orbital cellulitis in the differential diagnosis of periocular inflammation. This condition is more commonly associated with sinusitis than with periocular trauma as an antecedent disorder.^[42] Most series report a 50% to 75% incidence of sinusitis or other upper respiratory infection in association with orbital cellulitis.^[83] The bacteria that most commonly cause orbital cellulitis are *Staphylococcus aureus*, *Streptococcus pyogenes*, and *Streptococcus pneumoniae*.^[52] Anaerobes are frequently present in cases of chronic sinusitis and should be suspected in orbital cellulitis associated with long-standing sinus disease.^[52] If not treated aggressively, orbital cellulitis may be associated with life-threatening infection of the central nervous system. Before antibiotics became available, approximately 19% of persons with orbital cellulitis died of intracranial complications and 20% of survivors became blind in the involved eye.^[52] This disorder requires hospitalization and intravenous antibiotic therapy. Interim therapy should include levofloxacin 500 mg twice a day. Alternative antibiotic choices are ciprofloxacin 750 mg twice a day or amoxicillin/clavulanate 875 mg/125 mg every 8 hours. A decongestant should be added if sinusitis is present, and emergent evacuation should be undertaken.

Orbital pseudotumor is an inflammatory disease of the orbit that may present very much like orbital cellulitis. The differentiation between these two entities may be difficult.^[42]

There would typically not be a history of preceding sinusitis. A reasonable approach in the wilderness is to begin therapy with levofloxacin 500 mg twice a day and arrange for emergent evacuation. Prednisone (80 mg a day) should be added if there is no response to antibiotic therapy, there is no fever or sign of central nervous system involvement, and evacuation has not been possible by 24 to 48 hours after presentation. If prednisone therapy is initiated, its efficacy should be evaluated after 48 hours. If there has been a decrease in pain, erythema, edema, or proptosis, therapy should be continued until evacuation is accomplished. If there has been no response after 48 hours, the prednisone may be discontinued without tapering.

PERIOcular TRAUMA

Eyelid Laceration

The most important aspect of managing an eyelid laceration is to carefully exclude the presence of penetrating injury to the globe. Clues to the presence of an open globe are noted in that section below.

A lid laceration that is horizontally oriented on the eyelid, does not penetrate the full thickness of the lid, and does not involve the lid margin is relatively easily managed. In the absence of an ability to properly irrigate, disinfect, and suture the laceration, it should be managed by irrigation with the cleanest disinfected water available, application of topical antibiotic drops (ciprofloxacin, ofloxacin, or tobramycin) to the laceration, drying the surrounding skin surface, and then closing the laceration with tape strips. The wound may then be treated with antibiotic ointment (bacitracin or erythromycin) 4 times a day for 3 to 4 days. Alternatively, the laceration may be left open, treated with antibiotic ointment 4 times a day, and repaired 1 or 2 days later.^[42] The laceration should be observed frequently while healing. If redness or discharge develops, the victim should be started on levofloxacin 500 mg once daily or dicloxacillin 500 mg every 6 hours, the wound closure tape should be removed from the laceration, and evacuation should be expedited, especially if the response to oral antibiotics is poor.

Complicated lid lacerations, defined as stellate or complex, or involving the lid margin or the canthi (medial or lateral end of the palpebral fissure), are more difficult to manage. These lacerations may result in secondary functional difficulties if ocular lubrication or lacrimal drainage becomes impaired. In addition, cosmesis may be poor if a meticulous repair is not done. These

wounds should be managed by irrigation with the cleanest disinfected water available, application of antibiotic ointment, and coverage with a sterile dressing. Evacuation for definitive repair should be expedited.

Instillation of Adhesive Drops into the Eye

Inadvertent instillation of a "superglue" (cyanoacrylate-type adhesive) compound into the eye may bind the lids tightly together. Overnight application of a pressure patch with

eye pads presoaked with water has been reported to make manual separation of the lids possible and eliminate the need for general anesthetic and surgical separation of the lids.^[58] Ophthalmic ointment inserted through any small opening in the adherent lids has also been reported to facilitate resolution.^[48] Once the lids are separated, the eye should be checked for a corneal abrasion.^[71]

CHEMICAL INJURY TO THE EYE

The mainstay in the management of any chemical eye injury is immediate and copious irrigation of the ocular surface with water from whatever source is most readily available. In the wilderness, bottled water or intravenous solution is the best option. If neither of those is available, treated (filtered and disinfected) water from a drinking container is the next best option, with untreated water a last resort. Instillation of several drops of tetracaine will make the procedure much less uncomfortable for the victim. Irrigation should be continued for a minimum of 30 minutes.^[42] The two most damaging chemicals are strong acids and alkalis.^[42] Sulfuric acid from an exploding car battery is a typical acid, whereas cleaning products, such as drain cleaners, are typical alkalis. Caustic alkalis are more likely to damage the eye than acids because of their profound and rapid ocular penetration. Do not attempt to neutralize the corneal surface with acidic or alkaline solutions. Chemicals other than acids and alkalis may be uncomfortable when they are encountered but are less likely to produce significant long-term damage.

After a minimum of 30 minutes of flushing has been completed, the eye should be examined for retained particles. These should be removed with a moistened cotton-tipped applicator.^[42] Treatment for an acid- or alkali-induced injury includes ciprofloxacin or ofloxacin drops 4 times a day until fluorescein staining confirms that the corneal epithelial defect that typically accompanies these injuries has resolved. Topical prednisolone 1% should be added if there is significant inflammation. Prednisolone drops should be used every hour while awake for 3 days. Eye pain is managed with scopolamine drops 4 times a day for 3 days and oral pain medications.^[69] Evacuation should be expedited if: (1) the cornea is found to be opaque, (2) a large epithelial defect is found on fluorescein staining, or (3) significant pain persists after 3 days. Another sign of serious injury is blanching of the conjunctiva in the limbal area.^[42]

ACUTE LOSS OF VISION IN A WHITE, QUIET EYE

Vision may be variably decreased with many of the disease entities that are noted later in the Acute Red Eye section. This section addresses sudden loss of vision that occurs in a white, quiet eye. A differential diagnosis is provided in [Box 22-3](#) . Disorders that cause this symptom are often difficult to diagnose without ophthalmic instruments (none of which are included in the kit shown in [Box 22-1](#)). There are few treatments for most of these disorders likely to be effective in a wilderness setting. Although an afferent pupillary defect (Marcus Gunn pupil) may be present, this is a nonspecific finding that would be expected with most of the disorders in [Box 22-3](#) , except for vitreous hemorrhage and high-altitude retinal hemorrhage.

An important question that must be asked in the face of acute loss of vision in a white, quiet eye is "Does this person have giant cell arteritis?" Giant cell arteritis (GCA), also called temporal arteritis, can cause devastating anterior ischemic optic neuropathy, often first noted on waking and which usually becomes permanent.^[24] Subsequent involvement of the second eye is common if GCA in the first-stricken eye is not promptly treated.^[24] Although visual loss has been reported to occur in both eyes simultaneously, there is typically a delay of 1 to 14 days before the second eye is affected.^[1] Loss of vision in the second eye can be prevented in most cases by the prompt initiation of high-dose corticosteroid therapy.^{[1] [24] [28] [55]}

Arteritic anterior ischemic optic neuropathy is typically a disease of older individuals, with one large study reporting a mean age of 70 years and the age of the youngest patient as 53 years.^[1] Clues to diagnosis are temporal headache, jaw claudication, fever, weight loss, transient visual obscurations, and polymyalgia rheumatica (generalized myalgias).^[55] The visual obscurations seen in GCA usually last 2 to 3 minutes.^[55] If a person is felt to be

suffering from GCA, he or she should be started on prednisone 80 mg qd and evacuation expedited.

OF ACUTE LOSS OF VISION IN A
WHITE, QUIET EYE**

Retinal detachment

Central retinal artery occlusion

Anterior ischemic optic neuropathy

Optic neuritis

Central retinal vein occlusion

Arteritic anterior ischemic optic neuropathy

Vitreous hemorrhage

High-altitude retinal hemorrhage

If one suspects a retinal detachment based on a history of high myopia (extreme nearsightedness), floaters, or photopsias (flashing lights), expedited evacuation should be undertaken because of the need for surgical repair. Loss of central vision caused by a retinal detachment usually means that the macula is involved and that surgical repair is urgent rather than emergent. Ross and Kozy^[65] found that a delay to surgery of up to 1 week in macula-off rhegmatogenous retinal detachments did not affect final visual acuity. Expedited evacuation to a facility that has retinal surgery capability will allow for more precise determination of the urgency for surgical repair.

If the victim is at altitude (above approximately 3048 m [10,000 feet]), high-altitude retinal hemorrhage (discussed below) should be suspected and further ascent avoided.^[10] Descent of at least 915 m (3000 feet) should be undertaken as soon as feasible.^[10]

Another potentially treatable cause of sudden loss of vision in a white, quiet eye is central retinal artery occlusion (CRAO). Previous conventional therapy for CRAO of ocular massage, pentoxifylline, and anterior chamber paracentesis has been reported to be unsuccessful in restoring vision in 40 of 41 patients with CRAO, even though 11 patients presented within 6 hours of visual loss and 17 presented within 12 hours.^[66] Primate retinas can tolerate no more than 100 minutes of ischemia caused by a complete blockage of retinal blood flow.^[27] However, fluorescein angiography has shown that in humans, CRAO is seldom complete, and that therapy begun up to 6 hours after

visual loss may be successful in restoring vision.^[66]

Hyperbaric oxygen was reported successful in restoring vision on two separate occasions in one patient with recurrent branch retinal artery occlusions associated with Susac's syndrome.^[41] Oxygen is supplied to the retina from both the retinal and choroidal circulations. Under normoxic conditions, approximately 60% of the retina's oxygen is supplied by the choroidal circulation. Under hyperoxic conditions, the choroid is capable of supplying 100% of the oxygen needed by the retina.^[41] When retinal arterial flow is interrupted, the retinal tissue undergoes a period of ischemia. Blood flow may be spontaneously reestablished, as frequently happens with arterial obstruction, or ischemia may continue until cell death and necrosis occur.^[45] The period of time during which the tissue is ischemic, yet capable of recovery, is called the ischemic penumbra.^[45] Hyperbaric oxygen is not always required for a reversal of retinal ischemia. The author has treated a monocular patient who suffered a central retinal artery occlusion in his only seeing eye and presented to the emergency department within an hour of visual loss. The victim's vision improved from 20/400 to 20/25 within minutes on supplemental oxygen by mask. Unfortunately, however, his vision decreased rapidly to 20/400 whenever the supplemental oxygen was removed. The victim was heparinized and maintained on supplemental oxygen for approximately 10 hours, at which time the removal of oxygen no longer caused a decrease in vision. If oxygen is being carried for an extreme altitude summit attempt or for other purposes, a person with sudden painless loss of vision should be given a trial of oxygen administered in as high a concentration as possible to see if this therapy results in visual improvement.

Care should be taken when monocular visual loss occurs. Although central vision may still be normal in the fellow eye, depth perception may be impaired and the victim may therefore be at increased risk of a fall during evacuation.

ACUTE RED EYE

[Box 22-4](#) provides a partial list of disorders that can result in an acute red eye. In the absence of a slit lamp, the diagnosis must rely on the basic techniques of history, penlight inspection, fluorescein staining, response to administration of topical anesthesia, and pupillary status. The discussion of the differential diagnosis of the acute red eye that follows uses these clinical findings to establish the diagnosis. A pictorial representation is shown in [Figure 22-1](#). The term *fluorescein positive* is used to denote an eye with a discrete area of staining noted with cobalt blue light after instillation of fluorescein dye. Some conditions, such as blepharitis, viral keratoconjunctivitis, and ultraviolet (UV) keratitis, may cause a pattern of punctate staining referred to as *superficial punctate keratitis* (SPK).

Traumatic Ocular Disorders

Obvious Open Globe.

If there is a history of trauma and penlight inspection of the eye reveals an obvious open

536

Figure 22-1 Algorithm showing wilderness diagnostic procedure for the acute red eye.

globe (such as the eye in [Figure 22-2](#)), the examination should be discontinued and a protective shield placed over the eye. Do not apply a pressure patch or instill any topical medication. There are two primary concerns in the management of this condition. The first is to minimize manipulation or additional trauma to the eye that might raise intraocular pressure and result in expulsion of intraocular contents through the corneal or scleral defect. The second is to prevent development of posttraumatic endophthalmitis, an infection of the aqueous and vitreous humors of the eye. This typically has devastating visual results, with only 30% of victims in one study retaining visual acuity greater than or equal to 20/400.^[38] *Staphylococcus epidermidis* is the most

common pathogen implicated, but *Bacillus cereus* is a very aggressive pathogen often isolated in this condition. [38] After the shield is placed, the victim should be started on levofloxacin 500 mg twice a day. Trovafloxacin 200 mg once a day is a reasonable alternative choice for prophylaxis because of its very broad antibacterial spectrum [29] [80] and good ocular penetration. [50] Ciprofloxacin 750 mg twice a day is a third option. A person with an obvious open globe needs surgical repair as soon as possible and

Figure 22-2 Obvious open globe (corneoscleral laceration). (Courtesy Steve Chalfin, MD.)

should be evacuated emergently. Because there is a possibility that air may have been introduced into the eye, barometric pressure changes during evacuation should be minimized, if possible. However, this consideration is secondary to the need for expeditious transport to a facility where surgical repair can be performed.

Box 22-4. DIFFERENTIAL DIAGNOSIS OF THE ACUTE RED EYE

- Obvious open globe
- Corneal abrasion
- Corneal ulcer
- Subconjunctival hemorrhage
- Traumatic iritis
- Hyphema
- Occult open globe
- Herpes simplex virus keratitis
- Corneal erosion
- Acute angle closure glaucoma

Figure 22-3 Occult open globe with uveal pigment at the limbus and a peaked pupil. (Courtesy Steve Chalfin, MD.)

Figure 22-4 Corneal abrasion. (Courtesy Steve Chalfin, MD.)

Occult Ruptured Globe.

A penetrating injury to the eye or a ruptured globe may not always be obvious. Clues to occult rupture include large subconjunctival hemorrhage with chemosis, dark uveal tissue present at the limbus, distorted pupil ([Figure 22-3](#)), fluorescein leak from a linear or punctate corneal epithelial defect, mechanism of injury (hammering metal on metal, impaling injury, etc.), or decrease in vision. If an occult globe rupture is suspected, the victim should be treated as described previously for an obvious open globe. The relatively less severe appearance of the injury does not eliminate the threat of endophthalmitis, so levofloxacin therapy should be initiated.

Corneal Abrasion.

A corneal abrasion is disruption of the protective epithelial covering of the cornea ([Figure 22-4](#)). This results in intense pain, tearing, light sensitivity (photophobia), and

increased susceptibility to infection until the defect has healed (usually in 2 to 3 days). There is typically a history of antecedent trauma or contact lens wear. The sine qua non for this diagnosis is an epithelial defect on fluorescein staining. Standard treatment consists of bacitracin ointment followed by application of a pressure patch, although a recent study has shown that small (less than 10 mm²), noninfected, and non-contact lens-related abrasions healed significantly faster with less discomfort when they were not patched.^[33] In a wilderness setting, the nonpatching option has the additional advantage of not rendering the victim completely monocular and adversely affecting visual field and depth perception. If the nonpatching option is chosen, the victim should be treated with topical fluoroquinolone drops or bacitracin ointment 4 times a day until the corneal epithelium is healed. Diclofenac drops 4 times a day should be helpful in reducing discomfort. Sunglasses help alleviate photophobia. Repeated use of a topical anesthetic for pain control is contraindicated. If the abrasion is contact lens-related, the eye should *not* be patched because of the increased risk of corneal ulcer present with a contact lens-related abrasion^[60]; contact lens-related corneal abrasions should be treated with topical fluoroquinolone drops every 2 hours while awake until the epithelial defect has resolved to ensure coverage against *Pseudomonas*. An abrasion associated with vegetable matter should also not be patched.^[60] If the abrasion is large or the victim's discomfort severe, scopolamine drops once or twice a day may be added to the antibiotic. (Wait 5 minutes between each drop.) Much of the pain associated with corneal abrasion and ulcer is due to ciliary muscle spasm, which is relieved by scopolamine. The rationale for using scopolamine only with a very painful abrasion in the wilderness is that this medication will cause the pupil to dilate (and the eye to become very sensitive to light) and accommodation to relax (with a resultant decrease in near visual acuity) for approximately 5 to 7 days.

An oral analgesic may be required for pain control. The victim should be monitored daily for development of a corneal ulcer (noted on penlight examination as a white or gray infiltrate on the cornea) and for progress in healing of the epithelium (as measured by resolution of fluorescein staining).

Corneal Ulcer.

The term *corneal ulcer*, as used here, denotes acute bacterial, fungal, or protozoal infection of the cornea. Chronic corneal epithelial defects caused by a variety of autoimmune or inflammatory processes are also referred to as corneal ulcers at times, but these disorders are beyond the scope of this chapter. Although a corneal ulcer ([Figure 22-5](#)) is an infectious process, it is often preceded by a traumatic corneal abrasion. The other predisposing condition for a corneal ulcer is contact lens wear, which results in microtrauma to the corneal epithelium and may allow bacteria or other microorganisms to infect the cornea. Corneal ulcers are typically significantly painful. A small white or gray infiltrate on the cornea can be appreciated by a careful penlight examination. If not treated aggressively, the small initial lesion may progress to the much larger infiltrate shown in [Figure 22-5](#) with a correspondingly

Figure 22-5 Corneal ulcer. (Courtesy Steve Chalfin, MD.)

more severe impact on visual acuity. Fluorescein staining reveals an epithelial defect overlying the infiltrate. The associated pain is usually significantly decreased by application of a topical anesthetic, but ciliary spasm may cause pain relief to be incomplete.

An inadequately treated corneal ulcer may result in visual loss from dense corneal scarring or ocular perforation with subsequent endophthalmitis. Management of this disorder in the past included hospital admission for treatment with concentrated and frequently administered aminoglycoside and cephalosporin topical drops. Recently, outpatient therapy with fluoroquinolone eye drops has been shown to be comparable in efficacy with fortified antibiotic preparations.^[30] ^[53] Treatment for corneal ulcer, then, should be with ciprofloxacin or ofloxacin, 1 drop every 5 minutes for 3 doses initially, then 1 drop every 15 minutes for 6 hours, then 1 drop every 30 minutes thereafter around the clock.^[60] Scopolamine 1 drop 2 to 4 times a day may help relieve discomfort caused by ciliary spasm. Repeated use of topical anesthetics for pain control is contraindicated. Systemic analgesia may be required if pain is severe. Expedited evacuation is recommended.

Traumatic Iritis.

Iritis refers to inflammation of the iris or, more accurately, the anterior uveal tract of the eye. It may also be called *anterior uveitis* or *iridocyclitis*. The sine qua non of this condition is inflammatory cells in the anterior chamber of the eye, which must be visualized with a slit lamp. In the wilderness, this diagnosis must be presumptive. Iritis may accompany a corneal abrasion or result from blunt trauma. The diagnosis rests primarily on the presence of significant posttraumatic pain without a corneal abrasion or ulcer noted on fluorescein staining, or on pain that persists after the abrasion is healed. Treatment is with prednisolone 1 drop 4 times a day for 3 days. Scopolamine 1 drop twice a day may be added if pain is severe enough to justify the blurred vision that scopolamine therapy will entail.

Figure 22-6 Subconjunctival hemorrhage. (Courtesy Steve Chalfin, MD.)

Figure 22-7 HypHEMA. (Courtesy Steve Chalfin, MD.)

Subconjunctival Hemorrhage.

Subconjunctival hemorrhage ([Figure 22-6](#)) is a bright red area over the sclera of the eye that results from bleeding between the conjunctiva and the sclera. It is easily visible without the use of a slit lamp. This injury is innocuous and resolves over a period of several days to several weeks without treatment. In the presence of antecedent trauma, one should be alert for another, more serious injury. In particular, if hemorrhage results in massive swelling of the conjunctiva (chemosis), an occult globe rupture should be suspected.

HypHEMA.

The term *hypHEMA* is defined as blood in the anterior chamber. Although this is usually seen in the setting of acute trauma, it may also be caused by other conditions, such as iris neovascularization. The eye should be examined with the victim sitting upright. If enough blood is present, it collects at the bottom of the anterior chamber and is visible as a layered hypHEMA ([Figure 22-7](#)). This may not be appreciated if the victim is examined while in a supine position or if the amount of blood is very small.

539

Figure 22-8 Herpes simplex virus keratitis. (Courtesy Steve Chalfin, MD.)

Although most hypHEmas resolve without sequelae, this disorder may be complicated by an acute rise in intraocular pressure or corneal blood staining. Treatment in the wilderness consists of activity restriction (walking only), prednisolone drops 4 times a day, avoidance of aspirin or nonsteroidal antiinflammatory drugs (NSAIDs), and use of an eye shield until the hypHEMA has resolved. Diamox 250 mg 4 times a day by mouth should be added if available to treat the potentially increased intraocular pressure. Retinal injury and/or an occult ruptured globe may accompany traumatic hypHEMA. A hypHEMA victim requires ophthalmologic evaluation, so expedited evacuation should be undertaken.

Nontraumatic Fluorescein-Positive Acute Red Eye

Herpes Simplex Virus Keratitis.

The essential element in this diagnosis is the characteristic dendritic epithelial pattern on fluorescein staining ([Figure 22-8](#)). There will often be a history of previous episodes of herpes simplex virus (HSV) keratitis. Treatment is trifluorothymidine 1% drops 9 times a day.^[60] Treatment is continued until the corneal staining has resolved, at which time the frequency of dosing is reduced to 4 times a day for 1 week. Trifluorothymidine was not included in the list of eye medications to be taken on the expedition because trifluorothymidine drops require refrigeration. If a significant delay is anticipated before evacuation, HSV keratitis may be treated by using tetracaine 3 to 5 drops given 1 minute apart to anesthetize the cornea and then performing a gentle Q-tip debridement of the epithelial lesion.^[60] The resulting epithelial defect should then be treated as described in the Corneal Abrasion section.

Corneal Erosion.

A corneal erosion is an epithelial defect caused by nontraumatic disruption of the corneal epithelium. The fluorescein staining pattern seen with corneal erosion may be identical to that seen with corneal abrasion; pain and photophobia are present with both disorders. The diagnosis is made when the apparent corneal abrasion has no history of trauma to explain its presence. There is often a history of previous similar episodes. The two primary causes for corneal erosion are corneal dystrophies and previous ocular trauma.^[55] Recurrent corneal erosions are believed to be caused by a defect in healing between the hemidesmosomes of the corneal epithelium and the underlying basement membrane.^[42] At night, the epithelium may become adherent to the closed eyelid during sleep. When the individual awakens and opens his or her eyes, the corneal epithelium is pulled away from the basement membrane by movement of the lid. This accounts for the typical history of acute onset of pain on awakening. Signs and symptoms include pain, tearing, and foreign body sensation.^[42]

Treatment of these lesions may be difficult. The cornea should be inspected for a loose sheet of epithelium that remains partially attached to the corneal surface. If this is present, try to debride it with a cotton-tipped applicator after topical anesthesia with tetracaine. The lesion is then managed initially in the same manner as a corneal abrasion. There is a high rate of recurrence if follow-up treatment with 5% sodium chloride ointment each evening or anterior stromal puncture is not undertaken.

Corneal Abrasion and Corneal Ulcer.

Both lesions may occur as complications of contact lens wear. Management has been described above. Contact lens-related corneal abrasions have a relatively high incidence of progressing to corneal ulcers.^[33] Therefore they should not be patched and should receive topical antibiotic therapy with ciprofloxacin or ofloxacin drops every 2 hours while awake until the epithelial defect has resolved. Contact lens wear *in both*

eyes should be discontinued immediately. If an ulcer is related to contaminated lens solutions, infection in the first eye may be followed rapidly by a similar occurrence in the other eye.

Nontraumatic Fluorescein-Negative Acute Red Eye (Pain Not Significantly Improved by Topical Anesthesia)

Acute Angle-Closure Glaucoma.

This diagnosis is easily made when the intraocular pressure can be measured with a tonometer. Intraocular pressure is normally between 10 and 21 mm Hg. With acute angle-closure glaucoma, the pressure may increase to 50 or 60 mm Hg or higher. Although handheld tonometers are available, they will not often be present outside of hospitals or clinics. The most important clues to the diagnosis of angle-closure glaucoma in the wilderness setting are the characteristics of the pain and the status of the pupil. Angle-closure glaucoma victims do not have the mild burning or foreign body type of pain typically seen with conjunctivitis, blepharitis, or other external eye diseases. Angle-closure glaucoma produces a pain that is usually deep and severe. Although corneal abrasions

and corneal ulcers may also be accompanied by severe pain, the pain in these two disorders is usually significantly relieved by topical anesthetics. This is not true of the pain seen with acute glaucoma, scleritis, or iritis. In these disorders, the pain is rarely if ever significantly relieved by topical anesthetics. In acute angle-closure glaucoma, the pupil is usually found to be mid-dilated (6 to 7 mm) and vision is usually decreased. This disorder generally affects persons over 50 years of age^[42] and is more common in persons of Asiatic ethnic origins. There is often a history of previous transient episodes of eye pain. Nausea and vomiting may be present. An eye with acute angle-closure glaucoma is shown in [Figure 22-9](#).

The usual treatment is topical antioocular hypertensive medications and laser iridotomy, which allows the aqueous humor to bypass the pupillary block. This relieves the angle closure with a resultant decrease in intraocular pressure.^[42] In the wilderness setting, treatment should be with 2% pilocarpine one drop every 15 minutes for 4 doses,^[55] then 4 times a day in *both* eyes, since there is a high rate of subsequent occurrence of angle-closure glaucoma in the fellow eye. Pilocarpine alone may be successful in relieving the angle closure and lowering the pressure, but this is not a reliably effective treatment because ischemia of the pupillary sphincter muscle may prevent pilocarpine from exerting its miotic effect. Diamox 250 mg 4 times a day by mouth should be added if available. Evacuation should be emergent if pain is not relieved, since even 1 day of very high intraocular pressure may result in permanent damage to the optic nerve and loss of vision.

Nontraumatic Iritis.

Signs and symptoms of nontraumatic iritis that may be appreciated without a slit lamp include pain, redness, photophobia, limbal flush, and decreased vision.^[55] There is often a history of previous episodes. An eye with nontraumatic iritis is shown in [Figure 22-10](#) . (The pupil is iatrogenically dilated.) Iritis not associated with corneal trauma is typically more severe

Figure 22-9 Angle-closure glaucoma. (Courtesy Steve Chalfin, MD.)

than the traumatic variety but may range from mild to very severe and typically is not significantly relieved by topical anesthesia. Fluorescein staining is negative and the pupil is usually miotic, thus helping differentiate iritis from angle-closure glaucoma. Iritis is far more common than angle-closure glaucoma and may be associated with a number of systemic infectious and inflammatory diseases. In the wilderness setting, the emphasis should be on immediate treatment with prednisolone 1% 1 drop every hour while awake. Scopolamine 1 drop 1 to 4 times a day may be added for pain control and to prevent posterior synechiae (pupillary scarring) if inflammation is severe. If pain is not significantly decreased in 24 to 48 hours, oral prednisone 80 mg a day should be added to the treatment regimen and maintained until evacuation. Evacuation should be expedited, since posterior synechiae and elevated intraocular pressure may develop.

Scleritis.

It may be difficult to differentiate between nontraumatic iritis and scleritis without a slit lamp, but scleritis is much less common than iritis. The characteristics of the pain are similar, with pain, photophobia, scleral injection, and tearing.^[55] Scleritis is often associated with rheumatologic disease and may be either nodular or diffuse.^[55] The diffuse form of scleritis is shown in [Figure 22-11](#) . The initial treatment of scleritis in the wilderness setting is topical prednisolone drops 1 drop every hour while awake and an NSAID, if available. Prednisone 80 mg a day should be added if there is no improvement in 24 to 48 hours and maintained until an expedited evacuation.

Nontraumatic Fluorescein-Negative Acute Red Eye (No Discomfort or Discomfort Improved by Topical Anesthesia)

Conjunctivitis.

One of the most common disorders in this diagnostic category is conjunctivitis. Etiologic

agents of infectious conjunctivitis include bacteria,

Figure 22-10 Nontraumatic iritis. (Courtesy Steve Chalfin, MD.)

541

viruses, chlamydiae, fungi, and parasites.^[42] Acute allergic conjunctivitis may also be encountered, especially in a wilderness setting. The keys to diagnosis are the presence of discharge or tearing, relatively mild burning or foreign-body type discomfort that is relieved by topical anesthesia, and a negative (or SPK) fluorescein staining pattern. The diagnosis of conjunctivitis should be questioned in the absence of discharge or tearing. The primary exception to this statement is allergic conjunctivitis, which may not generate a significant discharge. In this case, bilaterality, significant ocular itching, and a history of ocular or systemic allergies will help make the diagnosis. With infectious conjunctivitis, there are often signs or symptoms of an accompanying upper respiratory infection (URI) or a history of contact with other persons who have recently suffered from conjunctivitis.

Treatment of conjunctivitis in the wilderness setting is with ciprofloxacin or ofloxacin drops (1 drop 4 times a day for 5 days) if there is a yellowish discharge. Tobramycin 0.3% drops or trimethoprim/polymixin B drops are acceptable alternatives.^[42] This should be an adequate treatment time if conjunctivitis is bacterial. Symptoms that persist for more than 5 days suggest a viral etiology. These symptoms may take several weeks to clear, just as some viral URIs take several weeks to resolve. If there is only tearing or a watery discharge, suggesting a viral etiology, treatment with artificial tears and cool compresses may be substituted for antibiotic therapy. The victim should be instructed on infection precautions, since viral conjunctivitis can spread rapidly through a group. This is especially true if the discomfort caused by conjunctivitis is severe and accompanied by significant photophobia. These symptoms suggest epidemic keratoconjunctivitis (EKC), which, in addition to having a prolonged course, is very uncomfortable because of the corneal involvement. An eye with EKC is shown in [Figure 22-12](#). Sunglasses should be part of the treatment. Scopolamine 1 drop 2 to 4 times a day may be required to reduce discomfort.

Figure 22-11 Diffuse scleritis. (Courtesy Steve Chalfin, MD.)

As noted previously, if the predominant ocular symptom is itching, allergic conjunctivitis should be suspected. Allergic conjunctivitis may be treated with cool compresses and/or systemic antihistamines. Severe ocular itching may be treated with a 3-day course of prednisolone, 1 drop 4 times a day.

Hyperacute conjunctivitis with marked lid edema, conjunctival hyperemia, chemosis, and copious purulent discharge should alert the care provider to the possibility of a gonococcal etiology.^[42] Gonococcal conjunctivitis may progress to vision-threatening keratitis and should be treated aggressively with levofloxacin 500 mg once a day, ciprofloxacin or ofloxacin drops 4 times a day, and expedited evacuation.

Bacterial and viral conjunctivitis are highly contagious. Individuals with infectious conjunctivitis should be informed of this fact and the importance of infection precautions emphasized.

Blepharitis.

Blepharitis is probably the most common external eye disease seen in the general ophthalmologist's office.^[16] It is often misdiagnosed as conjunctivitis. Differentiation may often be made by the history. Blepharitis tends to be a bilateral, chronic disease with recurrences and exacerbations. There is chronic flaking and irritation of the skin at the base of the eyelashes that may occasionally be complicated by bacterial superinfection. An eye with blepharitis is shown in [Figure 22-13](#). There may be an association with skin disorders, such as seborrheic dermatitis or acne rosacea.^[16] The victim often has a history of chronic ocular itching and burning. Fluctuating vision may be present as well.^[16] A history of excessive mucous discharge in the eyes on waking is often present.

Treatment for blepharitis should focus on the lid margins. Bacitracin or erythromycin ophthalmic ointment should be applied thinly to the lid margins at bedtime for 4 weeks. Lid hygiene is directed at reducing the amount of debris on the lid margins and consists

Figure 22-12 Epidemic keratoconjunctivitis (EKC). (Courtesy Steve Chalfin, MD.)

Figure 22-13 Blepharitis. (Courtesy Steve Chalfin, MD.)

of warm, moist compresses applied to the eyelids 1 to 4 times a day for 5 to 10 minutes, followed by gently wiping away the moistened lash debris. Artificial tears may relieve the sensation of "dry eye" that often accompanies blepharitis.^[16]

Ultraviolet Keratitis.

The diagnosis of ultraviolet keratitis is easy to make in the presence of a severely sunburned face and bilateral red, painful eyes. The discomfort typically does not start until 6 to 10 hours after UV exposure and may awaken the victim.^[55] Symptoms range from mild irritation and foreign body sensation to severe pain, photophobia, and lid spasm.^[55] Fluorescein staining usually reveals a punctate staining pattern.

Treatment consists of bacitracin or erythromycin ophthalmic ointment applied to the eye 4 times a day (an acceptable alternative would be fluoroquinolone drops 4 times a day) and sunglasses. In a severe case, one or both eyes may be patched to aid in pain control, although it may be better to patch only the more severely affected eye so that the victim is not deprived of vision in both eyes.^[10] Scopolamine (1 drop twice a day) may be added for pain control. Systemic analgesia may also be required. The victim should be reexamined every day until there is no longer an SPK pattern present on fluorescein staining, at which time antibiotic therapy may be discontinued. The duration of discomfort from UV keratitis is typically 24 to 48 hours.^[55]

Conjunctival Foreign Body.

The symptom of ocular foreign body sensation does not necessarily mean that a conjunctival or corneal foreign body is present. Although the presence of a conjunctival foreign body may be strongly suspected based on the abrupt onset of discomfort following a gust of wind or other mechanism for depositing foreign material in the eye, definitive diagnosis requires visualization of the offending material, which may sometimes be quite difficult. [Figure 22-14](#) shows an eye with a conjunctival foreign body. The victim

Figure 22-14 Conjunctival foreign body. (Courtesy Steve Chalfin, MD.)

is often able to help with foreign body localization before the instillation of topical anesthetic drops.

Treatment consists of a careful search for the foreign body using adequate lighting. Topical anesthesia makes the victim much more agreeable during the search and removal efforts. A handheld magnifying lens or pair of reading glasses will provide magnification to aid in the visualization of the foreign body. Eyelid eversion with a cotton-tipped applicator helps the examiner identify foreign bodies located on the upper tarsal plate. Once located, the foreign body should be removed with a cotton-tipped applicator after the eye has been anesthetized and the cotton-tipped applicator moistened with tetracaine. The eye is then stained with fluorescein to check for a corneal abrasion. If no foreign body is visualized but the index of suspicion is high, vigorous irrigation with artificial tears or sweeps of the conjunctival fornices with a moistened cotton-tipped applicator after topical anesthesia may be successful in removing the foreign body.

Several types of foreign body merit special mention. If the foreign body identified is one that may have penetrated into the eye, such as a large thorn, the victim should be managed as described in the Obvious Open Globe section. Hot ashes or cinders from a campfire may strike the eye, resulting in both a foreign body and a thermal burn. Immediate instillation of topical anesthesia will provide temporary pain relief to facilitate foreign body removal and will also stop any ongoing thermal injury. After the foreign body has been removed, the corneal abrasion that typically results from a thermal injury to the cornea should be managed as outlined in that section.

Dry Eye.

Symptomatic dry eye is commonly encountered in the wilderness, especially in mountainous areas where the air is very dry and significant wind is often present.^[10] Dry eye is usually bilateral and may result in secondary tearing.^[60] There may be a history of

previous episodes of symptomatic dry eye. Individuals with chronic dry eyes are usually middle-aged or older and may have a history of autoimmune disorders. The discomfort is usually relieved by topical anesthesia.

Treatment is with artificial tears used as often as needed to relieve symptoms. Dehydration may contribute to this condition, and adequate fluid intake should be

maintained. The use of sunglasses may provide protection from the wind and be of significant benefit in managing this disorder.

Contact Lens Overwear Syndrome.

The considerations here are much as described in the Dry Eye section, except that the symptoms are magnified by the presence of contact lenses.

Contact lens rewetting drops and sunglasses are the first line of management. Should these measures be ineffective in relieving symptoms, the contact lenses should be removed. If significant SPK are present on fluorescein staining, ciprofloxacin or ofloxacin drops 4 times a day should be used until the SPK have resolved.^[10] Contact lenses should not be replaced in the eye until the eye is symptom-free. An individual who wears contact lenses in the wilderness should *always* carry a pair of glasses that can be used if contact lens problems arise.

Episcleritis.

Episcleritis is a benign, self-limited, inflammatory condition of the lining of the eye between the conjunctiva and the sclera.^[42] There is usually sectorial redness without discharge ([Figure 22-15](#)). There is often a history of previous episodes. Discomfort is typically mild or absent. The presence of severe pain, photophobia, or decrease in vision suggests another cause. Episcleritis is often misdiagnosed as conjunctivitis, but the lack of a discharge and the sectorial redness usually seen in episcleritis will help differentiate between the two disorders.

Episcleritis is usually self-limited and resolves without treatment over 3 to 4 weeks.^[42] If symptoms are troublesome, it may be treated with prednisolone drops 4 times a day for 3 to 5 days.

SOLAR RETINOPATHY

The retina is protected from UV radiation damage because this high-energy radiation is absorbed by the cornea and the lens of the eye. However, visible and near-infrared light of sufficient intensity may reach the retina and cause photochemical damage.^[42] In the wilderness setting, this would most likely occur as the result of staring at the sun or a solar eclipse. Shortly after such an exposure, the individual may experience blurred or distorted vision, a central scotoma, and/or a headache. Visual acuity is often reduced to the 20/40 to 20/70 range. There is no effective therapy for this injury, but visual acuity may return to normal over a period of several months in mild cases.

LOCATING A DISPLACED CONTACT LENS

Soft contact lens wearers may occasionally have one of their lenses become displaced, causing blurred vision and a foreign body sensation. Once the lens is displaced, it may be hard to locate. The conjunctival fornix of the lower lid is easily examined by distracting the lens from the globe with gentle downward finger pressure applied to the lower lid. If the contact lens has been displaced into the superior conjunctival fornix (usually the case), it may be more difficult to locate. If visual inspection with a penlight and a handheld magnifying lens is not successful in finding the lens, gentle digital massage over the closed upper lid directed towards the medial canthus often results in the contact lens emerging at that location. Several minutes of massage may be required. A few drops of artificial tears often facilitates the process. If this maneuver is unproductive, the eye may be anesthetized with a drop of tetracaine, the upper lid distracted from the globe with upward finger pressure, and the fornix swept with a moistened cotton-tipped applicator.

IMPROVISATION (see also [Chapter 19](#))

If you encounter a person with known or suspected globe rupture, it is of paramount importance to ensure that subsequent inadvertent trauma does not cause extrusion of ocular contents. If an eye shield is not available, one may be fashioned with duct or rigger's tape and any available rigid flat or concave object that can be placed over the eye. Examples include small cups or bowls to provide a good standoff distance between the eye and the improvised shield. Improvised wound closure strips can be made by tearing rigger's or duct tape into ¼-inch widths. Spectacles and sunglasses can be improvised by making a pinhole in a piece of paper or cardboard. (Make the pinholes before placing the paper or cardboard in front of the eyes!) Take note of the

544

TABLE 22-1 -- Pressures and Equivalent Oxygen Fractions at Altitude

FEET	METERS	ATMOSPHERIC PRESSURE (mm Hg)	EQUIVALENT OXYGEN (%)	PARTIAL PRESSURE OF OXYGEN (mm Hg)
Sea level	Sea level	760	20.9	159
4,000	1,219	656	18.0	137
7,000	2,134	586	16.1	122
10,000	3,048	523	14.4	109
15,000	4,572	429	11.8	89
20,000	6,096	347	9.5	73
25,000	7,620	282	7.8	60
29,028	8,848	253	7.0	53

restriction in peripheral vision caused by using pinhole glasses. If the purpose is to improvise sunglasses rather than to achieve a refractive effect, the pinhole can be larger or fashioned into a horizontal slit to improve peripheral vision. Improvised magnifying glasses for examining the eye or other small areas may be made by simply using a pair of reading or hyperopic glasses. Another refractive improvisation technique involves a handheld magnifying lens. This convex lens with its plus refracting power can be used

to provide a variety of hyperopic refractive corrections by moving the lens to various distances in front of the eye.

THE EYE AT ALTITUDE

Ocular disorders associated with altitude exposures have been addressed in a recent review article.^[10] The sections from that paper that address ocular disorders likely to be encountered in mountaineering are included below.

Altitude Exposures and Ocular Physiology

A number of significant effects on visual function resulting from the hypoxia of altitude were described by Wilmer and Berens^[88] in their classic article. The decrease in ambient pressure at altitude causes a hypobaric hypoxia despite a constant oxygen fraction of 0.21 as noted in [Table 22-1](#) . Retinal blood flow has been shown to increase by 128% after 4 days at 5300 m (17,384 feet).^[22] This increase in blood flow results in clinically observable changes, such as increase in diameter and tortuosity of retinal vessels and optic disk hyperemia, which are seen in most unacclimatized persons at altitudes above 4573 m (15,000 feet).^{[22] [35] [46] [59]}

Because of its avascularity, the cornea receives most of its oxygen supply from the surrounding atmosphere,^[74] so it may suffer hypoxic dysfunction even if the inspired gas mix is not hypoxic, as noted below in the Refractive Changes at Altitude after Refractive Surgery section. This is an important factor when considering topics such as the suitability of contact lenses and refractive surgical procedures for mountaineers and aviators.

Figure 22-16 High-altitude retinal hemorrhages. (Courtesy Dr. M. McFadden, UBC, Vancouver, BC, in association with Dr. C. Houston, Burlington, Vt.; Dr. G. Gray, DCIEM, Toronto, Ontario; and Drs. Sutton and P. Powells, McMaster University, Hamilton, Ontario.)

High-Altitude Retinal Hemorrhage

There are many reports of retinal hemorrhages ([Figure 22-16](#)) in mountain climbers.* These have been described as high-altitude retinal hemorrhages (HARH) or as part of the more inclusive term *altitude retinopathy*.^[8] A classification for HARH has been developed by Weidman.^{[85] [86]} Butler, Harris, and Reynolds^[9] reported an incidence of HARH of 29% in climbers on a Mt. Everest expedition at altitudes ranging from 5300 to

8200 m (17,385 to 26,896 feet). McFadden et al^[46] found that 56% of their subjects had HARH at an altitude of 5360 m (17,581 feet) and that one had a retinal nerve fiber layer infarct (cotton wool spot) ([Figure 22-17](#)). They also reported that exercise at altitude was associated with both an increased incidence of HARH and fluorescein leakage from the retinal vessels. Hackett and Rennie^[26] described HARH in 4% of 140 trekkers examined at 4243 m (13,917 feet) at Pheriche in the Himalayas. These authors also found a significant correlation of retinal hemorrhages with symptoms of acute mountain sickness (AMS). Kobrick and Appleton^[35] found no retinal

McFadden, UBC, Vancouver, BC, in association with Dr. C. Houston, Burlington, Vt.; Dr. G. Gray, DCIEM, Toronto, Ontario; and Drs. Sutton and P. Powells, McMaster University, Hamilton, Ontario.)

Figure 22-18 The normal fundus as sea level (left). The same fundus at 5400 m (right). Note the vascular engorgement and tortuosity at altitude. (Courtesy Dr. M. McFadden, UBC, Vancouver, BC, in association with Dr. C. Houston, Burlington, Vt.; Dr. G. Gray, DCIEM, Toronto, Ontario; and Drs. Sutton and P. Powells, McMaster University, Hamilton, Ontario.)

hemorrhages in eight subjects examined after 48 hours at 4573 m (15,000 feet) in a hypobaric chamber, although all subjects displayed the marked vascular engorgement and tortuosity typical of the eye at altitude ([Figure 22-18](#)). Differences in the incidence of HARH for exposures at similar altitudes may be due to differences in time at altitude before examination, acclimatization schedule, exercise levels, examination techniques, and the presence of concurrent conditions that may predispose to HARH.

HARH has been reported to be associated with both altitude headache and a history of vascular headache at sea level.^[67] Rimsza et al^[61] noted that HARH may occur at lower altitudes in individuals with chronic lung disorders that interfere with oxygenation. Their case report described a woman with cystic fibrosis who had climbed as high as 3049 m (10,000 feet) but was at 1677 m (5500 feet) when she noted a sudden decrease in vision associated with preretinal hemorrhage of the right eye. They also noted that the ocular findings of cystic fibrosis are similar to those seen with altitude retinopathy.^[61]

Although HARHs are often not associated with acute visual symptoms,^{[8] [59] [84] [91]} they may result in a loss of visual acuity or paracentral scotomas.^{[21] [39] [70] [84]} Lang and Kuba^[39] reported a person who experienced decreased visual acuity and central scotoma from HARH resulting from a 7000-m (22,960-foot) altitude exposure. Permanent deficits in visual function are uncommon but have been reported.^{[70] [84]} Shults and Swan^[70] reported that four survivors of an ill-fated Aconcagua expedition in Argentina in 1973 were found to have severe HARH after an altitude exposure of 6860 m (22,500 feet). Two of the survivors suffered apparently permanent paracentral scotomas.

No reports were found of a progressive decrease in visual acuity or progressive enlargement of paracentral scotomas as a result of remaining at altitude after the development of HARH.^[10] Weidman^[84] reported a case in which further ascent after the development of HARH resulted in additional lesions. HARH that results in decreased visual acuity should be a contraindication to further ascent.^[10] Butler and Harris^[8] recommended that evacuation of individuals with decreases in visual function resulting from HARH (in the absence of high-altitude cerebral edema [HACE] or high-altitude pulmonary edema [HAPE]) be considered nonemergent unless reexamination indicates a progressive deterioration of vision or increasingly severe retinopathy. HARH resolves over a period of 2 to 8 weeks after the altitude exposure is terminated.^[84]

Cortical Blindness at High Altitude

Hackett^[25] reported six cases of cortical blindness at high altitude. These victims were found to have intact pupillary reflexes. Descent, Gamow (hyperbaric) bag recompression, or supplemental oxygen breathing should be used in persons with neurologic dysfunction at altitude.

Ocular Motility

Kramar^[37] reported that convergence insufficiency was found in women with altitude illness. Basnyat^[2] noted that lateral gaze palsy and other focal neurologic deficits, often in the absence of other symptoms of AMS or HACE, are seen commonly by physicians in the Himalayan Rescue Association. Rennie and Morrissey^[59] reported a person with nystagmus at altitude that was associated with ataxia and intention tremor. Ocular motility abnormalities should be managed in the same way as cortical blindness at high altitude as described in the preceding paragraph.

Contact Lenses in Mountaineering

Contact lenses may be used successfully at high altitude.^{[11] [91]} Clarke^[11] noted that contact lenses were used successfully by five members of the British Everest Expedition in 1975 up to altitudes as high as 7317 m (24,000 feet). Use of contact lenses at altitude during trekking or mountaineering entails several considerations beyond those encountered in normal use. In general, overnight use of extended-wear contact lenses

not recommended because of the associated increased rate of microbial keratitis. Even soft contact lenses decrease the oxygen available to the cornea. Lid closure during sleep further accentuates corneal hypoxia. Removing contact lenses at night, however, presents logistical problems in the mountaineering setting. Practicing acceptable lens hygiene during an expedition is difficult. The mountaineer who leaves contact lenses in a case filled with liquid solution in the tent outside of his or her sleeping bag at night may awaken to find the solution and lenses frozen solid.

Guidelines for military personnel using contact lenses in austere environments have been developed and apply to the expedition setting^[10] :

1. Disposable extended-wear lenses may be left in the eye for up to 1 week. If the wearer is still in the field at the end of this period, the lenses should be removed and discarded. After an overnight period without lenses, new lenses may be inserted, with strict attention to contact lens hygiene.
2. Contact lens wearers should *always* have backup glasses available for use in the wilderness in case a lens is lost or becomes painful.
3. Individuals who wear contact lenses on expeditions should carry both fluoroquinolone eye drops and contact lens rewetting solution. Both types of drops may freeze if not protected from the cold.
4. Contact lens wearers often note that their eyes become dry. This discomfort may be alleviated with contact lens rewetting drops.
5. Contact lens wearers often note increased sensitivity to sunlight. Individuals who wear contact lenses in the field during daylight hours should carry sunglasses.

Continuous wearing of disposable contact lenses for a week, followed by discarding of the lenses and insertion of fresh lenses after an overnight period without a lens, is a controversial approach to contact lens wear in an expedition setting. Whether or not the reduction in lens handling offsets the increased risk of microbial keratitis resulting from overnight wear is not known. The decision to wear contact lenses while mountaineering should be made carefully. Microbial keratitis (corneal ulcers) can pose a significant threat to vision under the best of circumstances. Should this disorder occur with a 7- to 10-day delay to definitive ophthalmologic care, the danger of permanent loss of vision is great. Any eye pain that occurs in contacts lens wearers in the wilderness should be managed as described previously in the Acute Red Eye section. Considering all the potential problems, a good pair of prescription glacier glasses or laser refractive surgery might be a more reasonable alternative than contact lenses as a long-term solution to the refractive needs of mountaineers.

Refractive Changes at Altitude after Refractive Surgery

An acute hyperopic shift in persons who have had radial keratotomy (RK) and then

experience an altitude exposure was reported by Snyder in 1988^[75] and White and Mader in 1993.^[87] This effect has been observed at altitudes as low as 2744 m (9000 feet).^[75] A dramatic example of this phenomenon was that experienced by Dr. Beck Weathers in the Everest tragedy of May 1996 in which eight climbers lost their lives. Dr. Weathers had undergone bilateral RK years before the expedition. He noted a decrease in vision, which started early during his ascent.^[36] Author Jon Krakauer recalls that "... as he was ascending from Camp Three to Camp Four, Beck later confessed to me, 'my vision had gotten so bad that I couldn't see more than a few feet.'"^[36] This decrease in vision forced Dr. Weathers to abandon his quest for the summit shortly after leaving Camp Four and nearly resulted in his death. Another report describes two expert climbers who experienced hyperopic shifts of three diopters or more during altitude exposures of 5000 m (16,400 feet) or higher on Mt. McKinley and Mt. Everest.^[12]

Mader and White^[43] found that the magnitude of the hyperopic shift was 1.03 +/- 0.16 diopters after 24 hours at 3659 m (12,000 feet) and 1.94 +/- 0.26 diopters at 5183 m (17,000 feet). Ng^[51] reported no refractive change after 6 hours in post-RK eyes at a simulated altitude of 3659 m, suggesting that the hyperopic shift requires more than 6 hours to develop. Further studies by Mader et al^[44] at 4299 m (14,100 feet) on Pike's Peak revealed that: (1) subjects who had undergone RK demonstrated a progressive hyperopic shift associated with flattened keratometry findings during a 72-hour exposure; (2) control eyes and eyes that had undergone laser refractive surgery (photorefractive keratectomy [PRK]) experienced no change in their refractive state; (3) peripheral corneal thickening was seen on pachymetry in all three groups; and (4) refraction, keratometry, and pachymetry all returned to baseline after return to sea level. Winkle^[89] demonstrated that exposing post-RK corneas to 100% nitrogen via goggles at one atmosphere for 2 hours caused a significant hyperopic shift of 1.24 diopters and corneal flattening of 1.19 diopters in post-RK eyes. Corneal thickness increased in both post-RK and control eyes but was not associated with a hyperopic shift in control eyes. This is strong evidence that the effect of altitude exposures on post-RK eyes is caused by hypoxia rather than by hypobarism and further illustrates that breathing a normoxic inspired gas mix will not protect against the development of hypoxic corneal changes.

The effect of the post-RK hyperopic shift seen at altitude depends on the postoperative refractive state (undercorrected patients may actually have their vision improve) and the accommodative abilities of the individual.^[43] The work of Mader and his colleagues has

provided compelling evidence for myopic mountaineers that PRK instead of RK is their refractive surgical procedure of choice. Individuals who have undergone RK and plan to undertake an altitude exposure of 2744 m (9000 feet) or higher while mountaineering should bring multiple spectacles with increasing plus lens power.^[43] To my knowledge, a post-RK hyperopic shift has not been reported in airline passengers or flight crew. This may be because the latent period required for this phenomenon to develop exceeds the duration of most commercial flights or because the approximate 8000-foot cabin pressure on most commercial flights does not produce sufficient corneal hypoxia for a hyperopic shift to occur.

Ultraviolet Radiation Damage (see also [Chapter 14](#))

Ultraviolet radiation is divided into UV-A (320 to 400 nm), UV-B (290 to 320 nm), and UV-C (100 to 290 nm). Almost all UV-C radiation is absorbed by the earth's ozone layer.^[54] ^[77] The cornea absorbs all radiation with wavelengths of less than approximately 300 nm, and the lens absorbs almost all of the remaining UV-B radiation that reaches it.^[77] UV radiation is increased with high altitude, low latitude, and highly reflective environments.^[54] Altitude exposures associated with mountaineering entail exposures to increases in the amount of both incident and reflected UV light.

Acute exposure to high levels of UV radiation may result in UV photokeratitis,^[14] ^[77] whereas chronic exposures may be associated with cortical lens opacities,^[13] posterior subcapsular lens opacities,^[4] pterygia,^[3] and squamous cell carcinoma of the conjunctiva. ^[49]

Diagnosis and management of UV keratitis are discussed previously in this chapter. The best strategy for dealing with UV radiation-induced disorders is prevention. Most experienced mountaineers and trekkers are well aware of the need for sunglasses with high rates of UV absorption. UV attenuation in sunglasses depends on the size, shape, and wearing position, as well as the absorption properties of the optical material used.^[63] The use of a brimmed hat is another effective means of decreasing UV exposure to the eye.^[54] ^[64] In conjunction with the use of topical sun-blocking agents, a hat may also help prevent a series of cutaneous neoplasms from being a lasting reminder of previous mountaineering expeditions.

Sunglasses Selection in Mountaineering

What type of sunglasses should be worn by individuals on mountaineering expeditions? Absorption of essentially all UV radiation is a key consideration, since radiation in this portion of the electromagnetic spectrum is not visible and serves only to produce adverse effects in the eye. Another critical consideration is the amount of visible light transmitted. Sunglasses that suffice for everyday use may not be adequate for use in the mountains, especially while on snow or glaciers. The comfort zone for luminance is approximately 350 to 2000 candelas/m² . ^[77] An outdoor environment consisting of sunlit fields and foliage may have a luminance of 3000 to 7000 candelas/m² ; a bright beach may have a luminance of 6000 to 15,000 candelas/m² . Standard sunglasses that transmit 15% to 25% of visible light reduce the luminance in these situations to within the comfort range. In contrast, bright sun reflected off snow or clouds may result in luminances of 15,000 to 30,000 candelas/m² . Sunglasses with visible light transmittance in the 5% to 10% range are needed to reduce luminance to a comfortable range in these circumstances. (The 1986 American National Standards Institute [ANSI] standards for nonprescription sunglasses recommend that tinted lenses with visible light transmittances of less than 8% not be used for driving.^[77]) Sideshields or deeply wrapped lens designs should be used.^[77] Infrared absorption is important in certain industrial occupations, such as glass, iron, and steelworkers,^[77] but is less important in protective eyewear to be used outdoors. [Table 22-2](#) provides desirable characteristics in selecting sunglasses for mountaineering or other environments with high levels of

luminance and UV radiation.^[10]

Photochromic Lenses

Photochromic lenses change transmittance or color when exposed to light or UV radiation.^[77] They are designed to transmit a greater percentage of incident light

TABLE 22-2 -- Sunglasses Selection Criteria for Mountaineering

SUBJECT	CHARACTERISTICS
UV absorption	99% to 100%
Visible light transmittance	5% to 10% [*]
Lens material	Polycarbonate or CR-39 [†]
Optical quality	Clear image without distortion [‡]
Frame design features	Large lenses; side shields or "wraparound" design; fit close to face; good stability on face during movement; lightweight; durable
Color	Gray [§]

*Glasses with less than 8% transmittance of visible light should not be worn while driving. Sunglasses or any tinted lenses with a visible light transmittance of less than 80% should not be worn while driving at night.^[77]

†Glass lenses typically have very good optical clarity and scratch resistance but are heavier and more expensive.

‡Hold the sunglasses at arm's length and move them back and forth. If the objects are distorted or move erratically, the optical quality is probably less than desirable. Also, compare the image quality between several different pairs of sunglasses to get a basis for comparison.

§The use of colored lens tints can alter color perception and possibly compromise the visibility of traffic signals. Neutral gray absorbs light relatively constantly across the visible spectrum and avoids these problems.^[77]

when indoors or in conditions of reduced illumination and a reduced amount of light when exposed to higher levels of illumination. This is accomplished in one example of glass lenses by incorporating an inorganic silver halide into the lens. When the lens is exposed to sunlight, this compound decomposes into its component silver and halide ions and the lens turns dark gray.^[77] When the lens is removed from sunlight, the process reverses. When selecting photochromic lenses, the adequacy of indoor light transmittance can be judged while trying them on. The outdoor transmittance should be approximately 5% to 10% as noted in [Table 22-2](#) if the glasses are to be used for mountaineering. Most photochromic lenses have outdoor transmittances of approximately 20%, which should suffice for less highly reflective outdoor environments.^[77]

Several plastic photochromic lenses are now available. The darkening process in plastic lenses is accomplished by organic light-sensitive compounds that are suspended in a thin layer near the front of the lens. Plastic photochromic lenses generally do not darken well enough to be used as sunglasses in bright environments. In addition, unlike glass photochromic lenses, the photochromic reaction typically used in plastic lenses usually fades in 1 to 2 years.^[77]

THE EYE AND DIVING

The ocular aspects of scuba diving and other hyperbaric exposures were reviewed in a 1995 paper.^[9] The sections from that paper that address the hyperbaric environment, ocular barotrauma, the ocular manifestations of decompression sickness and arterial gas embolism, ophthalmic considerations in fitness-to-dive evaluations, and the differential diagnosis of decreased vision after diving are included here. An expanded discussion of these items, as well as additional material on diving after eye surgery, the effect of common eye medications on fitness to dive, and the use of hyperbaric oxygen to treat ocular disorders, may be found in the review article.

The Hyperbaric Environment (see also [Chapter 59](#))

At sea level, the body is exposed to one atmosphere (ATA) of pressure. This magnitude of pressure may also be expressed as 760 mm Hg, 33 feet of sea water (FSW), and 14.7 pounds per square inch (psi).

The normal atmospheric pressure of 1 ATA is often used as a reference point from which other pressures are measured. When one states that the intraocular pressure (IOP) is 15 mm Hg, what is meant is that the IOP is 15 mm Hg more than the surrounding environment. In point of fact, the absolute pressure inside the eye at sea level is 775 (760 + 15) mm Hg. The IOP that is measured with a tonometer is therefore a "gauge" pressure, meaning that the pressure displayed is the actual pressure minus the atmospheric pressure.

Ophthalmic Considerations in the Fitness-to-Dive Evaluation

A diver should have adequate visual acuity to be able to read his or her gauges and function safely underwater. Possession of a driver's license is a convenient indication that a potential diver has sufficient visual acuity to meet this standard.^[9] A person who has recently undergone ophthalmic surgery should refrain from diving until the recommended convalescent interval has passed.^[9] Individuals who suffer from glaucoma may dive safely unless they have had glaucoma filtering surgery performed.^[9] Systemic carbonic anhydrase inhibitors are best avoided in glaucoma patients who wish to dive because of possible confusion between medication-induced paresthesias and decompression sickness.^[9] Any individual who is suffering from an acute ocular disorder that causes significant pain, decreased visual acuity, or other disabling symptoms should refrain from diving until these symptoms have resolved.^[9]

Underwater Refractive Correction

If contact lenses are to be used for diving, soft contact lenses are preferred.^{[5] [17] [32] [47]} Hard (polymethylmethacrylate) contact lenses have been associated with corneal edema during decompression and after dives.^{[72] [73]} These changes are caused by formation of nitrogen bubbles in the precorneal tear film during decompression, which interferes with normal tear film physiology and results in epithelial edema. Bubble formation would be expected to be more common during dives with significant decompression stress.

Although the increased gaseous diffusion properties of rigid gas-permeable contact lenses theoretically decrease the chance of bubble formation in the tear film, use of these lenses while diving has been demonstrated to cause bubble formation under the lens, leading to secondary corneal epithelial disruption.^[76] The author has treated one diver with foreign body sensation and blurred visual acuity that occurred during ascent while wearing gas-permeable contact lenses. Symptoms resolved upon removal of the lens at the surface.

Corneal edema was not observed in one series in which soft contact lenses were studied.^[73] The most frequent complication of soft contact lens use in diving is loss of the lens.^{[32] [34]} The risk of lens loss can be minimized by ensuring a good seal on the face mask and minimizing the amount of water that gets into the air space of the mask. Should the mask become displaced during the dive, narrowing of the palpebral fissures helps decrease the chance of the contact lens floating off the surface of the eye.^[32]

A prescription ground face mask is another refractive alternative, as is a face mask with a lens bonded onto the surface of the mask. Masks and lenses may be lost in high swells or rough surf, however, leaving a

diver without refractive correction. When contemplating the purchase of an expensive prescription face mask, one needs to be mindful of the corollary of Murphy's law that applies to diving: "Weight belts always fall on the face masks with prescription lenses."

Ocular Barotrauma

The eye is normally filled with noncompressible fluid and solid tissues and is therefore protected from barotrauma. However, once a mask is placed over the face, a different circumstance exists. The face mask is an air-filled space bounded on one side by the eyes and ocular adnexa. As a diver descends, if he or she does not expel gas through the nose into the airspace of the face mask, a relative negative pressure develops in this space. If this negative pressure becomes great enough, the eyes and ocular adnexa are drawn towards the space. Marked lid edema with ecchymosis and subconjunctival hemorrhage may develop as tissues and blood vessels are disrupted by this distention.

These signs may be alarming to the diver but typically resolve without sequelae. In a more severe case, such as that which may occur when an unconscious diver sinks a significant distance in the water column, more serious injury, including hyphema, may occur.^[19] A diver with face mask barotrauma is shown in [Figure 22-19](#) .

Barotrauma is also possible in persons with gas bubbles in the anterior chamber or vitreous cavity. Pressure-induced changes in the volume of this bubble may result in retinal, uveal, or vitreous hemorrhage, as well as partial collapse of the globe. Permanent loss of vision may ensue. One person who attempted to dive while an iatrogenic bubble was present in the vitreous cavity noted the immediate onset of very severe eye pain upon descent and quickly aborted his dive.^[56] Persons with intraocular

Figure 22-19 Mask squeeze in a diver who descended to 45 FSW without exhaling into his mask. (Courtesy Kenneth W. Kizer, MD.)

gas should not be allowed to dive as long as the bubble remains in the eye. The necessity of adding extra gas to the face mask during descent makes it obvious that swim goggles, which cover only the eyes and not the nose, should never be used for diving.

Decompression Sickness

Ocular involvement in decompression sickness (DCS) was first reported by Sir Robert Boyle, who observed gas bubbles in the anterior chamber of the eye of a viper that had been experimentally exposed to increased pressure.^[6] Ocular manifestations of DCS are infrequently reported in the ophthalmic literature,^[9] but there are a number of reports of ocular involvement with DCS in the diving medical literature.^{[7] [9] [18] [62]} Reported manifestations include nystagmus, diplopia, visual field defects, scotomas, homonymous hemianopias, orbicularis oculi pain, cortical blindness, convergence insufficiency, optic neuropathy, and central retinal artery occlusion.^[9] The incidence of visual symptoms in patients with DCS was found to be 7% in one large series.^[62]

Fluorescein angiography of divers has documented retinal pigment epithelial abnormalities indistinguishable from those seen in eyes with choroidal ischemia. These changes are attributed to decompression-induced intravascular gaseous microemboli. The incidence of these lesions was related to the duration of diving and a history of DCS. Although no diver was reported to have suffered a loss of visual acuity from these abnormalities, the long-term effects of this phenomenon remain to be studied.^[9]

DCS may also result when an individual without a hyperbaric exposure is suddenly

exposed to a decrease in pressure. Altitude DCS presenting as optic neuropathy has been reported.^[7] The risk of DCS may be increased if an altitude exposure is undertaken after diving without allowing a sufficient time interval for excess nitrogen taken up during the dive to leave the body.^[9]

DCS is treated with oxygen breathing and recompression on an emergent basis. Ophthalmologists seldom encounter this disease in an acute setting because most divers know to seek recompression therapy for signs or symptoms of DCS. Since treatment generally results in resolution of all symptoms, most persons with visual symptoms before treatment are asymptomatic after recompression treatment and are therefore not referred to ophthalmologists.^[6] Should an ophthalmologist encounter a person with acute ocular disturbances consistent with DCS after a hyperbaric or hypobaric exposure, the victim should be referred emergently to the nearest available recompression chamber and diving medicine specialist, since DCS may worsen rapidly if not treated. Physicians unsure of the location of the nearest diving medicine specialist or recompression chamber can call the Divers Alert Network at Duke University (919-684-8111).

550

Incomplete response to treatment or recurrence of symptoms after treatment may bring a victim with ocular DCS to the ophthalmologist on a less emergent basis. The victim should be managed in conjunction with a diving medicine specialist. Recompression therapy and hyperbaric oxygen should be administered even when a significant delay has occurred between the onset of symptoms and initial evaluation of the victim, since treatment may be effective despite delays of up to several weeks.^[7] ^[9]

Arterial Gas Embolism

Retrochiasmal defects, such as hemianopias or cortical blindness, are found with arterial gas embolism. Central retinal artery occlusion may result from gas emboli in the ophthalmic artery.^[9] Management is similar to that for DCS, with emergent recompression and hyperbaric oxygen therapy indicated in all cases.

Differential Diagnosis of Decreased Vision after Diving

DCS and arterial gas embolism should be considered whenever vision is acutely decreased after diving because of the possible emergent need for recompression therapy, especially if any other manifestation of DCS or arterial gas embolism are present. Other disorders may also affect vision after a dive. Corneal edema resulting from the formation of gas bubbles under polymethylmethacrylate and rigid gas-permeable contact lenses may cause decreased vision. A soft contact lens wearer who complains of blurred vision after a dive may have a lost or displaced lens.

Another possible cause of nondysbaric decreased vision after a dive is epithelial keratopathy induced by chemical agents used to reduce face mask fogging. The

time-honored application of saliva or toothpaste to the interior surface of the mask reduces but does not eliminate fogging. This led to the development of commercial antifog agents designed to be applied to the inside surface of face masks. These agents may contain volatile compounds potentially toxic to the corneal epithelium, including glycols, alcohols, and phenol derivatives. Exposure to these compounds may result in blurred vision, photophobia, tearing, and blepharospasm that may not develop until several hours after the dive.^[90] Slit lamp examination typically reveals diffuse superficial punctate keratopathy. Development of this syndrome commonly results from improper use of the antifog agent, such as overly generous application or failure to rinse the mask before use.

The author has treated several persons with recurrent mild ocular irritation and blurring of vision after dives on which soft contact lenses were worn. The lenses were noted to be tightly adherent to the cornea, probably as a result of a decrease in water content in the lens after contact with hypertonic sea water. Symptoms were relieved with a few drops of isotonic artificial tears.

**Box 22-5. DIFFERENTIAL DIAGNOSIS
OF DECREASED VISION AFTER
DIVING**

Decompression sickness
Arterial gas embolism
Bubbles under contact lenses
Displaced contact lens
Antifog agent keratopathy
Contact lens adherence syndrome
Transdermal scopolamine

A diver sometimes uses a transdermal scopolamine patch (placed behind the ear) to prevent motion sickness. This may result in mydriasis, decreased accommodation, and blurred vision in the ipsilateral eye. A differential diagnosis of decreased vision after diving is presented in [Box 22-5](#).

ACKNOWLEDGMENTS

I thank Drs. Steve Chalfin, Dave Harris, and Dave Perlman for their much-appreciated contributions to the preparation of this chapter.

Chapter 23 - Dental and Facial Emergencies

Henry J. Herrmann

Acute conditions involving the mouth and related structures can disrupt recreational activities in the outdoors. A simple toothache, although not life threatening, can cause disabling pain. At the other end of the spectrum, odontogenic infections or major facial trauma are associated with high morbidity and mortality. This chapter discusses toothaches, temporomandibular joint (TMJ) disorders, oral infections, maxillofacial trauma, local anesthesia for dental emergencies, the dental first aid kit, and prevention.

MAXILLOFACIAL PAIN

The causes of maxillofacial pain are myriad, and the diagnosis of head and neck syndromes can be exceedingly difficult. [Box 23-1](#) is a partial listing of pain-producing conditions. Fortunately, most of these syndromes are relatively rare. Only the most commonly encountered are covered in this chapter.

Pulpitis

The common toothache is caused by inflammation of the dental pulp. It may be difficult for the victim to identify the offending tooth because the pain often radiates to the eye or ear region, or is referred from one dental arch to the other. The painful tooth is rarely sensitive to percussion or palpation. An obvious cause, such as a large carious lesion, is sometimes found on examination of the mouth, but often all of the teeth appear intact. If the pulpitis is mild, the condition is characterized by pain that is only elicited by hot, cold, or sweets, and disappears within seconds when the stimulus is removed. Moderate pulpitis is characterized by greater discomfort and an increasing interval between removal of the stimulus and resolution of the pain. In its most severe form, pulpitis causes intense, continuous, and debilitating pain.^{[4] [17]} Emergency treatment recommendations follow.

Mild Pulpitis (Characterized by Transient Thermal Sensitivity).

Examine the mouth visually. Structures will likely appear within normal limits. However, if a defect in a tooth is found, it should be temporarily filled. Reassure the victim that although this condition is annoying, rapid progression is unlikely.

Moderate Pulpitis (Longer Episodes of Pain).

Proceed as for mild pulpitis. Treat with a nonnarcotic analgesic (ibuprofen 600 mg PO q6h prn pain).

Severe Pulpitis (Intense, Continuous Pain).

The preferred approach to severe pulpitis is pain relief using a local anesthetic, followed by evacuation of the victim. A nerve block with bupivacaine 2% with 1:200,000 epinephrine (Marcaine) can provide up to 8 hours of excellent pain relief without central nervous system (CNS) depression (see section on local anesthesia). Large doses of narcotics should not be used because they are likely to compromise the victim's ability to participate in evacuation. In an extraordinary circumstance, an experienced rescuer

could locate the offending tooth, expose the pulp, remove the inflamed pulpal tissue with a barbed broach, and cover the opening with a temporary filling material. Extraction is also an option in a case of severe pulpitis, but is to be discouraged for a number of reasons (see section on exodontia).

Periapical Osteitis

Inflammation of the supporting structures at the root of a tooth is characterized by constant, often throbbing pain. Unlike pulpitis, the affected tooth is easily located. The victim can usually point to the exact source of the pain, or the examiner may gently tap individual teeth, observing for tenderness. The area over the apex of the tooth is usually tender to palpation, but there is no frank swelling. Although trauma to a tooth can result in periapical inflammation, the most common cause is egress of bacteria and breakdown products from the necrotic pulp. Minor swelling around the apex extrudes the tooth slightly, causing increased forces on the tooth during occlusion and thus intensifying the pain. Emergency treatment includes an analgesic (ibuprofen 600 mg PO q6h prn pain) and/or a local anesthetic and a soft diet. Ideally, the contacting areas of the opposing tooth are reduced to relieve occlusal forces. Because this is generally impractical in the field, the victim should be given a strip of leather or something similar to place between the teeth on the nonpainful side. This will keep the offending tooth out of occlusion and reduce the pain.

Cracked Tooth Syndrome

With cracked tooth syndrome (CTS), the victim complains of momentary, sharp pain when chewing certain foods. Often, the victim reports that the tooth feels "weak" or that "it only hurts when I bite on something hard just the right way." These symptoms occur when forces of the proper magnitude and direction open the incomplete fracture within the tooth. Significantly,

there is no pain on chewing soft foods. This condition usually progresses slowly. The victim should be advised to avoid chewing on the affected side and to seek definitive dental treatment as soon as possible.

Box 23-1. SOME CONDITIONS THAT CAUSE FACIAL PAIN

Pulpitis (acute, chronic, hyperplastic)

Periapical osteitis (acute, chronic)

Cracked tooth syndrome

Periodontal infections

 Periodontal abscess

 Acute necrotizing ulcerative
 gingivitis

 Primary herpetic gingivostomatitis

 Pericoronitis

Temporomandibular joint disorders

Maxillary sinusitis

Neurologic pain

 Trigeminal neuralgia

 Trigeminal neuritis

 Herpes zoster neuritis

 Postherpetic neuralgia

Atypical facial pain

Psychogenic facial pain

Dental causalgia (atypical odontalgia)

Vascular pain

 Migraine headache

 Temporal arteritis

 Cluster headache

Referred pain

Temporal arteritis
Cluster headache
Referred pain
Pulpitis
Subacute thyroiditis
Myocardial infarction or angina pectoris

Maxillary Sinusitis

The pain of maxillary sinusitis is generally described as a relatively continuous, throbbing ache that is intensified by postural change. A typical statement is "My tooth really hurt when we were hiking down that hill. I could feel it pound with every step. When we got to camp, I lay down, but it got even worse." The pain may be unilateral or bilateral. It is usually located in the infraorbital region and is often referred to the cheek, frontal region, and the maxillary premolars and molars. A complaint of multiple toothaches in the maxilla, with little or no evidence of carious teeth, should immediately raise suspicion for maxillary sinusitis. In addition to pain, there is tenderness elicited by pressure infraorbitally or over the bony prominence above the first molar. The victim also generally has an elevated temperature and nasal or postnasal discharge. Treatment of maxillary sinusitis includes an analgesic (ibuprofen 600 mg PO q6h prn pain), inhalation of steam, oxymetazoline (Afrin) 0.05% in each nostril, 1 spray bid, to shrink the nasal membranes and improve sinus drainage, and an antibiotic. Appropriate choices include amoxicillin 875 mg with clavulanic acid 125 mg (Augmentin) PO bid for 10 days, or trimethoprim 160 mg with sulfamethoxazole 800 mg (Septra DS) PO bid for 10 days. Azithromycin (Zithromax), 500 mg PO the first day and 250 mg PO for four days, is a convenient alternative.

Temporomandibular Disorders

Considerable disagreement remains concerning the etiology, classification, and treatment of temporomandibular disorders (TMD). The subject is confusing because TMD is actually a cluster of unrelated conditions, multifactorial in origin and with overlapping symptoms, that often respond to a variety of therapies, including placebos. [6] Included under the classification of TMD are two groups of sufferers: those with masticatory muscle involvement (myofascial pain and dysfunction [MPD]) and those with TMJ problems. A brief summary follows.

Myofascial Pain and Dysfunction.

Muscle hyperactivity is an important etiologic factor in MPD. In some persons this may result from parafunction (e.g., gum chewing, clenching or grinding the teeth). Occlusal interferences can also cause muscle hyperactivity. This occurs when a lower tooth contacts an upper tooth prematurely during mouth closure and a reflex causes jaw

muscle contraction that shifts the mandible in such a way as to avoid the premature contact. Psychologic stress is also an important factor in causing excessive muscle tension.

Participants in wilderness activities are exposed to many of the risk factors for MPD. The high physiologic and psychologic demands of many expeditions lead to considerable stress. Increased jaw function, such as that required to chew granola, jerky, and other dried foods common on wilderness expeditions, is another factor that may precipitate an acute episode of MPD. Symptoms of MPD include pain in the muscles of mastication, which is usually unilateral and increases with chewing, headache, earache, intermittent clicking of the TMJ, limitation of jaw movement, and a change in bite. The victim may have a history of acute onset, or a long saga of exacerbation, remission, and various treatments.

The examiner may find objective signs, such as audible clicking of the TMJ, tenderness of the jaw muscles to palpation, tenderness of the TMJ to palpation, and abnormal jaw movements, such as inability to open the mouth widely, or deviation of the chin to one side on opening. Emergency treatment consists of resting the muscles (e.g., soft diet and control of tooth clenching and grinding habits) and the application of

554

moist heat. Holding a soft material such as a folded gauze between the front teeth often gives immediate relief because it keeps the teeth from touching and allows the muscles to relax. An analgesic (ibuprofen 600 mg PO q6h) should be given on a scheduled basis, rather than as needed, to break the cycle of muscle pain and spasm. A muscle relaxant, such as metaxalone (Skelaxin) 800 mg PO tid or cyclobenzaprine (Flexeril) 10 mg PO tid, or sedative, such as diazepam (Valium) 2 to 10 mg PO tid, may be helpful if primary treatment is ineffective. Muscle relaxants and sedatives, especially in higher doses, can cause significant CNS depression, so they should be used in the lowest effective dosage and only if more conservative therapy has failed.

Mandibular Dislocation.

Dislocation of the mandible and inability to close the mouth can result from external trauma or sudden wide opening of the mouth, such

Figure 23-1 Open and closed lock vs. condylar fracture. **A**, The normal temporomandibular joint with cartilaginous disc, shown in blue. **B**, In a mandibular dislocation, the

condylar head is anterior to the cartilaginous disc. No teeth are touching. **C**, In a condylar fracture, the joint is positioned normally, but the muscles of mastication have pulled the posterior portion of the mandible upwards, creating premature contact of the posterior teeth.

as occurs with yawning. The condition may be unilateral or bilateral. If there is a history of trauma, a condylar fracture should be suspected ([Figure 23-1](#)). A dislocated mandible is reduced by placing the rescuer's thumbs on the victim's lower molars and moving the mandible down, then posteriorly, and then up. If muscle spasm is severe, sedation might be necessary.^[6] After reduction of the mandible, the victim must avoid wide mouth opening. The victim should place one hand under the chin or position the chin against the chest when yawning. It is also helpful to place a bandage around the head and under the chin for several days to limit jaw movement.

Anterior Disc Displacement.

Anterior displacement of the TMJ's cartilaginous disc with reduction to a normal position on mouth opening causes clicking in the joint. Generally, this is not associated with pain or severe dysfunction. However, if the disc is displaced and does not

555

reduce on mouth opening, the victim may not only have pain, but also limited jaw movement (closed lock). Closed lock can occur suddenly while eating or talking, it may be present on awakening, or it can be associated with trauma. There is joint tenderness, and the chin deviates toward the affected side on attempted mouth opening.^[6] Similar restriction of mandibular function may be caused by muscle spasm. However, with myospasm the affected muscles are firm and extremely tender, whereas in closed lock the muscles are usually normal.

The victim can often reduce a closed lock. Have the victim close his or her mouth until the teeth almost touch, then move the mandible as far as possible to the affected side, and finally swing the mouth fully open. If these maneuvers fail after three attempts, consider manual reduction. The rescuer places his thumbs on the victim's lower molars, presses downward, pulls the mandible forward, then gradually moves the mandible up and back.^[6] This may require sedation with oral diazepam (Valium) 2 to 10 mg.

MAXILLOFACIAL INFECTIONS

Aphthous Ulcers

The etiology of aphthous ulcers is unclear. One opinion is that they represent an autoimmune attack on the oral mucosa, followed by secondary infection. The lesions are round, superficial, and have a red halo. They occur on movable mucosa and can be quite painful. The victim usually gives a history of similar ulcerations. The lesions typically last 10 to 14 days.

Many treatments have been proposed, but none have been found to be predictably effective. The best approach appears to be application of a topical steroid to reduce pain and hasten healing by 3 to 4 days. Mix fluocinonide 0.05% (Lidex) ointment with Orabase and place the mixture gently over each ulcer 6 to 8 times per day, especially after meals and before bedtime. Do not mix the medications until you are ready to apply them, and do not rub the mixture into the lesions. Other options include premixed preparations, such as Kenalog in Orabase, which can be applied to the ulcer 6 to 8 times per day; these preparations are more convenient but deliver only about 10% of the antiinflammatory effect. Dexamethasone (Decadron) elixir (0.5 mg/5 ml, rinse with 5 ml for 2 minutes and expectorate qid) or a systemic steroid (prednisone, 40 mg PO qd for 3 days, then taper) can be used for a very severe case.^[20] If these preparations are not available, tincture of benzoin or a topical anesthetic (viscous lidocaine 2%) can be applied to the dried surface of the ulcer before meals and at bedtime to control the pain.

Viral Infections

Herpes labialis (cold sore, fever blister) is the most common oral viral infection. It is characterized by yellow, fluid-filled vesicles that rupture to leave ragged ulcers. Other locations for recurrent herpetic outbreaks include the palate, tongue, and buccal mucosa. The victim can be given acyclovir (Zovirax) 200 mg PO five times daily for 5 days. It is important to begin treatment as soon as the victim becomes aware of a prodromal "tingle" or paresthesia. Use of sun-blocking agents on the lips helps prevent herpes labialis (see [Chapter 14](#)).

Primary herpetic gingivostomatitis is characterized by a thin zone of very red, painful gingiva just next to the teeth. Other areas of mucosa, such as the tongue, may also be involved, and close inspection may reveal tiny vesicles or ulcers. Sore throat, lymphadenopathy, and low-grade fever are also present. This and other viral infections of the oral cavity are self-limited. The victim should be reassured that the condition will resolve in about 10 days. Treatment involves the use of an analgesic (ibuprofen 600 mg PO q6h prn pain) and soothing mouth rinses such as warm saline or a mixture of equal

amounts of diphenhydramine (Benadryl) elixir 12.5 mg/5ml with kaolin-pectin (Kaopectate) and viscous lidocaine 2% (rinse and expectorate 5 ml q2h).

Yeast Infections

Oral yeast infections occur most commonly in persons who are debilitated, immunocompromised, or taking an antibiotic. Classic oral candidiasis (thrush) is characterized by white patches on the mucosa that can be rubbed off, leaving a red and raw surface. Candidiasis can also present as an erythematous mucosa without any white patches, or as chronic angular cheilitis. Candidiasis is treated with an antimycotic mouth rinse (nystatin oral suspension 100,000 units/ml, rinse with 5 ml for 2 minutes and swallow qid for 10 days) or lozenges (clotrimazole [Mycelex] troche 1 qid, leave in mouth 5 minutes and expectorate remains). In the field, nystatin preparations meant for vaginal treatment can be used (Mycostatin vaginal suppository used as an oral lozenge tid for 10 days).

Bacterial Infections

A bacterial infection in the maxillofacial region can become a serious health threat. In a wilderness setting, it should be treated aggressively. The majority of odontogenic infections are caused by mixed populations of aerobic and anaerobic bacteria. These organisms are almost always present as normal oral flora, but because of a change in the relative numbers of various bacteria or because of a change in the oral environment, an infection can become aggressive.

The behavior of an organism, such as the production of collagenase or hyaluronidase, determines the clinical presentation. Thus an infection may present as a diffuse cellulitis or localize as an abscess. Oral infections generally spread slowly, but rapid spread to a deep facial space can occur. Regional lymphadenopathy is common,

whereas severe systemic symptoms are rare. Although bone is often involved, osteomyelitis is uncommon.

Acute Apical Abscess/Cellulitis.

An acute apical infection begins with bacteria invading the dental pulp. The infection then spreads to surrounding bone through the apical foramen and then along the path of least resistance. Because the apices of most teeth are located closer to the facial aspect of the jaw, swelling is much more common in the facial soft tissues, as opposed to those on the lingual or palatal side.

The victim presents with pain and swelling, often fluctuant and usually in the buccal vestibule. There is often a history of prior toothache, but at this stage tooth pain is often

absent. The offending tooth can be localized by percussion, the site of the swelling, the condition of the teeth, and by using radiographs if available. The affected tooth does not respond at all to hot or cold. The victim may be dehydrated from decreased fluid intake.

The primary treatment for an apical abscess ([Figure 23-2](#)). is drainage.^[5] ^[7] This can be accomplished with incision, extraction, or endodontic therapy. The treatment chosen depends on the equipment and personnel available, the advisability of retaining the offending tooth, and ultimately, on clinical judgment. An antibiotic is necessary only if complicating factors exist^[5] ^[7] ^[17] ([Box 23-2](#)). Penicillin (Pen VK 500 mg PO qid) is the most commonly used antibiotic in dental practice,^[17] but a cephalosporin, such as cephalexin (Keflex) 500 mg PO qid, typically carried on wilderness expeditions, is acceptable. Combination antibiotic therapy is not indicated except for life-threatening sepsis or when organisms particularly sensitive to combination therapy have been identified. There is some evidence that hesitance to obtain drainage combined with over-reliance on chemotherapy can lead to serious exacerbation of dental infections. ^[7]

Incision and Drainage.

Incision and drainage (I and D) is often the treatment of choice in an emergency situation. An I and D can be performed by someone other than a dentist using commonly available supplies. It is indicated for fluctuant swelling caused by an apical abscess, and it may also be effective for nonfluctuant swelling associated with infection. Infiltration of a local anesthetic helps to reduce the pain of incision. If a local anesthetic is unavailable, adequate anesthesia can often be obtained by applying cold to the area to be incised, using ice, snow, or frigid water. An incision is made down to bone in one swift motion and a knife blade or the beak of a hemostat is used to spread the incision. A **T**-shaped drain may be improvised from a piece of latex glove (Figure 23-3 (Figure Not Available)) and retained without sutures. Hydration, a soft diet, an analgesic (ibuprofen 600 mg PO q6h prn pain), and warm saline rinses are helpful postoperative measures.

Figure 23-2 The left side of the figure shows a periodontal abscess. A periapical abscess is depicted on the right.

Compound maxillofacial fractures,
including all fractures of
tooth-supporting bone

Exarticulation (avulsion) of teeth

Soft tissue wounds open for 6 hours or
more before closure

Surgical procedures under nonsterile
conditions

Deep Fascial Space Infections.

An acute apical infection occasionally spreads beyond the local region. The rescuer

should be suspicious of any dental infection that causes swelling or tenderness in the floor of the mouth, swelling of the tongue, dysphagia, breathing difficulty, or trismus, or that fails to respond to appropriate therapy. The most commonly involved fascial spaces are the canine, buccal, masticator, and submandibular spaces.

557

Figure 23-3 (Figure Not Available) Incision and drainage technique. **A**, Fluctuant abscess. **B**, Abscess incised with scalpel. Purulent drainage is removed by suction or caught in gauze sponges. **C**, Cross section showing incision carried to the bone. **D**, The incision is spread with a hemostat. **E**, A "T" drain will often stay in place without sutures. **F**, Drain in place. (Redrawn from Ingle JI, Beveridge EE: *Endodontics*, ed 2, Philadelphia, 1976, Lea & Febiger.)

The canine space is located lateral to the nose. Infection originates in the maxillary canine tooth, and swelling causes the eye to close. The infection is drained through an intraoral approach over the root of the canine tooth.

Buccal space infection is characterized by a rounded swelling of the cheek. The offending teeth are the maxillary and mandibular molars. Drainage is obtained extraorally through an incision below the lower border of the mandible that will hide the scar.

The masticator space is divided into the masseteric, pterygoid, superficial temporal, and deep temporal spaces, all of which communicate. The hallmark of involvement is trismus. Swelling may be minimal because of the deep location of the abscess. The masseteric and pterygoid spaces are drained at the angle of the mandible, whereas the temporal space may be drained from an intraoral approach or through an incision just superior to the zygomatic arch.

The mylohyoid muscle divides the floor of the mouth into the sublingual and submandibular spaces. These communicate posteriorly and with their counterparts across the midline. An infection originating in a mandibular tooth can involve these spaces. If only the sublingual space is infected, an intraoral approach is used for drainage, avoiding damage to Wharton's duct. If the submandibular space is involved, an extraoral approach is used. All incisions in the facial area are made parallel to the branches of the facial nerve.^[8] ^[16]

Fascial space infections are potentially life threatening. The likelihood of widespread sepsis increases, cavernous sinus venous thrombosis and mediastinitis are

558

possible, and the airway may become compromised.^[9] The most feared infection is Ludwig's angina, a bilateral submandibular space infection that elevates the tongue, obstructs breathing, and is associated with high mortality. A mild dental infection can

progress to a life-threatening emergency in as little as 48 hours.^[7]

Treatment of fascial space infections includes airway management, proper hydration and electrolyte balance, aggressive I and D, intravenous antibiotics, and pain control.^[7]
^[9] ^[19] Because these objectives are best met in a controlled environment, any person with a suspected fascial space infection should be evacuated immediately.

Chronic Apical Abscess.

The hallmark of chronic apical infection is a draining fistula or "gum boil." Because the bacteria have a route to escape, they do not cause pressure or pain, although the tooth may be mildly sensitive when eating. Such an abscess is not truly an emergency, but if the victim is overly concerned that the condition may worsen before definitive care is provided, an antibiotic can be given.

An infected deciduous tooth also usually presents with a fistula and a mild amount of swelling at most. Happily for the child, pain is rarely present. Emergency care involves an antibiotic, with the dosage adjusted for the child's weight; I and D is performed only if the abscess is not draining. Extract the tooth only if it is very loose and it will be weeks until comprehensive care is available.

Periodontal Abscess.

A periodontal abscess is an accumulation of pus between the gingiva and the tooth (see [Figure 23-2](#)). Swelling is near the gingival margin rather than in the vestibule, as would be the case with a periapical abscess. The tooth is sensitive to percussion, but responds appropriately to hot and cold. There is always a potential communication between the abscess and the mouth. The passage can be found by probing the gingival margin with a small, blunt instrument, using a local anesthetic if available. Gentle probing will establish drainage; no incision is necessary. Hot saline rinses are prescribed, and a rapid recovery is almost invariable.

Pericoronitis.

Pericoronitis is an infection of the gingival flap over a partially erupted tooth. The most common site is the mandibular third molar. Pericoronitis is usually caused by streptococci and seldom produces purulence. The condition may mimic streptococcal pharyngitis or tonsillitis. The primary site of infection is always tender, and trismus is a common sign. Field treatment consists of saline irrigation of the space under the flap using a syringe. Place the victim on hot saline rinses every 2 hours and begin antibiotic therapy.

Acute Necrotizing Ulcerative Gingivitis (ANUG).

ANUG, also known as *trench mouth*, is characterized by ulceration and blunting of the interdental papillae. The gingiva between the teeth appears punched out and is covered by a gray/white pseudomembrane, whereas the surrounding gingival tissue is very red.

The victim's primary complaint is pain, but he or she may also report gingival bleeding, a metallic taste, and a foul odor. This infection is caused by fusiform bacteria and spirochetes. It usually occurs in young adults with poor oral hygiene, stress, and suboptimal nutrition (conditions that may be present during difficult wilderness expeditions). The most important treatment is gentle debridement of plaque, calculus, and food from around the teeth. Resolution may require several sessions of careful cleaning 1 to 2 days apart. Each session of debridement will result in some healing, which will allow more aggressive treatment the next time. The victim is also given an antibiotic (metronidazole [Flagyl] 500 mg PO qid) and analgesic (ibuprofen 600 mg PO q6h prn pain) and instructed to keep the area clean with good brushing, flossing, and rinsing (warm saline and/or diluted hydrogen peroxide, if available).⁴

EXODONTIA

A dental extraction is considered definitive treatment and should be attempted in the field only under extraordinary circumstances ([Box 23-3](#)). Extraction requires trained personnel, specialized instruments, and profound anesthesia, which may be difficult to obtain. Premedication with a sedative and/or narcotic may be necessary. Intra-operative and postoperative complications are common. Providers of emergency care should focus on treating

pain and infection with local anesthetics, analgesics (ibuprofen 600 mg PO q6h prn pain or hydrocodone 7.5 mg and acetaminophen 750 mg [Vicodin ES] PO q4 to 6h prn pain), I and D, and/or antibiotics (see section on periapical abscess) as appropriate for each case. Extraction or other definitive care can then be rendered after evacuation, and the tooth can often be saved.

**Box 23-3. FACTORS TO CONSIDER
BEFORE EXTRACTION OF TEETH**

Desires of the victim

Victim's medical history

Available alternative treatments

Difficulty/desirability of evacuation

Certainty of diagnosis (are you sure
you have the correct tooth?)

Possible complications if the tooth is
not extracted

Factors relating to the difficulty of the
procedure

Mobility or immobility of the tooth

Position of the tooth

Condition of tooth structure above
the gingiva

Patient's mouth-opening ability

Available supplies and instruments

Experience of rescuers

Possible complications arising from the
extraction

Fractured root(s)

Fractured alveolus

Soft tissue injury

Root tip lost in the sinus

Prolonged bleeding

Localized osteitis (dry socket)

Other factors to consider before exodontia are the degree of mouth opening possible, the relationship of the root to the maxillary sinus, the condition of the clinical crown, the alignment of the tooth in the dental arch, and a history of previous endodontic treatment (after root canal treatment, a tooth is usually very brittle).^[14] If, after careful consideration of all factors, extraction is deemed the best course of treatment, proceed as follows.

Review the victim's medical history. In a wilderness setting, it is unlikely you will be faced with a case complicated by medical conditions such as a blood dyscrasia, anticoagulant therapy, or severe cardiovascular disease, but you must be certain before the surgery begins. Persons with most types of heart murmurs or recent prosthetic implants should be premedicated with an antibiotic^[10] ([Box 23-4](#) and [Box 23-5](#)). Consider the emotional state of the victim and decide if sedation is prudent.

Box 23-4. RECOMMENDATIONS FOR ANTIBIOTIC PROPHYLAXIS BEFORE INTRAORAL PROCEDURES LIKELY TO CAUSE SIGNIFICANT BLEEDING

CONDITIONS FOR WHICH PREMEDICATION IS RECOMMENDED

Prosthetic joint replacement if within 2 years of placement, or if victim has insulin-dependent diabetes, previous prosthetic joint infection, or hemophilia

Prosthetic heart valve replacement

Previous endocarditis

Complex cyanotic congenital heart disease

Surgically constructed systemic pulmonary shunt or conduit

Most congenital cardiac malformations other than those listed below

Acquired valvular dysfunction (e.g., rheumatic heart disease)

Hypertrophic cardiomyopathy

Mitral valve prolapse with valvular regurgitation and/or thickened leaflets

CONDITIONS FOR WHICH PROPHYLAXIS IS NOT RECOMMENDED

Isolated secundum atrial septal defect

CONDITIONS FOR WHICH PROPHYLAXIS IS NOT RECOMMENDED

Isolated secundum atrial septal defect

Surgical repair of atrial septal defect, ventricular septal defect, or patent ductus

Previous coronary artery bypass graft surgery

Mitral valve prolapse without valvular regurgitation

Physiologic, functional, or innocent heart murmur

Previous rheumatic fever without valvular dysfunction

Cardiac pacemaker or implanted defibrillator

Coronary artery stent

Box 23-5. REGIMENS FOR ANTIBIOTIC PROPHYLAXIS BEFORE INTRAORAL PROCEDURES LIKELY TO CAUSE SIGNIFICANT BLEEDING

STANDARD REGIMEN

Amoxicillin 2 g PO 1 hour before procedure

CHILDREN

Amoxicillin 50 mg/kg PO 1 hour before procedure, not to exceed adult dose

UNABLE TO TAKE ORAL MEDICATIONS

Ampicillin 2 g IM/IV 30 minutes before procedure

PENICILLIN ALLERGY (CHOOSE ONE OF THE FOLLOWING)

Clindamycin 600 mg PO 1 hour before procedure

Clindamycin 600 mg IV 30 min before procedure

PENICILLIN ALLERGY (CHOOSE ONE OF THE FOLLOWING)

Clindamycin 600 mg PO 1 hour before procedure

Clindamycin 600 mg IV 30 min before procedure

Clindamycin 20 mg/kg PO 1 hour before procedure (for children)

Clarithromycin 500 mg PO 1 hour before procedure

Cephalexin 2 g PO 1 hour before procedure

From Dajani AS et al: JAMA 277:1794, 1997.

Plan the procedure and gather all necessary equipment. Secure a good light source and a means to keep the field dry—either suction or plenty of gauze. It is important to have the victim's head supported. Therefore it may be best to place the victim in a supine position with the head slightly elevated. Obtain good local anesthesia and test by touching the soft tissues with a sharp instrument. A 4 × 4-inch gauze curtain placed in the rear of the victim's mouth will prevent aspiration of teeth and debris.

Teeth are inflexible and brittle. Heavy forces, especially if applied quickly (high acceleration), break teeth. Bone has more flexibility, the degree of which depends on the individual victim. Judiciously applied, moderate

560

forces will slowly expand the bone. The exodontist must be attentive to feedback from the forceps because the bone and tooth will "tell you what they want to do." The tooth will eventually be delivered in the same direction as if it continued to erupt. However, do not attempt to "pull" the tooth in that direction initially. The direction of force needed to loosen a tooth depends on the anatomy of the root. A straight, conical root can be loosened by twisting forces. This technique often works well on the upper front teeth. Sometimes a tooth can be removed by alternating 30 seconds of steady pressure toward the cheek with 30 seconds steady pressure in the opposite direction until the root gradually loosens.^[23]

A variety of instruments can be used to apply force to the tooth. Elevators are firmly wedged between tooth and bone in the interproximal area. Avoid putting pressure on the adjacent tooth. Forceps should be applied as far apically as possible. Spend plenty of time working the forceps well under the gingiva. Lower molars are often removed with "cowhorn" forceps, which in addition to applying the usual forces, are designed to apply force to the tooth in a coronal direction simply by squeezing the handles. However, an experienced exodontist using careful technique and a single forceps (number 151 universal forceps) will have success extracting almost any nonimpacted tooth, whereas a reckless operator using dozens of specialized instruments will still have difficulty.^[23]

Despite the utmost care, a tooth may break during the extraction procedure. If this occurs, stop and take a minute to reevaluate the situation. The root canals will probably now be exposed. If you are treating a case of infection, perhaps drainage can be obtained through the root canal. If you are treating a case of severe pulpitis, perhaps the pulpal tissue can now be removed. Remember that you are rendering emergency care, and it may not be necessary to remove the remaining root at that time. Some teeth are impossible to remove without sectioning, or they can be removed in only one direction.

Once the tooth has been removed, compress the expanded socket using the thumb and forefinger. If the gingiva is quite loose, placing a suture may help speed healing. Have the victim apply direct pressure to the wound by biting firmly on a gauze pack for 30 minutes while sitting in an upright position. Complete hemostasis may require several hours of steady pressure. Caution the victim to avoid rinsing, spitting, tooth brushing, and smoking for 24 hours. Application of cold and the use of an appropriate analgesic will reduce swelling and pain. Beginning the day after surgery, have the victim rinse with warm saline to cleanse the area.

A common postoperative complication is persistent bleeding several hours after the extraction, accompanied by a poorly organized clot that looks like a piece of raw liver growing out of the socket. Remove the "liver clot" and have the victim apply firm, uninterrupted pressure to the socket by biting on a gauze pack for 20 minutes. If the victim cannot do this, the rescuer will have to apply manual pressure. If bleeding continues after 20 minutes, consider packing the socket (e.g., using Gelfoam, Surgicel, or sterile gauze) and/or suturing. Then resume direct pressure. A dry tea bag used as a compress may provide chemical hemostasis because of the tannic acid.

Another postextraction complication is acute alveolar osteitis, or "dry socket." The victim reports moderate to severe pain, foul odor, and a bad taste, beginning about 3 days after a dental extraction. Examination reveals an empty socket and exposed bone caused by loss of the blood clot, but no suppuration. Treatment consists of gentle irrigation with warm saline followed by packing with a strip of gauze dipped in eugenol. Also administer an oral analgesic. Change the pack every 24 to 48 hours until the symptoms subside, which may take up to 10 days. The victim should avoid alcohol, smoking, and carbonated beverages during treatment.

TRAUMA TO THE FACE AND JAWS

It is essential to quickly evaluate the general condition of an injured victim (see [Chapter 18](#)).^[13] The primary survey identifies and corrects any inadequacy in respiration or circulation. The mouth and pharynx should be examined for foreign bodies, such as blood clots, tooth or bone fragments, or dentures. If the airway is still obstructed, it may be necessary to perform a chin lift or jaw thrust, or insert an oropharyngeal airway to hold the tongue forward (see [Chapter 17](#)). Care should be taken not to hyperextend the neck because of the possibility of a cervical spine fracture. If there is no indication of a neck fracture, sometimes merely placing a victim on his side rather than in a supine position facilitates respiratory exchange. If all of these measures fail, endotracheal intubation or performance of a cricothyroidotomy or, less commonly, a tracheotomy may be necessary. Once a victim's airway is secured and he is hemodynamically stable, perform a secondary survey.

Injuries to the Teeth and Supporting Tissues

Question the victim about the time and nature of the accident, symptoms, loss of consciousness, nausea, vomiting, visual disturbances, and headache. A baseline mental status examination and cranial nerve assessment may be warranted. Clean the face, mouth, head, and neck of blood and debris. This will unmask soft tissue injuries and facilitate diagnosis. Gently reflect the lips with teeth closed to examine soft tissues and occlusion. Carefully examine any lacerations to determine if they penetrate through the lip and/or contain foreign material. Examine all of the teeth for fractures.

561

A blow to the chin or a whiplash injury may produce fractures of the posterior teeth as the mandible is forcibly closed. Examine fractured teeth carefully for pulp exposure. This will require drying the teeth with gauze. Tap each tooth with an instrument handle. Tenderness denotes injury to the periodontal ligament, whereas a high-pitched, metallic sound indicates ankylosis. Test each tooth for abnormal mobility. Electrical pulp vitality testing, dental radiographs, and soft tissue radiographs are obtained if available.^[2] ^[11] ^[15]

A classification of traumatic injuries to the teeth and supporting structures is given in [Box 23-6](#). Note that these injuries often occur in combination, with one tooth exhibiting two or more injuries, or several teeth exhibiting various sequelae of trauma. Each injury requires definitive treatment, but proper emergency care will improve the prognosis and make the victim more comfortable. Treatment of most injuries requires, or is at least

facilitated by, infiltration of a local anesthetic.^[2]

Specific Dental Injuries

CROWN INFRACTION.

Blows to the teeth sometimes produce small craze lines in the enamel. These superficial fractures look like tiny surface cracks on an old porcelain dish. Reassure the victim that minimal damage has occurred and treatment is not necessary.

*From Andreasen JO, Andreasen FM:
Textbook and color atlas of traumatic
injuries to the teeth, ed 3, St. Louis, 1994,
Mosby.*

UNCOMPLICATED CROWN FRACTURE.

In an uncomplicated crown fracture, the tooth has been fractured, but no pulp tissue is visible. The tooth may be sensitive to cold, but otherwise all tests are within normal limits. No emergency treatment may be necessary. Irritating sharp edges can be smoothed with a fingernail file. If thermal sensitivity is moderate to severe, a soothing topical antiinflammatory dressing (e.g., Intermediate Restorative Material [IRM], L.D. Caulk Co., Milford, Delaware) can be held in place with aluminum foil or adhesive tape.

UNCOMPLICATED CROWN-ROOT FRACTURE.

Diagnosis and treatment of an uncomplicated crown-root fracture is identical to the uncomplicated crown fracture, except that the fracture is nearly vertical, leaving a small, chisel-shaped fragment attached only by the palatal gingiva ([Figure 23-4](#)). Removal of this mobile fragment will make the victim much more comfortable.

COMPLICATED CROWN FRACTURE.

In a complicated crown fracture, the pulp has been exposed. A small exposure that has not been grossly contaminated is capped with calcium hydroxide (Dycal, L.D. Caulk Co., Milford, Delaware) or IRM. If the exposure is large, or if the pulp tissue has been exposed for more than 24 hours, amputate about 2 mm of tissue with a sharp, sterile instrument. If bleeding continues for more than a few minutes, use a cotton pellet soaked in local anesthetic solution, hydrogen peroxide, or Dycal to obtain hemostasis. Fill the top of the canal with Dycal or IRM and protect the tooth as for a crown fracture ([Figure 23-5](#)).

COMPLICATED CROWN-ROOT FRACTURE.

In a complicated fracture of the crown and root, the tooth has been fractured obliquely, resulting in a mobile fragment attached

Figure 23-4 Crown-root fracture. The mobile fragment (a) should be removed. The larger fragment (b) should be left in place.

562

Figure 23-5 Complicated crown fracture. Treatment of a complicated crown fracture.

to the palatal gingiva and pulp exposure. First remove the mobile fragment as in a crown-root fracture. Then treat the pulp exposure as in a complicated crown fracture. ^[2]

ROOT FRACTURE.

A root fracture may be difficult to diagnose without radiographs. There will be slight to severe malposition of the crown, but this could be caused by luxation of the entire tooth or a root fracture with luxation of the coronal portion. Reposition the tooth as precisely as possible and splint rigidly (see section on splinting). Hard tissue union of the fragments usually occurs within 3 months. If the coronal portion of the tooth proves impossible to stabilize and definitive treatment is days away, remove the mobile fragment, but do not attempt to extract the apical fragment. ^[2] ^[15]

CONCUSSION AND SUBLUXATION.

Concussion and subluxation injuries to the tooth's supporting structures (i.e., periodontal ligament, bone, and gingiva) cause sensitivity to percussion. The tooth remains in its proper position. However, in subluxation the tooth is abnormally mobile, whereas mobility is normal with concussion. Emergency treatment consists of shortening the

opposing tooth so that the victim can occlude comfortably.

INTRUSION.

A tooth that has been driven into the bone by a vertical force will demonstrate little mobility and a high-pitched, metallic tone on percussion. Emergency treatment is palliative only. Endodontic treatment (to prevent inflammatory root resorption) and orthodontic extrusion should begin within 2 weeks of injury. Intrusion is associated with a poor long-term prognosis.^[2]

EXTRUSION.

The extruded tooth is partially displaced from its socket and extremely mobile. Gentle, steady pressure is used to reposition the tooth, allowing time to displace the blood that has collected in the apical region of the socket. After reduction, the tooth is splinted for 2 to 3 weeks. The splint should allow physiologic movement of the injured tooth.

Figure 23-6 Technique used to reduce lateral luxation.

LATERAL LUXATION.

In lateral luxation injuries, the tooth is often displaced by a horizontal blow, yet it is not mobile because the apex is locked into its new position in the alveolar bone. A high, metallic tone on percussion is another clue that this has occurred. This injury and its treatment are painful. [Figure 23-6](#) shows how two fingers are used to reduce the tooth. One finger guides the apex down and back while the other repositions the crown.^[2] This requires judicious, but sometimes quite firm application of force. The tooth may snap back into position and be quite stable. Splinting is necessary if mobility is present after reduction.

EXARTICULATION.

When a tooth is totally avulsed from bone, the prognosis after replantation depends on the health of the periodontal ligament cells, some of which are still attached to the root surface and some

of which line the socket wall.^[3] To preserve the vitality of these cells, certain guidelines should be observed. Keep the time before replantation to a minimum. Immediate replacement is ideal. If the tooth must be stored, keep it moist. Less than 15 minutes in air is associated with a good prognosis; longer than 2 hours results in a poor prognosis.^{[3] [11]} If possible, the tooth should be stored in a Save-A-Tooth container (Smart Practice, Phoenix), which uses a soft mesh to suspend the tooth in Hank's balanced salt solution. Alternative transport mediums are whole milk, saline, the victim's saliva, sports drinks, and water, in that order of preference. The concept is to preserve the health of the periodontal ligament cells in the most isotonic, pH balanced solution at hand. If no container is available, use a plastic bag, plastic wrap, or saturated cloth to keep the tooth from drying. Handle the tooth by the crown only. Never scrub, curette, or use a disinfectant on the root surface; gently rinse with saline to remove debris. When removing clotted blood from the socket, use gentle irrigation and suction, and avoid scraping the socket walls. Ease the tooth back into place with slow, steady pressure. After replantation, nonrigidly splint the tooth for 1 week. Administer an antibiotic for 5 days and give appropriate antitetanus prophylaxis. Endodontic therapy should be instituted within 2 weeks.^{[3] [11] [15]}

The preferred approach to tooth avulsion or severe luxation is immediate reduction in the field, followed by evacuation for definitive treatment. The next most desirable option is to store the tooth properly and transport victim and tooth for replantation within a few hours of injury. If field conditions prevent either course of action, a delayed replantation procedure is indicated. Store the tooth dry. Three weeks after the injury, the necrotic pulp tissue is removed and the tooth is disinfected, fluoridated, and surgically replanted. The aim of delayed replantation is to produce ankylosis between tooth and bone.^[2]

ALVEOLAR SEGMENT FRACTURE.

Alveolar segment fracture is characterized by displacement of two or more teeth as a unit. The teeth are not mobile with respect to one another. The apices may be locked into their abnormal position, as in lateral luxation. The segment is repositioned (this may be painful even with local anesthesia), and rigid splinting is placed for 4 to 6 weeks.

Proper Reduction.

It is sometimes difficult to know when a displaced tooth has been returned to its proper position. Usually a tooth should be positioned similarly to its contralateral mate. Sometimes asking the victim can help; it may be that one tooth has always been longer than the others, or in a different position. However, occlusion is always the best guide to proper position. If the victim bites and contacts only the injured tooth, further positioning is necessary. In many cases, it is not possible to completely reposition the tooth because of swelling or organized clot formation. Therefore

Figure 23-7 Arch bar and wire splint,

Figure 23-8 Cross sectional view of an arch bar and wire splint. **A**, The widest part of the tooth. **B**, The position of the wire on the stable teeth. **C**, The position of the wire on the mobile tooth or teeth.

some adjustment of the opposing tooth (try using an emery board or file from your pocket knife) may be necessary to allow proper occlusion. If the injured tooth receives additional trauma each time the victim bites, it will be uncomfortable, and healing will not occur.

Splinting.

When the goal of splinting is to establish a normal, fibrous union between the tooth and the bone, a short-term, nonrigid technique is used. When hard tissue union is desired (e.g., with root fracture or alveolar segment fracture), longer-term rigid splinting is used.^[2] Ideally, a single avulsed or loosened tooth is usually bonded to the adjacent tooth or teeth with the acid etch and composite technique.^[2] ^[15] For fractures of the jaws or alveolar segments, arch bars and wire splints are often used ([Figure 23-7](#) and [Figure 23-8](#)). The rescuer lacking adequate materials must use ingenuity and improvisation to splint teeth. During a very short evacuation, the victim could hold the tooth in approximate position

564

Figure 23-9 Suture used to stabilize a loose or avulsed tooth. The suture also passes through the palatal tissue (hidden from view).

by closing on a gauze pad. Softened wax can be adapted to a loosened tooth and the teeth on either side to lend support. [Figure 23-9](#) shows how a suture can be used to

hold a tooth in place for a period of a few days. For a sturdier splint, a crude arch bar can be cut from a SAM splint or made from a paper clip and dead-soft wire obtained from copper wiring or twist ties. Note the proper positioning of the wire on the injured tooth and the anchor teeth (see [Figure 23-8](#)).

Injuries to Primary Teeth.

Injuries to the deciduous teeth offer unique challenges, not the least of which is behavioral management of a young child. Splinting is very difficult because of the small amount of tooth structure available. In general, heroic efforts should not be made to save primary teeth.^[2] Exarticulated deciduous teeth should not be replanted. Severely extruded teeth, infected teeth, or those intruded into the developing permanent tooth should be extracted. Because the permanent tooth follicle lies to the lingual side of the primary tooth root, the typical frontal impact displaces the crown toward the palate, but levers the root apex away from the permanent tooth ([Figure 23-10](#)). Most minor subluxations and luxations require only symptomatic treatment. As long as the displaced tooth does not interfere with occlusion, reduction is contraindicated. Spontaneous repositioning often occurs over a period of weeks. Fragments of primary roots need not be extracted because normal resorption will still occur.

Epistaxis

Although most cases of nosebleed are trivial, some can become life threatening as a result of respiratory compromise secondary to aspiration of blood, or extensive blood loss resulting in hypotension. Therefore the condition should never be neglected. The nasal mucosa is laced with numerous superficial blood vessels that serve to warm and humidify inspired air. A particularly rich collection of vessels, and a common site of anterior nosebleed, comprise Kiesselbach's plexus on the nasal septum (Figure 23-11 (Figure Not Available)). Spontaneous epistaxis is more

Figure 23-10 When a deciduous tooth is traumatized, the typical direction of force as the child falls forward is shown by arrow *A*, and the apex of the deciduous tooth is levered away from the developing tooth bud, as shown by arrow *B*.

common in environments that are cold, dry, dusty, or smoke-filled.

In evaluating a victim with epistaxis, first determine if the bleeding is unilateral or bilateral, and whether it is coming from an anterior or posterior site. A nosebleed usually occurs on one side of the nasal cavity. However, in a victim with profuse bleeding, the blood can pass behind the nasal septum and also appear on the unaffected side. Most

victims bleed from an anterior site, which can be visualized on intranasal examination. Posterior epistaxis is usually caused by traumatic injury to the sphenopalatine artery (see Figure 23-11 (Figure Not Available)). The bleeding point cannot be seen on intranasal examination.

The first step in treating a person with a nosebleed is to have him sit upright with his head tipped slightly forward so that blood will drip passively out of the nose rather than flow posteriorly into the throat, causing choking and possible aspiration or vomiting of swallowed blood. Ask the victim to blow his or her nose to remove any clots. If suction and a nasal speculum are available, the nasal cavity can then be examined to determine the site of bleeding. When there is minor bleeding from the anterior aspect of the nose, the victim can be instructed to pinch the nostrils together for at least 10 minutes. Hold the soft tissues tightly against the septum. Pinching the bony bridge of the nose will not provide direct pressure on the bleeding vessels.

If nose pinching does not stop the bleeding, apply a topical vasoconstrictor. Choices include cocaine 4%,

Figure 23-11 (Figure Not Available) Nasal anatomy. Kiesselbach's plexus is the most common site of anterior epistaxis. The sphenopalatine artery is the most common site of posterior epistaxis. Insert tubes and instruments in the direction of the nasopharynx, not the cribriform plate. (From Fleisher GR, Ludwig S: *Textbook of pediatric emergency medicine*, Philadelphia, 1999, Lippincott Williams & Wilkins.)

ephedrine 5%, aqueous epinephrine 1:1000, phenylephrine 0.5% (Neo-Synephrine), or oxymetazoline 0.05% (Afrin). Vasoconstrictors can also be found in some local anesthetics, asthma medications, and southwestern desert plants of the genus *Ephedra* (e.g., Mormon Tea, joint-fir, canatilla, tepopote). Vasoconstrictors can be applied by drip, spray, on a cotton pledget, or with a cotton-tipped applicator. Objects placed in the nose should have a string attached, or other method of easy removal, and should be aimed posteriorly. Avoid pushing material laterally into the turbinates or superiorly toward the cribriform plate (see Figure 23-11 (Figure Not Available)). Leave the vasoconstrictor in place between 10 minutes and 24 hours.

When there is more vigorous anterior nasal bleeding, nose pinching or the topical application of a vasoconstrictor may not be effective. In such an instance, the bleeding site can be injected with 0.5 to 1 ml of lidocaine containing 1:100,000 epinephrine, which will have a tamponading and a vasoconstricting effect. Alternatively, a small piece of oxidized regenerated cellulose (Oxycel or Surgicel), gelatin sponge (Gelfoam), or microfibrillar collagen (Avitene) can be placed directly over the bleeding site. Once the bleeding has stopped, the victim should be instructed not to blow the nose or probe the area for 48 hours. Increasing the humidity of inspired air may help prevent a recurrence of the bleeding. Placing the victim in a tent with several other persons, or with a pot of boiling water, and placing a handkerchief over the victim's nose while outside, will humidify and warm the air before it reaches the nasal mucosa.

If the bleeding cannot be controlled by the previous methods, anterior nasal packing is required. This involves placement of ½-inch strip gauze impregnated with an antibiotic or petroleum jelly into the nasal cavity. The adult victim requires 3 to 4 feet of such gauze to adequately pack the nose and tamponade the bleeding. The gauze is layered in tiers starting on the nasal floor and proceeding to the roof of the nose. Both ends of the gauze are left outside the nose and taped to the face to prevent inadvertent aspiration. Expandable packing (Weimert Epistaxis Packing, Rhino Rocket), with an applicator device for rapid deployment, or a Foley catheter can also be used for anterior nasal tamponade. Because anterior nasal packing blocks sinus drainage and can predispose to sinusitis, the victim should be placed on prophylactic amoxicillin, 875 mg with clavulanic acid 125 mg (Augmentin) PO bid, until the packing is removed in 48 hours.

Because it is not possible to visualize the site of posterior epistaxis, the victim requires a posterior nasal

pack or placement of a Foley catheter or nasal balloon.^[4] Placing the conventional posterior nasal pack involves first gently inserting a lubricated soft tube into each nostril until the ends can be visualized in the back of the throat, grasped with a hemostat, and brought out through the mouth. Use Foley catheters, nasogastric tubes, chest tubes, or improvised substitutes, such as one of the products used to hold sunglasses in place. A cylindrical pack of 4 × 4-inch gauze pads is prepared and held in shape by tying three silk sutures around it and leaving the ends long. The pack should be the same diameter as a circle made by the victim's thumb and forefinger (the "OK" sign). The two end sutures are attached to the oral ends of the catheters (Figure 23-12 (Figure Not Available)). The nasal ends of the catheters are then pulled carefully back out of the nose until the pack is firmly positioned against the posterior aspect of the nasal cavity above the soft palate. The sutures are then detached from the catheters and tied over a bolster placed underneath the nose. The middle suture remains outside of the mouth and is secured externally to be used to remove the pack 48 hours later.

A 14 to 16 French Foley catheter with a 30-ml balloon can also be used as a posterior pack. The lubricated catheter is inserted through the nose into the posterior pharynx, inflated 10 to 15 ml, and then gently pulled back into the nasopharynx and held in position by clamping the external end with a hemostat. Commercially available preshaped nasal balloons can also be used to treat posterior epistaxis.^[4] Air is preferred over saline for inflating nasal balloons as a safety precaution in case of breakage.

Nasal Fracture

Because of the prominence of the nose, nasal fracture is the most common facial fracture. It is often accompanied by abrasions, lacerations, and epistaxis. Nasal bleeding should be managed first. Once this bleeding is controlled, any facial wound

should be properly cleansed. Local anesthesia may be needed to accomplish removal of foreign material. Plain lidocaine or another local anesthetic without a vasoconstrictor is recommended when injecting the nose. Particulate matter is removed either by irrigation or scrubbing with a sterile brush. This is essential to avoid infection and prevent tattooing.

Abrasions should be covered with an antiseptic or antibiotic ointment (e.g., mupirocin, bacitracin) and washed gently twice daily with a mild soap and warm water to prevent crusting. Small laceration edges can be reapproximated with tape closure. Deeper lacerations require interrupted sutures. Remove sutures in 3 to 5 days, at which time tape strips can be placed if additional stabilization of wound margins is necessary.

Once soft tissue injuries have been managed, the nose should be assessed for possible fracture by observing it for symmetry from the front and from below. If swelling has already occurred, this may be difficult to determine. However, palpation of the bridge may reveal

Figure 23-12 (Figure Not Available) Inserting a posterior nasal pack. (From Fleisher GR, Ludwig S: *Textbook of pediatric emergency medicine, Philadelphia, 1999, Lippincott Williams & Wilkins.*)

displacement that is not visible, and crepitus can sometimes be felt. Point tenderness may also be indicative of a fracture, but it can also be associated with soft tissue injury.

After external examination of the nose, the interior of the nasal cavity should be examined for lacerations and septal hematoma. Remove blood clots with a swab or suction to improve visibility. Small lacerations may not require treatment, but large lacerations should either be closed with resorbable sutures or covered with Oxycel, Gelfoam, Surgicel, or Avitene to control bleeding. Any deviation, bulging, or widening of the nasal septum may be indicative of a hematoma. However, septal deviation may have been present before the injury. To determine if a hematoma is present, the area can be pressed with a cotton-tipped applicator. A hematoma will feel soft, and the area may be temporarily indented by the pressure.

A septal hematoma needs to be drained to prevent pressure necrosis and loss of nasal support or the formation of a septal abscess, which can also produce destruction of the septum. The area is anesthetized by injection of a local anesthetic or the application of a topical anesthetic (benzocaine 20%), and a small incision is made in the most inferior aspect of the hematoma. The nasal passage should then be packed with ½-inch gauze impregnated with petroleum jelly or antiseptic to prevent recurrence of bleeding.

Because most surgeons prefer to treat nasal fracture after the swelling has subsided (5 to 10 days after injury), such an injury does not require immediate treatment.^[12] As long as there is no active bleeding, and any abrasions and lacerations have been treated, the victim has at least 3 to 5 days before definitive management is indicated. If the nose appears straight as the swelling subsides, and the victim can breathe easily through

both nostrils, there probably was no fracture, or a fracture exists with only minimal displacement and further treatment may not be necessary. In the interim, the nose can be protected from further injury by a splint made by cutting a triangular piece of a SAM splint large enough to fit the contour of the nose. Rest the splint on the adjacent part of the face without placing pressure on the nasal bridge. This shield is held in place by strips of adhesive tape. Nasal packing is not necessary unless it is used to control epistaxis or recurrent septal hematoma. Penicillin VK or amoxicillin 500 mg PO should be administered four times each day for 5 days.

Jaw Fracture

Any person who has suffered a head or facial injury should be examined for a jaw fracture.^[13] First, evaluate occlusion by having the victim bite the teeth together. Any deviation of the bite or change in the level of the occlusal plane, especially in the mandible, should raise the suspicion of a fracture. Usually there will also be a tear in the gingival tissues and bleeding and ecchymosis at the site of the discontinuity. A sublingual hematoma is a common sign of a mandibular fracture. In edentulous areas, there will also be a discrepancy in the level of the bone, often accompanied by a disruption in the mucosa.

If no obvious tooth or bone displacement is noted, bimanual examination of the body of the mandible should determine if any abnormal movement can be detected. It is particularly important to evaluate any area of contusion in the soft tissue. In addition to preternatural movement, a grating sound can occasionally be heard when a fracture is present.

The mandibular condyles should be evaluated, especially if the chin has sustained a traumatic blow. A unilateral fracture is suspected when there is a shift of the midline of the mandible to the painful side on mouth opening. A bilateral fracture will often result in an anterior open bite (see [Figure 23-1](#)). Normally, the condyles can be palpated by placing a forefinger in front of the external auditory meatus. If the condyle cannot be palpated, or if it does not move significantly when the mouth is opened, a fracture may be present.^[13] ^[21]

The maxilla is examined for possible fracture by grasping the anterior segment between the thumb and forefinger and gently rocking the jaw anteroposteriorly and laterally. If a complete (Le Fort I) fracture is present, the entire maxilla will move ([Figure 23-13](#)). With a unilateral fracture, only one half of the maxilla will move. If a complete maxillary fracture is detected, the presence of a pyramidal (Le Fort II) fracture extending to the nasal area needs to be considered. The maxilla should again be rocked gently while the bridge of the nose is grasped between the thumb and forefinger of the opposite hand. Any movement of the nasal complex is indicative of a pyramidal fracture. Because this fracture also extends through the infraorbital rim, this

Figure 23-13 Classification of midface fractures. (Redrawn from *Oral and maxillofacial surgery services in the emergency department, Rosemont, IL, 1992, American Association of Oral and Maxillofacial Surgeons.*)

area should be palpated for the presence of a step deformity. However, care must be taken not to confuse a fracture with the infraorbital foramen, which can also be felt in this region. If a fracture is present, the victim will feel numbness below the eye and in the upper lip and lateral aspect of the nose. This is caused by injury to the infraorbital nerve.

The third type of midface fracture, the Le Fort III, involves detachment of the midface from the base of the skull. This is a complex injury often accompanied by intracranial trauma. There is generally subconjunctival hemorrhage and bilateral periorbital edema and ecchymosis. Usually the eyelids are swollen shut. Laceration of the meninges causes cerebrospinal fluid (CSF) to leak from the nose. To distinguish CSF from mucus, hold a clean, white handkerchief under the nose for a moment and then allow the material to dry. Mucus will stiffen the fabric, whereas CSF will dry as a double ring without stiffening the fabric. When CSF rhinorrhea is suspected, an antibiotic (penicillin VK 500 mg PO qid) should be administered, but the nose should not be packed.

Fractures of the zygomaticomaxillary complex generally result from a blow to the cheek. The most common findings are subconjunctival hemorrhage and ecchymosis and swelling of the lids. There may be double vision caused by displacement of the globe and/or entrapment of extraocular muscles. As with a Le Fort II

fracture, there is numbness in the distribution of the infraorbital nerve. Because of the depression of the cheekbone, the victim's face will have a flat appearance.

Fracture of the zygomatic arch can occur as an isolated injury. Such a fracture results in a depression on the lateral aspect of the face. Because the coronoid process of the mandible is located beneath the zygomatic arch, this type of fracture can also result in inability to fully open the mouth.^[13]

The best treatment for a jaw fracture is immediate immobilization. Even if perfect alignment is not achieved, fixation will make the victim more comfortable, reduce

bleeding, and avoid further displacement of the fragments. Fractures that pass through the tooth-supporting portion of the mandible may be quickly stabilized with a bridle wire, or more securely held with an arch bar (see [Figure 23-7](#)). Fractures in more posterior locations can be temporarily immobilized with a bandage ([Figure 23-14](#)), which should pull the mandible in a superior direction. Do not pull the chin posteriorly, because this can displace the fracture and compromise the airway. More rigid fixation can be obtained with intermaxillary wiring, which involves placing arch bars on upper and lower arches, placing the teeth in proper occlusion, and then connecting the upper arch bar to the lower bar with elastics or thin wire.

A posteriorly displaced Le Fort fracture should be disimpacted using forward traction. If the mandible is intact, the maxilla can be held in place by forcing mouth props (commercially available or improvised) between the upper and lower molars. Significant bleeding from the nasal cavities sometimes accompanies midface fractures. However, any tamponade of the nasal cavities will displace the mobile maxilla inferiorly unless it is first stabilized from below with mouth props.

A victim with facial bone fractures should be evacuated to a hospital for definitive treatment. In the interim, an antibiotic (penicillin VK 500 mg PO qid) and pain medication should be given. However, strong narcotics should be avoided if there is an associated head injury to avoid respiratory depression in an already obtunded victim.

Soft Tissue Injuries

Wounds of the oral mucosa and face should be treated after repair of the dental injuries and jaw fractures. Lacerations are likely to be reopened if closed before intraoral manipulations. Soft tissue injuries should be thoroughly irrigated and cleansed of foreign debris to prevent infection and tattooing. Tissue debridement should be very conservative. The excellent blood supply to this region means that wounds can be closed with sutures or other wound closures with little fear of infection if treatment can be accomplished within 6 hours of the injury. Sutures should be removed in 3 to 5 days, after which tape strips can be placed for additional stabilization

Figure 23-14 A simple bandage can be used to temporarily stabilize a jaw fracture.

of the wound margins. Facial abrasions should be gently washed twice daily with mild soap and warm water and then covered with an antiseptic ointment to prevent crusting. Small lacerations of the oral mucosa need not be closed. Use direct pressure for hemostasis.

Through and through lacerations, which are common in the lower lip, are first closed intraorally, after which the remainder of the wound is closed in layers from an extraoral approach. A laceration crossing the vermilion border of the lip requires careful alignment to avoid disfigurement. Deep lacerations of the soft palate will involve the muscles and must be closed in layers. Maintain traction on the tongue while lingual lacerations are sutured. Have an assistant or the victim grasp the tongue with gauze and hold it forward. After any intraoral repair, have the victim avoid rinsing for 24 hours and advise a liquid, nondairy diet. After this period, initiate rinsing four times a day with warm saline, chlorhexidine gluconate 0.12%, or diluted peroxide.

A facial laceration may be complicated by damage to associated structures ([Figure 23-15](#)). Injury to the lacrimal drainage system is present if a probe inserted into the punctum at the medial corner of the lid emerges into the laceration. Damage to the parotid duct should be suspected if there is leakage from the wound when Stensen's duct is irrigated with saline. Evidence of facial nerve damage is sought by observing the victim move the eyebrows, eyelids, and mouth. If facial nerve injury occurs behind a vertical line through the lateral canthus of the eye, evacuation for immediate repair is recommended.

569

Facial nerve injuries posterior to this line should be repaired as soon as possible. 1–5, branches of cranial nerve VII. (Redrawn from *Oral and maxillofacial surgery services in the emergency department*, Rosemont, IL, 1992, American Association of Oral and Maxillofacial Surgeons.)

Orthodontic Emergencies

Orthodontic appliances sometimes cause soft tissue irritation or ulceration. Cover the offending fixture with soft wax. Sometimes a protruding wire can be bent until the sharp portion faces away from the soft tissues. If a bracket or wire becomes excessively loose, it can usually be removed with judicious tinkering. If a wire needs to be cut and small wire cutters are unavailable, try repeatedly bending the appliance until the metal fatigues and breaks.

LOCAL ANESTHESIA

Local anesthesia is a prerequisite to many emergency dental, oral, and maxillofacial procedures. Anesthesia of any upper tooth and the associated buccal soft tissues can be obtained by infiltration. Approximately 2 ml of a local anesthetic solution is placed as close to the apex of the tooth as possible, just above the periosteum. By holding the syringe parallel to the long axis of the tooth, the needle tip is guided in the proper direction ([Figure 23-16](#)). Two percent lidocaine with 1:100,000 epinephrine is commonly used, although 2% bupivacaine with 1:200,000 epinephrine (Marcaine) is useful

Figure 23-16 Technique for infiltration of a local anesthetic.

Figure 23-17 Technique for blocking the inferior alveolar nerve near the mental foramen. The shaded teeth will be anesthetized.

for long-term pain relief. Other available local anesthetics can be substituted.

The mental nerve block is a simple method for obtaining anesthesia of the teeth and buccal mucosa from the second premolar forward. Proceed as for the infiltration, except that the target area is the mental foramen, located between the apices of the lower first and second premolars ([Figure 23-17](#)). After depositing the solution, gently massage the area for about 30 seconds.

Figure 23-18 When administering the inferior alveolar block, the target area **(A)** lies on the medial surface of the mandibular ramus, halfway between the rescuer's thumb and forefinger. Keep the syringe parallel to the occlusal plane, as shown in **B**.

The inferior alveolar nerve block is more difficult to learn, but it produces anesthesia of all of the lower teeth up to the midline and the buccal soft tissues forward of the mental foramen. The lingual nerve is also blocked by this injection, producing numbness of the anterior two thirds of the tongue and lingual gingiva. [Figure 23-18, A](#) , shows how the deepest concavity on the anterior border of the mandibular ramus is palpated by the thumb while the deepest concavity on the posterior border is palpated by the index finger. The target area is then halfway between the rescuer's thumb and index finger. ^[22] In [Figure 23-18, B](#) , the syringe is kept parallel to the plane of the lower teeth, and the mucosa is punctured just medial to the rescuer's thumbnail. When bone is contacted in the target area, the anesthetic solution is deposited. Experienced dentists miss the target area, and thus fail to produce adequate anesthesia, in about 10% of injections. ^[22]

DENTAL FIRST-AID KIT

Items necessary to manage dental emergencies can be added to a wilderness first-aid kit without a large sacrifice of space or weight. Cavit (Premier Co., Norristown, Pennsylvania) is temporary filling material that requires no mixing and is easy to use. Squeeze a small amount of the material from the tube and place it in the tooth. Wet a dental packing instrument (or cotton-tip applicator or toothpick) to prevent sticking and pack the Cavit well. Then remove any excess. Have the victim bite to displace material that would interfere with occlusion. The filling material will set in a few minutes after contact with saliva.

Zinc oxide/eugenol cements (Intermediate Restorative Material [IRM], L.D. Caulk Co., Milford, Delaware) consist of a liquid and a powder. Start with two drops of the liquid and begin mixing in the powder. Keep adding powder to make a dough that is as dry as possible. Dip the instruments in some powder to keep the mixture from sticking. Insert and shape the filling material as explained previously. Zinc oxide/eugenol cements have several advantages compared to Cavit. They are significantly stronger and can be mixed to a doughy stage for filling or slightly thinner for use as a cement. Most important is the soothing effect of eugenol on teeth with pulpitis. However, the liquid often leaks from its container, lending a pervasive odor to the backpack and tent; wind tends to blow the powder away; and the material is difficult to mix and is a sticky mess to insert into the tooth.

A more complete kit for extended expeditions should include a number 151 universal extraction forceps and a straight elevator for extracting teeth. A mouth mirror, orthodontic wax, dental floss, dental syringe, 30-gauge needles, and anesthetic cartridges complete the kit. These items fit in a small case and weigh about 14 ounces. A custom dental first aid kit is preferred over commercial dental "travel kits" that contain unnecessary items and lack essential ones.

In an outdoor situation, techniques must often be adapted or improvised depending on the items available. For example, [Figure 23-9](#) shows how a suture can be used to splint an avulsed or extruded tooth. A temporary filling can be fashioned from softened candle wax, an emery board can be used to smooth a sharp tooth, or a pocket knife can be used to perform a drainage procedure.

PREVENTION

The vast majority of dental emergencies can be prevented, beginning with pretrip planning. Before any extended

571

travel in a remote area, each person should have a thorough dental examination, radiographs, periodontal care, and treatment of potentially troublesome teeth. The Peace Corps requires certification that examination and treatment have been performed before assignment to developing countries. The National Science Foundation has similar requirements, and in addition requires impacted and unopposed third molars to be extracted before travel to Antarctica.

Once in the wilderness, minimal precautions can have significant effects. Lip balm with sunscreen can inhibit herpes labialis outbreaks. Routine personal oral hygiene will prevent many odontogenic infections and painful inflammatory conditions. Ideal care should include twice daily tooth brushing and flossing. Toothpaste is not essential, because mechanical removal of plaque and stimulation of the gingiva are the most important aspects of oral care. The fuzzy end of a hickory twig can be used if a toothbrush is not available. In the wilderness, daily oral hygiene not only helps prevent dental emergencies, but it also contributes to an overall sense of well-being and helps buoy morale when, for example, an expedition is tent-bound by bad weather.

Helmets are essential for preventing trauma in rock climbing, white-water kayaking, and mountain biking. It is estimated that custom-made mouth guards prevent over 200,000 injuries every year in interscholastic sports.^[18] Their use in backcountry recreation, now almost nonexistent, would probably also be very beneficial in appropriate circumstances.

Part 5 - Rescue and Survival

574

Chapter 24 - Wilderness Emergency Medical Services and Response Systems

Franklin R. Hubbell

When an accident or medical crisis occurs in the wilderness or backcountry away from access to immediate assistance, the chain of events set in motion will hopefully lead to a successful rescue. However, how it unfolds varies tremendously, depending on the part of the world in which the critical events occur. Currently, no national or international standard for wilderness emergency medical services (EMS) and response exists. Instead, the configurations of personnel and policies reflect local, national, and international influences. In the United States, wilderness EMS are the most diverse, since they are provided by a wide range of agencies and individuals with a wide variety of training and certification levels, ranging from first aid to paramedic. Canadian wilderness EMS are generally provided through the military, whereas in European wilderness situations, physicians have a prominent role.

The American Alpine Club's Safety Committee gathers, reviews, and analyzes mountaineering accidents that have occurred throughout North America and publishes the annual report *Accidents in North American Mountaineering*. The data collected illustrate both the necessary diversity of wilderness and mountain rescues and current limitations ([Box 24-1](#)).

Several states have established (or are in the process of establishing) working protocols for providing care in the wilderness or "extended care" environment. With increased natural and human-made disasters, EMS systems worldwide have suddenly found themselves essentially operating in "wilderness" settings because of prolonged

exposure to hostile environments, delayed evacuation and transport times, and lack of medical resources and direction. Prehospital personnel almost always provide care for much longer than the "golden hour" and have been hard pressed to utilize their street-oriented skills in these extended care situations.

Internationally, the Union Internationale des Associations d'Alpinisme (or International Union of Alpine Associations [UIAA]) has established criteria and courses for postgraduate training for physicians in mountain medicine. This allows physicians in the European Union to become certified in wilderness medicine and to practice the relevant skills in an appropriate arena.

The foundation has been set for national standards in providing emergency care and rescue by the adoption and implementation of the Incident Command System (ICS). This system has been used in coordinating forest firefighting tactics in the western United States. It has evolved into a template usable by any agency that may become involved with an emergency effort.

The ICS was developed to coordinate the many departments and individuals responding to large-scale forest fires. Since these fires can involve hundreds of departments with thousands of individuals, a system is needed that establishes a hierarchy of command and a common language of leadership and communication.

The assimilation of ICS into rescue and EMS offers a solution to the single biggest problem facing these services: how to coordinate and interface a variety of teams working on the same rescue effort. When each team follows its own set of operating procedures, standing orders, leadership protocols, terminology, and egos, it often makes it virtually impossible to effectively and safely coordinate a major rescue effort.

The ICS works well, and organizations such as the National Fire Academy and various state EMS offices have tried to adopt and implement it at all levels of emergency response. The ICS is now increasingly the standard for responding to any emergency situation, ranging from a single department answering a call to a minor motor vehicle accident to a complex search and rescue effort involving many agencies and rescue teams. [Chapter 25](#) discusses the basics involved in the ICS. As it becomes widely adopted and used, it will establish a national standard on which can be built national prehospital standards, including wilderness or "extended care" protocols.

Wilderness emergency medicine is a combination of emergency medical training and outdoor wilderness skills. Blending these elements, although essential, is not necessarily natural or easy. The art and science of prehospital emergency medicine began over 30 years ago in the United States and has evolved into a highly regimented and well-defined subspecialty of emergency medicine. We now have first responders, emergency medical technicians (EMTs), and paramedics, and a well-organized EMS system exists nationwide. However, this last statement may be somewhat misleading because each state has an independent EMS system and regulations so that a truly national standard does not yet exist.

The only national prehospital EMS standard that currently exists is via the National

This organization offers individual state EMS systems standardized written and practical examinations for first responders, EMT-basics, intermediates, and paramedics. This guarantees that, regardless of where someone was trained, he or she will be tested using the same standard. According to the Registry, there are approximately 110,000 EMT-basics, 11,000 EMT-intermediates, and 41,000 EMT-paramedics currently certified by their agency. However, since not all states recognize the National Registry certification or participate in this particular standardization, the actual numbers of certified emergency care providers are considerably higher.

Box 24-1. MOUNTAIN SEARCH AND RESCUE FACTORS IN THE UNITED STATES

1. Search and rescue is the responsibility of national parks, state parks, county sheriffs, or state conservation officers, depending upon the state or park.
2. The vast majority of backcountry and technical rescues are carried out by volunteer rescue groups.
3. Ninety percent of all rescues are carryouts on foot rather than airlifts by helicopter or fixed-wing aircraft.
4. At least 95% of rescues are performed without physicians present, instead using the skills of first responders, emergency medical technicians, and paramedics, who may or may not be trained in wilderness medicine and rescue techniques.
5. Only two of the major climbing areas, Yosemite and Grand Teton National Parks, use helicopters extensively.
6. Only Denali National Park uses fixed-wing aircraft extensively and helicopters occasionally.
7. Only three national parks have rangers who are trained specifically for technical rescue, advanced medical support, and helicopter

- fixed-wing aircraft extensively and helicopters occasionally.
7. Only three national parks have rangers who are trained specifically for technical rescue, advanced medical support, and helicopter operations: Yosemite, Grand Teton, and Mt. Rainier National Parks.
 8. National and state parks are not mandated with a "duty to rescue." However, virtually all parks provide rescue service. Most parks have a budget for these activities.
 9. Many roadside climbing areas and popular backcountry areas are not within the jurisdictions of parks. Technical and backcountry rescues carried out at these locations are often performed by local rescue squads, fire departments, and ambulance units, usually without the benefit of specialized training or technical backcountry skills.

Training programs that focus on rapid response, rapid intervention, and rapid transport to advanced care facilities exist nationwide. Prehospital personnel are prepared to work within the framework of the "golden hour," when time is precious and critical actions save lives. This is a nationally accepted urban standard to which all EMS personnel are currently trained. Although this standard is appropriate for evaluating and training urban EMS personnel and response systems, it is often not adequate for rural, wilderness, mountain, or "extended" EMS personnel and response systems. In these situations, patient care is measured in hours and days rather than minutes.

Traditional EMS recognizes rapid notification (the 911 system), dispatch, response, assessment, thorough prehospital care, transport, evaluation, and critical care in a hospital emergency department. Rapidity is the most critical factor that distinguishes urban emergency medical care from wilderness emergency medical care. However, time is not the only difference. Wilderness emergency medicine is governed by a complex set of medical skills and protocols, equipment requirements, and other specialized skills, including different attitudes or psychologic requirements, each of which combine premeditated action with improvisation. A productive mental attitude comes largely from the individual's training, expertise, and experience in the outdoors.

In mountain and wilderness outdoor activities, including mountain and wilderness rescue, haste truly makes waste, which may, in certain circumstances, cost lives. As a result, wilderness and mountain rescue teams must achieve a balance between the urgency of the situation and the necessity for adequate preparation. This is not an easy or natural blend of emotions and skills. On one hand, trained EMS professionals are always primed and ready to go, feel comfortable moving rapidly, act quickly, and think on their feet. On the other hand, skilled outdoorspeople are always eager and willing to travel into the backcountry but understand the necessity of thorough preparedness. This attitude ensures that not only is each team prepared but that each individual is

prepared. The team must be organized from a leadership perspective and know where it is headed, what injuries to anticipate, and how weather will affect the rescue. The team counts on each individual member being physically and mentally prepared. This difficult task requires recognition of the differences between short-term and long-term care during a rescue so that a safe and successful extended care rescue can be achieved.

Mountain rescue, wilderness rescue, rural rescue, white-water rescue, expedition medicine, disaster medicine, air-sea rescue, search and rescue, cave rescue, and avalanche rescue are all likely to be extended rescues. Once rescue personnel reach a victim, they will usually be with the person for hours, providing extended emergency care. The terms *extended rescue* and *extended emergency care* refer to rescue efforts that are outside that first golden hour, which has relevance mostly for acute and severe trauma situations.

Many of the recommendations in [Box 24-2](#) need further development and may be considered controversial.

In particular, specialized wilderness medical training with standardized protocols has yet to be developed.

Box 24-2. RESCUE PERSONNEL AND TRAINING IN THE UNITED STATES

1. Most technical rescue personnel in the United States are climbers or skiers who have added rescue techniques and medical training to their skills.
2. There are about 600,000 EMTs in the United States.
3. There are a growing number of wilderness EMTs trained in the skills of extended victim care in the backcountry environment.
4. Key skill elements of medical training for wilderness medical and rescue training include the following.
 - a. Thorough victim assessment skills and monitoring
 - b. Technical skills and the authority to perform the following:
 1. Airway management, to include endotracheal intubation.
 2. Shock management to

- b. Technical skills and the authority to perform the following:
 1. Airway management, to include endotracheal intubation.
 2. Shock management to include intravenous therapy
 3. Use of the military antishock trousers (MAST) garment
 4. Oxygen administration
 5. Use of appropriate medications
 - a. Epinephrine for anaphylactic reactions
 - b. Antibiotics for compound fractures
 - c. Acetazolamide, nifedipine, and furosemide for acute high-altitude problems
 - d. Pain medications for musculoskeletal trauma
 6. Field rewarming techniques
 7. Field reduction of fracture-dislocations
- c. Victim packaging and transportation skills
5. Key skill elements of technical training for rescue personnel in the United States include the following:
 - a. Appropriate climbing skills for terrain (rock, ice, snow, glacier)
 - b. Radio communications skills and protocols
 - c. Helicopter and fixed-wing protocols
 - d. Training and expertise in using the Incident Command System in field protocols

SEQUENCE OF EVENTS IN BACKCOUNTRY RESCUE

The principles and standards of a wilderness or mountain rescue (extended care rescue), including organization, specialized skills and knowledge, and essential components of the team, can best be illustrated by reviewing the sequence of events during a typical backcountry rescue in North America ([Box 24-3](#)).

Occurrence of the Critical Event

The critical event occurs when an individual participating in an activity away from immediate help is suddenly stricken by injury or illness. The key factor is immobilization. The fact that the injured or ill person cannot self-evacuate or move to seek shelter or stay warm results in the need for a rescue. Once the victim or others in the party realize this, the need to seek help becomes obvious.

Box 24-3. SEQUENCE OF EVENTS IN BACKCOUNTRY RESCUE

1. The critical event occurs: an injury or illness that requires assistance and evacuation.
2. A decision is made to "get help" and someone goes for help.
3. The emergency medical system is notified of the emergency.
4. The emergency medical system is activated, or "dispatched."
5. Eventually, the "extended rescue team" is notified and mobilized.
6. The rescue team assembles and organizes, then leaves the trailhead (may be preceded by a "hasty team").
7. The team locates the victim.
8. The team provides appropriate "extended emergency care."
9. The team organizes and evacuates the victim to the appropriate facility.
10. The team returns to base, is debriefed, and prepares for the next

7. The team locates the victim.
8. The team provides appropriate "extended emergency care."
9. The team organizes and evacuates the victim to the appropriate facility.
10. The team returns to base, is debriefed, and prepares for the next rescue.

Making the Decision to Get Help

Before anyone leaves to seek assistance, the victim's companions should perform a physical examination, record vital signs, determine the level of consciousness, and provide appropriate emergency care, which may entail moving the victim into protective shelter. Victim information should be summarized in a note that accompanies the individual(s) going for help. A map depicting the victim's exact location and a list of the other party members, noting their level of preparedness to endure the environmental conditions, should be included. The individual(s) going for help should carry appropriate provisions. To prepare information adequately generally takes 30 minutes to 1 hour. However, thorough preparation rarely occurs. Often, someone suddenly yells, "I'll get help" and disappears, running down the trail with sparse vital knowledge.

With the improvements and availability of communications technology, such as cellular phones and global positioning systems, backcountry adventurers may have more rapid access to the EMS system from the mountains. Whether this will increase the number of inappropriate callouts remains to be determined. Recent reports indicate that reliance on fallible technology may be responsible for outdoorspeople using poor

judgment in terms of trip planning. Assuming that help is just a phone call away, hikers are taking more risks.

Notifying the Emergency Medical System

Eventually, the messenger notifies someone in authority that an emergency has occurred and help is needed. Usually, the request is made to a central 911 system. If no central service is available, a local dispatch agency is notified. The agency contacts the closest emergency medical service, which can be a rescue squad, ambulance corps, fire department, or first response team.

Activating the Emergency Medical System.

Notification of an emergency usually occurs via pagers worn by individual members. An alert tone is followed by an oral message describing the emergency, its location, and type of response required.

At this point, a wide variety of events can occur, involving agencies within and outside the EMS system. Even in areas of the United States with well-organized extended care

rescue teams, the team may be notified last. Ideally, it should be notified immediately, but all too often this is not the case. Instead, local agency responders are notified and rush around trying to determine how quickly they can reach the victim.

Notifying and Mobilizing the Extended Rescue Team.

The first step is to notify team members. In many parts of the United States, organized and coordinated extended rescue teams do not exist, so a "team" is created of relatively untrained volunteers willing to hike in and assist. The task of further organizing and coordinating the rescue effort generally falls on the shoulders of a local rescue squad, fire service, or police department, which may or may not be willing and prepared to manage and execute an extended or technical rescue.

In the parts of the United States where backcountry use is common and backcountry accidents occur regularly, extended care rescue teams have generally evolved from local EMS squads with skilled outdoor enthusiasts. Some teams offering local search and rescue capabilities may be coordinated locally (such as the Appalachian Mountain Club, Stonehearth Open Learning Opportunities [SOLO], and Mountain Rescue Service in the White Mountains of New Hampshire); other teams may be part of a nationwide system responding to incidents throughout the country and be coordinated on a regional or national level (such as the National Cave Rescue Commission). Coordination of extended care rescue teams may also come under the jurisdiction of a law enforcement body, such as state conservation officers (e.g., New Hampshire Fish & Game), sheriff's department (e.g., the Los Angeles County Sheriff in California), or a statewide coordinating system (e.g., the Pennsylvania Search and Rescue Council). Organized teams can be quite sophisticated in their dispatching function so that all members can be notified simultaneously, or they may use a more "low-tech" telephone tree to call out members.

Assembling and Organizing the Rescue Team

Once members are notified, they assemble at a common location (rescue station) to organize the rescue effort. The first task is to define the type of rescue to establish equipment needs. Estimating the time it will take to effect the rescue and assessing the need for other agency involvement and assistance are also primary tasks. The questions to be answered and the variables to be considered may include the following:

1. Time of day: will this be a night rescue?
2. Weather: what are the current weather conditions at the rescue location and what is the forecast?
3. When did the accident occur?
4. What are the supposed injuries?
5. How many victims are there?
6. How many people are in the party?
7. How well prepared are they?
8. Does anyone in the party have medical expertise?
9. Do we know the exact location, or is this a search and rescue?
10. Is a "hasty team" needed? Has it left for the scene yet?

11. Is each of the team members prepared? Does each have personal equipment, a bivouac kit, head lamp, food, and water?
12. Is each member trained and skilled in this particular type of rescue?
13. Who is on the medical team?
14. Who is on the evacuation team?
15. Is the team equipment organized and divided up?
16. How urgent is the situation? Is a helicopter required? Is one available?
17. Are the weather conditions appropriate for an air rescue?
18. Will multiple agencies be involved? If so, are radio frequencies coordinated?

Once the team is assembled and all pertinent issues have been addressed satisfactorily, the team is transported to the trailhead (launch point) to begin the search.

Commonly, a hasty team starts out ahead of the main team. Once the hasty team has enough information to locate the victim, they travel as lightly as possible, with only enough gear to ensure their own safety and to equip them to manage the victim's primary injuries. The goal is to reach the victim as quickly as is reasonably possible and deliver primary care, then apprise the rest of the team of the victim's condition, equipment needs, and environmental concerns.

Locating the Victim

How long it takes to locate the victim varies tremendously, depending on distance, terrain, weather conditions, mode of transportation, and whether the victim's exact location is known. A general rule of thumb for a

team responding on foot is that it will take 1 hour for each mile through the backcountry. If a search is involved, all bets are off. A search and rescue effort can involve many agencies, individuals, and days (see [Chapter 25](#)).

Providing Appropriate "Extended Emergency Care"

Once the victim is located, appropriate medical care can be provided. The rescue team should ensure its own safety; wet clothes should be replaced with warm, dry clothing, and members should check for emerging problems within their group. While the medical team cares for the victim, the evacuation team secures shelter, prepares warm drinks, establishes and maintains communications, and plans and organizes the evacuation.

Companions with the victim may have been affected by the environment while waiting for the rescue team to arrive and require assistance. They may need to be assessed and treated for hypothermia, frostbite, heatstroke, heat exhaustion, and dehydration.

Regardless of what transpired before the medical team arrived, a complete victim

assessment is essential. Do not assume that all the injuries have been found or that all medical conditions have been managed properly ([Box 24-4](#)).

Box 24-4. VICTIM ASSESSMENT

PRIMARY SURVEY: LOCATING AND TREATING LIFE-THREATENING PROBLEMS

A—Airway Management

Is the airway open?

Is the airway going to *stay* open?

B—Breathing

Is air moving in and out?

Is the airway quiet or silent?

Is breathing effortless?

Is the respiratory system intact?

Is breathing adequate to support life?

C—Circulation

Is there a pulse?

Is bleeding well controlled?

Is capillary refill normal (less than 2 sec)?

Is circulation adequate to support life?

D—Disability

Conscious vs. unconscious

Level of consciousness—awake/verbal/painful/unconscious (AVPU) or Glasgow Coma Scale

Cervical spine stabilization

E—Environment

Level of consciousness—awake/verbal/painful/unconscious (AVPU) or Glasgow Coma Scale

Cervical spine stabilization

E—Environment

Internal vs. external

Is the victim warm and dry?

Protected from the cold ground

Protected from the elements

SECONDARY SURVEY: WHAT IS WRONG AND HOW SERIOUS IS IT?

Vital signs: Indicate the condition of the victim

RR—respiratory rate and effort

PR—pulse rate and character

BP—blood pressure (systolic/diastolic)

LOC—level of consciousness (AVPU or Glasgow Coma Scale)

TP—tissue perfusion: Skin color, temperature, and moisture

Capillary refill (less than 2 sec)

Victim examination: Head-to-toe examination to locate injuries

AMPLE history:

Allergies

Medicines

Past medical history

Last food/drink

Events leading up

SOAP NOTE: To record and organize victim data

Subjective: Age, gender, mechanism of injury, chief complaint

Objective: Vital signs, victim examination, AMPLE history

Assessment: Problem list

Subjective: Age, gender, mechanism of injury, chief complaint

Objective: Vital signs, victim examination, AMPLE history

Assessment: Problem list

Plan: Plan for each problem

In the extended care environment, the victim must be monitored for *changing* conditions that indicate an underlying problem. Awareness of environmental emergencies is particularly important, with constant care to prevent hypothermia, frostbite, heatstroke, heat exhaustion, and dehydration. To do this, it is necessary to monitor the victim and write a new SOAP note at least every 15 minutes:

Subjective: Is the victim comfortable, too hot, too cold, hungry, thirsty, or in need of urination or defecation?

Objective:

Vital signs—are they stable? Record these.

Victim examination—recheck all dressings, bandages, and splints; are they still controlling bleeding? Are they too tight or too loose? (Swelling limbs can cause bandages or splints to impede circulation, resulting in ischemic injuries or worsening frostbite or snakebite.)

579

Assessment: Has the initial assessment changed?

Plan: Is the rate of evacuation still the same?

Evacuating the Victim to the Appropriate Facility

While providing emergency care, part of the team is designated as the evacuation team. This group has evaluated the various options for evacuation. To properly evaluate the situation, the first information they need is provided by the medical team leader, since they need to know the status of the victim to establish the pace. If the victim's condition is stable, time is less important; if the victim's condition is critical, time is critical.

The evacuation team must explore different options. If speed is a consideration, weather conditions are reviewed and the availability of a helicopter-assisted rescue is determined. If a helicopter is not an option, the fastest route out is established. If time or speed is not critical, the safest means of evacuation that is easiest on the victim and rescuers is defined. A general rule for the duration of an evacuation is that it will take 1 to 2 hours for every mile to be covered, requiring six well-rested litter bearers for every

mile. Thus a 4-mile carryout will require a 24-member litter team and can take 4 to 8 hours to complete. Eventually, the team reaches a trailhead and the victim is transferred to an ambulance for transport to a hospital emergency facility.

Returning to Base

The team returns to base to reorganize equipment in preparation for the next extended rescue, and to debrief. Because people are exhausted and hungry, the debriefing session is often canceled. However, establishing a mechanism to debrief the rescue effort is imperative so that they can learn from the shared experience, discuss victim care, and work through problems. Whenever several different emergency organizations with disparate rescue and emergency personnel combine to perform a complex rescue, there may be tension, bruised egos, and concerns about the medical care provided or evacuation plan used. These problems deserve to be discussed and managed in real time as expediently as possible so that teams will cooperate successfully in the future, improve their performance, and provide the best possible patient care on the next rescue. This process minimizes the burnout syndrome that can occur with volunteer teams.

TEAM ORGANIZATION AND FUNCTION

The organization of an extended care rescue team is based on both training of individuals and type of rescue. The structures of teams can vary from loosely knit groups of friends with no leadership hierarchy to paramilitary organizations with rigid leadership roles.

Team members require personal knowledge, experience, and expertise in the particular aspect of extended care and rescue in which they will participate, as well as knowledge and expertise in the principles of extended emergency care, extended rescue techniques, and technical rescue skills.

Personal Knowledge, Experience, and Expertise

Individuals who want to be part of an extended rescue team need to acquire outdoor skills *before* they become part of a rescue team. Every member must have extensive knowledge of likely environmental emergencies: hypothermia, frostbite, heat syndromes, snakebite, dehydration, lightning strike, and so forth. Each must understand general principles of weather behavior. Rescuers need to be comfortable with route finding, map and compass, personal preparedness, and bivouac and survival skills. The knowledge, skills, and equipment that a skilled outdoorsperson should possess are often referred to as "the ten essentials" (see [Box 24-5](#)). The

same skills, knowledge, and equipment commonly used by the outdoor enthusiast are essential on a mountain rescue.

Box 24-5. THE TEN ESSENTIALS

1. *Attitude*

Positive belief that you can make things better

Will to survive

2. *Fuel to burn: food*

High-carbohydrate foods that require no preparation

High-carbohydrate foods that can be made into a drink

3. *Quench your thirst: water*

A minimum of 2 L/day if not active

Up to 3 L/hr if active

Ability to make more pure disinfected water

4. *Stay warm and dry: clothing*

Warm clothing that retains heat even if wet

Waterproof raingear, top and bottom

5. *Get dry: shelter*

Ability to improvise shelter or bivouac

A bivouac ("bivy") kit (see [Box 24-6](#))

Ability to improvise shelter or bivouac

A bivouac ("bivy") kit (see [Box 24-6](#))

6. *Get warm: fire*

Ability to warm water (stove, candle, fire)

Ability to build a fire (waterproof matches and tinder)

Ability to make kindling or tinder (folding knife)

7. *Know where you are going: navigation*

Map and compass skills and route-finding skills

Ability to move about at night (headlamp)

8. *Know the environment: weather*

Basic understanding of weather patterns

Knowledge of how to react to severe weather, lightning

9. *Getting help: signaling*

Whistle, preferably plastic

10. *Providing help: first aid kit*

Basic small personal trauma kit

Box 24-6. BIVOUAC KIT

Two large garbage bags (emergency shelter or raingear)

10 × 10 foot sheet of plastic and 100 feet of parachute cord (shelter)

Emergency space blanket (shelter, ground cloth)

Stocking cap (warmth)

Spare socks (warmth and can act as spare mittens)

Metal cup (to warm liquids)

Gelatin (to make a drink)

Two plumber's candles (to warm water or start fire)

Waterproof matches or lighter

Knife

Compass

Whistle

All of these items fit neatly into a small stuff sack that is 6 × 6 inches and weighs less than 1 pound when filled.

Extended Rescue Techniques and Skills

Specific skills and techniques applicable to a particular situation include those of search and rescue, vertical and technical rock climbing, and white-water navigation. Snow or winter camping or avalanche rescue may be required, depending on the environment. Extended rescue teams should require their members to have, at a minimum, the working knowledge and equipment in [Box 24-7](#) .

Knowledge is acquired over time. Specific medical, rescue, and technical skills are obtained and retained through courses, continuous training, and refresher programs. [Appendix A](#) at the conclusion of this chapter provides a list of schools, institutes, and organizations that are involved in mountaineering research, standards development, and training programs.

Wilderness and Mountain Rescue Team Organization

Organization of wilderness and mountain rescue teams is where the greatest diversity exists, since no universal standard has been established. Teams vary from local mountain rescue teams with extreme skills and qualifications for providing mountain rescue care to informal collections of friends without leadership. Other, more "professional," teams are operated under the jurisdiction of law enforcement agencies with paramilitary hierarchy and leadership. This diversity is particularly noticeable in the United States because the vast majority of teams are composed of volunteers who are not reimbursed for their rescue efforts.

In Europe, mountain rescue teams are professional and employ full-time personnel. They charge for rescue efforts, with the fees providing money for personnel, equipment, helicopters, technical gear, and ongoing training. As with any "profession," standards have evolved. As a result, there are more standards in Europe than in the United States. Still, there is variation from European country to country, especially in leadership and organization.

In many parts of the world, especially remote and wild areas, organized and available rescue teams do not exist. If someone is in need of help, the expedition team necessarily becomes the rescue team.

TRAINING OF WILDERNESS EMERGENCY MEDICAL TECHNICIANS

The best way to develop an appreciation for the vast difference between what is required of the traditional (urban) EMT and what is required of the extended care or wilderness emergency medical technician (WEMT) is to compare their respective course curriculums.

The Department of Transportation (DOT) is responsible for developing and updating the EMT curriculum in the United States. This curriculum is considered the minimum national standard for EMT students to qualify for the National Registry or an individual state practical and written examination. Passage of such an examination enables a student to become certified as a National Registry or state EMT.

A national standard for WEMT curricula does not yet exist. Despite the lack of a DOT-like standard, there are several similar curricula for wilderness emergency care at the EMT level. Based on the recommendations of the Wilderness Medical Society and other groups that address the issues of wilderness prehospital emergency medicine, these curricula adhere to the same principles of long-term patient care, which can be used for comparison with the standard DOT curriculum.

A WEMT course typically contains all of the material in the DOT EMT course curriculum plus what is necessary to acquire the skills attendant to long-term wilderness emergency care. Typical EMT courses are approximately 100 hours with 10 additional hours of emergency department observation time. The WEMT module carries an additional 48 to 80 hours of training.

Box 24-7. KNOWLEDGE, SKILLS, AND EQUIPMENT FOR EXTENDED RESCUE TEAMS

MOUNTAINEERING SKILLS

Understanding fabrics and clothing systems and their seasonal variations (see [Chapter 70](#))

Fabrics and fibers

Layering techniques

Vapor barrier systems

Waterproof fabrics, raingear systems

Footgear

Personal protection equipment

Helmets

Harnesses

Gloves

Goggles, sunglasses

Hearing protection

Backcountry equipment

Internal or external frame packs and soft packs

Shelter (natural and human-made)

Specialty equipment: snow shoes, crampons, ice axes, stoves, skis

Backcountry travel

Route finding

Map and compass: map reading, dead reckoning, types of maps, compass reading, bearings, magnetic vs. true bearing, triangulation, global positioning systems

Survival skills: the ten essentials

Map and compass: map reading, dead reckoning, types of maps, compass reading, bearings, magnetic vs. true bearing, triangulation, global positioning systems

Survival skills: the ten essentials

MOUNTAIN AND EXTENDED EMERGENCY MEDICAL SKILLS

Emergency medical training should be at a minimal level of first responder or higher (emergency medical technician, paramedic, registered nurse, nurse practitioner, physician's assistant, or physician). Regardless of the level, training must include specific information on wilderness and extended emergency care procedures. Topics of extended care training and principles should include the following:

Patient assessment system

Cardiopulmonary resuscitation

must include specific information on wilderness and extended emergency care procedures. Topics of extended care training and principles should include the following:

Patient assessment system

Cardiopulmonary resuscitation

Airway management, including endotracheal intubation and needle decompression for tension pneumothorax

Shock and control of bleeding, including the use of intravenous (IV) therapy for fluid resuscitation

Long-term wound care and prevention of infection

Musculoskeletal injury management, including specific information on diagnosis and long-term management of the following:

Sprains and strains

Fractures, including how to reduce or realign angulated fractures

Diagnosis and reduction of dislocations

Management of compound fractures

Management of chest injuries, including decompression of a tension pneumothorax with a needle thoracostomy

Spinal cord injury diagnosis and management

Head injury, including recognition and management of increasing intracranial pressure

Management of environmental emergencies

Hypothermia and frostbite, including the use of IV fluids

Heatstroke and heat exhaustion, including the use of IV fluids

Dehydration and nutrition, acute and during evacuation

Lightning injuries

Animal attacks, insect bites, and reptile and marine envenomations, including anaphylactic reactions and the use of epinephrine and antihistamines

Contact dermatitis, such as poison ivy, oak, and sumac

Sunburn and snowblindness

High-altitude injuries, including acute mountain sickness, pulmonary edema, cerebral edema

Near drowning

Sunburn and snowblindness

High-altitude injuries, including acute mountain sickness, pulmonary edema, cerebral edema

Near drowning

Diagnosis and management of acute medical emergencies

Chest pain (myocardial infarction, angina, costochondritis)

Shortness of breath (asthma, anaphylaxis, pneumothorax)

Seizures and cerebrovascular accidents

Acute abdomen (peritonitis, constipation, diarrhea)

Pyelonephritis and septic shock

Victim lifting and handling techniques (body elevation and movement [BEAM], free of any movement [FOAM])

Improvising techniques: "emergency medicine barehanded" (see [Chapter 19](#))

Training in the use of the Incident Command System

Bloodborne pathogens and infectious disease prevention

582

Monitoring of bodily functions (hunger, thirst, and need to excrete)

General understanding and appreciation for the difference between urban (short-term) and wilderness (long-term) emergency care

MOUNTAIN AND EXTENDED RESCUE SKILLS

Understanding equipment used in wilderness search and rescue operations, including maintenance and care

Ropes, slings, carabiners, harnesses, helmets

Litters, litter harnesses, haul systems

Litter patient packaging equipment

Basic radio communications

Care and maintenance of communications equipment

Procedures and protocols

Basic radio communications

Care and maintenance of communications equipment

Procedures and protocols

Basic helicopter operations and procedures

Approach to a helicopter

Safety considerations

Landing zones

Haul techniques

Interagency relations

Basic understanding of search procedures

Basic understanding of rescue procedures

Basic understanding of Incident Command System and its use in search and rescue management

Basic rope handling and knot tying skills

How to care for and handle ropes

LEADERSHIP

Leadership and followship training

Ability to use the Incident Command System

A typical WEMT course outline appears in [Box 24-8](#) . The topics in boldface are peculiar to a WEMT program, whereas the other topics are those required in a DOT EMT course. Hours per topic illustrate the time required for both EMT and WEMT training. This outline is arranged in the current DOT EMT recommended format, with the WEMT material added on a per topic basis; topics are not necessarily listed in the order that they would be taught for a particular course. An explanation follows of the extended emergency medical care material that WEMTs must learn.

Introduction to Emergency Care

"Wilderness vs. urban emergency care" is an introductory presentation to illustrate the differences between urban ("golden hour") emergency care and extended, or "wilderness," emergency care. For WEMTs, it will in certain instances be necessary to learn two different modalities of therapy, one for short-term (less than 1 hour) care and one for long-term or extended (several hours to days) care.

"Backcountry rescue gear inspection" is a hands-on review of gear for the outdoor practice sessions and backcountry mock rescues. The course staff must inspect the participants' boots, clothing, raingear, and rescue equipment to determine their adequacy for the particular environment in which they will be deployed. Inspecting equipment not only ensures the safety of each individual in the course but also teaches a standard for preparedness, awareness, and attention to details that is critical for wilderness travel and emergency care.

"Medical legal issues" is usually offered early in a course so that the participants are aware of the legal concerns surrounding practicing medicine as EMTs and WEMTs. WEMTs need to be aware of protocols existing where they will become licensed.

"The human animal—our natural physiologic limits" is an overview lecture of how humans fit into the natural environment and of their daily nutritional requirements and natural limitations. The WEMT must understand physiologic limits, such as those of endurance, temperature, and altitude, and the consequences when these limits are exceeded.

Patient Assessment Systems

"Patient assessment in the wilderness and practice" takes the newly learned skills of patient assessment and adapts them to the backcountry. The WEMT must be

583

584

knowledgeable and skillful in wilderness patient assessment, a step-by-step approach to the first 5 minutes of scene safety and patient care. The WEMT will develop an awareness of potential life-threatening dangers in the environment, how to ensure personal safety and the safety of others, how to approach a victim safely, how to perform primary and secondary surveys to determine the extent and severity of injuries, and what impact the environment might have on the victim.

Box 24-8. EMT AND WEMT COURSE CURRICULA AND HOURS PER TOPIC*

1. Introduction to emergency care

Wilderness vs. urban emergency care (1 hour)

Backcountry rescue gear inspection (1 hour)

Medical legal issues (1 hour)

Blood-borne pathogens

Overview of human systems—anatomy and physiology (2 hours)

The human animal—our natural physiologic limits (2 hours)

2. Patient assessment systems

Primary survey—ABCs (1 hour)

Secondary survey (1 hour)

Patient assessment practice (2 hours)

Patient assessment in the wilderness and practice (3 hours)

3. Cardiopulmonary resuscitation (8 hours)

Mannequin practice and certification (8 hours)

Cardiopulmonary resuscitation (CPR) teaching, practice, and testing to American Heart Association standards

4. Airways, oxygen, and mechanical aids to breathing (3 hours)

Airways, oxygen, CPR, and mechanical aids to breathing in the wilderness environment—uses and limitations (6 hours)

Airways: oropharyngeal, nasopharyngeal, esophageal obturator airway, endotracheal intubation

Oxygen administration

Suction techniques

Airways: oropharyngeal, nasopharyngeal, esophageal obturator airway, endotracheal intubation

Oxygen administration

Suction techniques

5. Bleeding and shock (3 hours)

Shock, intravenous (IV) fluids, and long-term patient care (4 hours)

Practice starting IV infusions and fluid administration (4 hours)

Use of pneumatic antishock garments (PASG) (3 hours)

Use of PASG in the wilderness (1 hour)

6. Soft tissue injuries (3 hours)

Long-term wound care (1 hour)

7. Principles of musculoskeletal care

Fractures of the upper extremities (3 hours)

Fractures of the pelvis, hip, and lower extremities (3 hours)

Fracture laboratory—practice in assessment and management (3 hours)

Musculoskeletal trauma management in the wilderness (3 hours)

8. Injuries of the head, face, eye, neck, and spine (3 hours)

Practical laboratory: spinal cord injury management (SCIM) (3 hours)

Head trauma, increasing intracranial pressure (1 hour)

SCIM: Long-term care and improvising (1 hour)

9. Injuries to the chest, abdomen, and genitalia (3 hours)

Chest trauma in the wilderness (3 hours)

10. Medical emergencies I (3 hours)

Poisoning, bites and stings, heart attack, stroke, dyspnea

10. Medical emergencies I (3 hours)

Poisoning, bites and stings, heart attack, stroke, dyspnea

Medical emergencies II (3 hours)

Diabetes, acute abdomen, communicable disease, seizure, substance abuse, and pediatric emergencies

Medical emergencies in the wilderness (3 hours)

11. Emergency childbirth (3 hours)

12. Burns and hazardous materials (3 hours)

Long-term care of burns (1 hour)

13. Environmental emergencies (3 hours)

Hypothermia, frostbite, immersion foot (4 hours)

Heatstroke, heat exhaustion, dehydration (4 hours)

Drowning (2 hours)

High-altitude emergencies (2 hours)

Barotrauma (2 hours)

Animals that bite and sting (2 hours)

Plants—contact dermatitis (2 hours)

Marine animals that bite and sting (2 hours)

14. Psychologic aspects of emergency care (3 hours)

15. Lifting and moving patients (3 hours)

Use of Stokes litters and improvising litters (3 hours)

16. Principles of vehicle extrication (4 hours)

Practice laboratory (3–8 hours)

Principles of backcountry evacuation (4 hours)

Search and rescue organization and execution (4 hours)

Practice laboratory (3–8 hours)

Principles of backcountry evacuation (4 hours)

Search and rescue organization and execution (4 hours)

Wilderness mock rescue with or without overnight (8–12 hours)

17. Leadership and followship skills

The Incident Command System

18. Ambulance operations I (3 hours)

Ambulance operations II (3 hours)

Helicopter-assisted rescues (3 hours)

19. Review (3–6 hours)

Testing—written and practical examinations (16–20 hours)

20. Emergency department observation time (10 hours)

*Topics in boldface are peculiar to WEMT programs, whereas the other topics are required topics covered in a DOT EMT course.

Airways, Oxygen, and Mechanical Aids to Breathing

"Airways, oxygen, cardiopulmonary resuscitation, and mechanical aids to breathing in the wilderness environment—uses and limitations" addresses one of the most important lifesaving and life-maintaining skills in emergency medicine: the ability to establish and maintain a patent airway. Unfortunately, most EMTs are not provided with the training and tools they need to properly maintain an open airway in an unconscious victim. Failure to perform endotracheal intubation can be disastrous for such a victim.

Endotracheal intubation is commonly used by EMT-intermediates and paramedics and other advanced life support (ALS) personnel in cardiac arrest settings and for unconscious, unresponsive victims. In the extended care environment, the use of intubation in a cardiac arrest situation is not nearly as common as it is for the normothermic, unconscious, and unresponsive person, who has probably suffered head trauma. In this situation, without intubation, the only way to maintain a patent airway while lifting, moving, and transporting a victim in a litter is to place the victim on his or her side. Gravity pulls the tongue forward and allows secretions to drain from the mouth. Oropharyngeal, nasopharyngeal, and esophageal obturator airways and tongue pin-pull

techniques may temporarily keep the tongue from occluding the airway, but they are ineffective in preventing vomitus, blood, or saliva from entering the airway. Also, during evacuation in a Stokes litter, constant monitoring of a victim's airway is virtually impossible, which makes endotracheal intubation of paramount importance. The WEMT should know how to establish and maintain a patent airway, including the use of endotracheal intubation.

"Oxygen administration" presents the use of supplemental oxygen, for which both EMTs and WEMTs follow the same general guidelines. Even though oxygen is important to prehospital care, its use has significant logistic limitations in the backcountry. The WEMT must realize that carrying large quantities of oxygen into the backcountry is impossible. Small D and E cylinders can be carried, but each provides high-flow oxygen for only 20 to 30 minutes. Oxygen is a compressed gas in a tank, so as it expands, it cools dramatically and may contribute to hypothermia. To prevent this, the gas should be preheated by wrapping the oxygen tubing around a chemical heat pack during administration.

"Suction techniques" presents the use of suction devices to clear the airway, which is similar for EMTs and WEMTs. Hand-operated, as distinct from battery-operated, suction devices are usually used in extended care scenarios.

Bleeding and Shock

"Shock, intravenous (IV) fluids, and long-term patient care" and "Practice starting IV infusions and fluid administration" provide information about the care of victims in shock.

In the urban management of shock, the essential component is recognition. Once shock is recognized, the victim can be rapidly transported to an emergency department or intercepted by paramedics for definitive care, namely fluid resuscitation.

In the extended care environment, WEMTs must be able to manage the shock syndrome by providing appropriate definitive care. During extended evacuations, WEMTs should know how to administer IV fluids to stabilize hypovolemia. This includes starting a peripheral IV line, maintaining the catheter placement, using proper fluids, and prewarming the solutions before and during administration.

"Use of pneumatic antishock garments (PASG) in the wilderness" discusses the use of these garments for victims in shock. The practice of treating shock using PASG has largely fallen out of favor. As long as an IV line can be established and maintained, fluid administration is the definitive method for managing shock. The WEMT must be aware that the PASG has other uses. In the extended care situation, use of the PASG may be invaluable in stabilizing a fractured pelvis to control internal blood loss and prevent shock. It may be useful in conjunction with a traction splint for a fractured femur. An added benefit is that the PASG may facilitate a comfortable and well-padded ride for the victim in a Stokes litter. However, WEMTs must recognize the limitations of a PASG. The primary drawback in the backcountry is the potential for cold injury. Once the apparatus is inflated, the decrease in peripheral circulation greatly increases the risk for cold injuries or frostbite to the lower extremities. This can be prevented by properly

packing the feet with chemical heat packs and adequately insulating the lower extremities in the litter. Careful monitoring of the lower extremities every 15 minutes is essential.

Soft Tissue Injuries

"Long-term wound care" covers proper wound management once bleeding has been controlled, and further care if more than 12 hours will be required to bring the victim to definitive care. The principles of long-term wound care are to stabilize the wound and prevent and control infection.

585

To prevent infection, the WEMT must know how to sterilize or disinfect fluid and how to properly debride and rinse out a contaminated wound. Once the wound is cleaned and debrided, the edges can be approximated but not tightly closed, since this may increase the risk of abscess formation and a life-threatening infection. Training in suturing techniques to close wounds is not currently recommended.

Even the most fastidiously cleaned wound can still become infected, particularly in a remote setting, because of constant exposure to microbes. Recognition of wound infections and appropriate management are important. The WEMT must learn to use specific antibiotics in extended care settings of greater than 3 days and for prophylaxis with grossly contaminated wounds and compound fractures. Antibiotic therapy is not controversial, since various safe broad-spectrum antibiotics can cover most wound infections with minimal risk of a severe allergic reaction. In certain circumstances the benefits of antibiotic administration clearly outweigh the risks.

Principles of Musculoskeletal Care

"Musculoskeletal trauma management in the wilderness" presents the treatment of injuries. In an urban setting, the primary concern with fracture and dislocation care is that the injury site be splinted properly to prevent further injury. In the extended care environment, the primary concern is to maintain proper circulation distal to the site of the injury. This may require straightening an angulated fracture or reducing a dislocation.

When an angulated fracture occurs, distal circulation can be impaired, putting the soft tissues at considerable risk for ischemic injury or frostbite. Under normal circumstances, it would take hours for moderate ischemia to cause irreparable soft tissue injury, but in the backcountry, prolonged time under hostile weather conditions frequently occurs, which decreases the amount of heat and oxygen being transferred to the extremity.

Knowing how to properly straighten out an angulated fracture significantly decreases the risk of secondary ischemic injury and frostbite, controls bleeding at the fracture site, and diminishes pain. It is much easier to splint and stabilize a fracture in proper position if it

is straight than if it is angulated.

Approximately 3 additional hours of training are needed to teach a WEMT how to straighten an angulated fracture and reduce dislocations. Without an x-ray, it is impossible to see the exact positioning of bone fragments or disarticulated joints, making it difficult to know exactly how to manipulate the bone. The concern is that if a jagged bone end is moved improperly, secondary injury might occur: part of a neurovascular bundle might be severed, a fascial sheath surrounding a muscle might be cut, or the bone ends might erupt through the skin. Fortunately, all of these structures are richly endowed with pain receptors. If the sharp end of a bone fragment begins to impinge, it causes a dramatic increase in pain at the site. A commonly used technique is to straighten the angulated site slowly while maintaining constant gentle traction. With each 1 to 2 cm of movement, the victim is asked if the new position is better or worse (causes less or more pain). If the pain diminishes with movement, the reduction is proceeding properly; if pain increases, all movement is stopped and the extremity is returned to the previous position of improvement. While still under gentle traction, the extremity is repositioned and another attempt at reduction is made.

As long as nothing is forced and movement is achieved slowly under gentle traction, angulated fractures can be easily realigned and dislocations reduced without the need for pain medication or any risk of further injury.

Musculoskeletal injuries in the long-term care setting must be carefully monitored. It is essential to reinspect the injury site at reasonable intervals for circulation, sensation, and motion. Fracture sites swell; as a result, even the best splint can act as an inadvertent tourniquet. Immobilized extremities cool because of lack of activity and impaired circulation, also increasing the risk of ischemic injury or frostbite.

Injuries of the Head, Face, Eye, Neck, and Spine

"Head trauma, increasing intracranial pressure" addresses one of the leading causes of death from backcountry accidents. Many who die of head trauma in the wilderness would have survived in an urban setting because of rapid access to definitive care. The WEMT must be able to recognize a potentially serious head injury long before the victim is at risk of brainstem herniation.

In the extended care environment, there are few situations when the team should hurry. One such situation is the presence of significant head trauma, for which the only appropriate care may be rapid evacuation to a facility where the victim can be put into the hands of a neurosurgeon.

It is important to establish and monitor the level of consciousness. The AVPU (awake, verbal, pain, unresponsive) scale is used. Within the primary survey, an initial evaluation of disability or neurologic status is made. After that, level of consciousness is reevaluated every 15 minutes to observe in particular for any evidence of increasing intracranial pressure.

Injuries to the Chest, Abdomen, and Genitalia

Chest trauma is significant for the WEMT because it can result in a pneumothorax that can evolve into a tension pneumothorax. WEMTs need to be taught how to inspect, palpate, percuss, and auscultate the chest for significant injuries to the respiratory system. It is not difficult to train an individual to detect breath sounds, determine the presence of a pneumothorax, and monitor a pneumothorax for its development into a tension

586

pneumothorax. Unlike increasing intracranial pressure, for which there is little to do but evacuate the victim, a tension pneumothorax can be relieved, increasing the chance of survival. The easiest and most effective technique a WEMT may learn is needle thoracostomy in the fifth intercostal space in the midaxillary line.

Medical Emergencies

Diagnosing medical emergencies in the wilderness requires the WEMTs to be aware of essential signs and symptoms.

Environmental Emergencies

The typical EMT course includes 3 to 6 hours of training in management of environmental emergencies. A WEMT course will have a minimum of 22 hours of additional training in environmental emergencies.

"Hypothermia, frostbite, and immersion foot" covers cold injuries, which are among the most common environmental injuries seen in the backcountry. The WEMT must understand principles of thermoregulation; heat production and heat loss; recognition of hypothermia, frostbite, and immersion foot; and appropriate care.

"Heatstroke, heat exhaustion, and dehydration" provides necessary information about the balance of heat production and heat loss in a hot environment and the fluid requirements necessary to support physiologic cooling. WEMTs need to know how to recognize and provide long-term care for victims of heatstroke, heat exhaustion, and dehydration.

Lifting and Moving Patients

"Use of Stokes litters and improvising litters" discusses the primary device for evacuation from the backcountry. Even when a helicopter is used, the victim is usually "packaged" in a litter before being loaded. WEMTs must know the specific techniques for victim packaging in a litter to protect and support injuries. Use of the proper carrying

techniques and methods of belaying a litter up or down a steep slope are critical to the safety of everyone involved.

Ambulance Operations

"Helicopter-assisted rescues" describes the use of helicopters in backcountry rescue efforts and evacuation. WEMT training should address the dangers, hazards, and limitations of helicopters.

APPENDIX: Research, Standards, and Program Resources

The following is a list of organizations and committees dedicated to some aspect of extended medical, rescue, and technical training. Many are also active in mountain, wilderness, marine, or disaster rescue and management efforts.

American Alpine Club
710 Tenth Street, Suite 100
Golden, CO 80401
303-384-0110

Resource: Publishes *The American Alpine Journal* and annual *Accidents in North American Mountaineering*. Has committees dedicated to establishing and promoting standards in safety and education in mountaineering.

American Mountain Guides Association
710 Tenth Street, Suite 101
Golden, CO 80401

Resource: Dedicated to establishing and maintaining standards for mountaineering and professional mountain guides. Publishes quarterly *Mountain Bulletin*.

Appalachian Mountain Club
P.O. Box 298
Gorham, NH 03581
603-466-2727

Resource: Active mountain rescue team that offers a variety of workshops on outdoor skills, environmental issues, and wilderness medical and rescue skills. Publishes quarterly *Appalachia*.

Appalachian Search and Rescue Conference
P.O. Box 440, Newcomb Station
Charlottesville, VA 22904
804-674-2400 (emergencies only)

Resource: Wilderness EMS agency, search and rescue, course and materials development.

Center for Emergency Medicine of Western Pennsylvania
230 McKee Place, Suite 500
Pittsburgh, PA 15213-4904

Resource: Offers various wilderness EMT and wilderness command physician training courses.

International Society for Mountain Medicine
Clinique Generale de Sion
1950 Sion, Switzerland
Resource: An international organization dedicated to research and education in mountaineering. Publishes quarterly *The Newsletter of the ISMM*.

Mountain Rescue Association
5301 D North 33rd Drive
Phoenix, AZ 85017-2802
Resource: National wilderness rescue organization dedicated to the development of standards and certification of mountain rescue teams.

Nantahala Outdoor Center
US 19 West, Box 41
Bryson City, NC 28713
704-488-2175
Resource: Offers a variety of courses on white-water rescue and wilderness medical and rescue training.

National Association for Search and Rescue
4500 Southgate Place Suite 100
Chantilly, VA 20151
703-222-6277
Resource: National information resource for search and rescue, as well as certifications in various search functions. Publishes quarterly journal *Response*.

National Cave Rescue Commission
c/o National Speleological Society
Cave Avenue
Huntsville, AL 35810
205-852-1300
EMERGENCY: *National Rescue Coordination 1-800-851-3051*
Resource: Active national cave rescue team.

National Ski Patrol System, Inc.
Ski Patrol Building, Suite 100
133 South Van Gordon
Lakewood, CO 80228
303-988-1111
Resource: Active rescue teams and ski patrols. Offers an outdoor emergency care course, various ski patrol certifications, avalanche training, and introductory mountaineering training.

Stonehearth Open Learning Opportunities (SOLO) and North American Rescue Institute (NARI)

P.O. Box 3150
Conway, NH 03818
603-447-6711

Resource: An international organization dedicated to developing and offering a variety of courses and certifications in wilderness and marine medicine, rescue, leadership, and outdoor skills. An active mountain rescue team. Publishes bimonthly *Wilderness Medicine Newsletter*.

Union Internationale des Associations d'Alpinisme (UIAA) (International Union of Alpine Associations)

President of the UIAA Medical Commission
Bruno Durrer, MD
Dokterhuus
3822 Lauterbrunnen
Switzerland

Resource: An international organization dedicated to the promotion of standards, safety, awareness, and education in mountaineering worldwide. Produces multiple publications on mountain safety and medicine.

United States Coast Guard Headquarters

2100 Second Street, SW
Washington, DC 20593-0001
202-267-1012 (Boating Operations)

Resource: Active national marine rescue military organization. Source of information and various boating-related certifications.

Wilderness Medical Associates

RFD 2, Box 890
Bryant Pond, ME 04219
207-665-2701, 800-742-2931

Resource: Offers a variety of courses and certifications in wilderness medical and rescue courses.

Wilderness Medical Society

P.O. Box 2463
Indianapolis, IN 46206
317-631-1745

Resource: A physician-based national wilderness medical organization with various committees dedicated to education in wilderness emergency medicine. Particular attention to education for physicians. Publishes quarterly newsletter and *Wilderness and Environmental Medicine* (formerly *Journal of Wilderness Medicine*).

Wilderness Medicine Institute of the National Outdoor Leadership School

300 Tenth Street
P.O. Box 9

Pitkin, CO 81254

303-641-3572

Resource: Offers a variety of courses and certifications in wilderness medicine and rescue.

Chapter 25 - Search and Rescue

Donald C. Cooper
Patrick H. LaValla
Robert C. Stoffel

As ever-increasing numbers of outdoor users turn to the wilderness for recreation, the medical community and search and rescue (SAR) organizations will contend with a growing number of lost, sick, and injured persons. Wilderness search, rescue, and medical intervention are unique in several ways. All aspects of SAR are enormously time consuming. Simply raising the alarm for someone lost or injured in an isolated area may take hours, days, or even weeks. Organizing a response, including obtaining equipment and transportation for responders, requires a variable amount of time, depending on the level of preparedness of the response organization. Finding, gaining access to, stabilizing, and transporting a victim to definitive care can be a lengthy process.

Because it takes many persons to perform a wilderness rescue (six or eight persons are required to carry a litter 1 mile), logistic considerations such as food, shelter, and transportation for responders quickly create their own problems. SAR personnel are subjected to the same risks and environmental stresses that compromise victims. To obviate further tragedy, they must have a heightened awareness of potential danger, adverse conditions, and personal limitations. In addition to basic and advanced life-support training, rescuers must have extensive wilderness experience that combines practicality with creativity and resourcefulness. SAR personnel must have training in survival, improvisation, communications, leadership, navigation (e.g., map, compass, and global positioning system [GPS]), first aid, and specific SAR techniques. Many interventions, such as cardiopulmonary resuscitation, defibrillation, tube thoracostomy, tracheal intubation, and intravenous therapy, are difficult—if not impossible—in the wilderness setting. Examinations may be hampered by the bulky clothing necessary to keep the victim warm and dry. Medications and equipment are subject to rough handling and extremes of temperature, which may render them ineffective, unsterile, or inoperative (see [Appendix](#) at end of this book).

Finally, decision making that optimizes patient care while not unduly risking the

well-being of SAR personnel requires experienced leadership grounded in both common sense and technical skill. Perhaps the demands of SAR were best summarized by the wise rescuer who said that climbers, divers, hikers, and other outdoor enthusiasts get to choose where they practice their skills, but SAR personnel have no such choice. The situation, usually urgent, dictates where and when rescuers practice their art. The same situation that already compromised at least one person's health or well-being subsequently endangers the SAR participants.

This chapter introduces medical professionals to the unique search, rescue, and medical problems encountered in wilderness, remote (including urban disaster environments), and backcountry situations. The rudiments of SAR coordination, resources, and specialized problems will be discussed. This information will help medical personnel understand how the SAR community works and provide an educational foundation to help prevent situations requiring undue risk, or SAR personnel themselves from having to be rescued.

SEARCH AND RESCUE: AN OVERVIEW

SAR systems provide the response for overdue, lost, injured, or stranded persons, usually in connection with outdoor activities and environments. In the context of SAR, "wilderness" can take on several meanings. For instance, most consider wilderness to be regions that are uninhabited and uncultivated. Personnel may be called out to search a natural area such as a large park or desert, but it is equally likely that a search will be urban, in an area devastated by a natural disaster such as an earthquake or hurricane. Because the majority of the population in the United States resides in urban areas, emergency responders and SAR personnel are far more likely to encounter urban wilderness than a natural one. However, this chapter focuses on the nonurban setting.

Types of SAR emergencies vary nationally, as do the responders. Programs, equipment, and personnel differ geographically in accordance with local needs and available resources. SAR can probably be best defined as "finding and aiding people in distress—relieving pain and suffering."^[15] SAR often involves a great many volunteers and entails a multitude of skills. For example, the eruption of Mt. St. Helens, one of the nation's most catastrophic disasters, resulted in the largest peacetime SAR operation in the history of the United States.

SAR operations can benefit comprehensive emergency management, providing a training ground and experience builder for disaster response capability at the most elementary level. The management concepts used in SAR operations establish foundation principles for providing response capability to large-scale emergencies and disasters. Nearly every type of hazard mentioned in comprehensive emergency management plans (local and state disaster coordination plans developed

in all states) requires search and rescue.^[14] Management of these SAR operations can range from directing the actions of a few responders in a small community hit by a minor earthquake to managing an effort involving thousands of searchers in a large urban calamity. Often, large situations involve several political subdivisions and coordination of air and ground resources. Local governments and other agencies that participate in SAR response must coordinate diverse multiskilled responders. In addition, many agencies that collectively support multiorganizational SAR responses operate under their own specific statutory authority.

SAR operations entail a motivating time factor that focuses on a successful conclusion: finding or rescuing a lost subject before he or she succumbs to the effects of the

environment, injuries, or a specific hazard. To be effective, extremely diverse organizations must be drawn together in a life-threatening situation with a commonality of purpose; this is even more true during a community-wide disaster.

Search and Rescue in the United States

National Search and Rescue Plan.

SAR involves many agencies and volunteers, and the federal government assumes some responsibilities for overall coordination, especially of federal or military resources requested by local or state agencies.

The U.S. National SAR Plan^[20] (*website: www.uscg.mil/hq/g-o/g-opr/icSAR/nsp.htm*) was first published in 1956 and identifies federal responsibilities in search and rescue. It is also the basis for the National Search and Rescue Manual, which discusses SAR organization, resources, methods, and techniques.

The National SAR Plan is implemented and maintained by the National SAR Committee (NSARC), formerly the Interagency Committee on Search and Rescue (ICSAR), which includes representatives from each of the six signatory federal agencies (Departments of Transportation, Defense, Commerce, and the Interior; the National Aeronautics and Space Administration [NASA], and the Federal Communications Commission [FCC]). NSARC reviews SAR matters affecting all agencies, including recommendations by participating agencies for plan revision or amendment, and makes appropriate recommendations. It encourages federal, state, local, and private agencies to develop equipment and procedures that will enhance the national SAR capability and promote coordinated development of all national SAR resources.

There are three geographic regions of jurisdiction identified in the National SAR Plan:

1. *Inland area*: Continental United States, except inland Alaska and waters under jurisdiction of the United States.
2. *Maritime area*: U.S. waters, Hawaii, specific areas off the west coast of Canada (south of Alaska), the high seas, and those commonwealths, territories, and possessions of the United States lying within the "Maritime area," which has two parts: the Atlantic and the Pacific.
3. *Overseas area*: Overseas unified command areas, inland Alaska, areas not included in Inland or Maritime regions.

A "SAR coordinator" or agency responsible for SAR in the specific region administers each of the areas. The United States Air Force (USAF) is the coordinator for the Inland area, the United States Coast Guard (USCG) is responsible for the Maritime area, and the appropriate overseas unified command (and the Alaskan Air Command) tracks its respective areas in the Overseas area. Each SAR coordinator establishes agreements with military, civilian, state, local, and private agencies to ensure the fullest practical cooperation and utilization in SAR missions. SAR coordinators maintain files of these

agreements and lists of the agencies and the locations of their SAR facilities.

Although the federal government provides guidance, national policy protects the desires of state and local agencies to direct and control their own SAR resources. Therefore each state and local government is encouraged to assume SAR responsibility within its geographic boundaries and capabilities. The federal role is to coordinate federal agencies in support of those at the local and state levels to create a cooperative national SAR network.

The USCG and USAF both operate rescue coordination centers (RCCs) in the United States, but each service takes a slightly different approach. The Air Force RCC (AFRCC) coordinates inland SAR activities in the continental United States but does not directly conduct SAR operations. In most situations, the Civil Air Patrol (CAP), state police, or local rescue services carry out the actual SAR operations. In contrast, the USCG not only coordinates but also conducts maritime SAR missions.

U.S. Air Force Rescue Coordination Center.

Established in 1947 to meet the growing demand for SAR and its legislated responsibility, the original three AFRCCs have evolved into a single RCC located at Langley Air Force Base in Hampton, Virginia, under the Air Combat Command (ACC). The peacetime mission of the AFRCC is to build a coordinated SAR network, ensuring timely, effective lifesaving operations whenever and wherever needed. As of August 1996, the AFRCC recorded the prosecution of over 58,000 SAR missions, resulting in over 12,800 lives saved.^[21]

The AFRCC functions around the clock and is staffed by people trained and experienced in the coordination of SAR operations. The center is equipped with extensive audio and digital communications equipment and maintains a comprehensive resource file listing federal, state, local, and volunteer organizations

that conduct or assist SAR efforts in the United States, Canada, and Mexico.

There are four types of authorized AFRCC missions: search, rescue, MEDIVAC, and mercy.

SEARCH.

Once a distress situation is determined to exist but a location is unknown, federal SAR forces may be activated to search for, locate, and relieve the distress situation. The object of these searches may take the form of overdue aircraft, emergency locator transmitters (ELTs), hunters, hikers, or children.

RESCUE.

A rescue mission entails the use of federal SAR forces to recover persons in distress whose location in a remote area is known, but who need assistance. This may be in the form of transportation to safety or to an adequate medical facility. These requests are normally received by the AFRCC from park-service personnel or the local law-enforcement authority.

MEDIVAC.

The transportation by federal assets of persons from one medical facility to another is defined as *aeromedical evacuation*, or MEDIVAC. Requests are normally received from a local hospital when no commercial transportation is available, the person's life is in jeopardy, and time is critical. Each request is evaluated, and the decision to use federal resources is weighted heavily by the attending physician's medical opinions.

MERCY.

A mission to transport blood, organs, serum, medical equipment or personnel to relieve a specific time-critical, life-threatening situation is referred to as a *mercy mission*. Requests are normally referred from a local hospital authority or, in some cases, the American Red Cross when commercial transportation is not available.

Although the AFRCC will accept and act on initial notification from any person or agency, it will attempt to determine the urgency and the facts pertaining to the situation before obliging itself. Several aspects of the situation are considered before a mission is opened, including the following:

1. Medical evaluation and urgency
2. State agreement requirements
3. Posse Comitatus Act
4. Conflict of interest with commercial resources
5. Resource availability

The medical condition of the victim or victims is the most important aspect of mission consideration. The AFRCC will only consider a request valid when there is an immediate threat to life, limb, or sight. A mission will only be started to prevent death or the aggravation of a serious injury or illness. The observations and opinions of a physician at the incident site weigh heavily on the decision to open a mission, and a flight surgeon is on call at the AFRCC when a local physician is unavailable.

Each state has an agreement on file in the AFRCC describing the responsible agency and coordinating requirements for the various types of SAR missions. Each request for federal assistance is evaluated to ensure the requirements stipulated in the relevant agreement are met. Title 18 USC 1385 (the Posse Comitatus Act) prohibits military participation in civil law-enforcement activities. Although there are some exceptions to

the prohibition, as a general rule, Department of Defense (DOD) forces, including the CAP, will be restricted from participating in searches in which the person being sought is evading searchers, is a fugitive, or when foul play is considered.

On MEDIVAC or mercy missions in which the patient is not eligible for DOD medical benefits, federal assets cannot be used when commercial resources are available. Even when a patient is unable to pay or is destitute, commercial resources will be checked for availability and provided the opportunity to accept the mission before allocating federal resources.

Although any SAR-capable asset belonging to the federal government may be requested, each resource is evaluated for distance from the distress location, special equipment requirements, urgency of the situation, and which resource can best accomplish the mission. Military forces may be called on to assist in civilian SAR missions. However, their participation in these activities must not interfere with their primary military mission.

Once the decision has been made to use federal resources, a mission number is assigned and SAR forces are selected based on the geographic location and mission requirements. The Air Force coordinator will then work closely with the responsible agency in an attempt to provide the resources best suited to accomplish the mission.

The AFRCC can be contacted as follows:

U.S. Coast Guard Rescue Coordination Centers.

The USCG is designated as the federal SAR coordinator for the Maritime area, which is divided into two areas: Atlantic and Pacific. These areas are divided into several districts, which are further divided into groups (several per district) and stations. A 24-hour alert status is maintained year round at all levels, and Coast Guard resources can be underway or airborne within minutes of notification of a SAR mission. At its headquarters, each area and district maintains a fully staffed operations center responsible for coordinating operations

within that area or district on a 24-hour basis. When coordinating SAR missions, these operations centers are called "rescue coordination centers" (RCCs). Although minor SAR incidents are often resolved at the station or group level, the district or area assumes the duties of the SAR mission coordinator (SMC) in more complex or large-scale missions.

The USCG is arguably involved in more SAR missions than any other organization or agency on the face of the earth. It is also notable that the USCG is a separate federal agency under the Department of Transportation, not the Department of Defense as is the Air Force.

An important global service of the USCG is the Automated Mutual-Assistance Vessel Rescue (AMVER) system. AMVER involves ships, regardless of flag, voluntarily providing information about their capabilities (i.e., medical personnel on board, rescue equipment) and regularly reporting their location to a global computer system that tracks their whereabouts. When a situation arises that requires SAR capabilities, a surface picture (SURPIC) is produced that graphically shows the location of all AMVER participants in the vicinity. The RCC can use this information to select the best one or several ships to respond to the emergency, allowing all others to continue their voyages. Today approximately 12,000 ships from over 140 countries participate in AMVER, representing approximately 40% of the world's merchant fleet. An average of 2700 ships are on the AMVER plot each day, with over 1 million voyages tracked annually. The AMVER system has saved over 1500 lives since 1990.^[22]

A "preventive SAR" service provided by the USCG as a direct result of the Titanic disaster is the International Ice Patrol, whose operations are funded by SOLAS (Safety of Life at Sea) Convention signatories. Since 1913, the Ice Patrol has amassed an enviable safety record, with not a single reported loss of life or property caused by collision with an iceberg outside the advertised limits of all known ice in the vicinity of the Grand Banks. However, the potential for a catastrophe still exists, and the Ice Patrol continues its mission using high-tech sensors and computer models.

The USCG also performs or coordinates the medical evacuation of seriously ill or injured persons from vessels at sea if the patient's condition warrants it and USCG assets are within range. For less serious situations, USCG flight surgeons will offer medical advice via radio. On rare occasion, the RCC may coordinate with a U.S. Navy (USN) ship to allow a USCG MEDIVAC helicopter to refuel to extend its range. Also on rare occasion, the RCC may coordinate with the USAF to dispatch pararescue personnel to parachute to the vessel and stabilize the patient. In either case, these actions are taken only in the most serious situations where one or more lives depend on such drastic actions.

If a vessel is reported overdue or unreported (i.e., failed to check in when expected), USCG assets may or may not launch immediately, depending on whether the overdue craft is thought to be in immediate danger. Regardless, an extensive investigative effort

will be initiated immediately. During this investigation, a preliminary communications check (PRECOM) and extended communications check (EXCOM) will likely take place. These actually include more than just contacting intended destinations. They also include interviewing persons who may be knowledgeable about the craft and dispatching USCG vehicles and/or small boats to physically check harbors, marinas, launching ramps, and the like. In addition, an urgent all-ships broadcast is initiated requesting information on any recent or future sightings that might be the missing vessel, and EXCOMs are repeated on a regular basis.

If none of these communications and investigation efforts produce positive results (i.e., locating the vessel and/or indications that the persons on board are not in immediate danger), a search will be undertaken. Search planning is conducted by the RCC staff, but additional assets can be requested from other agencies (i.e., USAF and USN) and/or foreign governments in a position to assist. With the assistance of the USCG's Computer Assisted Search Planning (CASP) system, the RCC develops scenarios based on the available information. These scenarios are then weighted according to a subjective estimate of how likely each one is to represent the true situation. The further analysis of available information leads to the development of probability maps (using CASP), after which a search is planned and orders are issued to all participating units. The search continues until either the survivors are found and rescued, or it is deemed that further searching would be fruitless. ^[6]

Because SAR regions are not construed as boundaries to effective SAR action, and much of the Inland area borders on the Maritime area, coordination between the AFRCC and the USCG RCC is a daily occurrence. Missions that traverse both areas will be coordinated through the AFRCC or the appropriate USCG RCC. It is not unusual for the USCG to call on the AFRCC for a particular resource needed to prosecute a mission in the Maritime area, or conversely, the AFRCC to utilize a USCG resource in the Inland area.

The USCG RCC can be contacted as follows:

Mailing address: USCG Headquarters, Commandant (G-OPR), 2100 Second Street SW, Room 3106, Washington, DC 20593-0001

Phone: (202) 267-1943

Fax: (202) 267-4418

U.S. Mission Control Center.

The U.S. Mission Control Center (USMCC), located in Suitland, Maryland, is the U.S. operational component of a multiagency, multinational

program that uses satellites to detect and accurately position emergency beacon signals from aircraft, vessels, and people in distress. This program is called the *SAR Satellite-Aided Tracking (SARSAT)* program, and the USMCC is one of 23 interconnected MCCs around the world that handle data distribution for the system. The National Oceanic and Atmospheric Administration (NOAA) operates Earth-observing satellites that are used to carry, among other things, SARSAT instruments that can detect and relay emergency signals from beacons activated by people in distress. These SARSAT payloads are provided by Canada and France, but Russia operates very similar instruments, known as COSPAS, aboard satellites that are part of a navigation system. The USMCC is administered by the SARSAT Operations Division of NOAA, which also represents U.S. interests in international COSPAS-SARSAT meetings. The USMCC is staffed 24 hours a day, 365 days a year. However, the vast majority of alert data distribution is handled automatically.

Together, the COSPAS-SARSAT system is being used in an international cooperative SAR effort in which the objective is to help save the lives of aviators, mariners, or anyone in distress who activates an emergency beacon. Aircraft carry ELT beacons that are normally triggered by the impact of a crash. Ships carry floating Emergency Position-Indicating Radio Beacons (EPIRBs) that are activated by immersion in water. Both devices can also be activated manually. These devices transmit on a radio frequency of 121.5 Megahertz (MHz) and/or 406.025 MHz. Using Doppler processing techniques, a beacon transmitting on the 121.5-MHz frequency can be located with an accuracy of about 10 to 25 km (5 to 12 miles) and may take as long as several hours to confirm. Alternatively, a beacon alerting on the 406 MHz frequency can be located within an accuracy of about 2 to 5 km (1 to 3 miles) and is usually confirmed in a matter of minutes. In addition, the 406-MHz devices have the capability of transmitting a unique identifier for which the MCCs maintain registration information about the owner of the device if the beacon was previously registered. In the near future, some 406-MHz devices will be coupled with electronic navigational receivers (such as GPS units) and will be able to provide both immediate alerting and accurate position information.

The COSPAS-SARSAT system consists of a network of satellites, ground stations, MCCs, and RCCs. When an emergency beacon is activated, the signal is received by a satellite and relayed to the nearest available ground station. The ground station, called a *Local User Terminal (LUT)*, processes the signal and calculates the position from which it originated. Once calculated, this position is transmitted to an MCC, where it is joined with identification data and other information on that beacon, if such information is available. The MCC then transmits an alert message to the appropriate RCC based on the geographic location of the beacon. If the location of the beacon is in another country's service area, the alert is transmitted to that country's MCC.

Before the inception of COSPAS-SARSAT, monitoring of ELTs depended largely on airborne aircraft or aviation ground facilities. This method provided irregular coverage, particularly in remote regions. Rapid location by satellite significantly reduces SAR time, improves survival chances for accident victims, and reduces exposure of SAR teams to

hazardous conditions often encountered during their missions.

Federal Aviation Administration.

The Federal Aviation Administration (FAA), through its Air Route Traffic Control Centers (ARTCCs) and Flight Service Stations (FSSs), monitors and flight-follows aircraft filing flight plans in the inland area. In some cases, individual citizens contact an FAA facility when they have knowledge of a probable SAR situation involving aircraft. Therefore the FAA is usually the first agency to alert the AFRCC of a distressed or overdue aircraft. The AFRCC is tied directly into the FAA's computer network, and FAA facilities use this system to alert the AFRCC.

Once the AFRCC is alerted, the FAA and AFRCC work together to determine the urgency of the situation and locate the aircraft. Initially, radio communications are reviewed to determine the last known location of the distressed aircraft. Concurrently, other FAA facilities begin a check of all possible airports where the aircraft might have landed. In the meantime, the AFRCC contacts relatives, friends, and business associates of the pilot or passengers aboard the missing aircraft, with the hope of establishing the whereabouts of the aircraft, or to gather information about the personnel aboard. Through these contacts, the AFRCC determines the pilot's intentions, flying capabilities, emergency equipment aboard, and other pertinent information that would assist if a search becomes necessary. Through experience, the FAA and AFRCC have learned that the majority of alerts for missing aircraft are due to the pilot failing to either close the flight plan or inform some person or agency of his or her intentions. For this reason, only a small percentage of alerts issued by the FAA result in an actual airborne search for a missing aircraft.

All ARTCCs have the capability to recall recorded radar data. The National Track Analysis Program (NTAP) can identify and track targets that are at a sufficient altitude to be tracked by radar regardless of whether they are being controlled by the ARTCC. NTAPs requested by the AFRCC have been proven to be a key ingredient in aircraft searches, providing the route of flight and last radar position.

With the congressional mandate requiring most aircraft to be equipped with an ELT, the FAA works very closely with the USMCC and the AFRCC to readily locate the source of ELT signals. All ELT signals reported to

FAA facilities are immediately forwarded to the AFRCC and jointly investigated as probable distress signals.

Civil Air Patrol.

In 1948 the CAP was permanently chartered by the U.S. Congress as the official auxiliary of the USAF. As such, this nonprofit organization of volunteers was charged

with three primary missions: the development of aviation through aerospace education, a cadet youth program, and emergency services.

Under their emergency services mission, the CAP provides SAR mission coordinators, search aircraft, ground teams, personnel on alert status, and an extensive communications network to emergency response efforts. Further, they provide services to national relief organizations during a disaster; the transportation of time-sensitive medical materials (e.g., blood and human tissue); and aerial reconnaissance, airborne communications support, and airlift of law-enforcement personnel in the national counter-drug effort. When CAP resources are engaged in a SAR mission, they are reimbursed by the USAF for communications expenses, fuel and oil, and a share of aircraft maintenance expenses. In addition, CAP members are covered by the Federal Worker's Compensation Act in the event of an injury while participating in a SAR mission.

The CAP is the AFRCC's prime air resource for the inland area. The AFRCC maintains an alert roster provided by CAP wings in each of the 48 contiguous states and is the central point of contact for CAP participation in SAR missions. The AFRCC also works closely with CAP national headquarters and directly provides input for CAP training in emergency services.

The CAP can be contacted as follows:

National HQ Civil Air Patrol, 105 South Hansell Street, Bldg. 714, Maxwell AFB, AL
36112-6332

Unit Locator: (800)-FLY-2338

Membership Development: (334) 953-4260

Public Affairs: (334) 953-4287

U.S. Coast Guard Auxiliary.

The U.S. Coast Guard Auxiliary is to the USCG as the CAP is to the USAF. The auxiliary is made up of citizens who volunteer their time and boats or aircraft to enhance and maintain the safety of boaters. The passage of the Auxiliary and Reserve Act of 1941 designated that civilian volunteers of the USCG be referred to as *auxiliary*. When America entered World War II, some 50,000 auxiliary members joined the war effort. After the war, their attention returned to recreational boating safety duties in compliance with the auxiliary's four cornerstones: vessel examination, education, operations, and fellowship. Today, as in 1941, auxiliarists are civilian volunteers whose activities are directed by policies established by the commandant of the USCG. Although under the authority of the commandant, the auxiliary is internally autonomous, operating on four organizational levels (smallest to largest): flotilla, division, district regions, and national.

When auxiliary resources are engaged under USCG "orders," they are reimbursed by

the USCG for communications expenses, fuel and oil, and a share of vessel/aircraft maintenance expenses. In addition, auxiliary members are covered by the Federal Worker's Compensation Act in the event of an injury while participating in an authorized mission.

Many members of the auxiliary spend their weekends providing free boating safety courses to the public and free courtesy safety inspections to boaters. However, members also respond to minor SAR incidents, and the local USCG station, group or district RCC coordinates their activities. Some auxiliaries have also become qualified to work in the RCCs or assist regular USCG facilities with regulating and patrolling regattas and other maritime events.^[23]

With its 33,000 members, the auxiliary saved nearly 500 lives in 1998 alone, in addition to assisting over 12,000 persons, performing over 139,000 courtesy marine exams, teaching over 6000 public and youth classes, and assisting the USCG in over 50,000 administrative and operational missions.^[22]

The USCG auxiliary website URL is: www.cgaux.org/cgauxweb/

Disaster Response in the United States.

The Robert T. Stafford Disaster Relief and Emergency Assistance Act (1988) provides the authority for the U.S. federal government to respond to disasters and emergencies to provide assistance to save lives and protect public health, safety, and property. The Federal Response Plan (FRP; available at www.fema.gov/r-n-r/frp/) was designed to address the consequences of any disaster or emergency situation in which there is a need for federal response assistance under authority of this legislation. The purpose of the FRP is to facilitate the delivery of all types of federal response assistance to states to help them deal with the consequences of significant disasters. The FRP outlines the planning assumptions, policies, concept of operations, organizational structures, and specific assignments of responsibility to the departments and agencies in providing federal response assistance to supplement the state and local efforts. It is applicable to natural disasters such as earthquakes, hurricanes, typhoons, tornadoes, and volcanic eruptions; technologic emergencies involving radiologic or hazardous material releases; and other incidents requiring federal assistance under the Stafford Act.^[4]

To facilitate federal assistance, the FRP breaks federal response into 12 functions called *emergency support functions* or ESFs. Each ESF is coordinated by a primary federal agency and assisted by multiple support agencies.

FEMA serves as the lead agency for ESF-9 (Urban SAR, or US&R or USAR) and, as such, coordinates the

National Urban SAR Response System. This system is a framework for structuring local

emergency services personnel into integrated disaster-response task forces. These task forces, replete with the necessary tools and equipment and requisite skills and techniques, can be deployed by FEMA for the rescue of victims of disaster and structural collapse. Currently, there are 27 FEMA US&R task forces spread throughout the continental United States trained and equipped to handle structural collapse rescue. They encompass local emergency service personnel from 18 states and can be deployed by FEMA to a major area disaster. Two task forces have also responded to several international disasters under the auspices of the U.S. Agency for International Development, Office of Foreign Disaster Assistance.

Each FEMA US&R task force contains 62 specialists, is designed to be self-sufficient for the first 72 hours of operation, and must be able to function for up to 10 days before being replaced. By design, there are two task-force members assigned to each position for the rotation and relief of personnel. This allows for round-the-clock task-force operations. In addition, all task-force members must be sufficiently cross-trained in their SAR skill areas to ensure depth of capability and integrated task-force operations.

After a request for federal assistance from a governor is received and approved by the president, task forces may be activated or placed on alert when a major disaster threatens or strikes a community or region. There are three regions: East, West and Central. Upon activation, alerted task forces start locating personnel and organizing their mobilization. Each task force is tasked with having all its personnel and equipment at the embarkment point within 6 hours of activation (the mobilization window). Depending on the location of the disaster, a task force will respond to the scene either by ground, using its own trucks, or via a military or civilian aircraft. Generally, an operational task force can be heading to its destination in a matter of hours. When the task forces are not on a FEMA-requested response, they function as technical rescue teams in their own communities and, in many cases, provide a regional or state-wide urban SAR capability.

A FEMA US&R task force includes four major functional elements:

1. *Search*: Canine, electronic, and physical capabilities to locate trapped victims.
2. *Rescue*: Evaluate compromised areas, structural stabilization, breaching, site exploration, live-victim retrieval.
3. *Medical*: Minimize health and safety risks, treat both task-force team members and trapped victims, provide critical incident stress debriefing.
4. *Technical*: Provide hazardous materials specialists, structural engineers, heavy rigging, communications specialists, and logistics specialists.

Typically, FEMA US&R task forces conduct the following operations:

- Perform physical SAR operations in damaged or collapsed structures
- Provide emergency medical care to task-force personnel, entrapped victims, and search canines
- Conduct reconnaissance to assess damage and needs and provide feedback to local, state, and federal officials
- Assess and/or shut off utilities to damaged buildings

- Conduct hazardous materials survey or evaluation
- Conduct structural/hazard evaluations of buildings needed for immediate occupancy to support disaster-relief operations
- Stabilize damaged structures, including shoring and cribbing operations

A comprehensive equipment cache totaling 58,000 pounds supports each task force. The cache elements sent to the disaster scene include communications and locating equipment, rope, and materials for rigging, hauling, lifting, and pulling. In addition, devices to facilitate shoring, structural movement sensing, victim extrication, cutting, and drilling are included to address a wide variety of potential SAR challenges.

The medical team includes four medical specialists and two physicians. Many of the medical specialists on US&R teams are both paramedics and firefighters and thus have experience in both rescue and prehospital medical care. Most of the physicians involved in US&R are emergency medicine specialists who have attended additional training in confined-space medicine, crush syndrome, hazardous materials, public health issues relevant to disaster management, and other issues important to the function of a US&R team. The medical team is designed to bring the emergency department to the field and carries all of the advanced life-support equipment available in any advanced life-support (ALS) ambulance.

The State's Role: Coordination and Support.

All states have passed legislation that provides for direct support to local government entities during emergencies or life-threatening situations, and most states have a specific agency responsible for overall coordination and support for local SAR problems. This support can take many forms, but most often it is in the area of coordination and "one-stop shopping" for resources. Each state must establish an agency or central location that is familiar with all aspects of emergency management and the resources available to aid in life-threatening situations. Many of these resources belong to the state and can be used to aid local jurisdictions.

A number of states, especially in the Northwest, have designated a state agency to be responsible for directing and coordinating air SAR activities. These state

departments, or divisions of aeronautics, develop and maintain aviation SAR response programs with cooperation and support from local and federal agencies. Experience shows that this system usually works better than those in other areas of the country that rely on the federal government to initiate and carry out aircraft SAR activities.

If a local emergency manager, sheriff, or fire chief requests outside assistance in the form of specialized teams, search dogs, air support, or enhanced communications, the state agency for civil defense, emergency services, or emergency management can in most cases locate the nearest resources available and coordinate the response. If any

federal resources are needed, such as air support or military personnel, the state agency provides a direct link to that resource. For instance, the AFRCC at Langley Air Force Base in Virginia has working agreements with all states that are updated annually. Technically, the resources of local and state governments must have been exhausted or be unable to perform a task before federal support can be rendered. However, policy provides for immediate aid when time is critical and in life-or-death situations. Much discretion is given to military installation commanders regarding aid to civilian authorities as long as the primary (military) mission of the resource is not impaired. In fact, most commanders appreciate the opportunity to fly actual missions. Access to these resources must be gained through the state and the AFRCC.

Every state's emergency management agency is responsible for providing support, guidance, training, and coordination to local political subdivisions within that state. As such, it produces a vital behind-the-scenes effort to help local jurisdictions prepare for emergencies, including SAR. The state also initiates the laws necessary to enhance effective actions for SAR response. Such legislation often indemnifies volunteer SAR teams, provides their medical coverage and insurance, and in some cases replaces personal property lost during SAR work. Although most volunteers work willingly until the job is done, this recognition and coverage by the state often provide additional incentives for volunteer participation.

Local Response.

The official response to the call for a wilderness SAR situation is usually delegated to a political subdivision within the state. The legal responsibility for SAR is generally vested with the county sheriff or chief law-enforcement officer at the local level, but this varies by region and state. In some cases it is the responsibility of state police agencies, and in others it belongs to land management agencies. The SAR response for one jurisdiction may differ greatly from that of another. For instance, many national parks in some areas of the country handle all of their own SAR incidents. Others jointly manage the function, whereas some rely entirely on outside resources. National forest land is managed solely by forest-service personnel, but when it comes to SAR, the forest service usually only supports the functions of the local responders.

In urban and suburban areas, police officers, firefighters, emergency medical technicians, and civil defense emergency organizations maintain some degree of disaster and emergency readiness through daily missions that involve SAR work. Fire departments have historically been responsible for rescue and response to emergencies within certain geographic or political areas, and volunteers augment many departments. Law-enforcement agencies also maintain full-time, efficient response systems designed for their particular SAR requirements. Ambulance and rescue vehicles operated by a variety of private enterprises and volunteer organizations augment existing local government services. Through local emergency response planning and coordination, these services respond to a spectrum of everyday emergencies, including fires, collapsed buildings, hazardous material spills, vehicle extrications, and home medical emergencies.

County sheriffs, reserve law enforcement, volunteer fire departments, and a variety of

volunteer and rescue units have been established to address local SAR problems. Delivery of SAR aid to rural and wilderness areas often presents many special logistic problems, which may be compounded by distance, terrain, and weather. The demand for wilderness SAR is often seasonal and unpredictable. Volunteer mountain rescue units, Explorer SAR groups, SAR dog teams, CAP squadrons, motorized units, and many types of volunteer composite teams (i.e., teams that have a variety of capabilities) are usually formed locally in response to the type and nature of recurring SAR problems. Regardless of who does it or what type of SAR emergencies occur, local resources and effort must be developed because they are closest to the problem. State and federal resources are subject to problems with time lag, distance, weather, logistics, and bureaucracy. The same storm or disaster that incapacitates a local area may also prohibit outside (and sometimes inside) emergency response and resupply.

Although official agency responses differ greatly around the country, one major factor remains constant—the dedicated and unfailing willingness of volunteers to respond and work until the job is done. The volunteer effort in SAR nationwide is the backbone of aid to people in distress, as is stated in the rescue service motto: "These Things We Do That Others May Live." The volunteer response has proved crucial to wilderness-type situations. Volunteer organizations, communications, and special skills cannot be replaced by any "official agency" resources.

ORGANIZATION OF A SEARCH AND RESCUE EVENT

SAR requires people who take action and meet objectives to achieve a common goal, often with one or more lives in the balance. For any combination of actions to be effective in a particular situation, the enterprise must be systematically coordinated and organized. All participants must know their responsibilities, what is expected of them, who is in charge, and to whom they answer. If this knowledge is lacking, the effort can quickly become chaotic, ineffective, and, very probably, dangerous. Nowhere are these issues more important than in an emergency situation in which time is of the essence.

Emergency response research is clear and specific. The four operational problems that continue to arise during emergency responses in the United States are ambiguity of authority, inability to communicate between agencies, poor use (or no use) of specialized resources, and unplanned negative interactions with the news media.^[14] ^[15] Accordingly, the key elements for success in SAR operations continue to be good coordination of resources (the right people and equipment in the

Figure 25-1 Functional hierarchy of the Incident Command System commonly used in SAR in the United States. (From Cooper DC, LaValla PH, Stoffel RC: *SAR fundamentals: basic skills and knowledge to perform search and rescue*, ed 3 (rev), Cuyahoga Falls, Ohio, 1996, National Rescue Consultants.)

right place at the right time), effective communications, and good management practices with trained leaders.^[14]

Incident Command System

The system designed to address the challenges of managing emergency incidents in the United States, including SAR, is called the *Incident Command System (ICS)*. It has been in use in the United States for many years.^[17] This function-based system was designed to be adaptable to various types and sizes of incidents in a proactive, rather than a reactive, manner. The system groups similar tasks into five functional areas: command, operations, planning, logistics, and finance/administration. Each of these functions is performed at every incident to one degree or another, and all can easily be

expanded as the size and complexity of the situation dictate. This expansion, however, is based on the premise that the span of control (the ratio of the subordinates to each supervisor) should never exceed seven to one and should more commonly be five to one. When this is exceeded, another level is added to the hierarchy to maintain an acceptable span of control ([Figure 25-1](#)).

The command section is led by the incident commander and provides overall management of the organization.

597

Within ICS, the command section is responsible for dealing with other agencies (liaison officer), the news media and other external influences (information officer), and for the overall safety of the operation and its participants (safety officer). If the incident is too small for these functions to be performed by separate individuals, the incident commander performs them.

The operations section is led by the operations section chief, who is responsible for coordinating and performing all tactical operations. This role is commonly performed by the incident commander until the incident becomes large and complex enough that the function must be performed by another individual. When multiple casualties are involved in an incident, their triage, treatment, and transport fall under the purview of the operations section. In such an incident the operations section is divided into functional groups, often including at least triage, treatment, and transport groups. The person in charge of managing and coordinating the efforts of each group is called the *group supervisor*. If the operations section is better divided using geography, a *division* rather than a *group* is formed. For instance, injured persons at an auto accident might be found on two sides of a road. An east division and a west division might be established to deal with the geographic separation of the resources. In a small organization, the supervisor of each division would answer directly to the operations chief.

To respond to specific challenges within an incident, a task force or strike team might be formed. A task force is any combination of single resources assembled for a particular tactical need, with common communications and a leader. For instance, FEMA combines search, rescue, and medical resources to form a US&R Task Force. A strike team, on the other hand, is a combination of a designated number of the same kind and type of resources with common communications and a leader. The number of resources used in the team will be based on what is needed to perform the function. For instance, four three-person hasty search teams may be combined to form a strike team. These two combinations of resources permit the necessary flexibility when allocating resources.

The planning section is led by the planning section chief, who is responsible for collecting, evaluating, and distributing all incident information. As with the other sections, the incident commander performs this function unless the size and complexity of the incident dictate otherwise. In SAR the planning section is particularly important

because it evaluates search evidence and determines, based on what has been learned, what future actions should be taken or how current actions should be modified. Because such interpretation and evaluation often require great technical knowledge, personnel such as hazardous materials specialists, physicians, structural engineers, and other technical specialists may be required to help the planning section develop and revise the incident action plan.

The logistics section is led by the logistics section chief, who is responsible for providing personnel, equipment, and supplies for the entire incident. This awesome task involves ensuring that personnel are available, rested, and fed; that all equipment, including communications equipment, is available and operable; that vehicles are fueled and repaired; and that medical care is provided for all incident personnel. Basically, logistics is charged with seeing that the physical tools required to meet the overall objectives are available, operable, and maintained.

If the size and complexity of the incident prevent the incident commander from monitoring finance and administrative issues, the finance/administration section is led by the finance/administration section chief. This section is responsible for tracking all financial data for the incident, such as personnel hours, resource costs, costs for damage survey, and injury claims and compensation.

Because most agencies involved in SAR can handle financial issues on their own, and most incidents are small and of short duration, the incident commander usually performs the functions of this section. Only in the largest or most complex incidents is it necessary for the incident commander to assign an individual or staff to perform finance section duties.

FOUR PHASES OF A SEARCH AND RESCUE EVENT: THE INCIDENT CYCLE

Every SAR event goes through four consecutive phases: locate, access, stabilize, and transport.^[2] This sequence, however, could more accurately be described as a continuum that begins with planning or preplanning for the incident. Because planning for the next incident should be affected by what happened during the last, the incident cycle is actually continuous and only pauses between incidents. Once first notice of an incident has been received and the locate phase begins, the goal is to progress through the access, stabilize, and transport phases as quickly, safely, and efficiently as possible. Planning between incidents allows decisions to be made in a calm environment without the urgency that often accompanies a SAR operation. Such plans identify who will be in charge, the organization of the operation, specific procedures, viable alternatives, and other decisions that are best made before an incident occurs ([Figure 25-2](#)).

Locate Phase

The first step in addressing any emergency situation is locating the subject or subjects in need of assistance. This may be as simple as asking for an address or as

598

Figure 25-2 The time-specific components of a SAR event vary with the type of incident. Note that all components take place in both incidents but require different amounts of time. **A**, Typical rescue operation. **B**, Typical search operation.

599

complex as conducting an extended search for a lost person or persons. If the subject is easily found, rescuers can quickly move into the access phase. However, if locating the

subject is difficult, this phase may turn into the crux of the SAR problem.

First Notice.

The first notice of an incident is often conveyed by relatives who report an injury or missing person, by a witness to an incident, by a government agency reporting distress signals (such as an ELT), by bystanders who perceive a problem, or by a 911 call. Once the initial notice is received, the individual taking the information must know what to do and whom to call next.

Planning Data and Its Uses.

Information gathered at the onset of an incident begins an ongoing investigation. It is used to determine the appropriate response and to help predict how the subject or subjects might react to the situation. This information is called *planning data* and includes any information that might affect what should be done to resolve the situation. Examples of planning data include the name of the subject, the situation that caused the problem, the last known location of the subject, the subject's physical and mental condition, the subject's plans (where was he or she going?), what resources are available, weather information (present and predicted), geographic information, and the history of similar incidents in the area. The purpose of collecting all of this information is to help decide what to do next while predicting what the subject might do to help or hinder the situation.

The investigation and gathering of information continue throughout the incident and are used to modify initial plans. As new information is acquired, an action plan is developed and revised until the end of the incident cycle, when planning for the next incident commences.

Once information is gathered, the urgency of the situation is assessed. This assessment ultimately determines the speed, level, and nature of any response and may indicate whether a nonurgent or an emergency response is needed. The specific information used in urgency determination includes the age and condition of the subject, current and predicted weather, and relevant hazards. [Figure 25-3](#) is an Urgency Determination Form, which can be used by SAR managers to determine how urgent their response should be.^[15] Urgency also contributes to allowable risks and thus influences searcher safety—a primary consideration for search managers.

Search Tactics.

During the initial "locate" phase of the incident, emphasis is on searching for the subject. Exactly how to accomplish this is a priority, especially if this part of the incident cycle is expected to be a problem. SAR managers first initiate techniques that increase the chances of locating the subject in the shortest time. These techniques are generally termed *tactics* and involve some action performed to find the subject. These actions can be passive (e.g., not requiring actual field searching) or active (requiring deployment of searchers in the field). Examples of passive tactics include confining the search area to

limit movement of the subject and others into and out of the area, identifying and protecting the point last seen (PLS) or the last known position (LKP), and attracting the subject, if he or she is expected to be responsive.

Generally, passive techniques are quicker and easier to apply, so they are started first. As the incident progresses, active tactics are initiated. In SAR management, efforts are almost universally made to apply quick response resources in areas likely to offer early success. The best resources are put in the most likely areas as early as possible. In addition, identifying and protecting the PLS or LKP are crucial passive techniques that can mean the difference between success and failure of the entire effort.^[15]

Active techniques include sending teams of searchers into an area to search for clues or the subject. They are categorized by level of thoroughness. For instance, a fast, relatively nonthorough search of high-probability areas is called a *type I search* ([Table 25-1](#)). *Type II techniques* can be applied when relatively rapid searches of large areas are desired. Thoroughness may increase, but more important, efficiency improves because larger areas can be searched with the same or fewer resources. Thus success is achieved sooner. *Type III techniques* are applied only when the absolute highest level of thoroughness is required. Unfortunately, this is almost always at the expense of time and efficiency. Basically, the greater the thoroughness, the more resource-intensive and time consuming the technique.

Clues and Their Value.

Clues are discovered during the investigative and tactical phases of a search. Their importance cannot be overemphasized. They may take the form of physical evidence such as a footprint or discarded item, an account by a witness, or information gleaned from the investigation. Clues serve as the rudder that steers the overall search operation. Relevant clues are the basis for all search strategy and can determine or modify all actions. Their powerful influence should be obvious; this is why searchers are taught to be "clue conscious" and to seek clues, not just subjects. There are many more clues than there are subjects.

People generate clues. A person exudes scent, takes up space, and, when traveling, leaves evidence of passing. This evidence is often discoverable if the appropriate resource is applied in a coordinated, organized

Figure 25-3 Urgency Determination Form.

TABLE 25-1 -- Summary of Active Search Tactics

	TYPE I	TYPE II	TYPE III
Criterion	Speed	Efficiency	Thoroughness
Objective	Quickly search high-probability areas and gain information on search area	Rapid search of large areas	Search with absolute highest probability of detection
Definition	Fast initial response of well-trained, self-sufficient, and very mobile searchers, who check areas most likely to produce clues or the subject the soonest	Relatively fast, systematic search of high-probability segments of the search area that produce high results per searcher hour of effort	Slow, highly systematic search using the most thorough techniques to provide the highest possible probability of detection
Considerations	Works best with responsive subject; offers immediate show of effort; helps define search area; clue consciousness is critical; planning is crucial for effective use; often determines where not to search	Often employed after hasty searches, especially if clues were found; best suited to responsive subjects; often effective at finding clues; between-searcher spacing depends on terrain and visibility	Marking search segment is very important; should be used only as a last resort; very destructive of clues; used when other methods of searching are unsuccessful

Techniques	Investigation (personal physical effort); check last known position for clues; follow known route; run trails and ridges; check area perimeter, confine area; check hazards and attractions	Open grid line search with wide between-searcher spacing; compass bearings or specific guides are often used to control search; often applied in a defined area to follow up a discovered clue; no overlap in area coverage; critical separation; sound sweeps	Closed grid or sweep search with small between-searcher spacing; searched areas often overlap adjacent teams for better coverage
Usual team makeup	Two or three very mobile, well-trained, self-sufficient searchers	May include three to seven skilled searchers, but usually just three	Four to seven searchers, including both trained and untrained personnel
Most effective resource	Investigators, trained hasty teams, human trackers, dogs, aircraft, any mobile trained resource	Clue-conscious search teams, human trackers and sign-cutters, dogs, aircraft, trained grid search teams	Trained grid search teams

search effort. Searchers must be sophisticated enough to discover this evidence and interpret its meaning before it is destroyed or decays. Because evidence important to a search effort is often easily destroyed once it is discovered, it is important to protect it from damage until it is completely analyzed.

Search Resources.

Resources are defined as all personnel and equipment available, or potentially available, for assignment to incident tasks. Specific types of active tactics are categorized by the resource that performs them, such as dog teams, human trackers, ground search teams, and aircraft. Other common resources include management teams (e.g., overhead teams, public information officers), water-trained responders (e.g., river rescue, divers), cold weather responders (e.g., ice climbers, avalanche experts, ski patrollers), specialized vehicle responders (e.g., snowmobiles, four-wheel-drive trucks, all-terrain vehicles, mountain bikes, horses), and technical experts (e.g., communications experts, interviewers, chemists, rock climbers, physicians, cavers). In addition to these, other less common resources might also be available. These could include attraction devices (such as horns, flags, lights, sirens), mine detectors (military), noise-sensitive equipment (super microphones), infrared devices (forward-looking infrared [FLIR] on aircraft, night-vision equipment, thermal imagers), thermistors, and even witches, seers, prophets, and diviners.

Just about any person or thing imaginable may be available for use in a SAR incident.

Their use is limited only by the creativity of those in charge. Here we discuss a few of the most common.

DOGS.

Dog teams are a common type of active search resource in the wilderness and are composed of a dog (occasionally more than one) and a human handler. The dog uses scent to search for and follow a subject while the handler interprets signals from the dog and searches visually for evidence. Three common categories are tracking, trailing, and air-scenting dogs.

602

Tracking dogs follow scent on the ground from a person's footsteps and usually very closely follow the trail where a person traveled, regardless of the wind. Trailing dogs follow scent that has fallen onto the ground from the subject along the route of travel. Unlike the tracking dog, the trailing dog may follow the scent at some distance from the actual tracks of the subject, and may therefore be more affected by wind. Tracking and trailing dogs are most effective when used in areas that have not been contaminated by humans other than the subject. Also, weather and time tend to destroy scent available to these types of dogs, so the earlier they are used in a search, the better their chances of finding something.

Air-scenting dogs work off-lead to follow a subject's scent to its source. Specifically bred and trained air-scenting dogs can even discriminate between individual humans. They may detect scent from articles of clothing and can often follow it to discover a person buried in rubble or snow or even submerged under water. Wind is very important to this type of dog, as are other environmental forces such as sun and rain. But as long as the source exists, an air-scenting dog can usually detect the scent carried in air currents and follow it to the source.

HUMAN TRACKERS.

Human trackers use their visual senses to search for evidence left by a person's passing. Human trackers "cut" or look for "sign" or discoverable evidence by examining the area where the subject probably would have passed. This process of looking for the first piece of evidence from which to track is called "sign cutting." Following the subsequent chain or chronology of sign is called "tracking." ^[3]

In SAR, most trackers use a stride-based approach called the step-by-step method. This simple, methodical approach emphasizes finding every piece of possible evidence left by a subject. However, its most important role is undoubtedly the ability to quickly determine the direction of travel of the subject and thus limit the search area.

Ground Search Teams

Hasty teams.

A hasty team is an initial response team of well-trained, self-sufficient, highly mobile searchers whose primary responsibility is to check out the areas most likely to first produce the subject or clues (e.g., trails, roads, road heads, campsites, lakes, clearings, and so on). Their efficiency and usefulness are based on how quickly they can respond and the accuracy of initial information.

Ideally, hasty teams should include two or three individuals who are knowledgeable about tracking. They should be clue oriented, familiar with the local terrain and dangers in the area, and completely self-sufficient. Also necessary are the ability to skillfully interview witnesses and to use navigational skills with pinpoint accuracy. Team members should be trained at least in advanced first aid. Hasty teams usually operate under standard operating procedures so they do not have to wait for specific instructions. They carry all of the equipment they might need to help themselves and the lost subject for at least 24 hours.

Grid teams.

Grid searchers use a more systematic approach to searching. They usually examine a well-defined, usually small segment to discover evidence ([Figure 25-4](#)). The classic approach to grid searching involves several individuals (almost always too many) standing in a line, shoulder to shoulder, walking through an area in search of either evidence or subjects. The distance between searchers can be varied to change thoroughness and efficiency (wide spacing is less thorough and more efficient). However, such resource-intensive approaches to searching are generally less preferred than those that use fewer personnel in a more efficient manner (such as tracking, dogs, or aircraft). In addition, close-spaced grid searching tends to damage evidence and is generally difficult to coordinate.

Although grid searching may be an acceptable approach in certain limited circumstances, experience has shown that when the subject of a search is a person, searching in this thorough manner should be used only as a last resort. Experiments involving grid searching have suggested that it is better to place searchers farther apart. This is usually a more efficient use of resources.

AIRCRAFT.

Aircraft serve the same purpose as grid searchers, only from a greater distance, at a greater speed, over a larger area, and usually with a lower level of thoroughness. Within a search effort, aircraft can serve both as a tactical tool to look for clues and as transportation for personnel and equipment. Both

Figure 25-4 Map used to brief ground team. (Photo courtesy Spectra Communications, Inc.)

fixed- and rotor-wing aircraft have their place in SAR and, like other resources, have their advantages and limitations. Among the most obvious limitations are the expense and complex use requirements of aircraft. Aircraft not only require specialized personnel and cost a great deal to operate, they also have very strict weather and environmental restrictions. For instance, it would be difficult to search from an aircraft in a snowstorm, and terrain may prevent searching certain areas from the air. However, most of these difficulties can be adequately addressed and minimized in a well-developed preplan.

Search Planning and Management Considerations.

State-of-the-art searching for lost persons has come a long way from the familiar lining up of volunteers shoulder to shoulder and walking in a straight line to search an area. Many new lifesaving concepts have been developed by the national SAR community. By borrowing from psychology, mathematics, and business and analyzing research on past incidents, search management has evolved into a sophisticated science. By studying human behavior, statistics, probabilities, leadership, and management, search managers have been able to improve search effectiveness and efficiency. ^[15]

Search management is determined by two general considerations: where am I going to look for the lost person? (strategy) and how am I going to find the lost person? (tactics). To be effective, modern searchers follow several basic principles and techniques, including the following:

1. Respond urgently—*a search is an emergency*
2. Confine the search area
3. Search for clues
4. Search at night
5. Search with a plan in an organized manner
6. Grid search (type III) as a last resort

Every day, firefighters, paramedics, police officers, and other emergency responders receive calls to perform their duties, and often they can only guess what they will find once they arrive. In response to this the concept of the "firehouse" response has evolved. This concept calls for emergency responders, much like emergency physicians, to assume the worst until proven otherwise. Thus they respond with "lights and siren" to most calls just in case the situation is serious. Furthermore, they often respond in this way even when the reporting party specifies that the situation is minor,

claiming that a certain percentage of individuals reporting incidents are wrong in their assessment. Essentially, the situation is considered an emergency until proven otherwise.

For years, searching has been considered less urgent than other emergencies. While emergency responders were running with lights and sirens to situations reported as "women not feeling well" or "dumpster on fire," reports of a lost child or an overdue hiker were relegated to the "let's wait and see" category. Through years of experience, search managers now know that a search is as much an emergency as any other call for help. Furthermore, if an urgent response is mustered, the situation can be resolved faster, more successfully, and usually with less effort. Thus a search should be considered an emergency that justifies an urgent response, a high priority, a thorough assessment, and immediate action.

Search Theory.

The mathematical basis for searching and the study of search theory had its beginnings during World War II in the work of the U.S. Navy's Anti-Submarine Warfare Operations Research Group (ASWORG) and was originally based on searching for the wakes of warships as seen by aircraft flying over the ocean.^[5] The results of this work were collected in a seminal report by B.O. Koopman in 1946,^[12] but the report was not declassified and generally available until 1958.^[1] In 1980 Koopman developed a somewhat expanded version of this work, which was published in his book *Search and Screening: General Principles with Historical Applications*.^[13] Although Koopman's work is clearly aimed at naval interests, the general theory of search he established is applicable to virtually any type of search problem. Since this early work, search theory has undergone continuous research and development by agencies such as the USCG and USN in both the maritime and aeronautical environments, mining and oil businesses in the search for mineral and petroleum deposits, and even archeologists in the search for lost cities, such as Troy.^[18]

The fundamental usefulness of search theory lies in its ability to help determine where and how to search. It accomplishes this by (1) quantifying the likelihood of a lost subject being in a particular area, as well as the likelihood of searchers finding the subject; and (2) offering tools with which one can estimate the chances of success of a particular search.

The application of search theory requires the appropriate use of probability theory, a branch of mathematics that is used for estimating the likelihood of uncertain events, in planning a search. The chances that the lost person or clue is in the search area is called *probability of area (POA)*. The probability that a search resource will find the lost person or clue if it indeed is in the area being searched is called *probability of detection (POD)*. The mathematical combination of these two important variables produces a product called *probability of success (POS = POA × POD)*. The foremost objective, and major challenge, for search planners is to combine the appropriate search resources (sensors producing POD) with appropriate segments of the search area where the subject is likely to be (POA) to produce the most POS in the least amount of time. On

this seems to be a straightforward proposition. However, additional critically important factors, such as resource detection capability, environmental influences, search object characteristics, probability density, probability distribution, coverage and sweep width, conspire to make the most correct search action a complex, unintuitive series of difficult choices.

Although software is available to assist in the mathematical decisions, less than optimum but historically acceptable results have been achieved when a search manager applies the principles of search management as an intuitive combination of hard science and sage experience. In the final analysis, search success is based on more than just science. At its finest, it involves the artistic application of science and a high degree of organizational and management skill sprinkled with intuition and punctuated with a bit of luck.

Lost Subject Behavior.

Modern search management is also based on the use of what is called a *complete "subject profile."* Such a profile identifies as much as is known about the missing subject, including general state of health, past experiences, and state of mind, through the use of a form called the *Lost Person Questionnaire*. This information is collected and used by search managers to predict how an individual would react in various situations. Analysis of this information from past incidents and understanding how the involved individuals behaved in given circumstances have offered great insight for search managers.

Although it is not difficult to appreciate the importance of predicting how a subject might react when lost, the scientific approach to the subject began with William G. Syrotuck's seminal paper in 1977, *Analysis of Lost Person Behavior: An Aid to Search Planning*.^[19] This paper was based on the premise that individuals will have similar travel habits when compared with others in the same "category." The six categories Syrotuck described include small children (1 to 6 years), children (6 to 12 years), hunters, hikers, elderly (over 65 years), and "miscellaneous adults," such as nature photographers, fruit gatherers, bird watchers, and other outdoor enthusiasts. He also included two "special categories" (mentally retarded persons and despondents) for which he had very little data. In his study, Syrotuck described the behavioral characteristics of a representative member of each category and computed "probability zones" for each based on distances traveled. This distance was measured "as the crow flies," or as a straight-line distance, between the point where the subject was last seen and the location where the subject was eventually found. Realizing that there was likely a substantial difference between how far a lost subject actually traveled and the crow's flight distance, Syrotuck argued that, "it is more important to realize that a known percentage of all lost persons is found within a one- or two-mile radius than it is to know how they got there." Syrotuck

studied 229 cases, most from wooded areas of Washington and New York states, and all involved subjects traveling on foot. ^[19]

Beyond identifying categories, Syrotuck also documented and described six other factors that may affect the search plan. He suggested that search personnel in possession of the following information could more accurately predict the subject's location:

1. Circumstances under which the person became lost
2. Terrain
3. Personality
4. Weather
5. Physical condition at time of loss
6. Medical problems

He went on to describe how one's general state of health, past experiences, and physical situation (e.g., hot, cold, altitude) contribute to predicting behavior patterns. How one reacts to being lost, he also suggested, can impact the type and quantity of clues (i.e., disrobing, discarding equipment), survivability (i.e., failure to build a fire), detectability (i.e., bright clothing, bad weather), and tendency to follow travel aids such as rivers, roads, and trails. In all, Syrotuck produced the first scientific description of how people might react to being lost, and how searchers could use this information to improve operations.

Following the theme of lost-person behavior and using the crow's-flight distance, Koester and Stooksbury^[9] performed a retrospective study of persons who suffered from dementia of Alzheimer's type (DAT) and who became the subjects of organized SAR efforts in Virginia. They studied 82 cases (initially) from the Virginia Department of Emergency Services' (DES) lost subject database and compared the DAT patient's behavior to that of elderly lost subjects that possessed normal cognitive abilities. Their findings were of great interest to search managers in that this was the first time research of this type had been conducted for the inland SAR community. Koester and Stooksbury also described a "subject profile summary" and suggested specific search techniques for lost DAT patients. Notable in their findings were the facts that none of the subjects in the cases they studied yelled for help, and they were usually found 0.5 miles (0.8 km) from the PLS. Since this initial research, Koester^[10] ^[11] has continued to analyze the Virginia DES data ([Table 25-2](#) , [Table 25-3](#) , [Table 25-4](#)).

Also using the crow's flight distance, Hill^[9] described distances traveled and probability zones for lost persons in Nova Scotia. However, Hill found it useful to modify and add to Syrotuck's categories of lost persons. For instance, Hill broke young people into four categories, children 1 to 3 years, children 4 to 6 years, children 7 to 12 years, and youths 13 to 15 years. He described characteristics for fishermen, skiers, and walkaways (i.e., people who walk away from a constant-care situation), and additional characteristics for those who are despondent.

Taking a slightly different approach, Heth and Cornell^[7] published a study of 162 incidents of persons lost in wilderness areas in southwestern Alberta, Canada. They tabulated crow's-flight distance traveled and angular dispersion of travel (the angle from a line that connects the PLS with the intended destination) by different categories of wilderness users. They formed 10 categories of outdoor user ([Table 25-5](#)) and included only subjects propelled by muscle (no machinery). Interestingly, Heth and Cornell found a behavioral distinction between "front country" users (i.e., front to parking lots, groomed trails, frequent signage, good and available maps attracted users with a large range of outdoor experience and skill) and "backcountry" users (i.e., remote areas, undeveloped, attracted prepared and experienced users). Not unlike Syrotuck and Hill, Heth and Cornell discovered that, with the exception of despondents, there is a similar distribution of distance traveled by persons lost outdoors. However, they went further and suggested that there might be a linear relationship between certain data sets. For instance, their analysis indicated that hikers travel about 2.3 times farther than campers, and cross-country skiers breaking trail travel about 5.4 times farther than cross-country skiers using groomed trails. The implication is that if archival data are possessed for one category in one region and are compared with categories of lost subjects similar to those described by Heth and Cornell, a scalar parameter could be applied to extrapolate crow's-flight distances for other subject categories. Such a possibility is exciting to search managers who only rarely have access to relevant and reliable archival data.

Search managers have used these behavioral studies, and others, in a number of valuable ways. By direct analysis and limited extrapolation, search managers have been able to find answers to important planning questions that are helpful in determining where and

TABLE 25-5 -- Formal Estimates of Crow's Flight Distance (in km) Between the PLS and the Point Found for (N) Persons Lost During Different Wilderness Activities

ACTIVITY GROUP	PERCENTILE			
	25	50	75	90
Campers (18)	.722	1.559	3.001	4.931
Cross-country skiers: break trail (5)	4.537	9.795	18.860	30.988

Mountain bikers (18)	3.759	8.116	15.626	25.675
Scramblers (7)	1.165	2.515	4.843	7.958
Walkaways (14)	.701	2.007	5.486	14.274
Other (13)	1.765	3.812	7.339	12.058

NOTE: Estimates for despondents and walkaways were based on a different Wakeby distribution than that used to estimate the percentiles of the other user categories.

how to search. Such efforts have also taught search managers the importance of collecting behavioral data on lost persons, and the predictive value of such data.

Access Phase

After the subject is located, the search is over. Rescuers must now gain access to the subject to assess and treat injuries, evaluate the situation, and mitigate the problem. Accomplishing these objectives may be as simple as walking into a room with the subject or as complex as reaching an astronaut in space. Regardless, planning for this eventuality should be complete and ready to be carried out at the conclusion of the locate phase.

Once rescuers reach a subject, the situation and scene must be assessed. In emergency services terminology, this is called the *size-up*. The size-up consists of identifying hazards to the subject and rescuers, then developing a strategy to deal with the problems. For instance, a subject might be trapped by a winter storm in a high alpine environment. Safety considerations for rescuers entering such a hostile and dangerous environment would certainly influence further actions and may well take precedence over the entire rescue effort.

Specialized skills may be required for rescuers to safely gain access to the scene. For instance, rescuers may need to rappel to a patient who has fallen onto a ledge in terrain such as the Grand Canyon. Or rescuers may need to climb sheer rock faces to reach an injured mountaineer on Half Dome in Yosemite National Park. These are examples of how complex the access phase of a rescue may be and point to the importance of thorough and proper planning.

If the size-up indicates that the situation or environment is so hazardous that remaining on scene poses an immediate threat to the subject, accelerated rescue techniques may be required. Accelerated rescue techniques are immediate actions required to remove a subject

from a dangerous environment without stabilization. They often entail deviations from local standard operating procedures and protocols. Examples of such situations include poisonous gas environments (e.g., in caves), fires, unstable terrain (such as avalanches and rock slides), adverse weather (hurricanes, thunderstorms, severe snowstorms), or any hostile environment that threatens the subject, rescuers, or both.

Stabilize Phase

The stabilize phase has three primary components: physical, medical, and emotional. Once rescuers have access to the subject, the scene must be quickly evaluated, or sized-up, for immediate physical hazards and threats from the environment or situation. Scene safety is an initial priority in the size-up, and risks to rescuers and the subject must be weighed against the benefits to be gained. An example of physical stabilization would include an occupied automobile teetering on the edge of a cliff. Before the occupant can be medically assessed, the situation (i.e., the automobile) must be stabilized to best protect the rescuers and the patient. Other examples of physical stabilization might include protecting the patient from further injury (e.g., removing them from the hazardous environment, applying a helmet) or removing the hazard (e.g., extinguishing the fire, securing the teetering auto).

Once the physical environment is stabilized and free from immediate hazards, medical management and stabilization commence. This process usually follows accepted procedures, starting with primary and secondary physical examinations and basic and advanced life support. It should include full-body immobilization, usually in a litter; specific site immobilization of fractures and related injuries; treatment of shock and other hemodynamic compromise; and protection from the environment. The goal of medical stabilization is usually to prepare the subject for transportation to a definitive care facility. If medical care is not required, confirming this fact may be all that is required at this stage before moving into the transport phase.

Emotional stabilization is necessary because an anxious victim is a hazard to rescuers and himself or herself. Again, the goal is to best protect both the rescuers and the victim. Simple, calm communication with the victim, slowly describing what happened and what rescuers are doing, is often enough to calm a nervous victim.

Stabilization, like assessment, should continue throughout the transport phase. The overall objective is to prepare the victim for transport to definitive care while maintaining his or her comfort and safety.

Transport Phase

In the fourth phase of SAR, the subject is moved to definitive care. For this to occur, the stabilized subject must be "packaged" so that he or she can be moved safely and efficiently while stabilization and assessment continue. Transportation types range from foot travel, with the subject walking on his or her own, to evacuation by aircraft. The appropriate mode of transportation is determined by weather, type and severity of injuries, overall urgency, terrain, available resources, and other related factors.

Rescue Equipment.

Today's rescues occur in many remote and unusual environments and often require extremely technical rescue equipment and skills. Responders trained in the appropriate

techniques and technologies should be the only personnel to apply them. Much of the gear and many of the techniques have been derived from those first developed by mountaineers, climbers, cavers, and, more recently, white-water enthusiasts.

Rescue equipment is generally broken down into three broad categories: personal gear, rescue software, and rescue hardware. Personal equipment includes such items as footwear, gloves, helmets, articles of clothing, eye protection, and other protective apparel. Software is equipment such as rope, webbing, slings, and harnesses that are made of soft, strong synthetic materials specifically designed and manufactured for rescue. Hardware is such equipment as carabiners, cams, friction devices, pulleys, and litters made of steel and alloys specifically designed and manufactured to endure the rigors of rescue.

PERSONAL EQUIPMENT.

Rescuers must often wear special equipment to protect them from accidents and hazards. Head, eye, and hand protection is considered mandatory in virtually all rescue environments. Additional personal equipment requirements are dictated by the rescue environment and the specific needs of the situation ([Figure 25-5](#)).

Special gear.

In addition to the usual challenges of the rescue environment, certain hazards require specialized equipment. Examples of such equipment include fire-resistant clothing worn by structural and wildland firefighters, personal flotation devices (PFDs) used by rescuers in and around water ([Figure 25-6](#)), netting used in outdoor settings when insects become a problem, bulletproof garments used by law-enforcement and military rescue personnel, and chemical protective suits worn when exposure to hazardous materials is possible.

No clothing or protective gear meets all of the requirements for involvement in or around a rescue scene. Rescuers study situations so that they understand all hazards before anyone becomes involved. Their conclusions help them identify protective-equipment requirements. Gear that may be necessary for one environment can be dangerous in another. A firefighter's turnout gear may be required in a structure fire but can be deadly in a river rescue situation. Every

Figure 25-5 Even though the personal equipment necessary is dictated by both the rescue environment and the needs of the specific situation, it includes head, hand, foot, and eye protection as a minimum.

Figure 25-6 Rescuer wearing a personal flotation device (PFD) and helmet often used for rescue in and around moving water.

Figure 25-7 Example of ½-inch, nylon, static, kernmantle rope of the type commonly used in rescue. Rescue rope should be checked over its entire length for damage before use.

rescuer is responsible for understanding the rescue environment and how to best prepare for it.

SOFTWARE

Rope.

Rope is by far the most versatile piece of rescue equipment and serves as the universal link in most rescue environments. The material from which the rope is made (such as nylon, polyester, or polyolefins) and the design (laid, kernmantle, flat) are important in the consideration of the use for which a rope is intended.

In most rescue environments, nylon is preferred because of its overall strength, resistance to abrasion, and ability to stretch and absorb energy. Natural fiber ropes such as hemp are no longer considered for use in rescue—synthetic materials are far better.

Although design and amount of materials used influence strength, new ½-inch diameter nylon rescue rope usually has a tensile strength in excess of 9000 pounds ([Figure 25-7](#)).

The most common design of rescue rope is *kernmantle*, a term derived from German, meaning "core in sheath." With this design, a core of material (often parallel fibers) is surrounded by a braided sheath. The sheath protects the inner core, which supplies much of the strength of the overall rope. Other designs such as laid (twisted) and braided are also used in rescue rope.

Kernmantle rope is either "dynamic" or "static." Dynamic kernmantle stretches more than 4% of its length to

609

absorb the impact of a fall, and it is used primarily in lead climbing. Static kernmantle stretches less (no more than 4% of its length); it is used in rescues in which a great deal of stretch would be a nuisance or even dangerous.

Because of the importance of rope in the rescue chain, frequent inspection, care, and maintenance are important. Rope used in rescue is kept clean, inspected often, and protected from sharp edges, high temperatures, sunlight, chemicals, and abrasion. In addition, a detailed history of rescue ropes is kept so that an educated decision can eventually be made regarding each rope's removal from rescue service (see [Chapter 72](#)).

Webbing.

Flat rope or webbing is another common link in rescue systems. It comes in two common configurations: flat and tubular. Tubular webbing is manufactured as a tube in such a way as to seem flat when in use. In cross section, however, it is obviously tubular and a bit less stiff than true flat webbing. One-inch-diameter tubular webbing can be used in rescues to tie anchor slings and harnesses. It has a tensile strength of approximately 4000 pounds when new.

Flat webbing is flat in cross section. Its strength is directly proportional to the amount of material used in its manufacture. Automobile seat belts are an example of the material used in rescue harnesses, anchor slings, and anywhere strong, flat software is beneficial ([Figure 25-8](#)).

Harnesses.

Harnesses come in many sizes and shapes; they are used to attach something (usually a rope) to a person's body. They may be "full-body," encompassing the thorax and the pelvis ([Figure 25-9](#)); "seat," encompassing only the pelvis (see [Figure 25-5](#)); or

"chest," encompassing only the thorax. Each type of harness has its use and associated advantages and disadvantages. Classically, the most common harness for climbing has been the seat harness. However, rescue practitioners have been trying to standardize the full-body harness for rescuer use, with the separate seat and chest harnesses having only limited special use by trained individuals.

Webbing can be tied into a large loop (runner) and applied to a person in such a way as to serve as an improvised harness. Although this is not a preferred method of attachment to a rope, it can work if other harnesses are not available.

HARDWARE

Carabiners.

Carabiners are large, safety pin-type mechanisms used to connect various elements of a rescue system, such as a rope and anchor. They are occasionally called "biners," "snap links," or "crabs," and consist of a spring-loaded gate that pivots open, a spine that supports most of the load and lies opposite the gate, a latch, and depending on the specific style, a locking mechanism.

Steel and aluminum are the two materials from

Figure 25-8 *Left, Tubular webbing with cross section visible. Right, Flat webbing used in anchor sling.*

Figure 25-9 Full-body harness. Note that the harness encompasses both the pelvis and the thorax.

which carabiners are most commonly made. Size for size, steel is stronger and heavier, but aluminum is lighter and stronger pound for pound. In rescue, steel is almost always preferred unless weight is a factor, as in remote alpine situations.

Common shapes of carabiners include oval, D, offset D, pear, and large offset D. The design best suited for any situation is dictated by the specific use. No matter what the

shape, carabiners used in rescue usually have a mechanism for locking the gate closed so that opening it takes a special effort. This design feature not only

610

Figure 25-10 Various types of carabiners. *Top to bottom:* (1) RSI Big hook, steel, screw locking hinged gate; (2) alloy, offset D, screw locking hinged gate; (3) RSI Twist Link, steel, screw locking hinged gate; (4) SMC extra large, rescue, steel, screw locking hinged gate; (5) Tri-link, steel, triangular, screw lock; (6) Auto-lock, swivel-mount, steel, quarter twist locking hinged gate (NFPA 1983 certified). Note that locking carabiners should always be locked when in use.

Figure 25-11 Example of figure-8 plate descending device (with "ears") commonly used in rescue.

improves the strength of the device, but also reduces the chances that a carabiner will open accidentally at a bad time ([Figure 25-10](#)).

Descending/friction devices.

Many different descending devices exist today, but they all do primarily the same thing: apply friction to the rope to allow controlled lowering of a person or load. The most common descending devices in rescue are the figure-8 plate and the brake bar rack.

The figure-8 plate gets the name from its general shape. It has two rings of different sizes. The larger ring produces friction on the rope, whereas the smaller ring is used primarily as an attachment for the load (e.g., the rescuer during rappel). Friction is produced by passing a bight of rope through the large ring and around the small ring, then attaching the small ring to either an anchor (for a lowering system) or a rescuer's harness (for a rappel or abseil) with a locking carabiner ([Figure 25-11](#)).

The brake bar rack, or simply "the rack," uses either steel or aluminum bars on a steel

rack to produce friction on a rope. When the rope is threaded alternately around the bars and the load or rescuer is attached to the "eye" in the rack, friction is applied. The number of bars applied to the rope and the distance between them can be varied to change the friction. This variable friction allows versatility not available with the figure-8 plate; however, the rack takes a bit more training to use safely ([Figure 25-12](#)).

Figure 25-12 RSI Super Rack brake bar rack in use.

611

Ascenders.

Ascenders are devices that grip or hold the rope. They have been adapted from climbing and caving equipment, with which they are used to ascend or climb a fixed rope. In rescue, they are used to climb fixed lines when necessary, but they can also be used in hauling systems to grip the rope. In this way, they hold fast when the rope is pulled in one direction and allow the rope to slide easily when it is pulled in the other direction ([Figure 25-13, A–D](#)).

When ascenders are used to climb a rope, one is fixed to the rope and supports the load while the other is moved into position ahead. When this action is alternately repeated, a skilled climber can move up a rope with relative speed and ease. Selected rope hitches (e.g., a Prusik hitch) can be used in lieu of an ascender.

Figure 25-13 **A**, Gibbs ascender applied to rope. When the eye of the cam is pulled, the cam squeezes the rope and holds fast. When the cam is released, the device can be moved on the rope. **B**, Gibbs ascender dismantled with shell around rope. Note cam (*upper left*) and pin (*bottom*). **C**, Clog handled ascender. Although used where climbing a fixed rope is required, handled ascenders are rarely used in rescue. **D**, A 3-wrap Prusik hitch can often be used in lieu of a mechanical ascender.

Pulleys.

Pulleys are simple machines that apply a turning wheel to reduce friction on a rope as it rounds a turn. In rescue, these metal devices serve primarily to change the direction of a rope, such as within a mechanical advantage system. The "sheave" is the wheel or pulley, and there may be more than one. The "side plate" or "cheek" is the side of the device that makes contact with the anchor at the "hook," which is usually the weakest part. The axle or "sheave pin" is what the wheel turns on; it is supported by the side plates. In rescue pulleys the side plates are movable so that the pulley can be attached to a rope anywhere along its length ([Figure 25-14](#)).

The larger the diameter of the pulley, the more efficient the device. That is, the bigger the pulley, the more

612

Figure 25-14 Two types of pulleys commonly used for rescue. *Top*, 2-inch double pulley. *Bottom*, 2-inch, "Prusik-minding." Note that rescue pulleys are applied to rope by removing the carabiner and swiveling the side plate to allow the introduction of the rope.

friction (theoretically) is reduced. A rule of thumb often used by rescuers is that a pulley with the largest diameter possible should be used, but never less than four times the diameter of the rope. Therefore, because ½-inch (11 mm) rope is commonly used in rescue, a pulley diameter of at least 2 inches should be used.

A variation of the pulley is the edge roller. This device uses 4- to 6-inch open-face pulleys to both reduce the friction of a rope passing over an edge and reduce damage to the rope by protecting it from excess abrasion. Single units can protect the rope from 90-degree angles, and multiple units tied together can provide protection for complex projections.

Litters.

Litters or stretchers are the conveyances in which victims are transported when they cannot travel under their own power. New high-technology materials and designs have greatly improved the choices available. In past years, rescuers were forced to settle for either wooden backboards, old military stretchers, the wire Navy Stokes basket, or the "scoop" stretcher. Today, strong, lightweight synthetic materials and inventive designs

have improved the strength, weight, durability, and comfort of litters.

The goals have not changed during the continuing evolution of the perfect wilderness transportation device. Rescuers still want a device that is comfortable for a person in pain, serves well as a platform for assessment and medical care during transport, allows for full-body immobilization while offering complete security, and protects its occupants from the rescue environment. See [Chapter 27](#) for additional information regarding specific litters, packaging, handling, and evacuation techniques.

ANATOMY OF A SEARCH AND RESCUE INCIDENT

To summarize how all of the previously discussed information fits together, it is convenient to dissect a SAR incident into its component parts and then analyze how all of the parts fit together ([Figure 25-15](#)).

From the SAR operative's perspective, an actual callout is merely an interruption of planning for an incident. That is, people involved in SAR are constantly in a state of readiness and prepared to respond. When a situation occurs, this planning stage is suddenly interrupted by the report of an incident or first notice. The individual taking the information is charged with conveying it to the appropriate authority. The authority determines the urgency, continues the investigation process, begins to develop an operational strategy, and generates an incident action plan. At the same time, those in charge begin to muster appropriate resources to carry out the action plan. In SAR, this is termed *resource callout*, or just *callout*.

Once notified of an incident, individual resources are gathered at a collection point and signed in. The sign-in process enhances safety and allows tracking of resources, which helps those in charge determine the quantity and type of resources available. Once signed in, resources are allocated to assignments designed to meet the goals of the action plan within a reasonable time. This physical implementation of plans in the field is called *tactics* and is a direct outgrowth of the incident action plan.

Allocation of resources in the field continues until there is reason to suspend a phase of the operation. If the subject is found, the search is suspended and the access phase can commence. Once rescuers have access to the subject, the focus turns to stabilization and transportation. If at any point the operation cannot be continued (e.g., the subject was never found, access cannot be gained, transportation is impossible), suspension and demobilization may occur without completion of the entire cycle. The decision to discontinue active search efforts is difficult and involves complex management issues, almost always of the no-win variety.

When a situation is resolved, mission suspension and demobilization begin. In larger incidents this may involve structured deactivation of multiple resources, pulling teams out of the field, dismantling facilities, completing documentation, and returning resources to

Figure 25-15 Time progression or the "anatomy" of a search from a searcher's (operational) perspective. The process is actually a continuous cycle that pauses in the planning and preparation phase until an incident occurs.

service. Basically, everyone finishes what he or she was doing and gets ready to do it again. All of this takes planning and preparation and should be addressed in the overall preplan long before it is required.

After every incident, participants realize that if they had it all to do again, they would do some things differently. If these thoughts and ideas are not documented, they can be lost, and future responses may be cursed to repeat past mistakes. This is one reason that every incident should contain some type of evaluation of the entire mission, known as the *post-incident critique*. The critique can be formal, involving every participant at a sit-down meeting, or informal, involving just a brief discussion of recent events. The critique documents lessons learned and provides a basis for revising the preplan. Thus the cycle continues, and lessons learned from one mission influence the next.

SEARCH AND RESCUE ENVIRONMENTS WITHIN THE WILDERNESS SETTING^[4]

SAR teams throughout the world are frequently called on to solve complex problems in a wide spectrum of environments. Even within the environments addressed in this text, widely diversified subenvironments exist that present unique sets of problems and hazards to SAR personnel. When confronted with the numerous and dangerous environmental conditions found in the wilderness setting, SAR personnel must be prepared to work where others have been unable to cope. A military motto becomes the SAR credo: "Adapt, improvise, overcome."

Some of the specialized subenvironments and their associated conditions within which SAR team members may have to work are listed in [Box 25-1](#) .

It is beyond the scope of this text to discuss in detail how SAR personnel adapt to each of these environments, but it is important to note that adaptation and improvisation are required in nearly all wilderness situations. The particular improvisation depends on the situation, as well as the skill and experience of the individuals involved.

**Box 25-1. SEARCH AND RESCUE
CONDITIONS**

Mountainous terrain
Vertical rock
Vertical ice
Flat ice and ice holes
Snow fields and avalanches
Crevasses
Caves
Mines
Wells
Booby-trapped stills and gardens
Air shafts
Fast water and white-water streams
Coastal white-water surf
Flash floods
Slow-rising floods
High winds and storms
Seas and lakes
Snow and blizzard conditions
Hazardous material dump sites

Regardless of the type of rescue environment encountered by rescuers, the following general rules should be followed:

1. Use technical personnel for technical rescue.

2. If the subject is dead, evacuate only when there is no risk to team members, or at least when the hazard has been assessed and the risk justified.
 3. Stabilize the subject before evacuating; continue stabilization during transport.
-

614

4. Find, plan, and use the easiest route for evacuation.
5. If a litter must be carried, appoint someone to serve as route finder, with a radio and markers, to report potential hazards and problems.
6. Litter teams of six to eight persons per team should be used, with three teams minimum. Normally, there should be no more than 20 minutes per shift. Additional personnel may also be required to carry equipment.
7. Use accepted procedures to care for and protect the victim.
8. A radio carrier brings up the rear.
9. If using a helicopter for evacuation, make sure:
 - a. That the subject is briefed.
 - b. That the subject is protected.
 - c. That someone goes with the subject who knows what has been done medically.

Special Environments in Search and Rescue

Specialized SAR environments produce diverse problems and potential complications. Each environment presents its own obstacles to increase the complexity and difficulty of particular rescues.

Technical Rock.

Mountaineering, rock climbing, and casual scrambling have created a need for specialized SAR expertise. Individuals and groups involved in rock rescue have refined and developed techniques for most situations. The hallmark of a technical rock rescuer is the ability to improvise and modify tools or techniques to meet any crisis. He or she must be comfortable using climbing gear and being exposed to heights.

Once an individual is located in a rock environment and the situation is surveyed, it is necessary to gain access. Local groups familiar with particular well-known areas will have already solved this problem. The solution will involve either climbing up or dropping down to the victim. Safety for all persons involved is paramount, because an accident during a rescue is almost always catastrophic. Climbing up to the victim requires knowledge of rock-climbing techniques, and proper equipment and familiarity with its use are critical. Local outing clubs or mountaineering stores can be contacted for more detailed assistance. Specialized technical rock rescue teams, such as those sanctioned by the Mountain Rescue Association, routinely practice climbing techniques and solving vertical rescue problems.

Caves and Mines.

Standard obstacles in the environment include poor communications, extreme darkness, difficulty in lighting, small and wet spaces, and questionable atmosphere. The various environments included here are collectively termed *confined spaces*.

The levels of moisture in a water, or "live," cave can vary over a considerable range. Some are merely muddy; others have flowing rivers. Caves in the western United States are generally drier than eastern caves; however, humidity, wetness, and cold temperatures create potential for hypothermia in both areas, a fact that is greatly underestimated. Flooding is often a great problem, and many cavers have died because of inattention to the weather on the outside. During heavy rains, the caves become natural drains for streams. Wind and temperature are other underestimated problems associated with cave and mine emergencies. It is not unusual for strong winds to develop along subterranean passages, which intensifies convective air chilling.

Confined passages, low crawls, and squeezes pose unique problems for the rescue of injured cavers. The use of standard items such as litters, backboards, and splints may be impossible in such places. Confined passages with varying, often toxic, constituent gases can lead to difficulties for victims and rescuers alike. Occasionally, a self-contained breathing apparatus or surface-supplied air is required. The potential for toxic gases justifies extensive atmospheric monitoring while operating in the underground environment.

An essential part of any cave or mine rescue operation is thorough orientation to the hazards associated with a particular underground area. This involves pinpointing the locations of pits, waterfalls, siphons, canyons, and other difficult formations that may pose problems in extrication, search, or safety. Many caves have been mapped by the National Speleological Society and the National Park Service.

The real difficulties may begin only after a victim is located. The goal is to move the person rapidly, safely, and comfortably to the surface. Without practice underground, that task will be virtually impossible. Neoprene exposure bags similar to body bags have been used for this purpose and keep the individual dry and protected during what may be a very long and slow evacuation.

Medical care procedures must be performed under dark, cold, and muddy conditions. Experienced cave rescuers agree that repackaging supplies and equipment for underground use is essential. Streamlining kits, packs, and containers is imperative for unobstructed passage through tight spaces in cold, damp conditions.

Team members must carry a minimum of 24 hours of light in a helmet-mounted lamp; two additional sources of light, with spare bulbs and batteries; and waterproof matches and candles. Other equipment needed might include the following:

1. A high-quality helmet with chin strap and headlamp attachment
2. Sturdy, warm clothes and gloves for damp, dirty conditions for up to 24 hours; the material should be wool and the fit should allow good mobility
3. Lug-soled boots that are light and drain water

-
4. Nonstretch, specialized caving rope that is highly resistant to abrasion
 5. Wrap-around-style litter (or even an old conveyor belt) that can aid in dragging an injured person through small passages: a common Stokes litter may not always work well
 6. Wet suits for longer missions in extremely wet caves
 7. Harnesses and slings resistant to chemicals and water
 8. Plastic sheeting to divert water around a victim during evacuation
 9. Small portable pumps, a siphon hose, and plastic to divert, dam, or pump water around areas during operations
 10. Warm food and drink carried in thermally insulated containers

Essential caving skills include all of the capabilities for rock climbing, including vertical rope technique, ascending, rappelling, belaying, and being comfortable working at the end of a rope. All of these skills must be practiced until they can be done in the cold and wet without the benefit of light. Team practices are conducted both on the surface and underground, with participants being forced to work in mud, suffocatingly tight squeezes, soaking waterfalls, and complete darkness. This may be a difficult evolution for even the most experienced rescuer to endure, but just another "hang in the hole" for a seasoned caver.

White-Water River.

There are dozens of potentially dangerous problems in the river SAR (white-water) situation (see [Chapter 30](#)). Log and debris piles at various bends in the river can function as "strainers" for the recreational victim, but they may be death traps for the would-be rescuer. The banks of the stream may be deeply undercut, with treacherous overhanging debris and snags that can catch on clothing, equipment, and skin. Combined with muddy and rapidly rising water, these factors render river rescue difficult and unpredictable.

In fast-moving water, the single greatest problem is that responders underestimate the power and threat of moving water. Foolhardy heroics and overenthusiasm frequently lead to further tragedy. Cold-water immersion, coupled with wind and cold temperatures, predisposes everyone to hypothermia. Wet clothing, darkness, and injury add to the insult. The noise of moving water may obviate clear communications, and poor contact between the victim and rescuers or among the rescuers leads to confusion and danger.

All potential responders in this environment must know how to read the water for capsize points and other dangerous phenomena. The hydraulics of low-head dams, collapsed bridges, and other submerged structures can produce a drowning machine for unsuspecting individuals. Rescue team members must know how to protect themselves in fast-moving water at all times. Mandatory in this environment are good judgment, strong swimming ability, knowledge of all types of technical systems and equipment used in climbing, and a thorough understanding of river dynamics and hydraulic

influences.

WHITE-WATER AND RIVER RESCUE EQUIPMENT NEEDS.

In addition to standard rescue equipment, the following items should be considered when establishing rescue capability in the white-water and river environment:

1. Inflatable rafts or boats (Hard boats may not be as stable and are usually less preferred. Inflatables should be at least 14 to 16 feet long and 6 feet wide, with separate air chambers. The "spider boat," with two pontoons joined together in a catamaran-style craft, makes an excellent, stable rescue platform for moving water.)
2. A line gun or crossbow adaptation that will shoot a line at least 200 feet
3. Power winch or simple "come-along" that can be carried to remote sites
4. Lengthy (150 to 300 feet) durable floating ropes in rope bags
5. Floating throw-rope bags with approximately 60 feet of line
6. A lightweight litter with enough flotation to keep a packaged patient's head out of the water; standard rescue litters often have adaptations for this purpose
7. Fire-hose end caps with air-hose adapters, which allow the fire hose to be inflated with air and used in a shore-based rescue
8. PFDs for every rescuer who will be exposed to the water environment; wet suits and helmets for rescuers who will be directly involved in moving water
9. Dry extra clothing for victims and rescuers
10. Portable "loudhailer" or public address system
11. Portable lighting systems
12. Detailed maps, aerial photographs, or both, of the area, as well as information regarding river hazards during high, medium, and low water levels
13. Dry, buoyant storage bags for sensitive gear
14. Reliable, watertight communications capability for white-water noise and moisture conditions
15. Small surfboardlike Styrofoam boards ("boogie board") for swimming in moving water

White-Water Surf.

Like river white water, ocean surf can present some very different problems in rescue because there is no "average" beach. There are recurring rescue situations that pose unique problems in the white-water surf environment.

Figure 25-16 Runout. **A**, This phenomenon begins with an offshore sandbar. As waves roll in, the water level builds up behind the bar until a section gives way. **B**, As the sandbar "dam" gives way, the water develops a very rapid current running seaward. The recommended action is to swim

across the current until out of the pull.

Figure 25-17 Rip. A depression in the beach floor concentrates returning water into a strong current. To escape, a person should ride with the current or swim to the side and out of the pull.

Along with the potential for immersion hypothermia, lacerations and contusions can result from being dashed against barnacle-encrusted rocks in the wild and unpredictable ocean surf. Contact with venomous sea life is always a possibility. However, the greatest threat to ocean beach users is the action of the water itself and the possibility of drowning through inattention or unfamiliarity with ocean surf hazards in the form of runouts, undertows, and rips.

RUNOUT.

A runout occurs when an offshore sandbar or ledge is built up over a long period. Millions of tons of water flow over the bar during daily tidal changes. Eventually the water may equal or exceed the level outside the bar. Any weak spot in the bar usually gives way, causing a funnel effect ([Figure 25-16](#)). Water rushes toward the bar at a terrific rate, sweeping everything with it. This common phenomenon can be easily spotted from the beach. Usually 15 to 50 yards wide, it is characterized by choppy, jumbled-up, little waves. The water often has a dirty, foamy, or debris-laden surface moving seaward. If a bar is visible offshore, definite breaks can be seen where the water pours through. Surfers often seek runout currents for fast transportation out beyond shoreline waves.

Swimmers caught in a runout have two options. They may swim parallel to the shoreline out of the strip of current, or if the bar is visible (usually characterized by breaking waves), they may relax and let the current complete its runout. About 25 yards beyond the bar the current dissipates. This is an offshore phenomenon—current force increases near the bar but is often negligible near shore.

RIP.

A far worse problem close to the beach is a rip, which can knock children and even adults off their feet and carry them to deep water in seconds. Rips are caused by a slight depression on the beach where wave water rushes after breaking on shore. Water rushing to the depression soon becomes an irresistible seaward flow ([Figure 25-17](#)). It may be as narrow as 15 yards at its source and usually does not travel as far as a runout. Rips generally dissipate a few yards beyond the breakers. A rip looks like a runout, with a streak of turbulent discolored water or a line of foam leading directly out from shore. A swimmer has the same options as in a runout, either to swim parallel to the beach or to relax and ride the current until it ebbs. A person who swims straight toward the beach will never make it. A beach with several rips moving up and down in

unpredictable patterns is very dangerous. An unwary swimmer could panic and drown.

UNDERTOW.

On narrow, steep beaches a type of current known as *undertow* can be found. It is caused by gravity acting on water thrown up on the beach by wave action. Water retreating back down the steep shore continues under oncoming waves ([Figure 25-18](#)). Undertow is usually of very short duration and is ended by the next breaking wave. Wading near shore on a steep beach, an individual could be pulled under in this current and find himself or herself quickly in deep water. If the person resists the current, the next wave may break directly on the person's back. In some circumstances this could cause traumatic injury, especially to the neck

617

Figure 25-18 Undertow. This hazard develops on a steep beach where the water returns rapidly seaward after being tossed up by the wave action. A person should never fight this action but should relax and rise on the next wave.

and back. A person caught in an undertow should let the current pull until it ceases, then swim to the surface and ride the next wave into shore.

Cold, Snow, and Ice.

Perhaps no other type of SAR environment requires a more broadly based foundation of personal and team skills than winter snow and ice. These skills include downhill and cross-country skiing, snowshoeing, technical climbing, winter survival, and a good understanding of snow and ice physics. Unlike rock, snow and ice conditions change on a daily and even minute-to-minute basis. The effects of gravity, wind, temperature, slope, heat exchange, load factors, and avalanche (see [Chapter 2](#)) continually impose problems for missions under these conditions. Technical and nontechnical SAR problems in snow and ice environments take longer to address and are more taxing, technical, and complex. Combined with shorter days, extremes of weather, and the ever-present threat of hypothermia and localized cold injuries, technical missions of this type are unacceptable for all but the most experienced SAR personnel.

Versatility and improvisation are essential components of the overall strategy that must be used in snow and ice. Transportation of the victim is often one of the most difficult problems, but it can usually be resolved through detailed preplanning. Innovations such as covering a litter with a canvas cover or improvising an attachment to cross-country skis are clever solutions to common winter problems. Commercial products such as the Hegg Sled and the Sked Litter (see [Chapter 26](#)) have streamlined the laborious task of

transporting injured people through snow and ice.

MAGNITUDE AND CAUSES OF PROBLEMS IN WILDERNESS SEARCH AND RESCUE

It is impossible to report the exact number of backcountry SAR missions that occur each year in the United States. Some estimates are in excess of 100,000. In the United States, no federal agency is charged with gathering these data. With rare exception, only in the last few years have some states and local jurisdictions begun to collect and analyze SAR mission numbers and related information. Through the efforts of organizations such as the National Association for Search and Rescue, this vital information is now being used as a database to predict victim behavior and to improve the efficiency of SAR management.

Box 25-2. FACTORS THAT CONTRIBUTE TO SURVIVAL SITUATIONS AND SEARCH AND RESCUE MISSIONS

- Improper clothing, foot gear, or both
- Lack of rest (fatigue)
- Lack of adequate water (dehydration)
- Hypothermia or hyperthermia
- Too ambitious an undertaking for skills or proficiency
- Poor physical condition, lack of motivation, or both
- Inadequate or improper food
- Little or no planning
- Inadequate party for the goal, and lack of leadership
- Itinerary confusing or not known to others

Little or no planning
Inadequate party for the goal, and lack of leadership

Itinerary confusing or not known to others

Individuals could not recognize a physical, mental, or environmental threat

No preparation for adverse weather

Unfamiliarity with terrain and lack of map or compass

"It can't happen to me" philosophy

Most wilderness accidents are the result of inexperience or lack of preparation, often aggravated by fatigue, lowered body temperature, and other medical management problems, rather than the direct result of natural phenomena such as avalanche or rock fall.

In an effort to save lives through education, the Washington State Department of Emergency Management SAR Division has been recording statistics on SAR missions for over 20 years. The goal of this effort has been to find out what factors in each SAR mission may have caused a problem for the subject. [Box 25-2](#) is an overview of that data, compiled in an attempt to create a preventive SAR subject profile.

In addition to the factors listed in [Box 25-2](#), the data pointed out some extremely interesting characteristics. Using broad-based generalizations, the analysts were able to further describe a potential SAR victim. Although the data were gathered only from the state of Washington, they have application in nearly every state and have to some degree been substantiated by other statistics.

The average SAR victim is a composite outdoorsman (e.g., hunter, fisherman, skier, hiker, climber, boater, photographer). Most do not do any of these activities well and are not members of organized groups that specialize in these pursuits. Most reside in densely populated areas and travel some distance for recreation

and outdoor pursuits. They usually travel too fast and too far to acclimatize well to the terrain, altitude, and environmental conditions encountered. Interviews show that they also generally ignore signs of weather change, environmental hazards, body indicators, and written warnings concerning danger or safety. Most wilderness or backcountry emergencies are solved by either the victim or outside help within 72 hours. The decisions and actions taken by the victims during the first 6 hours of the situation (such

as emergency shelter, improving clothing, firecraft, signaling) are the most critical and influence the outcome most heavily. Of all precipitating factors, weather contributes the most to misery, carelessness, and the ultimate SAR mission.

Chapter 26 - Litters and Carries

Donald C. Cooper
James Messenger
Timothy P. Mier

Every search and rescue event goes through a series of four consecutive phases. These phases are illustrated by the acronym LAST (*locate, access, stabilize, and transport*). This process ends with the movement of the patient (or patients) from the scene to either a medical facility or an area of comfort and safety (transport)^[6] (see [Chapter 25](#)).

In the United States the term *stretcher* suggests a flat, unsophisticated frame covered with canvas and used for carrying the sick, injured, and deceased short distances. The term *litter* can mean the same thing but usually suggests an apparatus specifically designed to immobilize and carry a patient longer distances. Over the years the subtle differences in the terms have been lost, and users have gravitated to one or the other. In the United States the term *litter* is used to describe all manner of rescue conveyance. In Great Britain, however, the preference is to use *stretcher* to describe the same devices. In this chapter the two terms are used interchangeably.

SIZE-UP

To select the best method for getting a patient to definitive care, the rescuer must make a realistic assessment of several factors. Scene safety is the initial priority. The necessary evaluation, called the *size-up* ([Box 26-1](#)), involves a (usually hasty) determination of whether the victim, rescuer, or both are immediately threatened by either the environment or the situation. Proper immobilization and patient packaging are always preferable, but sometimes the risk of aggravating existing injuries is outweighed by the immediate danger presented by the physical environment. In such a situation the rescuer has little choice but to immediately move the patient to a place of safety before definitive care is provided or packaging is completed.

Evacuation options are limited by three rescuer-related variables: (1) the number of rescuers, (2) their level of fitness, and (3) their technical ability. Carrying a victim, even over level ground, is an arduous task. At an altitude where just walking requires great effort, carrying a victim may be impossible. The specific rescue situation or environment encountered also may present challenges beyond the capability of the available rescuers. Complex rescue scenarios requiring specially trained personnel and special equipment are called *technical rescues* and often involve dangerous environments, such as severe terrain, crevasses, avalanche chutes, caves, or swift water. To avoid becoming victims themselves, rescuers must be realistic when evaluating their ability to perform these types of rescues.

DRAGS AND CARRIES

The most fundamental and expedient method of transporting an ill or injured person is by dragging or carrying them. Although these methods of transportation are far less than ideal and may not meet standard care criteria, the urgency of the situation may outweigh the risks involved. In addition, the process can be physically demanding, and rescuers can quickly become fatigued to the point of hazard. Therefore other options often should be considered before a victim is moved, especially a long distance. A drag or carry may be the best option when a person cannot move under his or her own power, injuries will not be aggravated by the transport, resources and time are limited, the need for immediate transport outweighs the desire to apply standard care criteria, the travel distance is short, or the terrain makes the use of multiple rescuers or bulky equipment impractical.

A "blanket drag" ([Figure 26-1, A](#)) can be performed on relatively smooth terrain by one or more rescuers rolling the victim onto a blanket, a tarp, or even a large coat and pulling it along the ground. This simple technique is especially effective for rapidly moving a person with a spinal injury to safety because the victim is pulled along the long axis of the body. In extreme circumstances the "fireman's drag" ([Figure 26-1, B](#)) can be used. In this type of drag the rescuer places the bound wrists of the victim around his or her neck, shoulders, or both and crawls to safety.

A carry should be considered only after it is confirmed that the victim cannot assist rescuers or travel on his or her own. Beyond simply lifting a person over one's shoulder in a "fireman's carry" ([Figure 26-2](#)) or acting as a human crutch, a more efficient one-person carry can be accomplished by using equipment, such as webbing, backpacks, coils of rope, or commercial harnesses. Equipment-assisted carries are particularly effective when an injured climber or hiker must be evacuated across a short distance over rough terrain or when a person must be quickly removed from a hazardous environment. In the simplest equipment-assisted carry, 4.5 to 6 m (15 to 20 feet) of webbing is

Figure 26-1 A, Blanket drag. B, Fireman's drag. Both techniques are intended to be used when expeditious transport over a short distance is required. (From Auerbach PS: *Medicine for the outdoors: the essential guide to emergency medical procedures and first aid*, ed 3, New York, 1999, Lyons Press.)

Figure 26-2 Classic fireman's carry: a single rescuer technique for short distance transport only. The rescuer must use his or her legs for lifting. (From Auerbach PS: *Medicine for the outdoors: the essential guide to emergency medical procedures and first aid*, ed 3, New York, 1999, Lyons Press.)

wrapped around the victim, who is "worn" like a backpack by the rescuer ([Figure 26-3](#)).

Similarly a backpack or split coil of climbing or rescue rope can be fashioned into a seat around the victim and hoisted by the rescuer. A rescuer can modify a large backpack by cutting holes in the bottom for the victim's legs, who then sits in it like a child would sit in an infant carrier ([Figure 26-4](#) and [Figure 26-5](#))

Box 26-1. EVACUATION SIZE-UP FACTORS

What are the scope and the magnitude of the overall situation?

Are there immediate life-threatening hazards?

What is the location, and how many victims are there?

What is the patient's condition? Is the subject able to assist rescuers?

- a. No injury (able to walk unassisted)
- b. Slight injury (able to walk unassisted)
- c. Slight injury (assistance required to walk)
- d. Major injury (requires considerable attention and assistance)
- e. Deceased

Is there a need for technical rescue?

Is the scene readily accessible?

What rescue resources (including rescuers and equipment) are available?

How far must the patient (or patients) be transported?

Are ground or air transport assets available?

A few commercial harnesses allow a lone rescuer and single patient to be raised or lowered together by a technical rescue system. A Tragsitz is one example ([Figure 26-6](#)).

For carrying infants and small children a papoosestyle sling works well and can easily

be constructed by the rescuer tying a rectangular piece of material around his or her waist and neck to form a pouch. The infant or child is then placed inside the pouch, which can be worn on the front or back of the rescuer's body.

If two rescuers are available, additional and often superior options for carrying a victim become possible. One option consists of two rescuers forming a seat by joining their hands or arms together. The victim sits on the "platform" and holds on to the rescuers for support. It is difficult to cover a long distance or rough terrain when using this technique ([Figure 26-7](#)).

A coil of climbing or rescue rope can be used to form a "two-rescuer split coil seat," with each rescuer slipping a side of the rope coil around his or her outside shoulder ([Figure 26-8](#)). The patient then sits on the "seat" formed by the rope. A similar approach involves using padded ski poles or stout limbs tied together and supported by backpacks worn by rescuers. The victim sits on the supported poles with his or her arms around the rescuers' shoulders. If the poles are properly padded and securely attached to sturdy rescuers, this technique can be quite comfortable for both rescuer and victim. This approach requires gentle terrain without narrow trails.

Spine injuries generally prohibit the use of drags or carries because the victim cannot be properly immobilized,

621

Figure 26-3 Web sling (tied into a loop) used to carry a victim. The rescuer must use his or her legs for lifting

Figure 26-4 Backpack carry.

Figure 26-5 Single-rescuer split coil carry. Note that the coil can be tied in front of the rescuer, and the wrists of the victim can be bound and wrapped around the rescuer's neck for more stability.

622

Figure 26-6 Tragsitz harness in use.

Figure 26-7 A, Four-handed seat used to carry a person. In this technique the upper body is not supported. **B**, Alternative four-handed seat that helps support the victim's back. (From Auerbach *PS: Medicine for the outdoors: the essential guide to emergency medical procedures and first aid*, ed 3, New York, 1999, Lyons Press.)

Figure 26-8 Two-rescuer split coil seat.

but drags or carries may be acceptable when immediate danger outweighs the risk of aggravating existing injuries. Drags are particularly useful for victims who are unconscious or incapacitated and unable to assist their rescuer (or rescuers) but may be uncomfortable for conscious victims. When a drag is used, padding should be placed

beneath the victim, especially when long distances are involved. The high fatigue rate of rescuers makes carries a less attractive option when long distances are involved.

LITTER IMPROVISATION

The simplest improvised litter is made from a heavy plastic tarpaulin, tent material, or large polyethylene bag ([Figure 26-9](#)). By wrapping the material around a rock, wadded sock, or glove and securing it with rope

623

Figure 26-9 Improvised handled soft stretcher.

Figure 26-10 Tying an improvised rope (nonrigid) stretcher.

or twine, the rescuer can fashion handles in the corners and sides to facilitate carrying. The beauty of this device is its simplicity, but it can be fragile, so care must be taken not to exceed the capability of the materials used. As an additional precaution, all improvised litters

Figure 26-11 Improvising a stretcher from two rigid poles and a blanket or tarp.

should be tested with an uninjured person before being loaded with a victim. This type of nonrigid, "soft" litter can be dragged over snow, mud, or flat terrain but should be generously padded, with extra clothing or blankets placed beneath the victim.

A coil of rope also can be fashioned into a litter, called a *rope litter* or *clove hitch stretcher*, but a 46- to 61-m (150- to 200- foot) climbing or rescue rope is required ([Figure 26-10](#)). The rescuer constructs the litter by laying out 16 180-degree loops of rope (8 on each side of center) across an area the desired width of the finished litter. The running ends of the rope are used to tie a clove hitch around each of the loops, and then the unused portion of rope can be passed through the loops on the other side and tied off. The litter is then padded with clothing, sleeping pads, and similar material. Lateral stability can be added by tying skis or poles to the finished product. Because of its nonrigid construction, this litter offers little back support and is best suited for victims with injuries that do not require immobilization.

A sturdy blanket or tarp can be used in combination with ski poles or stout tree branches. The blanket or tarp is stretched over the top of two poles, which are held about 1 m (3 feet) apart; tucked around the far pole; and folded back around the other pole. The remaining material lies over the first layer to complete the litter ([Figure 26-11](#)). The weight of the victim holds the blanket in place. A similar device can be improvised by passing the poles through the sleeves of two heavy, zipped (closed) parkas.

Figure 26-12 Packframe litter. Note that the sapling poles on the litter can be attached to the rescuer's pack frames to help support the victim's weight.

It may be necessary to transport victims with certain injuries (i.e., spine injuries; unstable pelvis, knee, or hip dislocations) on a more rigid litter. Ski poles, stout tree limbs, or pack frames can provide a rigid support framework for such a device. For

example, three curved backpack frames can be lashed together to form a platform ([Figure 26-12](#)). Ski poles or sturdy branches then can be fastened to the frames for use as carrying handles, and the platform can be padded with ground pads, sleeping bags, or a similar material.

Combining a rope litter with a rigid litter can provide more strength and versatility. The rescuer fashions this type of litter by first building a platform of poles or limbs, using a blanket as in a rigid litter, and placing the victim in a sleeping bag on the platform. The patient and platform are wrapped and secured with a length of rope. Because a mummy sleeping bag is used to encapsulate the victim, this device is sometimes called a *mummy litter*. Although this type of litter offers improved support, strength, and thermal protection, careful thought must be given to the physical and psychological effects such as a restrictive enclosure may have on the victim ([Figure 26-13](#)).

If long distances must be traveled or if pack animals are available, a litter may be constructed so that it can be dragged or slid along the ground like a sled. One such device is known as a *sledge* ([Figure 26-14](#)). This litter is fashioned out of two forked tree limbs, with one side of each fork broken off. The limbs form a pair of sledlike runners that are lashed together with cross members to form a patient platform. The sledge offers a solid platform for victim support and stabilization. If sufficient

Figure 26-13 Mummy litter. (From Auerbach PS: *Medicine for the outdoors: the essential guide to emergency medical procedures and first aid*, ed 3, New York, 1999, Lyons Press.)

effort is put into fashioning a smooth, curved, leading edge to the runners, a sledge can be dragged easily over smooth ground, mud, ice, or snow. Ropes also can be attached to the front of the platform for hauling and to the rear for use as a brake when traveling downhill.

A travois is a similar device that is less like a sled and more like a travel trailer (without wheels). A travois is a **V**-shaped platform constructed out of sturdy limbs or poles that are lashed together with cross members or connected with rope or netting. The open end of the **V** is dragged along the ground, with the apex lashed to a pack animal or pulled by rescuers. Although the travois can be dragged over rough terrain, the less smooth the ground, the more padding and support necessary for comfort and stabilization. A long pole can be passed through the middle of the platform and used for lifting and stabilization by rescuers when rough terrain is encountered.

When victims are transported in improvised litters, especially over rough terrain, they should be kept in a comfortable position, with injured limbs elevated to limit pressure

and movement. To splint the chest wall and allow full expansion of the unaffected lung, victims

625

Figure 26-14 A "sledge."

with chest injuries generally should be positioned so that they are lying on the injured side during transport. For a person with a head injury, the head should be elevated slightly, and for persons with dyspnea, pulmonary edema, or myocardial infarction, the upper body should be elevated. Conversely, when the victim is in shock the legs should be elevated and the knees slightly flexed. Whenever possible, unconscious patients with unprotected airways should be positioned so that they are lying on their side during transport to prevent aspiration.^[1]

RESCUE LITTERS AND STRETCHERS

The image most often associated with rescue immobilization and transportation devices in the United States is that of a traditional tubular steel and chicken wire-netted basket, which came to be known as the *Stokes basket*. Although this apparatus was and still is ubiquitous, many may recall the Thomas, Duff, Mariner, Brancard Piguillem, Perche Barnarde, Neil Robertson, MacInnes, and Bell stretchers for their evolutionary and robust designs. Today there are a variety of devices that meet the following two primary wilderness medical needs:

1. Immobilization and protection of a victim during transportation
2. Safe, comfortable, and stabilized transportation of a victim to definitive care

DESIRABLE CHARACTERISTICS OF A WILDERNESS STRETCHER

Peter Bell,^[2] rescue equipment historian and developer of Bell stretchers, has described several specific characteristics of a high-quality, useful rescue stretcher. Bell claims that "a good stretcher should":

1. Be as strong and robust as possible, with materials compatible with the rescue environment
2. Be as lightweight as possible
3. Have smooth edges that will not snag
4. Be devoid of small spaces that will trap or pinch fingers (rescuers' and patients')
5. Be large enough to provide strength, security, and comfort for the largest of persons when the device is in any position (horizontal, vertical, on its side, upside down, etc.)
6. Prevent worsening of injuries during use
7. Provide security for the victim regardless of his or her condition (e.g., slippery, wet, muddy)
8. Be comforting to the conscious victim
9. Be easy to use in the dark and in temperature extremes (very hot or cold)
10. Protect the victim from the environment (heat, cold, brush, rocks, etc.)
11. Be reliable for many years after many uses in extreme conditions
12. Be easy to carry and use when carrying a heavy, large person
13. Be portable (can be carried in a car, boat, plane, helicopter, etc.)
14. Be impossible to use improperly
15. Be easy to clean and sterilize

STRETCHERS

In the interest of brevity and with some technical latitude, this discussion describes stretchers in four categories: basket-style, flat, wrap-around, and mountain rescue.

Basket-Style Stretchers

The basket-style stretcher derives its name from its shape. The sides curve upward to protect the victim's sides and to prevent the victim from rolling out. Most basket-style stretchers combine a steel frame (solid, tubular, or both) with a shell of either steel wire netting ("chicken wire") or plastic. Many include wooden slats in the bottom to provide additional protection and support.

626

Most likely, basket-style stretchers initially were adopted by wilderness rescue organizations because they met fundamental needs and were sufficiently robust to endure great abuse in severe terrain. The seminal basket-style stretcher, called the *Stokes*, first appeared in the late 1800s and likely got its name from the fact that it was designed to be used on naval and commercial ships to remove casualties from the "stokehold," a room in which the boilers were stoked ([Figure 26-15](#)). However, at least one source makes an unsubstantiated claim that the device was invented in 1895 by Charles Stokes.^[8] The significant influence of this device is reflected in the fact that the *Stokes* was the first commercially available basket-style stretcher in the United States.

The original *Stokes* design included a leg divider meant to separate and support each leg individually. Many came to consider this configuration counterproductive when the use of long (16 × 72 inch) backboards and other spinal, full-body immobilization devices became widespread, especially for early treatment of trauma. Most current designs of the *Stokes* basket-style stretcher have eliminated the leg divider to allow full immobilization of a patient on a long backboard, which can be inserted into the basket. The Junkin Safety Appliance Company manufactures several *Stokes* basket-style stretchers, including models that break into two pieces and models with and without wooden slats or leg dividers, that meet the more robust military specifications (MIL-L-37957 and RR-L-1997) ([Figure 26-16](#)).

Although the traditional materials and design (i.e., tubular and flat, welded steel with a steel chicken wire covering) are still in use today, basket-style stretchers are more often constructed from tubular stainless steel or aluminum because of the added corrosion

resistance, increased strength, and reduced weight. Manufacturers, such as Junkin and Ferno, offer basket-style devices in full-rectangular and tapered-rectangular shapes. Both are also available in break-apart versions for easy carrying. Narrower versions (usually 19 inches wide, instead of 24) are available for use in confined spaces or caves, although cave rescuers rarely prefer any type of chicken wire litter.

Because of the importance of portability in wilderness areas, the break-apart capability is an adaptation to nearly all styles and types of litters. Junkin manufactures a version of the Stokes stretcher completely coated with a plastic material called *Plastisol*, which provides nonsparking, nonconductive, and antistatic properties. Junkin suggests that this coating allows improved purchase (handgrip) on the litter and offers insulation from the temperature of the metal. A collateral benefit of the coating is that it extends the life and integrity of the steel chicken wire netting.

Taking advantage of substantial improvements in polymer research, some manufacturers began producing

Figure 26-15 Traditional tapered Stokes litter with leg divider. (Courtesy Junkin Safety Appliance, Inc.)

Figure 26-16 Break-apart Stokes litter with wooden slats. Many manufacturers also offer accessory straps or backpack devices that allow the rescuer to carry the litter halves on his or her back. (Courtesy Junkin Safety Appliance, Inc.)

Figure 26-17 Ferno model 71 stretcher. (Courtesy Ferno.)

a stretcher shell composed of rigid plastic instead of steel mesh. Ferno's model 71 stretcher has an orange plastic shell wrapped around an aluminum frame and secured with aluminum rivets. Brass grommets in the plastic serve as attachment points for a lifting harness ([Figure 26-17](#)). At half the weight of a traditional steel Stokes, this device offers protection from snags and obstacle

penetration that cannot be provided by the wire netting of the Stokes. In addition, the plastic used is chemical resistant and the molded underside runners make it slide smoothly over flat ground, ice, and snow. Ferno offers a version with tow handles and a chain brake that is designed specifically for ski patrol applications so that a packaged victim can be "skied" down a slope or pulled along a snow-covered trail. The orange Ferno litter has a load limit of 270 kg (600 lb), but its usefulness in a vertical raise configuration depends on the integrity of the aluminum frame and the plastic shell; if one is compromised, both may fail. Because of this limitation and because of the lightweight materials used, bending or twisting the device should be avoided.

International Stretcher Systems also builds a basketstyle stretcher with an aluminum frame but uses a different approach for combining the frame with the shell. Their plastic shell is similar to the shell in the Ferno model 71 (high-density polyethylene), but it is placed outside a full aluminum skeleton to facilitate sliding over the ground. Inside the stretcher, a spring-suspended victim "bed" that doubles as the victim retention system has been added to protect the victim from the internal frame members. This bed minimizes transport shock and features built-in shoulder straps, pelvic padding, a head and chin immobilizing harness, foot and ankle straps, and a large "double-security" Velcro body restraint flap that wraps around the victim. The stretcher is lightweight (weighing 10 kg, or 22 lb) and high strength (holding up to 1134 kg, or 2500 lb) ([Figure 26-18](#)).

The Junkin model SAF-200-B includes parallel stainless steel top rails. The top tube is larger to allow comfortable hand-gripping and to provide an attachment for lifting bridles, and the smaller solid steel lower rail allows attachment of patient retention straps. The twin rail configuration keeps patient straps and lifting systems from interfering with each other and helps protect the attached materials from abrasion during use. Unlike the International Stretcher Systems device, the stainless steel frame in the Junkin stretcher wraps around the exterior of the basket, which is lined with a smooth-surfaced, permanently padded plastic shell. This design offers comfort for the victim but makes it difficult to slide on the ground because of the external, exposed steel frame members. The unit is heavy (weighing 14.5 kg, or 32 lb) but breaks apart for packing and marries well with a litter wheel to allow easier handling.

Bell Rescue Stretchers offers the Series 2 Ludlow stretcher, which is simply their strongest flat stretcher with deep basket sides added. This strong, stainless steel-framed design has fold-down sides, which simplify access with a backboard. The sides can be completely removed to revert the device back to a flat

Figure 26-18 International Stretcher Systems' "3-in-1" Basket Litter with flotation

added. (Courtesy International Stretcher Systems.)

stretcher. Other available variations on this theme from Bell include versions with shorter sides (the Otterburn), an open foot end (the Newark), and a steel plate welded into the bottom of the stretcher to help protect the victim (the Manchester). The Manchester weighs nearly 22.5 kg (50 lb) by itself. The manufacturer claims that the Series 2 models can all accommodate a long spine board and have been "proof tested" to between 500 and 720 kg (1102 and 1587 lb). The "bed" of Bell's Series 2 stretchers is made of 14 polypropylene web straps that cross between the steel frame members. This webbing also passes through two movable stainless steel spinal supports (flat steel frame members that run the length of the caudal two thirds of the litter). Four patient retention straps attached to the outermost rails, a patient shoulder strap, and integral lifting rings are supplied with the device. A slightly smaller, lighter, and less robust version, called the *Bell Emergency Stretcher* (discussed in the next section), also is available.

Flat Stretchers

Flat stretchers are generally flat and have very short or no sides. Restraint straps or built-in tie downs serve as the physical means by which the victim is secured in the litter. Although the specific characteristics of these types of stretchers vary greatly (from extremely lightweight to high strength), generally they are used when specific benefit is derived from their low-profile shape. Although this style of stretcher has been modified to allow dragging or sliding (e.g., mountain rescue stretchers), the primary purpose of the flat design is to reduce weight and profile for carrying or for specific applications, such as loading into an aircraft.

Although a simple, two-pole canvas litter is fine for use over short distances, uncomplicated terrain, or the battlefield (where haste is paramount), the lack of patient protection and immobilization capability limits its usefulness outside of the hospital or battlefield setting. A more modern version of this simple device is made of aluminum, folds for easy storage, and doubles as a long

Figure 26-19 The Junkin Air Rescue Stretcher (SAF-350) was designed for use in Bell Jet Ranger helicopters. This lightweight, flat stretcher folds for easy storage but is not designed for long carries. (Courtesy Junkin Safety Appliance, Inc.)

backboard. Another version is hinged at one end so that it can be spread along its long axis and slid under a patient on the ground with little movement or rolling. This "scoop" stretcher was commonly used by emergency medical service providers but has been supplanted by the use of long backboards. In the final analysis, both the military and aluminum iterations of the flat stretcher are intended for carrying a person short distances in an environment with few terrain obstacles or where complete security and

immobilization are not required.

Several successful varieties of flat stretchers have evolved over the years, including the Brancard Piquillem, the Junkin Air Rescue Stretcher ([Figure 26-19](#)), and a few of the Bell stretchers that are categorized as flat for the purposes of this discussion.

The Brancard Piquillem (*Brancard* is French for "stretcher" and *Pequillem* is a proper name) is a flat, old-style stretcher consisting of a canvas patient bed lashed to a steel and aluminum frame (weighing 14 kg, or 30 lb), which folds in half for easy carrying by one person. The design, which has evolved over the years in the European and British mountain rescue communities, includes a patient bed with a permanently attached, integral casualty bag lashed to the frame to protect and secure the victim. Full-length runners raise the stretcher a few inches above obstacles and allow for easy bare-handed gripping. This folding, portable design with integral patient protection made the Brancard Piquillem popular with mountain rescuers and served as the impetus for the evolution of several of the current styles of mountain rescue stretchers.

The Kendall Stretcher, from Bell Rescue Stretchers, has the same features as their Ludlow Stretcher without the basket sides (see the previous section). The Kendall has a stainless steel frame, integral lifting rings, a bed made of polypropylene web straps that cross between the frame members, color-coded patient retention (38-mm web) straps, and a detachable foot loop. The Kendall Stretcher can be used either side up; there is no top or bottom. A slightly less robust version of Bell's flat stretcher is their Basic Emergency Stretcher. This device is smaller and lighter (weighing 5.2 kg, or 11 lb, 8 oz) and works well in commercial and industrial settings where severe terrain is rarely encountered.

Troll Safety and Rescue Equipment produces the Alpine Stretcher, a folding, one-piece, steel-frame

Figure 26-20 The steel-framed Troll Alpine Stretcher has an integral patient retention system and a polyolefin bed. (Courtesy Troll USA.)

stretcher that has a short spinal protection strip below a rigid polyolefin bed. It is strong and flat, making it suitable for wilderness and mountain rescues in which vertical evacuation is required. The integral, color-coded full-body harness and folding capability make it easy to transport into the wilderness and securely package a patient ([Figure 26-20](#)).

Mountain Rescue Stretchers

Mountain rescue stretchers are essentially stronger, more robust flat litters with runners or skis attached to the bottom for easy movement over rugged terrain. Over the years, engineers and litter designers with mountaineering and rescue backgrounds have adapted rescue litter designs to meet specific practical needs of their environment. The result is the strongest and most robust platform available for patient treatment and transportation, but these benefits come at the cost of weight and size.

The Thomas Stretcher is an early and beautifully simple example of the mountain rescue device. Invented in the U.K. in the 1930s by Eustace Thomas (no relation to Hugh Owen Thomas, who invented the Thomas "half-ring" splint), it consisted of wood (ash) runners, an aluminum frame, a canvas bed, and six or seven patient straps attached to the rails. It also had locking, tubular, retractable handles that stowed in the tubular rails.^[5] The Thomas Stretcher is still manufactured, with some modifications, by Bell Rescue Stretchers in the U.K.

In the late 1950s, Donald Duff, a pioneer of mountain rescue in Scotland, designed a stretcher with a steel

tubular frame and no handles. Channeled steel runners extended along two thirds of the caudal end of the stretcher. It weighed about 13.5 kg (30 lb) and could be fitted with a wheel and undercarriage for easier movement over rocky terrain. Its profile was low and sleek, and the runners could be detached and the remainder folded in two for backpacking.^[4]

Although they have almost completely been replaced by more modern designs, two basket-style mountain rescue stretchers that evolved in Britain and Europe over the first half of this century deserve mention. The *Perche Barnarde* (*Perche* is French for "perch" or "pole" and *Barnarde* is a proper name) consists of a 2-m (7-foot) square section of steel tube from which a canvas casualty bag is suspended. The tube breaks into three pieces for easy carrying. The bag is attached to the tube at each end. Where the patient's shoulders would fall, a spreader bar is placed to keep the bag open. From each end of the steel tube extend two removable, bicycle-type handlebars fitted with pads so that the handlebars can rest on rescuers' shoulders. Although this device has been used successfully in many difficult mountain evacuations over the years, its limitations regarding patient comfort, protection, and immobilization are obvious.

The Mariner consists of a canvas bed attached to a steel sledlike frame. The bed functionally resembles a reclining chair in that the patient sits flexed at the hips and waist with the lower legs supported by a canvas platform. The frame is rounded from end to end and includes two steel runners to deflect obstacles. Two adjustable handles extend from each end of the frame for carrying. Today, the Mariner is used by several

U.K. mountain rescue teams and contributed significantly to the evolution of the mountain rescue stretcher.

The current British standard for mountain rescue stretchers includes two devices that are incredibly strong, durable, and unfortunately heavy. The Mark III Bell Rescue Stretcher (which weighs 24 kg, or 53 lb) and the model 6 MacInnes Rescue Stretcher (which weighs 22 kg, or 48 lb) ([Figure 26-21](#)) are intended to survive years of use in extreme mountainous environments. Both have break-apart versions for easy packing into isolated areas, and both incorporate lifting rings, skids, and head guards.

Flexible, Wrap-Around Stretchers

A focus on improving stretchers for particular environments or situations has led to major developments in a number of litter design areas. It is difficult for a single device to excel in every situation because enhancing one capability or characteristic can be detrimental to another. For instance, it can be difficult to achieve a substantial increase in strength while decreasing overall weight. However, new innovative stretcher designs and materials allow structural flexibility to meet specific needs.

Figure 26-21 MacInnes MK 6 Mountain Rescue Stretcher. Note the extending handles, folding head guard, and optional twin (solid) tires. (Courtesy MacInnes Rescue Stretchers.)

Flexible, wrap-around stretchers can be folded, rolled, or otherwise compacted for storage and "wrap around" in that they contain the victim to provide protection, immobilization, and often sufficient support for vertical lifting. The Neil Robertson Stretcher was the impetus for this entire category of device. Adapted from a Japanese design and first produced between 1906 and 1912, this wooden and canvas stretcher was originally made of bamboo and sewn by hand. The "Neil Rob" supplanted the Mansfield military stretcher in the U.K. and was first given the name *Hammock for Hoisting Wounded Men from Stokeholds and for Use in Ships whose Hoists are 2 feet, 6 inches in Diameter.*^[3]

The Neil Rob consists of wooden slats covered with semirigid canvas that are sewn the length of the stretcher. These slats wrap around the patient in mummy fashion, with arms in or out, providing protection without bulk. Full-body immobilization, protection, and a small cross section combine to produce a device well suited for use in small spaces or for situations in which the victim must be moved through a small opening.^[9]

For situations requiring full-body protection for the victim without complex restraint systems, the Reeves Stretcher (model 321011) and Ferno Flexible Stretcher (model 131 and 137) almost totally encapsulate the patient ([Figure 26-22](#)). Although not intended for vertical lifting, both include a durable, vinyl-coated fabric shell that wraps around the sides of the patient and integral wood or synthetic slats that provide

longitudinal rigidity. When used in conjunction with a cervical collar and spinal immobilization, these devices provide environmental and mechanical protection while allowing the victim to be carried through narrow passages.

The Reeves Sleeve (model 31220) is a compact immobilizing stretcher suitable for hand-carry situations or vertical environments. The device slides over a full backboard and depends on the backboard or short spinal immobilizer to provide rigidity ([Figure 26-23](#)).

630

Figure 26-25 Troll Evac II Body Splint and carrying bag. (Courtesy Troll USA.)

Figure 26-26 The Smith Safety Products (SSP) HD Rescue Stretcher and carrying bag constitute the basic package. When the detachable plastic shell (shown) is added, it becomes the SSP USAR Stretcher. (Courtesy Smith Safety Products, Inc.)

Skedco's SKED stretcher provides wrap-around protection similar to the Neil Rob, but a combination of shape and material, rather than integral slats, provides longitudinal rigidity ([Figure 26-24](#)). Light and compact when stored in its packable case, the flexible, low-density polyethylene plastic litter wraps around the victim to form a rigid sleeve that is superbly compact for maneuvering in tight quarters. A half-length version is available for moving persons from areas that are too confined for a full-length device when flexing the victim at the hips might facilitate extrication. The hard and smooth plastic material can be easily dragged over a variety of surfaces and offers substantial protection from penetrating obstacles. Though the SKED stretcher provides spinal protection, the manufacturer recommends using an Oregon Spine Splint (Skedco) or similar device when cervical spine immobilization is necessary. External lift slings are included with the SKED to allow vertical or horizontal lifting, and flotation is available for use in a marine environment.

Troll Safety and Rescue Equipment produces the Evac II Body Splint, which is designed for use in confined spaces and for technical rope evacuations ([Figure 26-25](#)). A flexible, heavy nylon moisture barrier gives moderate rigidity to the protective nylon covering with sewn-on web handles. The integral body harness eliminates the need for any additional casualty retaining straps, and the lightweight nature of the device allows superior portability in confined areas. However, the substantially tapered shape may make it difficult to package the victim with external splints. The device can be used horizontally, as a transportation device, or vertically, during technical evacuation.

The Ferno Paraguard Rescue Stretcher (model 1411) is based on a narrow patient "bed," which gets its foundation from a stainless steel and aluminum frame. The bed includes color-coded straps and wraps for victim packaging. The stretcher folds in half when not in use. It may be used in vertical environments and includes removable "bicycle-type" handlebars and shoulder harness assist straps that allow two rescuers to carry the stretcher from each end.

Smith Safety Products (SSP) manufactures a wraparound stretcher system that incorporates many of the features found individually in other products. The SSP HD Rescue Stretcher is based on a wrap-around shell made of multi-ply polyvinyl chloride (PVC) and closed-cell foam encased in a 1000-din Cordura nylon shell ([Figure 26-26](#)).

According to the manufacturer, this combination forms a comfortable, full-body splint that provides patient protection from temperature extremes. SSP's basic stretcher features built-in patient restraint straps (head, shoulder, and ankle) and a footrest. Their USAR Stretcher package offers, in addition to the basic

632

Figure 26-27 The Medical Devices International Immobile-Vac Full Body Mattress is a full-body splint that can be carried or inserted into other litters. (Courtesy Medical Devices International.)

features, a detachable plastic shell that provides a smooth surface for dragging or sliding and protection from snags or penetration. The USAR Response Set adds a patient bag made of thermal fleece.

Medical Devices International (MDI) makes the Immobile-Vac Full Body Mattress, which is a full-body vacuum splint on which the victim is carried ([Figure 26-27](#)). The vinyl-coated, fabric patient bed contains loose polystyrene (Styrofoam) beads similar to those in a beanbag chair. Once the victim is positioned on the mattress, a small hand pump is used to expel air from within it. This process creates a rigid, full-body splint that conforms to the victim's shape. This "cocoon" immobilizes the spinal column and extremities while providing a comfortable platform. The mattress has integrated web carrying straps that can be used to carry the patient directly, or the mattress can be inserted into a basket-style stretcher for added versatility and strength. The use of a basket stretcher will be necessary for high-angle rescue because the MDI device is not designed for vertical rescue by itself.

TRANSPORTATION HARDWARE ACCESSORIES

A number of wheeled devices can be attached to most basket-style stretchers. These devices take the carrying burden off rescuers in nontechnical evacuations and reduce the load on low-angle haul systems. One example is the Russ Anderson Litter Wheel, which incorporates a large, underinflated all-terrain vehicle tire into a lightweight aluminum frame that clamps to the underside of

Figure 26-28 The Stokes Chariot from Farrington Chariots. (Courtesy Farrington Chariots.)

the litter. This single wheel is positioned under the center of gravity, and the rescuers walk alongside the litter to steady and guide it, with the wheel carrying most of the load. When they encounter large obstructions, such as logs or trenches, rescuers simply lift the litter and continue rolling. One advantage of this device is that it reduces the number of rescuers required to move a litter safely over a long distance. When using this device, only two rescuers (one at each end) are required to tend the litter, but more may be used as necessary.

To meet a similar need, the Stokes Chariot (Farrington Chariots) employs a collapsible stainless steel frame with two attached 16-inch (outer diameter) wheels. With no axle between the wheels, the tires can be set to the outside of the frame for greater side-to-side stability or to the inside and under the frame to negotiate narrow trails or doorways. The draw bar end of the "chariot" is set up to receive either the T bar handle, for towing by rescuers on foot, or a hitch adapter, for towing behind motorized vehicles ([Figure 26-28](#)). International Stretcher Systems makes a similar device out of aluminum. It also can be folded for storage and employs wheels that can be repositioned on the frame.

Junkin and CMC Rescue market two useful stretcher accessories. The CMC Rescue Stretcher Insert is based on Yosemite Search and Rescue's idea to replace the chicken wire in the Stokes litter with a nylon bed, because chicken wire requires padding to allow even minimal patient comfort. A nylon bed allows for an integrated patient restraint system (harnesses) and greatly improves patient comfort. Junkin's Comfo-Pad takes a slightly different approach to the same problem by supplying padding where it is needed in this type of uncomfortable stretcher.

MacInnes and Bell integrate steel wire head protectors in their mountain rescue stretcher designs. This feature is important where falling rock is a hazard. CMC Rescue markets a similar aftermarket device

633

Figure 26-29 The CMC Litter Shield protects the victim from falling debris while allowing access to the head and face.

made of clear polycarbonate under the trademark CMC Rescue Litter Shield ([Figure 26-29](#)). It protects the victim's face from falling debris; allows for easy, rapid airway access; and can be moved out of the way because it hinges on the end of the litter. The shield stores compactly in the litter when not in use.

Flotation systems are available for some litters. Ferno and Skedco each offer this option to make their devices safer and more versatile in swift or open water rescue situations.

Most litter manufacturers offer specific devices or methods for carrying their devices into isolated areas. For instance, the SKED, Troll Evac II, and SSP HD Rescue Stretchers can be rolled up and carried in a special backpack by a single rescuer. Other manufacturers sell special backpacks or integral carrying harnesses for carrying half of their break-apart litters because of the greater weight.

Carrying a Loaded Litter

An evacuation is defined as *high angle* or *vertical* when the weight of the stretcher and tenders (stretcher attendants) is primarily supported by a rope and the angle of the rope is 60 degrees or greater.^[7] This type of situation is often encountered when a rescue is performed on a cliff or overhang or over the side of a structure and usually requires only one or two tenders. In high-angle rescues, most often the stretcher is used in the horizontal position to allow only one tender and to keep the victim supine and comfortable. However, when the packaged victim and stretcher must be moved through a narrow passage or when falling rock is a danger, the stretcher may be positioned vertically.

In a scree or low-angle evacuation, the slope is not as steep (less than 60 degrees), the tenders support more of the weight of the stretcher, and a rope system is still needed to help move the load. In this type of rescue, more tenders (usually four to six) are required and the rope is attached to the head of the stretcher. The head of the litter is kept uphill

during a low-angle rescue.

In a nontechnical evacuation, tenders completely support the weight of the stretcher during a carry out. Generally the terrain dictates the type of evacuation. If the stretcher can be carried without the support of a rope, it is a nontechnical evacuation. If rope is needed to support the load or to move the stretcher, it is either a low- or high-angle evacuation, depending on the angle of the slope.

Carrying a litter in the wilderness is difficult and requires many resources. It takes at least six rescuers to carry a person in a litter a short distance (0.4 km, or ¼ mile, or less) over relatively flat terrain. With six rescuers, four can carry the litter while the other two clear the area in the direction of travel and assist in any difficult spots. However, depending on the terrain and the weight of the victim, all six rescuers may be needed to safely carry the litter any distance. If the travel distance is longer, many more rescuers are required ([Figure 26-30](#)).

PATIENT PACKAGING

Patients (victims) on stretchers must be secured, or "packaged," before transport. Packaging consists of stabilization, immobilization, and preparation of a victim for transport. Physically strapping a person into a litter is relatively easy, but making it comfortable and effective in terms of splinting can be a challenge. The needs of a person secured and transported in a litter are great and should not be overlooked or underestimated. The rescuer's goals are as follows:

1. Package the person to avoid causing additional injury.
2. Ensure the victim's comfort and warmth.
3. Immobilize the victim's entire body in such a way as to allow continued assessment during transport.
4. Package the victim neatly so that the litter can be moved easily and safely.
5. Ensure that the victim is safe during transport by securing him or her within the litter and belaying the litter as necessary.

Generally, proper patient packaging must provide for physical protection and psychological comfort. Once packaged in a carrying device, a person feels virtually helpless, so transport preparation must focus on alleviating anxiety and providing rock-solid security. With this in mind, rescuers must provide for the victim's ongoing safety, protection, comfort, medical stabilization, and psychologic support.^[6]

Splinting and spinal immobilization are usually achieved by using a full or short backboard. The victim

Figure 26-30 Litter-carrying sequence. **A**, Six rescuers are usually required to carry a litter, but rescuers may need relief over long distances (greater than 0.4 km, or ¼ mile). **B**, Relief rescuers can rotate into position while the litter is in motion by approaching from the rear. **C**, As relief rescuers move forward, others progressively move forward. **D**, Eventually the rescuers who are furthest forward can

release the litter (peel out) and move to the rear. Rescuers in the rear can rotate sides so that they alternate carrying arms. Carrying straps (webbing) also can be used to distribute the load over the rescuers' shoulders. In most cases the litter is carried feet first, with a medical attendant at the head monitoring airway, breathing, level of consciousness, and so on.

is secured to the board, and then the victim (on the board) is placed into the litter. When the immobilized patient is finally placed into the litter, adequate padding (e.g., blankets, towels, bulky clothing, sleeping bags) placed under and around him or her contributes to comfort and stability. During transport, victims like to have something in their hands to grasp, to have pressure applied to the bottom of their feet by a footplate or webbing, and to be able to see what is happening around them. ^[6]

Because persons are so vulnerable to falling debris when packaged in a litter, especially in a horizontal high-angle configuration, a cover of some type should always be used to protect the victim ([Figure 26-31](#)). A blanket or tarpaulin works well as a cover to protect most of the body, but a helmet and face shield (or goggles) are also recommended to protect the head and face from projectiles. Alternatively a commercially available litter shield can be used and allows easy access to the airway, head, and neck ([Figure 26-29](#)). Because the head and neck usually require immobilization, the technique and equipment used to protect them should allow this. Remember also that the conscious victim desires an unobstructed view of his or her surroundings.

Carrying a person in the wilderness often requires that the litter be tilted, angled, placed on end, or even

635

Figure 26-31 Smith Safety Products (SSP) Thermal Fleece Patient Bag (model 323) was designed to provide thermal protection for the SSP HD Rescue Stretcher but also offers limited protection from falling debris. (Courtesy Smith Safety Products, Inc.)

Figure 26-32 One 10-m (30-foot) web or rope can be used to secure a person into a litter.

inverted. In all of these situations the victim must remain effectively immobilized and securely attached to the litter, the immobilizing device within the litter, and any supporting rope. Poor attachment can cause patient shifting, exacerbation of injuries, or even complete failure of the rescue system.

Manufacturers have taken several approaches to securing a person within the litter. Most integrate a retention or harness system directly into the litter. However, a few require external straps to secure the victim to the device. Many users suggest that an independent harness be attached directly to the victim to provide a secondary attachment point in case any link in the attachment chain fails.

When a harness is not available, tubular webbing, strips of sturdy material, or even rope can be used to secure the victim. One approach uses tubular webbing slings in a figure eight at the pelvis and shoulders to prevent the victim from sliding lengthwise in the litter.

A 10-m (30-foot) piece of 5-cm (2-inch) webbing or rescue rope can be used to achieve the same goal ([Figure 26-32](#)). The rope or web is laced back and forth between the rails of the litter in a diamond pattern until the victim is entirely covered and secure. Such a technique also easily incorporates a protective cover and support of the victim's feet.

Regardless of the techniques and equipment used, frequently checking vital signs (i.e., distal pulse and capillary refill) during transport can help ensure that any strapping does not obstruct circulation.

MOUNTAIN RESCUE STRETCHERS						
MacInnes Mountain Rescue Stretcher Mark 6	1324	218 × 47 × 26 cm	44 (20)	Stainless steel tube and rod	Aluminum	1000+ kg (P)
MacInnes Superlight Stretcher	896	189 × 53 × 31 cm	26.4 (12)	Stainless steel and aluminum tube	Aluminum alloy	NP
Bell Mountain Rescue Stretcher Mark 3	3192	2000 × 578 mm	48.4 (22)	Stainless steel, aluminum, titanium	Stainless steel wire mesh	1000 kg (P)
WRAP-AROUND STRETCHERS						
Ferno Flexible Stretcher Model 137	350	76.5 × 27.25 × 1 inches	19 (8.6)	Oak wooden slats	Vinyl-coated nylon	350 lbs (R)

Ferno Paraguard Model 1411	1828	72 x 11 x 4 inches	36.5 (16.6)	Stainless steel and aluminum alloy slats	NA	400 lbs (R)
Reeves Flexible Stretcher Model 101	215	78 x 28 inches	14 (6.3)	Wooden slats	Vinyl-coated nylon	300 lbs (R)
Reeves Sleeve Model 122	400	73 x 24 inches	14 (6.3)	NA	Vinyl-laminated nylon	Vertical: 5000 lbs (P)
						Horiz.: 1250 lbs (P)
MDI Immobile-Vac Full Body Mattress Model 81-A5000	445	81 x 36 inches	12 (5.5)	NA	PVC-coated polyester mesh	NA
SKED	450	84 x 36 inches	18 (8.1)	NA		Horiz.: 10000 lbs (R) ³
					Low-density easy glide polyethylene	Vertical: 5800 lbs (R) ³

SSP HD Rescue Stretcher ⁵	445	77 x 12 inches	8.9 (4)	Polyethylene sheeting	Cordura nylon	6000 lbs (P) ³
Troll Evac II Body Splint	575	79 x 26 inches	12 (5.5)	Polyolefin	Nylon 6.0 finished coated	6000 lbs (R) ⁶

Y, Yes; N, no; NA, not applicable; NN, not needed; NR, not rated; NP, not published; 1 = low, unlikely

1The weight of the ISS basket alone is 22 lbs; complete is 40 lbs (shell = 7 lbs; frame = 22 lbs; bed insert, lifting straps, restraint system, belts, and buckles = 11 lbs).

2The welded lift points on the Troll Alpine Stretcher are rated at 6000 lbs each.

3Strength rating is for bridle only.

4A KED, Oregon Spine Splint, or similar short spine board device is recommended for spinal immobilization.

5Smith Safety Products (SSP) adds an external polyethylene sheet to their "HD" (320) model to upgrade it to the "USAR" (321) model, which is less likely to snag obstacles than is the "HD" model.

6The rated strength listed is the tensile strength of the 44-mm flat web handles on the Troll Evac II Body Splint.

Chapter 27 - Aeromedical Transport

James P. Bagian
Robert C. Allen

Rapid provision of appropriate definitive care to acutely ill and injured patients is a major goal of all emergency medical services (EMS) systems throughout the world. The ability to rapidly transport and initiate treatment of severely ill or traumatized patients is important in decreasing morbidity and mortality. This is particularly germane to wilderness and environmental emergencies, where medical resources are scarce, transport times to definitive care facilities are often prolonged, and terrain and weather conditions are inherently difficult. Aeromedical transport crews can deliver emergency medical care at the scene, and the time to definitive care can be greatly decreased. This maximizes the patient's chance for a successful recovery.

AEROMEDICAL EVOLUTION

Rapid evacuation of trauma victims from an injury scene to the location of definitive care is a modern concept with roots in antiquity. The New Testament documented an early instance of prehospital care and transport: "A certain Samaritan . . . went to him and bound up his wounds, pouring oil and wine, and set him on his own beast and brought him to an inn, and took care of him."^[78]

The greatest impetuses to the advancement of emergency care and transportation have been epidemics and wars.^[61] Before the classical Greco-Roman period, injured soldiers were often left on the battlefield to die. Later, Homer described the use of chariots to evacuate fallen warriors during the Trojan War.^[48] Napoleon's forces devised horse-drawn carriages, or *ambulance volantes*, for the same purpose.^[52] The North American Indians devised the *travois*, a litter that could be pulled by a person or animal to transport ill or injured persons.^[59] The U.S. Army began a similar practice during the Seminole War of 1835–1842 and used it again in the Civil War. Major Jonathan Letterman established the process of rapidly clearing wounded soldiers to a point behind the battle line where they could be further triaged to an expectant area for persons with mortal wounds, a local treatment area for the "walking wounded," or a hospital if definitive care was feasible. The central concept was efficient access to surgery for the victim of trauma.

These developments were soon followed by the invention of flying machines. In France, Richet had prophesied the potentials of air transport in 1869.^[61] This was before the first balloon airlift. The prophecy was validated the following year during the Franco-Prussian War when the first documented aeromedical evacuations took place. During the Prussian siege of Paris, 160 wounded soldiers were evacuated and transported by hot air balloon over enemy lines.^[80]

In the United States, air evacuation took place soon after the Wright brothers flew in 1903.^[39] Grossman and Rhoades presented their idea of air transport of patients to the War Department in 1910, but the government refused to fund them. It was not until World War I that the U.S. military began to utilize aircraft to carry injured soldiers, and this occurred only rarely. However, the French transported patients as early as 1912 aboard Dorland ARII fighters converted to carry litters, despite the government's objection to the concept of aeromedical transport: "Are there not enough dead in France today without killing the wounded in airplanes?"^[39]

The United States began utilizing its first dedicated air ambulances in 1920, using the deHavilland DH-4A, followed by the Cox-Klemin XA-I. World War II saw the widespread application of fixed-wing aircraft for evacuation. More than 1.4 million were transported

from front-line hospitals to tertiary care facilities, with only 46 deaths en route.^[36] During this time the concept of medical care during transport was implemented. In November 1942 the War Department began to train flight surgeons, flight nurses, and enlisted medical personnel for aeromedical transport.^[39] Also during 1942, Igor Sikorsky produced a rotor-wing aircraft, called a "helicopter," which the army configured with external litters. It was used in an air evacuation for the first time in 1944 in Burma.^[36]

Helicopters did not enjoy widespread use until more reliable machines became available. The Sikorsky S-51 and later the Bell 47-B were deployed over the rugged terrain and uncertain roads of Korea with great success to provide wide-scale evacuation of wounded soldiers to Mobile Army Surgical Hospital (MASH) units. Although only 11 dedicated "Medevac" helicopters were used, more than 17,700 casualties were evacuated. For the first time, injury victims could travel directly from the point of injury to definitive surgical care.

This set the stage for the Army helicopter evacuation ("Dust Off") operations in Vietnam in 1962. With the

TABLE 27-1 -- Mortality Rates and Evacuation Times During Major Wars

CONFLICT	EVACUATION TIME (HR)	MORTALITY RATE (%)
World War I	18	18
World War II	4–6	3.3
Korea	2–4	2.4
Vietnam	1–2	1.8

From Stewart RD: Trauma Q, May 1985, p 1.

Bell UH-1A Iroquois ("Huey") under the leadership of Major Charles Kelly, the Army's 57th Medical Detachment became known for the courage and hard work of flight crews, who flew despite darkness, adverse weather, and enemy fire. Later, the turbine-powered Bell model UH-1H was used to evacuate up to nine patients at a time by hoist from above a dense jungle canopy. By 1967, about 94,000 injured men had been evacuated.^[69]

As air evacuation matured, the time from wound to definitive care declined from 18 hours in World War I to between 1 and 2 hours in Vietnam.^[88] Although medical advances have contributed to improved survival, battlefield mortality has steadily declined from 18% in World War I to 1.8% in Vietnam, perhaps more because of rapid aeromedical transport to definitive care ([Table 27-1](#)).

Unfortunately, emergency medical care for civilians greatly lagged behind the

developments in the military. In the late 1960s, rescue efforts were more organized, skilled, and rapidly performed for a man shot in the Vietnam conflict than for a civilian injured on U.S. highways.^[61] Civilian ambulances were said to be no faster than taxis.^[77]

Civilian transport began to change dramatically in the United States in 1966 when the National Academy of Sciences-National Research Council put forth the white paper *Accidental Death and Disability. The Neglected Disease of Modern Society* (U.S. Department of Health, Education and Welfare). This document was the impetus for improving EMS systems through the country, and soon the civilian sector began to emulate the military model.

Outside the United States, Germany and Switzerland had developed a network of helicopter and fixed-wing air evacuation and transport services that continue to provide rapid access to care from even the most remote areas.^[38] The first U.S. civilian aeromedical program was begun in 1969 as a joint effort between the Maryland State Police and the University of Maryland Center for the Study of Trauma (now the Maryland Institute for Emergency Medical Service Systems). Certain hospitals were designated as trauma centers, and victims of highway and other trauma were flown by police pilot-paramedic teams in a primary response role at the accident scene. Since 1970 the service has flown more than 199,000 missions.^[82]

With the development of faster and more powerful helicopters, reconfiguration of fixed-wing aircraft for aeromedical needs, enhanced knowledge of aeromedical physiology, and experience accumulated through more than 50 years of transport experience, the acceptance, utilization, and success of aeromedical transport are universal. The role of aeromedical transport in the wilderness setting continues to evolve as its importance in providing rapid emergency medical care to sick and injured patients is recognized.

TYPES OF AEROMEDICAL TRANSPORT PROGRAMS

Hospital-Based Programs

The most ubiquitous type of program is hospital based. Helicopter service is often provided in *primary* (to the accident scene) and *secondary* (to the community hospital emergency department) response roles. In addition, many hospitals provide fixed-wing transport in a secondary response role for long-distance transports or when transport by helicopter is impractical.

According to the Association of Air Medical Services, in early 1994 there were more than 175 hospital-or health care provider-affiliated and 20 freestanding rotor-wing transport programs in the United States. These services transported more than 172,000 patients in 1993. Nationally, approximately 70% of all flights are interfacility transports, and 30% are flights from the scene.^[63]

In a hospital-based transport program the hospital frequently leases the helicopter from a vendor, who also supplies the pilots, maintenance, and fuel. The hospital has the responsibility for providing the medical crew and determining the configuration of the crew. In addition, the program directors are responsible for medical control and quality improvement.

The hospital may choose to own the aircraft and contract with a vendor for operations or employ its own pilots and mechanics. In most cases the helicopter resides on a helipad atop or near the hospital, and the crew, which may consist of a specially trained flight nurse, flight paramedic, and physician, is quartered in the hospital ready for immediate launch (see Flight Crew).

Non-Hospital-Based Programs

Non-hospital-based service is provided by an entity that may be supported by a consortium of hospitals, or it may be an independent corporation, ambulance service, or aviation fixed-base operator (FBO). The aircraft may be owned or leased by the entity or by an aviation contractor. Although this is not a common model for

helicopter services in the United States, many fixed-wing services operate in this manner. A corporate airplane may be provided on demand for use in an air ambulance

mode with its interior reconfigured, or a dedicated airplane may be provided with a custom-made air-ambulance interior configuration, usually under a Supplemental Type Certificate (STC).

Public Safety, Police, or State Services

The aircraft (usually a helicopter) may be owned and operated by a governmental agency such as the state highway patrol and operated under part 135 of the Federal Aviation Regulations (FAR). As in the Maryland model, flight personnel typically include police pilots and emergency medical technician-paramedics.

Military Assistance to Safety and Traffic Program

The Military Assistance to Safety and Traffic (MAST) program was established to supplement the civilian EMS systems. Under this program, air medical evacuation services are supplied by active-duty military medical units to the extent that their training budgets allow, provided they can use actual patient transports instead of training exercises. The MAST mission is "secondary"; it is available only when its personnel and equipment are not being used in support of the unit's primary mission. MAST may be requested by the local EMS or disaster management agency. Typical aircraft include the Bell UH-1 and Sikorsky UH-60 (Black-hawk). The medical crew usually consists of medical corpsmen. The MAST program may not compete with similar civilian services.

Other Military Resources

The U.S. Air Force provides aeromedical transport in support of U.S. military disaster conditions. This service can be requested through the Rescue Command Center at Langley Air Force Base in Virginia. Other available resources include the Air National Guard and the U.S. Coast Guard. Many states have organizations (e.g., California Department of Forestry) that may be called on to assist in search and rescue (SAR) operations in preparation for aeromedical transport. Many other countries have analogous units; the Israeli Air Force, for example, operates a squadron that provides civilian and military rescue and evacuation services.

PATIENT MISSION TYPES

Primary Response

In a primary response role the aeromedical transport service responds to an accident scene or field location, usually at the request of police, fire, or local EMS personnel, and serves as the initial and sole mechanism of transport to the hospital. In this instance the aeromedical crew may function as "first responders." Helicopters are most suited to a primary response role. The required response times must be short (less than 10 minutes from call to take-off); thus the flight crew must be stationed at or near the launch site 24 hours a day. The service radius ("stage length") is short (typically less than 50 miles), and crews need to be experienced in techniques for landing in proximity to obstacles, under poor conditions, and on uncertain surfaces. In prehospital situations, patients' conditions vary widely, and often, little or no assessment or stabilization is performed before arrival of the flight crew. Medical personnel must possess a high degree of training and experience and should possess at a minimum emergency medical technician (EMT) skills required for patient extrication and stabilization at the scene.

Secondary Response

In the secondary response role a patient has already been transported by other means to a hospital where some degree of stabilization may have occurred. The aeromedical service transports the patient in the early stages of care from the emergency department of a hospital to a facility better equipped to offer definitive care. Response times required for this type of mission must be competitive with one-way ground transport times. Stage lengths are short to intermediate (150 miles). The transport vehicle is typically a helicopter, although in some remote and wilderness areas, fixed-wing services are also suited to this role. Flight crews used in a secondary response vary depending on the needs of the patient (see Medical Mission Types). The responding aeromedical service typically consists of flight nurses, paramedics, and in some cases flight physicians.

Tertiary Response

In a tertiary response an inpatient who requires specialized services unavailable at the current facility or who requests relocation is transported to a new facility. Tertiary transports may involve helicopters or fixed-wing aircraft, depending on the level of urgency, stage length, and the cost of transport. Commercial entities throughout the world specialize in this type of service.

MEDICAL MISSION TYPES

The needs of different patient types may be categorized by medical problem; this in turn dictates the requirements of the aeromedical transport service. In most hospital-based helicopter programs the majority of patients transported are categorized as adult trauma, cardiac, or medical noncardiac. A number of programs offer or specialize in pediatric, neonatal, perinatal, and organ transplant services, for which specialized crews and equipment may be required. In

643

addition, aeromedical transport programs that provide SAR operations require specialized equipment and training.

Trauma Patients

Trauma patients transported in the primary or secondary response modes may account for 20% to 60% of a hospital-based helicopter service's transport activity, depending on the hospital's function and capability as a trauma center and the relationship between the aeromedical service and the community EMS and public safety network. A study of one urban setting noted that 20% of helicopter missions were to injury scenes, which were located at a mean distance of 14.4 miles from the hospital. Of patients transported, 19% had penetrating trauma, and 81% blunt trauma (66% from motor vehicle accidents). The most common organ system injuries involved the head (65%), extremities (39%), chest (31%), and abdomen (27%). The overall mortality of transported patients was 24%. The most common procedures required at the scene were endotracheal (ET) intubation (41%) and cardiopulmonary resuscitation (CPR) (18.7%). The most common life-threatening conditions were cardiac arrest (18.7%), airway obstruction (5.1%), cardiac tamponade (3.2%), and tension pneumothorax (1.7%).^[33]

A multicenter study of blunt trauma victims transported by helicopter aeromedical services from both urban and rural environments found a mean trauma score of 13 (of 16), mean age of 29 years, and overall mortality rate of 15%.^[8]

These and other studies indicate the need for skilled crews in the transport of trauma patients.^[91] Medical personnel must have the ability to assess the patient adequately to detect frequent in-flight complications and to intervene with appropriate procedures, including intravenous (IV) cannulation, ET intubation, CPR, chest decompression, and

at times a surgical airway ([Box 27-1](#)).

In wilderness areas the flight crew must be skilled at victim extrication and operating in rugged terrain. They must be familiar with standard trauma care and the range of clinical entities most frequently seen in the wilderness setting. In addition, because resources may be limited and backup unavailable, they may be required to function semiautonomously. For this reason, protocols and standing orders are valuable. Most important are training, skill, and judgment.

Patients with Cardiac Disease

Patients with most cardiac disease most often are transported in a secondary or tertiary response role, by either helicopter or fixed-wing aircraft. They typically account for 20% to 50% of an aeromedical service's transport activity. The conditions of these patients are often medically complex. Technologically sophisticated treatment modalities may include antiarrhythmics, vasopressors, inotropes, vasodilators, thrombolytic agents, cardiac monitoring, arterial and central venous pressure monitoring, pacemakers, implantable defibrillators, and intraaortic balloon counterpulsation devices.^{[23] [30] [37] [50]} The flight crew must have sophisticated knowledge, expertise, and experience and may include a cardiac critical care nurse and a physician.

Patients with Medical, Noncardiac Conditions

Patients with medical, noncardiac conditions, like those with cardiac disease, are most often transported in the secondary or tertiary response mode by either helicopter or fixed-wing aircraft. This group consists largely of patients with acute neurologic disease or shock or who require assisted ventilation. ^[41] The spectrum of potential in-flight challenges includes cardiovascular problems, arrhythmias, hypotension, respiratory difficulties requiring acute airway management, seizures, and alterations in level of consciousness. The flight team must be able to manage an airway and operate a ventilator. Additional considerations relate to the cabin environment and need for pressurization if hypoxemia is present, if barotrauma is likely, or if trapped gas exists, as well as the need to predict the requirement for and manage finite oxygen resources in flight.

Pediatric Patients

Pediatric patients may have traumatic or medical conditions.^[9] ^[44] In a study of 636 pediatric patients transported by air in the Salt Lake City area, 57.5% were transported by helicopter and 37.5% by fixed-wing aircraft, with a mean stage length of 207 miles (helicopter, 82 miles; fixed-wing, 452 miles). Less than 1% of flights were from the scene. The patient age ranged from 3 weeks to 16 years, with 45% less than 1 year old. Trauma was the most common diagnosis (15.3% head injury, 9.3% multiple injuries), followed by neurologic illness (24.2%), respiratory failure or infection (20.1%), gastrointestinal or genitourinary problems (10.2%), metabolic disease (9.2%), cardiovascular disease (6%), and general pediatric surgical problems (5.7%). The overall mortality was 7%.^[60] Many of the considerations for pediatric transport are similar to those for adults, especially with older children. Infants may require an incubator, however, and flight crews must be experienced in caring for infants and children. Specifically, knowledge of pediatric advanced cardiac life support skills, including pediatric drug dosages, airway sizes, and fluid management, is essential.

Perinatal Patients

The need for expedient evaluation, preparation, and transport of the obstetric-gynecologic patient is increasing. Types of problems include ectopic pregnancy, pelvic inflammatory disease, toxic shock syndrome, abnormal fetal presentation, multiple gestation, diabetes in pregnancy, placenta previa, abruptio placentae, disseminated intravascular coagulation, preeclampsia-eclampsia, and preterm labor. The decision to transport patients in advanced preterm labor should be based on such factors as distance between hospitals, time required to cover the distance, personnel available for the transport, gestational age, and speed with which labor has progressed. The flight crew must be knowledgeable about these problems and comfortable with their treatment so as to ensure a favorable outcome for both mother and child.

Neonates

Neonates have unique anatomy and physiology, and the diseases that affect them require specific knowledge and skills by those involved in their transport. Specific issues include newborn assessment, including assignment of an Apgar score, airway clearance, temperature, homeostasis, and familiarity with neonatal resuscitation.^[3] Access to references concerning neonatal emergency drug dosages should be available.^[2] ^[72]

The ability to perform umbilical vein catheterization is an important skill for any member of the transport team involved in neonatal care. In addition, knowledge of fluid, electrolyte, and glucose requirements is essential.^[53] The flight crew involved in the transport of a neonate often includes a neonatal nurse and a neonatologist.

Search and Rescue

Wilderness search and rescue is a unique aspect of aeromedical care and transport that requires significant training and expertise. Most dedicated aeromedical aircraft in the United States are not well suited for SAR operations (see Aircraft for Search and Rescue). Most standard aeromedical crews are not trained in SAR techniques. Many aeromedical helicopters and some fixed-wing aircraft become involved in SAR activities, however, so it is important to be familiar with SAR techniques. In addition, outside the United States, persons providing aeromedical transport are frequently involved in SAR activities (see [Chapter 25](#)).

The keys to a successful SAR operation include proper communications, transport, evacuation, and medical treatment, in the setting of favorable weather conditions and topography. The helicopter, equipped with a hoist and winch, is one of the most effective means of providing SAR in the wilderness setting and is essential in mountainous regions. A long delay between the time of the accident and the call for assistance, combined with a serious injury, adversely affects patient outcome.

Helicopters are helpful in various SAR activities, including low-altitude search activity, search area evaluation, and movement of supplies and equipment. They may be the only means of extrication and rescue from the scene. Fixed-wing aircraft are also useful for search and can provide secondary transport, especially when long distances are involved.

The U.S. Air Force routinely uses helicopters and fixed-wing aircraft for long-distance SAR operations. Fixed-wing aircraft often arrive at the scene first and may deploy pararescuemen by parachute. If the rescue site is over water, the aircraft may also deploy an inflatable boat with motor and rescue equipment. The pararescuemen and their survivors are then recovered by surface vessels or by rescue helicopters that have been refueled aurally in order to reach the rescue site ([Figure 27-1](#)). This capability permits the rapid deployment of rescuers while allowing the most expeditious recovery of survivors and their delivery to definitive care. These services are on alert for all space shuttle launches to provide SAR support in the event of a mishap.

In the United Kingdom the Royal Air Force operates a helicopter SAR service that flew 1490 missions from 1980 to 1989, almost all of which involved vacationers along the coasts or in the mountains.^[55] The Danish helicopter rescue service was founded in 1966 and uses a Sikorsky (S-61) helicopter. Since 1973 its crew has included a physician trained in aerospace medicine and helicopter transport. From 1973 to 1989 it flew 5733

Figure 27-1 MH-60G Pave Hawk hoisting a pararescueman during a search and rescue exercise. A variant of the UH-60 Blackhawk, the Pave Hawk is flown by U.S. Air Force rescue squadrons. Modifications include forward-looking infrared equipment, night-vision-compatible cockpit lighting, terrain and navigation radar, air refueling probe, auxiliary fuel tanks, and hoist. (Courtesy U.S. Air Force.)

missions, 2075 of which involved direct medical intervention. The most frequent problems were abdominal trauma and cardiopulmonary diseases.^[95]

In the high Alps, more than 90% of all rescues are performed using helicopters (3000 per year).^[4] Of these, 5% are combined rescues; that is, the helicopter carries the rescuers below cloud level, near the site of the accident. Only 5% of mountain rescues are purely ground rescues, mainly necessitated by visibility.^[76] Currently a network of SAR systems extends throughout the Alps. In some countries (France, Italy, Germany, Austria, and Spain), air rescues are managed partially or totally by the army or the state. The aircraft most often used for this purpose are the Alouette III, Lama, Ecureil (French), Bolkow 105, 117 (German), Augusta AK 117 (Italian), and Bell (United States). In Switzerland the rescue system in remote terrain is managed by the Swiss Alpine Club and three air rescue companies, Swiss Air Rescue (REGA), Air Glaciers, and Air Zermatt. Switzerland may be unique in that its 18 strategically placed helicopter rescue bases allow an aircraft to reach any accident scene within 15 minutes of take-off. Since the foundation of REGA in 1952, more than 150,000 patients have been transported by either fixed-wing aircraft or helicopter.

Up to 8000 patients (5500 from accident scenes) are transported by helicopter every year. Twenty percent of these rescues require a winch, with one third of all winch operations occurring in accident sites that are difficult to reach.^[28] More than 75% of all persons rescued by winch were thought to have injuries requiring physician assistance at the scene. Eighty percent of all

Figure 27-2 Helicopter rescue in extremely difficult terrain. (Courtesy P. Bärtsch, MD, and the Swiss Alpine Club.)

Swiss air rescue missions are physician assisted, and 20% have a paramedic in charge. All the physicians and rescue crews are physically fit and trained in alpine techniques, since two thirds of all rescue missions performed from 1990 to 1993 were in

topographically remote and difficult terrain ([Figure 27-2](#)).

Difficult helicopter SAR operations are those that involve low visibility, strong winds, night missions, high-angle rescues, and long-line hoist operations (extension of the hoist cable up to 120 m [394 feet]). In addition, in mountainous regions, power cables and transport cables present a considerable risk. In all cases the rescue risks to the flight crew (as well as to the patient) must be weighed against the degree of injury and risk of further morbidity. The U.S. Air Force, Army, Navy, and Coast Guard equip and train groups to operate in these hostile rescue environments. Helicopters are frequently equipped with precision navigation systems and night vision, forward-looking infrared (FLIR), and thermal imaging equipment. The intense training and specialized equipment permit rescue operations under much more demanding conditions than those encountered by civilian services. Of the military services, only the U.S. Coast Guard has a primary mission of civilian SAR; Army, Navy, or Air Force groups may be requested to assist in civilian rescues in areas where they are available.

An increasing number of people participate in alpine sports, including mountain climbing, downhill skiing, mountain biking, and paragliding.^[30] A typical representation of the type of mountaineering accidents experienced

646

in the Swiss Alps is shown in [Table 27-2](#) . In addition to SAR in mountainous regions, aeromedical rescue presents great challenges to the medical and flight crews involved in rescues from sea and white water, floods, vertical rock faces, and avalanches.

Medical treatment of the survivors should begin immediately at the site of the accident unless

Figure 27-3 A, Jungle penetrator used as a hoist device on most military rescue helicopters. The streamlined shape allows it to slip through dense tree canopies to reach the ground. A foam flotation collar can be attached, making the penetrator buoyant. **B**, Jungle penetrator rigged for hoist. The seats are flipped down, and the safety straps are pulled out from their stowed position and passed over the head and under the arms of the victim, who then straddles one of the seat paddles. Although the penetrator has three seats, usually only one or two personnel are hoisted at a time. (Courtesy Robert C. Allen.)

weather conditions are deteriorating or the scene is inherently unsafe. If a hoist extraction is needed, the patient with potential multisystem trauma should be evacuated by a rescue net or basket (Stokes) litter with careful spinal immobilization. A tag line attached to the litter prevents spinning during hoist operations. The tag line should be attached with a weak link so that the tag line will break away if the litter becomes uncontrollable. Persons with minimal or isolated injuries may be hoisted by a jungle penetrator ([Figure 27-3](#)), rescue basket, or other dedicated hoist device. If a hoist device is not available, the victim may be hoisted by climbing harnesses or rescue belts. ^[27] The climbing harness or belt should be carefully inspected to make sure that it has not been damaged in the mishap, that it will withstand the strain of the hoist operation, and that it can be safely attached to the hoist cable.

The extent of medical treatment rendered on site before extraction depends on many factors, including the victim's condition, scene safety, medical supplies available, medical skill of the rescuers, weather conditions, aircraft loiter time, and flight time to definitive care.

Good communication between the flight crew and the rescue team is essential to the decision process. Aeromedical crews involved in mountain rescue need to have a thorough understanding of the unique medical problems frequently found in high-altitude rescue situations.

AEROMEDICAL AIRCRAFT

Many different types of aircraft can be adapted to the air ambulance role. Each type has its strengths and weaknesses. On the other hand, not all aircraft are well suited for SAR in wilderness areas. Matching the physical and flight characteristics of the aircraft to the needs of the mission is vital. In many circumstances, compromises must be made because of aircraft availability. Rescuers must consider the physical characteristics of the aircraft when caring for a victim in flight.

Cabin Space

Cabin space should be considered not only in terms of total interior volume in cubic feet, but also with regard to floor space, headroom, and the ergonomics of cabin layout. Ample headroom should be available for the patient to lie comfortably on a secured stretcher and for access by two crew members to all parts of the body. Specifically, access to the head is needed for intubation, the chest for CPR, and the extremities for monitoring perfusion. Some helicopters, such as the Aerospatiale AStar/TwinStar or the MBB BO-105, provide ample upper body access but only limited lower body access while in flight. The relationship of flight crew members when seated (and secured by seat belts) in proximity to the patient is important. The ideal configuration places one medical crew member at the patient's head for airway management and verbal interaction and one at the patient's side to monitor vital signs and perform necessary non-airway-related procedures. This arrangement is typified by the MBB BK-117 helicopter ([Figure 27-4](#)).

Although some rotor-wing aircraft, such as the BK, are theoretically capable of transporting two patients, this greatly increases demands on the flight crew and the aircraft and diminishes access to both patients. Policies and procedures regarding two-patient transport in these aircraft should be carefully considered. In some large helicopters, such as the CH-46, CH-47 or MH-53, there is enough room to work on multiple patients. Even on relatively large (by civilian standards) military helicopters, however, such as the Coast Guard HH-60J Jayhawk ([Figure 27-5](#)), space for patient care can be at a premium.

Cabin space can be more generous in fixed-wing aircraft. Cabin-class airplanes, such as the Beech King Air and Piper Cheyenne III, provide an aisle and capability to carry more than one patient and additional crew or family members.

Access for Patient Loading

The cargo door should be wide enough that the patient's stretcher can be maneuvered

into the aircraft without undue tilting, and it should be positioned comfortably near stretcher height to obviate the need for strenuous lifting during ground loading. Standard door configurations on many aircraft do not meet these needs. The "clamshell" doors on an MBB BK-117 helicopter and the oversized cargo door on a Gulfstream Commander 1000 work well for patient loading ([Figure 27-6](#)).

Useful Load

One of the most important considerations for a given patient transport is the aircraft's useful load. This difference

Figure 27-4 Stanford LifeFlight MBB BK-117. (Courtesy GERALYN MARTINEZ.)

Figure 27-5 U.S. Coast Guard HH-60J Jayhawk helicopter in low hover over water, preparing to lower hoist cable to the rescue swimmer. Note the extensive spray under the aircraft. 648

between the maximum take-off weight and the basic empty weight is a reflection of the load-carrying capability. In most EMS helicopters the useful load ranges between 1500 and 2800 pounds. On-board avionics, medical equipment, fuel, and crew weights must be

Figure 27-6 MBB BK-117 with rear clamshell doors open. (Courtesy Susan Lockman,

Figure 27-7 Weight calculation aboard aircraft.

subtracted from this value to yield the maximum allowable patient weight ([Figure 27-7](#)). Fuel weighs 6 pounds per gallon; a twin-engine helicopter may burn 70 gallons per hour (420 pounds per hour), requiring it to carry 600 pounds or more fuel for a 30-minute-radius flight (with 30-minute reserve). Thus it becomes evident that a flight crew of three weighing a total of 500 pounds with a full load of fuel, oxygen, and medical gear may not have the capability to carry even a small patient, especially on a hot day when the helicopter's performance (lift) is reduced. This consideration can become critical on flights from the accident scene, where terrain obstacles may require vertical take-off and climb-out, demanding maximum helicopter performance. Density altitude (a factor of the air temperature and the pressure altitude) is critical in the performance of helicopters in mountain regions. High altitude combined with hot weather can seriously degrade the performance of even the most powerful helicopters.

Weight and Balance

Not only must the weight of the loaded aircraft remain at or below the maximum allowed take-off weight for that aircraft, but the center of gravity (CG) must lie within fore and aft limits established by the manufacturer. Each loading configuration places the CG in a unique position, which must be calculated by the pilot before flight, or the flight characteristics may be adversely affected, compromising safety. This consideration may dictate where certain pieces of medical equipment, such as oxygen bottles, may be placed or where heavier crew members must sit.

On flights from the accident scene the patient's weight is approximated before departure. With pressure to hasten departure, accurate weight and balance calculations are difficult. Thus the aircraft used must have enough margin in the CG envelope that CG limits are not easily exceeded for the given mission profile.

Cruise Speed

One of the most basic reasons for transporting a patient by air is to take advantage of the greater speed of aircraft compared with ground vehicles. This allows the patient earlier arrival at the destination and minimizes time spent out of the hospital. Not only do aircraft have a speed advantage, but they can travel in a straight line from origin to destination without the curves and deviations present in surface travel. For an aircraft to

compete with a ground vehicle in speed in a primary or secondary response mode, it must be at least twice as fast as an ambulance, since the helicopter must fly round trip (outbound to destination and inbound with patient) in the time that the ambulance would travel one way. This is possible with most EMS helicopters, unless (1) the referral location has no suitable landing area (necessitating a time-consuming transit of crew and stretcher to and from the location), (2) ground "packaging" times for the flight crew with the patient are excessive, or (3) an ambulance has a clear, straight highway as a means of alternative transport.

Most EMS helicopters are capable of attaining 120 to 150 mph over the ground, although a headwind or tail-wind may hinder or improve these figures ([Table 27-3](#)). Piston twin-engine aircraft have a cruise speed range of 220 to 275 mph, turboprop aircraft of 300 to 385 mph, and jets of 400 to 535 mph or more.^{[22] [70]}

*Range includes fuel for warmup, taxi, climb, and 30-minute reserve.

Range

Aircraft range is limited by the amount of fuel, which is a function of fuel tank capacity and useful load. In most cases a trade-off is made between payload and fuel; the more weight in fuel, the less weight in passengers (or patients). The maximum time aloft can be calculated by dividing usable fuel on board by rate of fuel burn per hour at cruise speed. Multiplying maximum time aloft by cruise speed yields the maximum range. The Federal Aviation Administration (FAA), under FAR part 91.23, requires that a 45-minute fuel reserve remain at the conclusion of all flights conducted under instrument flight rules (IFR), and a 30-minute reserve under visual flight rules (VFR). Most EMS helicopters operate under VFR, whereas most fixed-wing operations are IFR. Because helicopters typically fly to and from a point at which refueling is not available, round-trip fuel must be carried; this effectively limits the customary radius of operation to approximately half the range (less required reserves). Although it is possible to refuel en route to an airport, this adds to the flight time. Therefore helicopters typically operate within a radius of 150 miles or less, unless the transport is one-way outbound or unless refueling at the destination is feasible. Fixed-wing aircraft operate from airport to airport; thus the radius of operation is closer to the maximum range with reserves. Many fixed-wing aircraft are capable of ranges in excess of 1000 miles, with some jets able to travel more than 2000 miles.

Pressurization

The partial pressure of oxygen in the atmosphere declines with increasing altitude so that at 5486 m (18,000 feet) it is one-half that at sea level. Part 91.32 of FAR requires the use of supplemental oxygen for the pilot at flight altitudes above 3810 m (12,500 feet) for longer

†Range estimated at cruise speed, less 45-minute reserve.

‡Approximate nonbalance-field take-off length.

than 30 minutes.^[31] Above 4267 m (14,000 feet), supplemental oxygen must be used by the pilot and all *minimum required* flight crew at all times. Technically a medical flight crew member is not a *required* minimum crew member for the operation of the aircraft; neither is the copilot of an aircraft operated under FAR part 135 and certified for single-pilot operations (as with most aeromedical aircraft). Thus the medical crew member is not required to wear supplemental oxygen, although doing so would be prudent, especially for smokers. At altitudes greater than 4572 m (15,000 feet), in addition to the above requirements, each occupant must be provided with supplemental oxygen (although there is no legal requirement to use it).

The effects of hypoxia with increases in altitude are more pronounced in patients with lung disease and preexisting hypoxia; this necessitates supplemental oxygen at much lower altitudes. Supplemental oxygen at night will enhance night vision even at altitudes below 3810 m and should be considered for the flight crew, based on operational

requirements.

To eliminate the need to provide supplemental oxygen, pressurization is available in many larger, fixed-wing aircraft ([Table 27-4](#)). A pressurized aircraft is able to pump air into the cabin to maintain a pressure differential between the cabin and outside air, generally 4 to 8 pounds per square inch (PSI). This allows the cabin atmosphere to be maintained at or below the equivalent of a 2438-m (8000-foot) altitude, despite actual altitudes of 9144 m (30,000 feet) or higher.^[62] Pressurization obviates the need for supplemental oxygen for crew members and nonpatient passengers, but passengers with lung disease may still require it. Also, by limiting the drop in cabin pressure that occurs with altitude, changes in trapped gas volumes, such as in ET tube cuffs, air splints, and the gastrointestinal tract, can be decreased or eliminated. Special categories of patients include those with dysbarism. Exposure to increased altitude, with its concomitant decrease in ambient pressure, should be avoided. If possible, sea-level ambient pressure should be maintained when transporting these patients.

On the other hand, helicopters are nonpressurized and generally fly at lower altitudes where altitude-related hypoxia is unlikely. One exception occurs in mountainous regions where altitudes required to rescue victims or cross mountain passes may exceed 3658 m (12,000 feet). Reasons for transporting patients at higher altitudes include terrain avoidance, the need to surmount adverse weather (which usually occurs within 6096 m [20,000 feet] above ground), and greater speed and fuel efficiency at higher altitudes.

Service Ceiling

The service ceiling is the maximum altitude at which an aircraft can still maintain a rate of climb of 30.5 m (100 feet) per minute. This ceiling is important in predicting an aircraft's ability to climb above adverse terrain and weather and in taking advantage of favorable winds aloft to maximize ground speed. In the western

United States, mountainous areas require flight at least 610 m (2000 feet) above the highest terrain along the route of flight, which means a 3658- to 4877-m (12,000- to 16,000-foot) service ceiling. These altitudes restrict most helicopters and require use of supplemental oxygen in nonpressurized airplanes. Flight operations that typically require flight at these altitudes should have access to aircraft with sufficiently high service ceilings and pressurization.

Runway Length

Although not a factor in helicopter operations, runway length restricts certain fixed-wing aircraft from landing. Most airports in rural areas have runway lengths between 610 and 1220 m (2000 and 4000 feet). Higher-performance airplanes usually have progressively longer runway requirements and may be unable to land and take off safely on these strips. Thus, when transport from a rural location with a short runway is requested, it is

important to determine the capability of the aircraft being used. Piston twin-engine aircraft can usually operate safely from a 762- to 914-m (2500- to 3000-foot) strip but may have difficulty with 610 m (2000 feet); turboprop airplanes require 762 to 1067 m (2500 to 3500 feet); and jets usually require runway lengths of 1220 m (4000 feet) or more.^[62] The take-off roll for airplanes increases with increasing temperature and airport altitude; on a hot day, many airplanes may be incapable of taking off from a short runway if heavily loaded.

In winter conditions, operating on icy runways may pose a safety hazard for braking. Turboprop airplanes and jets have a reverse thrust mode that can slow the aircraft on rollout without braking.

Weather Operations

Adverse weather conditions that may affect a given flight include restrictions in visibility resulting from precipitation, fog, haze, or clouds, as well as airframe icing, turbulence, and wind shear. Flight during instrument meteorologic conditions (IMC) requires adherence to IFR, whereas visual meteorologic conditions (VMC) allow alternative use of VFR. VMC for airplanes are defined as visibility of at least 3 miles and ceiling of at least 305 m (1000 feet) (departing from an airport in controlled airspace).^[31] The ability to fly IFR not only improves the likelihood that the mission can be undertaken and completed safely should clouds or adverse weather be present but also enhances the ability of the air traffic control center to follow the flight and properly separate aircraft.

IFR capability has drawbacks. Sophisticated and expensive equipment and training are required. Virtually all fixed-wing aircraft are capable of IFR operations, but most EMS helicopters are not. IFR operations are usually conducted from airport to airport (where an instrument approach is available), but most helicopters travel to and from nonairport points without an instrument approach. The percentage of actual missions canceled or aborted because of IMC is small in most rotor-wing programs. One study determined that inadvertent excursions into IMC occurred about 1.3 times per pilot per year, and the anticipated percentage of operations that would be conducted IFR, if it were available, was 9.4%.^[68] For most hospital-based programs the cost of upgrading to a more expensive IFR-equipped helicopter (especially if a copilot is necessary for IFR certification), plus the added expense of maintaining pilot IFR proficiency, would be prohibitive. As a rule, military helicopters fly with a pilot and copilot and are usually capable of flying in IFR conditions, although IMC are far from ideal for SAR operations.

Performance

Closely related to aircraft speed is its ability to climb, expressed in feet per minute (fpm). Known as performance, this ability dictates the type of aircraft used for a given aeromedical transport mission (see [Table 27-2](#)). The greater the performance (a complex function of power, weight, wing, propeller, and air density characteristics), the better is the aircraft's ability to outclimb adverse weather or to avoid rising terrain or obstacles. Helicopters are unique in their ability to hover above the ground effect, that is, to climb vertically out of the supporting cushion of air produced by the rotor wash. Helicopters perform better when they have a running start, building up forward speed

while still in the cushion of ground effect until translational lift is developed. Translational lift results from the forward to backward flow of air over the rotor blades. A helicopter's ability to climb vertically out of ground effect is limited by horsepower and weight. On a hot day at high altitude, performance may be insufficient to take off vertically. ^[46] This must be considered when selecting a landing site away from an airport. If a confined space surrounded by obstacles is selected, a vertical take-off may be required. ^[18]

Fixed-wing aeromedical aircraft are virtually all twin engine not only for enhanced speed, performance, and cabin space but also for the necessary redundancy of systems required for IFR operations under FAR part 135. If one engine fails, a second is available to allow flight to be maintained; however, if failure occurs during take-off, single-engine climb performance may not be adequate to provide lift. This fact may be critical if insufficient altitude has been gained to allow a return to the airport before obstructions are encountered. Therefore single-engine climb performance for various types of aircraft must be considered, especially if operating out of high-altitude airports, in hot weather, or in mountainous regions (see [Table 27-4](#)). In general, single-engine climb performance is about 200 to 290 fpm

652

Figure 27-8 A, U.S. Coast Guard C-130 Hercules aircraft. This long-range aircraft is used for ice patrol, fisheries management, and search and rescue. **B**, Coast Guard HH-65 Dolphin helicopter. This short-range light-lift helicopter is used for near-shore search and rescue, maritime fisheries enforcement, and law enforcement. (Courtesy US Coast Guard.)

in piston twins, 600 to 900 fpm for turboprops, and 1000 to 2000 fpm for jets. ^[62] The airplane with the best single-engine climb performance will provide the greatest margin of safety, but the cost of equipment, pilot training, and adequate runways will be high.

Aircraft for Search and Rescue

Search and rescue is a special type of aeromedical transport that demands aircraft uniquely suited to this role. The aircraft should have good visibility to the sides and below, the ability to fly slowly and to hover, the ability to land away from an airport, and adequate performance in high-density altitude conditions. In addition, certain extrication situations require the capability to hoist victims from rugged or hostile terrain.

Helicopters are the aircraft of choice for many SAR missions ([Figure 27-8](#)). Few hospital-based EMS helicopters are configured for hoist operations, and hospital flight crews are typically not trained in SAR techniques. The SAR mission differs from other types of medical missions in its requirement for low-level flight over potentially hostile terrain, its use of flight crews for visual surveillance for survivors or wreckage, the need for a prolonged hover if hoist operations occur, and the need for flight crew training in wilderness survival principles if a mishap occurs. Experience and training in these

activities are essential for safety. In general, military helicopters and their crews are better equipped and trained to carry out SAR operations. For example, U.S. Coast Guard and U.S. Air Force helicopters have radio locating equipment to pinpoint emergency location transponders (ELTs), also known as emergency position-reporting beacons (EPRBs); possess night vision and FLIR cameras to maximize the probability of visually locating a survivor; and have hoists that enable them to extract survivors from areas where landing is not an option.

Flight crews on these missions must be specially trained in the use of rescue equipment and must possess the appropriate medical qualifications and experience to deal properly with atypical EMS situations. U.S. Navy and U.S. Coast Guard rescue swimmers and U.S. Air Force pararescuemen are trained to enter the water or proceed on land to aid in the recovery of survivors. Navy and Coast Guard rescue swimmers receive basic medical training; pararescuemen are trained to the EMT-paramedic level and are given additional training in long-term care of trauma victims.

Special hazards exist in mountainous areas. High-density altitudes may limit an aircraft's performance, but local weather patterns may be erratic. On the leeward side of mountains or ridges, severe downdrafts may prevent a helicopter from hovering out of ground effect. The landing site selected should be free of terrain obstacles and should allow for a long, shallow approach and departure. Open areas away from the leeward side of mountains or ridges are preferable.

SAR aircraft may not routinely carry the same medical equipment (e.g., ventilators, pacemakers, and defibrillators) as the typical EMS helicopter. Therefore care should be taken to verify that the medical equipment carried on a SAR aircraft is adequate for the intended mission (see [Chapter 25](#)).

Pilot Requirements

Helicopter EMS are usually VFR operations, and the FAA has established minimum requirements for pilot experience. FAR part 135.243 specifies that the pilot in command of a helicopter carrying passengers for hire must have at least 500 hours of flight time, including at least 100 hours of cross-country time with 25 hours at night. Fixed-wing services are typically IFR operations, and pilots must have at least 1200 hours of flight time, including 500 cross-country, 100 night, and 75 hours of

actual or simulated instrument time. They must also be instrument rated and possess a commercial certificate.

Most EMS helicopter pilots have much more experience than the minimum requirements; one survey found 59% had more than 4000 hours and none fewer than 2000 hours.^[32] The pilot in command is solely responsible for the safety of all passengers and must decide whether to accept or decline a mission. For this reason the

pilot is often not told the nature of the medical mission until a decision to go is made. This decision should be based on the destination, weather conditions, environmental circumstances, and estimated time at the scene, airport, or destination facility. No mention of patient type or severity should be made to the pilot before the launch decision is made so that this decision is objective. The pilot has the final say on all decisions related to safety of flight.

Communications

Helicopter EMS units must have the capability to communicate on very-high-frequency (VHF) airbands assigned for air traffic control, flight service, and local airport Unicom. In addition, the ability to communicate with ground EMS and public safety via VHF and ultra-high-frequency (UHF) airbands is essential. Air use frequencies are accessible through standard aircraft communications transceivers, but EMS communications require additional radio equipment designed for this purpose. Additional needs include communication with the helicopter's base station, either on a locally assigned public-use frequency or a Federal Communications Commission (FCC)-assigned discrete frequency in the VHF airband. Another means of communication is aircraft 800-MHz radiotelephones that can access the surface telephone network. Communication over air-band frequencies requires strict adherence to FAA communications guidelines and a radiotelephone operator permit from the FCC.^[26]

Medical Equipment and In-Flight Monitoring

On-board medical supplies and equipment are typically tailored to the needs of a specific transport program and include medications, airway and ventilation supplies, dressings and bandages, IV fluids, immobilization devices, military antishock trousers (MAST), and stretchers.^[73] The U.S. Department of Transportation (DOT), in conjunction with the American Medical Association (AMA), has published guidelines for on-board equipment for air ambulance operation ([Box 27-2](#)).^[92]

Power

Most aircraft systems operate from 14 or 28 volts of direct-current (DC) power supplied by an engine-driven alternator or generator. This is not adequate to operate most medical devices, which require 110 to 120 volts of alternate-current (AC) power. Such devices cannot be used without an internal battery of sufficient charge to provide power for the duration of the mission, or unless a 110- to 120-volt AC power source is available from a power inverter, which must be installed under an STC. Power inverters are common components of EMS helicopters and dedicated fixed-wing aircraft that have been retrofit with a custom-made air ambulance cabin configuration, but they may not be a standard component in fixed-wing aircraft that support a dual role and use an interchangeable corporate configuration.

Stretcher

The patient stretcher must be secured to the aircraft according to the requirements of

FAR part 23.561 or 25.561 for seats: 3.0 g's upward (2.0 g's, part 25), 9.0 g's forward, and 1.5 g's sideways. For helicopters the requirements are 1.5 g's upward, 4.0 g's forward, and 2.0 g's sideways. Special configurations, especially those incorporating oxygen bottles and metal framework, may require an STC. Other guidelines (recommendations only) for stretcher configurations are for clear view and access to the patients with at least 30 inches of headroom and at least 12 inches of aisle beside the head. The stretcher should be at least 19 inches wide by 73 inches long.⁹²¹ If the patient is positioned with head forward, the acceleration that occurs during take-off of a fixed-wing aircraft may cause venous pooling in the lower extremities and transient hypotension. To prevent this, the patient can be positioned with feet forward.

Climate Control

The aircraft must be capable of maintaining a comfortable interior environment; about 24° C (75° F) is recommended. During summer months the extensive glass area on a helicopter can produce a greenhouse effect, which may necessitate air conditioning for the comfort of both crew and patient.

Lighting

Lighting should be available to enable the crew to attend to the patient's needs but not interfere with cockpit operations. Curtains or other physical barriers may satisfy this need.

Suction

Suction is a requirement for ambulance operations in most states and should be available at all times during aeromedical transport. Integral suction as a custom retrofit system or a portable battery-powered device can be used.

Oxygen

In general, enough oxygen should be provided for the flight, plus a 45-minute reserve (IFR; 30 minutes VFR).

654

655

656

In addition, oxygen should be carried to allow for ground handling time at either end.

The amount of oxygen required can be obtained by multiplying the desired flow rate in liters per minute (L/min) by the total duration of transport and patient loading and unloading. [Table 27-5](#) lists the capacities of various types of oxygen tanks and their respective weights. Some portable ventilators have a gas-driven logic circuit that requires additional air or oxygen. Electrically powered ventilators have a lower requirement for oxygen but carry the additional need for a power inverter. Most patients are transported with oxygen supplied by nasal cannulae (1 to 6 L/min). A single E-sized oxygen cylinder is adequate for short flights, although backup cylinders are usually carried. Patients intubated and maintained on 100% oxygen, as well as those ventilated on long flights, will exceed the capacity of an E cylinder quickly; several E cylinders or an H cylinder will be required.

Box 27-2. U.S. DEPARTMENT OF TRANSPORTATION-AMERICAN MEDICAL ASSOCIATION GUIDELINES FOR ON-BOARD MEDICAL EQUIPMENT FOR AEROMEDICAL TRANSPORT

BASIC MEDICAL EQUIPMENT RECOMMENDED FOR EACH FLIGHT

1/patient	Litter or stretcher with approved restraints
2/patient	Sheets
2/patient	Blankets
1/patient	Pillow with cover impervious to moisture
1/patient	Pillowcase
1 set	Spare sheets and pillowcase (if weight and space allow)
1 unit	Medical oxygen with manual control; adjustable flowmeter with gauge (0 to 15 L/min); attachment for humidification (NOTE: The oxygen unit must be attached to the aircraft in an approved manner. The amount of oxygen to be carried is determined by multiplying the prescribed flow rate times the length of time the patient must be on oxygen and adding a 45-minute reserve. The minimum amount of oxygen carried should be enough to supply one patient for 1 hour at 10 L/min. It may be necessary to carry a portable oxygen unit if oxygen is not available for patient transfer at some point in the flight.)
2 each	Oxygen masks in adult, child, and infant sizes
6	Connecting tubes
1	Oxygen key
1 unit	Portable suction with connecting tubes
2 each	Suction catheters (various sizes)
2	Tonsil suction tips
1 unit	Squeeze bag-valve-mask unit capable of receiving oxygen through an inlet, and delivering 80% to 100% oxygen through the mask; with masks in adult, child, and infant sizes (bags in adult and small child/infant sizes)

1 unit	Squeeze bag-valve-mask unit capable of receiving oxygen through an inlet, and delivering 80% to 100% oxygen through the mask; with masks in adult, child, and infant sizes (bags in adult and small child/infant sizes)
1 unit	Oxygen-powered, manually triggered breathing device (100-L/min flow rate)
1	Blood pressure cuff, sphygmomanometer
1	Stethoscope (NOTE: To record blood pressure readings, a Doppler or electronic stethoscope may be required if noise or vibration levels are high. An electronic unit must not cause electromagnetic interference on aircraft equipment.)
2 each	Oropharyngeal airways in adult, child, and infant sizes
1	Emesis basin
1	Urinal or bedpan or both
1/patient	Sound suppressors
1	Pneumatic antishock trousers with pressure relief valve
2	Cervical collars
2	20-gallon trash bags
1 box	Zipper-lock plastic bags or similar product
1	Flashlight, 2 D batteries or equivalent with spare batteries and bulb
2	Locking hooks (or other positive locking device for intravenous fluid containers)
1 qt	Drinking water
12	Paper cups

DRESSINGS AND SUPPLIES KIT, DESIGNED TO BE CARRIED ON EACH FLIGHT

4	Cardboard or air splints or equivalent in arm and leg sizes
12	Tongue depressors
2	Mouth gags or padded tongue depressors
1	Bandage scissors
4	Tourniquets
1 each	Rolls of adhesive tape, ½, 1, 2, 3 inch
1 each	Rolls of paper tape, various sizes
4	Kling bandages or equivalent
1	3-inch elastic bandage
1	4-inch elastic bandage
4	Kerlix rolls or equivalent
2 pairs	Sterile gloves

2 pairs	Sterile gloves
3	Petrolatum gauze
1 box	Adhesive bandages
6	Disposable surgical face masks
2 each	Syringes, 3, 5, and 10 ml (TB and insulin)
3 each	Needles, 18, 20, and 22 gauge
3 each	Needles, 19, 21 gauge, scalp/vein
2	Surgical dressings
24	Sterile gauze pads
6	Nonsterile gauze pads
2	Triangle bandages
2	Wrist restraints
2	Eye covers
1 roll	Aluminum foil, sterilized and wrapped
1	Large safety pin
2	Clinical thermometers
4	Airsick bags
12	Waterless towelettes
1 box	Tissues

MEDICATION AND INTRAVENOUS KIT, DESIGNED TO BE CARRIED ON EACH FLIGHT

2	Epinephrine HCl, 1:1000, 1 ml, prefilled syringe
2	Epinephrine HCl, 1:10,000, 10 ml, prefilled syringe with intracardiac needle
2	Aminophylline inj., 500 mg in 2-ml ampules
4	Atropine sulfate, 0.5 mg in 5-ml prefilled syringe
2	Diphenhydramine HCl, 50 mg/ml, 1-ml prefilled syringe
2	Dextrose, 25 g/50 ml, prefilled syringe
2	Intravenous injection sets with microdripper
2	Lidocaine HCl, 2 g/10 ml, prefilled syringe
3	Lidocaine HCl, 20 mg/ml, 5-ml prefilled syringe
6	Naloxone HCl, 0.4 mg/ml, 1-ml ampules
1	Nitroglycerin, 0.4 mg, sublingual tablets, 100
2	Digoxin inj., 0.5 mg/2 ml, ampules
4	Furosemide, 10 mg/ml, 2-ml ampules

4	Furosemide, 10 mg/ml, 2-ml ampules
2	Chlorpromazine HCl, 25 mg/ml, 1-ml ampules
6	Sodium bicarbonate inj., 3.75 mg/50 ml, prefilled syringe
2	Morphine sulfate, 15 mg/ml, prefilled syringe
1	Hydrocortisone sodium succinate, 100 mg/vial
1	Methylprednisolone sodium succinate, 1000 mg/vial
1	Plasma protein fraction, 250 ml with infusion set
2	Sterile water for injection, 20 ml
3	Diazepam, 5 mg/ml, 2-ml prefilled syringe
6	Alcohol swabs
1	Phenylephrine HCl, 0.25%, nasal spray
2	Ammonia inhalant solution, 0.5-ml ampule
2	Isoproterenol HCl, 1:5000, 1-ml ampules
1	Tourniquet
1	0.9% sodium chloride inj., 500-ml bag
1	0.9% sodium chloride inj., 250-ml bag
1	Lactated Ringer's inj., 250-ml bag
1	Lactated Ringer's inj., 500-ml bag
2	Lactated Ringer's inj., 1000-ml bag
3	Needles, 15 gauge, 1 ½ inch
1	Dextrose, 5% in water, 250 ml
1	Dextrose, 5% in water, 500 ml
1	Dextrose, 5% in normal saline, 250 ml
1	Dextrose, 5% in normal saline, 500 ml
1	Pressure pack or infusion pump
1 each	Drip tubing, regular and pediatric
2	Armboards
6	Alcohol wipes
1	Clean hemostat
1 each	Sterile hemostat, curved and straight
1	Nasogastric tube, 14 gauge
2	Sterile normal saline for injection, 20 ml
2 pair	Sterile gloves

2 pair	Sterile gloves
1	Knife handle
1	Subclavian set
1	No. 15 blade
1	Intravenous infusion cuff
1 each	Rolls of tape, 1 and 2 inch

AIRWAY MANAGEMENT KIT, DESIGNED TO BE CARRIED ON EACH FLIGHT

1	Laryngoscope with curved and straight blades in various sizes; spare batteries and bulb
As required	Adapters for attaching endotracheal tubes to oxygen, etc.
1	Rubber-shod forceps
1	Magill forceps
1	Esophageal obturator airway with gastric suction capability
1	McSwain dart or Heimlich valve
1	Syringe, 60 ml
1	Needle, 14 gauge
1	Syringe, 10 ml
1 each	Rolls of adhesive tape, 1 and 2 inch
1	Viscous lidocaine HCl, 2%
1 tube	Surgical lubricant

BURN KIT, TO BE CARRIED WHEN REQUIRED

3	Normal saline, 1 ml in plastic container
1	Sterile burn sheet, 57 x 80 inch
5 packs	Xeroform gauze, 5 x 9 inch
1	Irrigating syringe, 50 ml
2 pairs	Sterile gloves
4	Kerlix rolls
2 packs	Fluffy gauze

POISON DRUG OVERDOSE KIT, TO BE CARRIED WHEN REQUIRED

1	Irrigation tray
1	Surgical stomach tube for lavage
1 each	Specimen bottles for urine, gastric, and miscellaneous
2 each	Stomach tubes, 14, 16, and 18 Fr

2 each	Stomach tubes, 14, 16, and 18 Fr
1	Rubber stomach tube, no. 20
1 tube	Lubricant
1 box	Glucagon, 1 unit
2	Ipecac Syrup, 30 ml
1	Physostigmine salicylate, 1 mg/ml, 2-ml ampules
1	Pralidoxime chloride, 1-g kit
1	Activated charcoal, 10 g

OBSTETRIC KIT, TO BE CARRIED WHEN REQUIRED

1	Disposable obstetric pack with sheets, cord clamps, DeLee suction, plastic bag, silver swaddler, sterile gloves
2	Oxytocin, 10 units/ml, 1-ml ampule
1	Episiotomy scissors
1	Ring forceps

PEDIATRIC KIT, TO BE CARRIED WHEN REQUIRED AND ALWAYS WITH OBSTETRIC KIT

1	Pediatric laryngoscope handle with blades
1 each	Pediatric endotracheal tubes with stylette, 2.5, 3, 3.5, and 4 Fr
1	Pediatric Magill forceps
2	Bulb syringes
2	DeLee suction
2	Pediatric drip intravenous tubing
1 each	Feeding tubes, 3.5, 5, and 8 Fr
1	Pediatric blood pressure cuff, sphygmomanometer

ADDITIONAL EQUIPMENT FOR TRAUMA PATIENTS, TO BE CARRIED WHEN REQUIRED

1	Scoop stretcher
1	Long backboard
1	Foley catheter set
1	Femur traction splint
1	Suture kit

ADDITIONAL EQUIPMENT FOR CARDIAC PATIENT, TO BE CARRIED WHEN REQUIRED

1 unit	Cardiac monitor with strip chart recorder
--------	---

1 each	Spare ECG electrode for each lead
1	Spare roll of ECG recording paper
1 unit	Defibrillator with four pads and conductive gel (defibrillator may come as a unit with the cardiac monitor)
1	Rubber mat or other means of electrically isolating the patient from the aircraft
1	Cardiac board

ADDITIONAL EQUIPMENT FOR SPECIFIC PATIENTS, TO BE CARRIED WHEN REQUIRED

1 unit	Respirator capable of continuous ventilation, with ventilator, tubing, exhaled volume measuring device, set of tracheostomy endotracheal adaptors
1 unit	Incubator, with all equipment suitable for neonatal care

Ventilators

On short flights, most patients can be bag ventilated manually, with the addition of a positive end-expiratory pressure (PEEP) valve as needed. Manual ventilation has drawbacks. Minute ventilation can rarely be precisely controlled, leading either to respiratory acidosis or more often to alkalosis. The patient's tidal volume limits may be exceeded, with resultant pulmonary barotrauma. More important, the medical attendant will be completely occupied with ventilation and is

TABLE 27-5 -- Oxygen Tank Specifications

thus unavailable to perform other tasks. This takes on added importance if complex infusions are being administered or in-flight complications occur. The likelihood that manual ventilation will be unsatisfactory increases with the duration of transport, medical complexity of the patient, and severity of underlying lung disease.

Compact ventilators are available for use in the aeromedical transport environment.^[12] The simplest are pressure ventilators with a timing valve mechanism that will deliver a predicted minute ventilation at a given rate and tidal volume adjustable to patient size. These require that the patient have normal airway compliance. If airway resistance increases, smaller tidal volumes will result, and tidal volumes usually cannot be varied independently from rate. Volume-cycled ventilators

657

are superior and available in configurations in which tidal volume and rate can be varied independently. Oxygen bottles, a 50-PSI regulator, high-pressure gas lines, a patient breathing circuit, and source of humidification need to be present.

As mentioned, ET tube cuffs need to be appropriately monitored during flight to prevent overinflation resulting from decreased ambient pressure.

Infusion Devices

Several methods of IV infusion delivery are available in the aeromedical setting: gravity-feed microdrip or macrodrip tubing with the drip rate manually adjusted, gravity-feed automatic infusion regulators with a closed-loop drip-monitoring feedback mechanism controlling drip rate, and infusion pumps. If a pump is used over moderate or long transport distances, the internal battery power may be inadequate, necessitating an external source of power, usually an AC power inverter. With infusions that must be carefully maintained, an infusion pump is preferable. With frequent patient movement and manipulation, tubing can bend and kink, altering resistance to fluid flow. Air trapped in tubing (or in glass IV bottles) can expand with changes in altitude and increase or decrease the infusion pressure. Thus a reliable servocontrolled infusion system provides a margin of safety.

Monitor-Defibrillator

Combination monitor-defibrillators operate from internal batteries when 110 to 120 volts AC is not available. Other monitors capable of pressure monitoring from arterial lines or pulmonary artery catheters may be used, but these may have limited usefulness on flights of short duration, during which vibration and motion (turbulence) can introduce

artifact and erroneous readings, as may occur aboard a helicopter. These devices may find a greater role with dedicated fixed-wing aircraft that frequently transport critically ill patients over long distances. Noninvasive blood pressure measurement is reasonably accurate in most patients, although these devices may have insufficient sensitivity.^[57]

Potential hazards of defibrillation while airborne remain a concern, although trials support its safety.^{[23] [43]} Caution is still advised, and care should be taken to ensure that crew and aircraft systems are isolated from potential electrical contact (see Common Aeromedical Transport Problems). The pilot should be notified before defibrillation. It is unlikely that defibrillation will cause a problem with the aircraft, but if in a critical phase of flight (e.g., take-off, landing), the pilot may delay the shock until the critical phase of flight is accomplished.

Oximetry

Pulse oximetry is often indicated for optimal patient care. Pulse oximeters use a colorimetric method, with placement of a soft probe over a fingertip, in a thin skinfold such as an earlobe, or against the conjunctiva.^{[1] [84]} They may be extremely useful in aeromedical transport, during which other methods to detect changes in respiratory status are difficult.

Mechanical Resuscitators

Cardiac arrest resuscitation while airborne in a small cabin is difficult and physically demanding. In most instances a standard medical crew of two will be completely occupied in performing chest compressions and ensuring ventilation. Additional tasks may be impossible. Therefore a mechanical resuscitator may be used to prevent fatigue and free crew members for other tasks.^[67] Mechanical resuscitators are gas-powered devices capable of providing ventilation and chest compressions automatically. Some models provide only chest compressions.

FLIGHT CREW

Crew Configuration

One of the continuing controversies in aeromedical transport involves crew composition ([Table 27-6](#)). The ideal crew composition varies considerably with the mission profile. When the aircraft is involved in a primary response to the accident scene, inclusion of an EMT may be beneficial. The transport of patients whose illness or injuries are complex or whose clinical conditions are extremely unstable may benefit from the presence of a physician. All aeromedical transport programs include one or more of the following providers in the transport medical crew.

Emergency Medical Technician-Paramedic

EMTs are increasingly a part of the aeromedical flight team. In 1993, 71% of rotor-wing transport programs reported using an EMT-paramedic (EMT-P) as a member of the flight team, vs. 44% in 1988.^[15] Paramedics vary in their level of training depending on the state in which they work but usually follow DOT guidelines, which include three levels of certification. EMT-basic provides basic ambulance, rescue, and first-aid skills. EMT-intermediate may include IV and intubation skills. The EMT-paramedic level involves such skills as intubation, IV techniques, medication administration, defibrillation, and arrhythmia recognition and treatment. For an aeromedical flight team member, additional training relating to the aeromedical environment is desirable.^{[81] [92]}

EMTs can be of particular value in operations that necessitate frequent interaction with ground EMS. In some regions, helicopter EMS service is integrated into the regional primary response network so that they arrive at the accident scene before ground units, and flight team members experienced in scene assessment and victim extrication are essential.

RN, Registered nurse.

Flight Nurse

At least one flight nurse is part of almost all aeromedical transport programs; in 1993, 21% of rotor-wing programs reported using two flight nurses as the sole team members.^[15] Critical care or emergency nursing experience is usually a prerequisite, with additional training that includes patient assessment, advanced cardiac life support (ACLS), a trauma life support course, prehospital care skills, certain procedures such as ET intubation, advanced IV cannulation techniques, and in some cases, needle thoracotomy, venous cutdown, cricothyrotomy, and other specialized patient care activities. The flight nurse often is also a certified EMT.

Flight Physician

The experience and training of physicians involved in aeromedical transport depend on their role. Those who function as the on-line medical control physician communicate via radio or 800-MHz radiotelephone with the flight crew, monitor care, and give necessary orders. In the United States, physicians fly as a component of the flight team in a minority of aeromedical transport programs; in 1993, only 3% of all rotor-wing transport programs reported the routine use of a physician, vs. 10% in 1988.^[15] In helicopter EMS operations an emergency physician or trauma surgeon may be appropriate, whereas with fixed-wing transport of intensive care unit (ICU) patients an intensivist may be of value.

Physicians functioning in this role must have a current level of skill and expertise sufficient to address a wide range of clinical problems. They must also possess additional training relative to the airborne environment, including flight physiology, aircraft operations, and prehospital care ([Box 27-3](#)). Most important, they must function in this role with sufficient frequency so as to maintain their skills and remain safe and comfortable within the aeromedical setting. In doing so, they become an asset to the flight team rather than a distraction or liability.

Studies during the late 1980s and early 1990s attempted to determine whether a physician crew member has an effect on the outcome of patients transported by helicopter.^{*} Some studies concluded that a physician crew member had a positive impact on patient outcome, whereas others found no difference in outcome between similar cohorts of patients transported by flight crews with two nurses or a nurse and a paramedic. The cost of using a physician crew member is substantially higher than that of a nurse-nurse or nurse-paramedic crew configuration. Some argue that this higher cost would be offset by the decrease in hospital stay or lost person-years that would occur if a physician were a standard member of the flight crew. With advanced training in critical procedures and treatment protocols combined with on-line medical direction, a nonphysician flight crew usually functions as well as a crew that includes a physician. No objective evidence supports the benefit of a physician as a standard flight crew member.

Crew Member Stress

By its nature, aeromedical transport involves moving a gravely ill patient into an adverse environment with

*References [5] [6] [14] [40] [42] [75] [83] [85] .

659

limited resources. Under these conditions a medical crew of only two or three persons must perform complex tasks, solve difficult problems, and make life-or-death decisions. They must perform in a physically confining space that may be uncomfortable, and they must do so under time pressure and with little or no physical assistance. In some cases, rescuers' lives may be at risk. This scenario occurs in few other arenas of civilian medical care.

"Stress" describes an array of adverse physiologic and psychologic reactions that occur when a person perceives a threat to existence. Although stress may not diminish

performance, it may be responsible for errors, faulty judgment, and uneven manual skill performance. It may also affect the physical and psychologic health and satisfaction of the flight crew member.^[16]

When measured during patient flights, the level of anxiety among aeromedical crew members was significantly higher than during a baseline period on the ground.^[87] Factors that correlate with high in-flight anxiety levels include adverse weather conditions (e.g., low ceilings, high winds), severity of the patient's medical condition, complexity of illness or injuries, and the crew member's fatigue.

Efforts should be made to minimize stress among crew members. This includes frequent and adequate training; continuing education and feedback; adequate medical backup, including on-line medical direction, written protocols, and treatment guidelines that can aid in difficult decisions; a supportive rather than an intimidating or critical quality assurance program; adequate rest; and safe weather minimums. Both routine mission debriefing and critical incident stress debriefing (CISD) should be an integral part of all transport programs.^{[64] [65]}

FLIGHT PHYSIOLOGY

Aeromedical care is different from ground-based care not only because of special equipment and the space-limited environment, but also because of the hostile physical milieu.

Hypoxia and Altitude

The earth is blanketed by a sea of air. The troposphere lies in the first 9144 to 18,288 m (30,000 to 60,000 feet) and contains atmospheric moisture. Vertical convection currents, as well as a temperature decline with increasing altitude at a lapse rate of 2° C per 305 m (3.6° F per 1000 feet), occur here. Virtually all atmospheric weather occurs in this layer. Above this level lies the stratosphere, extending from 18,288 to 30,480 m (60,000 to 100,000 feet), where temperature remains relatively constant and no moisture or vertical convection currents exist.

Air exerts pressure on everything it contacts in an amount equal to the weight of the column of air above the point of reference. At sea level the atmospheric pressure is 14.7 PSI or 760 mm Hg. As the person ascends, a progressively smaller air mass remains to exert weight, and the pressure diminishes. At 5486 m (18,000 feet) the atmospheric pressure is one half of that at sea level, and at 8534 m (28,000 feet) it is one third as great

660

Figure 27-9 A, Atmospheric pressure vs. altitude. **B**, Alveolar (P_{AO₂}) and arterial (P_{aO₂}) oxygen tensions vs. altitude.

TABLE 27-7 -- Composition of Air

GAS	PERCENT
Nitrogen	78.09
Oxygen	20.95
Carbon dioxide	0.03
Other gases	0.07
Water vapor	1–5 at sea level

From Del Vecchio RJ: Physiologic aspects of flight, Oakdale, NY, 1977, Dowling College Press.

([Figure 27-9](#)). Similarly, under the weight of air, individual molecules tend to compact, so the density of air is also greatest at the surface and diminishes with increasing altitude.

These phenomena underlie most of the important physiologic consequences of flight. Air is composed of several gases, of which oxygen makes up approximately 21%, an amount that is relatively constant despite increasing altitude ([Table 27-7](#)).^{[25] [73]} Henry's law states that the quantity of gas that goes into solution depends on the partial pressure of that gas (and its solubility characteristics) as exerted at the air-water interface. The partial pressure of oxygen in alveolar air (P_{AO_2}) is determined by multiplying the fractional composition of oxygen in inspired air (F_{iO_2}) by the atmospheric pressure (barometric pressure, P_B) after the opposing vapor pressure of water (P_W , 47 mm Hg) has been subtracted. This is the basis of the alveolar air equation, as follows:

$$P_{AO_2} = F_{iO_2} \times (P_B - P_W) - P_{CO_2} / R$$

where P_{CO_2} is the arterial carbon dioxide tension and R is the respiratory quotient (approximately 0.8). Arterial oxygen tension (P_{aO_2}) in normal individuals is within 10 to 15 mm Hg of the P_{AO_2} . With lung disease characterized by ventilation-perfusion mismatch, intrapulmonic shunting, or severe diffusion defects, the alveolar-arterial (A-a) oxygen gradient is much larger, and higher amounts of inspired oxygen are required to produce sufficient oxygenation of arterial blood. The atmospheric P_{O_2} , P_{AO_2} , and the P_{aO_2} all decline with altitude ([Figure 27-9](#)). To some extent, P_{aO_2} can be maintained through hyperventilation as P_{CO_2} is reduced, but eventually P_{aO_2} will decline below 60% and hemoglobin will begin to desaturate greatly.

It is important during aeromedical transport to maintain hemoglobin saturation at or above 90%. Knowledge of the patient's preflight P_{aO_2} will enable a calculation of the patient's A-a oxygen gradient, which can then be subtracted from the P_{AO_2} calculated for the anticipated en route altitude (or cabin altitude in a pressurized craft) to yield the expected en route P_{aO_2} . Nomograms can be devised for this purpose ([Figure 27-10](#)). If the en route expected P_{aO_2} is unacceptably low, supplemental oxygen is required. The

F_{iO_2} required to maintain the P_{AO_2} at a given level can be calculated from the alveolar air equation as follows:

$$F_{iO_2} = (P_{AO_2} + P_{CO_2} / R) / (P_B - P_W)$$

Or, if $P_{CO_2} = 40$, $R = 0.8$, and $P_W = 47$ mm Hg, then:

$$F_{iO_2} = (P_{AO_2} + 50) / (P_B - 47)$$

This allows P_{AO_2} to be determined by adding the P_{aO_2} desired (the minimum acceptable is 60 mm Hg) to the known A-a oxygen gradient (calculated from the preflight blood gas). P_B can be estimated over the first 15,000 feet (4572 m) of ambient or cabin altitude as follows:

$$P_B = 760 - (23 \times \text{Alt})$$

where Alt is the altitude above sea level in thousands of feet. Transport cabin environments rarely exceed

Figure 27-10 Arterial oxygen tension (P_{aO_2}) at altitude vs. P_{aO_2} at sea level.

Locate the sea-level P_{aO_2} on the x axis and intersect with the cruise altitude (on the diagonal). Read across to find the P_{aO_2} at altitude (y axis).

these altitudes, since pressurized craft are usually capable of maintaining cabin pressure equal to 8000 feet (2438 m) or below at normal cruising altitudes. Nonpressurized craft must provide supplemental oxygen above 15,000 feet. Even a modest increase in F_{iO_2} is usually enough to maintain oxygenation under these circumstances, unless a severe A-a oxygen gradient exists, in which case the addition PEEP may be necessary. The previous equation would predict that a P_{aO_2} of 80 mm Hg at sea level on 40% oxygen would require that an F_{iO_2} of 50% at 8000 feet be maintained. An oximeter can simplify monitoring of oxygenation; as altitude increases, a

fall in oxygen saturation can be treated with increases in F_{iO_2} .

Effects of Pressure Changes

Trapped Gas.

Boyle's law states that the volume of a gas varies inversely with pressure. This means that trapped gases expand as an aircraft ascends to higher altitude (and lower pressure) and contract as it descends. The volume change can be determined from the following equation:

$$P_1 \times V_1 = P_2 \times V_2$$

Clinically, this is manifested by such alterations as expansion or contraction of air splints or MAST pants, changes in ET tube cuff size, expansion of bowel gas in cases of intestinal obstruction or ileus, expansion of

TABLE 27-8 -- Clinical Manifestations of Trapped Gas Expansion

TRAPPED GAS LOCATION	CLINICAL MANIFESTATIONS
Intestinal lumen	Abdominal pain, distention

IV bottle and tubing	Fow rate increase
Blood pressure cuff	Tourniquet effect
Endotracheal tube cuff	Air leak, hypoventilation

pneumothorax air space, and expansion of air trapped in IV lines (or glass IV bottles) (see [Table 27-8](#)). Certain precautions must be taken, such as the use of plastic IV bags and frequent monitoring of pressure cuffs.

Dysbarism.

Decompression sickness occurs mainly in scuba divers that ascend too soon after a dive. Too rapid a decrease in ambient pressure allows nitrogen bubbles to form in the microcirculation, which may lead to ischemia and tissue damage (see [Chapter 57](#)).

Care must be taken in the transport of an ill or injured diver to allow a surface interval of at least 12 hours before transport. An alternative is to attain at least a level D (PADI) dive stage, with a cabin altitude not to exceed 2438 m (8000 feet). If an individual must be transported abruptly after submersion, the transport must be conducted at the lowest possible safe altitude in a pressurized aircraft, to reduce the risk of decompression illness.

Motion and Acceleration

Aircraft not only move through space in a rectilinear fashion, which cannot be detected by human senses in the absence of visual cues, but also rotate about three axes: longitudinal (roll), vertical (yaw), and horizontal (pitch) ([Figure 27-11](#)). Motions about these axes are sensed by the semicircular canals located in the inner ear. Sensations from these organs are useful as an adjunct to visual cues. However, they may quickly lead to spatial disorientation, a phenomenon often experienced by individuals traveling in a turbulent environment without a visual frame of reference. For example, when an aircraft enters a bank to the right, the sensation may be initially correctly interpreted. However, after rollout of the stationary bank to a neutral position, a sensation of

662

Figure 27-11 Axes of movement in aviation.

rolling into a left bank may be sensed. If uncorrected, apprehension may follow. The best remedy for this effect is to maintain a visual reference to the correct position.

Vestibular stimuli, especially in turbulence with limited or no visual frame of reference, may result in motion sickness, manifested most often as nausea or vomiting. Affecting both patients and flight crews, motion sickness can be counteracted with antiemetics such as antihistamines (e.g., dimenhydrinate, 50 mg orally) or phenothiazines (e.g., prochlorperazine, 10 mg orally); however, these may produce sedation and are potentially hazardous in flight. Transdermal scopolamine patches applied behind the ear have been used as effective prophylaxis for nausea and vomiting during flight.

Noise and Vibration

Noise and vibration are components of all aircraft environments, especially helicopters. The most obvious impact of noise is on communications within the cabin, particularly with the patient, who is least likely to have a headset and access to the aircraft's

intercom. In addition, the patient's breath sounds are difficult if not impossible to hear, and thus other means to identify changes in respiratory status, such as pulse oximetry, must be employed.

Headsets are essential for effective communication among flight crew members aboard a helicopter, although they are usually unnecessary aboard larger fixed-wing aircraft. Noise may lead to permanent defects in auditory acuity if exposure is prolonged or recurrent. Veteran pilots demonstrate 10- to 20-dB reductions in high-frequency auditory acuity. Noise and vibration may also lead to stress and fatigue.

COMMON AEROMEDICAL TRANSPORT PROBLEMS

Pretransport Preparation

Once the decision is made to transport a patient by air and the appropriate aeromedical service is contacted, preparations must be made to ensure patient safety and comfort and to aid the flight crew in patient care. A study of the causes of ground delays in a rural inter-hospital helicopter transport program found that on arrival of the flight team, 31% of patients required minor interventions (insertion of IV line or nasogastric tube, blood transfusion, bladder catheterization, MAST application) before take-off, and 33% required major interventions (ET intubation, tube thoracostomy, central venous access).^[54] When no intervention was required, the mean ground time was 31.2 minutes, compared

663

with 57.4 minutes when one or more major interventions were required.

Extremity fractures splinted (traction splinting for femur fractures)

Copies of all available emergency department records and laboratory results, including a description of the mechanism of injury

To minimize delays, pretransport preparations should be made for victims of acute trauma ([Box 27-4](#)).

Patient Comfort

Motion, vibration, noise, temperature variations, dry air, changes in atmospheric pressure, confinement to a limited position or backboard, and fear of flying may cause patient discomfort.

Patient Movement

Patient handling and movement can contribute to morbidity and mortality in unstable patients.^[93] All transported patients should be adequately secured to the stretcher with safety straps to prevent sudden shifting of position or movement of a secured fracture. During transport from the ground to the aircraft cabin, attempts should be made to limit sudden pitching of the stretcher. DOT guidelines recommend design of cabin access such that no more than 30 degrees of roll and 45 degrees of pitch may occur to the patient-occupied stretcher during loading.^[62] The stretcher, in turn, should be adequately attached to the floor.

Motion sickness in the patient may be treated with an antiemetic such as promethazine (25 mg orally, intravenously, or intramuscularly) or prochlorperazine (5 to 10 mg orally, intravenously, or intramuscularly). Scopolamine disks are useful for prolonged flight and do not require parenteral or oral administration, although their antiemetic effects are not always uniform and may not occur until 4 to 6 hours after application. They may be best used to decrease motion sickness in the flight crew.

Noise

Noise can be avoided with hearing protectors, which are devices similar to headphones but without internal speakers. Inexpensive hearing protectors are available as deformable foam ear plugs. In some cases, headphones may be used in an awake patient if the crew wants the patient to communicate on the intercom system.

Eye Protection

When a patient is loaded on or off a helicopter with the rotors turning, the patient's eyes must be protected. Serious eye injuries can result from debris blown into the air. Lightweight sky diver goggles ("boogie goggles") are effective and inexpensive. The eyes must be protected even if the patient is unconscious. Taping temporary patches

over the eyes is also effective.

Respiratory Distress

Patients with respiratory disease or distress should have immediately treatable conditions addressed before take-off. ET intubation is essential if airway patency is threatened or if adequate oxygenation cannot be maintained with supplemental oxygen. It is better to err on the side of caution when making a decision about a patient's airway. During flight it is easier to treat restlessness in an intubated patient than airway obstruction or apnea in a nonintubated patient.

Nearly all patients should receive supplemental oxygen. F_{iO_2} should be increased with increasing cabin altitude to maintain a stable P_{O_2} ([Figure 27-12](#)). When oxygen saturation monitoring is unavailable and pretransport arterial oxygen content unknown, 100% oxygen may be administered throughout the flight to ensure adequate oxygenation. Patients with chronic lung disease who are prone to hypercapnia may have a deterioration in condition if the hypoxic drive is eliminated. In these patients the least oxygen necessary to maintain saturation above 90% is advisable; this amount may be estimated in advance or calculated from the alveolar air equation. Close in-flight monitoring is essential. Finally, altitude changes may affect ET cuff volume, so cuff pressure must be checked frequently.

Cardiopulmonary Resuscitation and Cardiac Defibrillation

CPR in an aircraft is difficult. The rescuers must perform several tasks simultaneously while ventilating the lungs or compressing the chest, all in a physically confining space. The crew must be familiar with modifications

664

Figure 27-12 Fraction of inspired oxygen required to maintain oxygen tension at 90 mm Hg (varying with altitude).

665

in technique.^[45] As previously mentioned, there should be no concern with airborne

defibrillation if all electronic navigational equipment on the aircraft has a common ground, as mandated by the FAA standards. Despite cramped quarters and sensitive electrical equipment, defibrillation can be safely performed in all types of aircraft currently used for emergency transport utilizing standard precautions routinely used during defibrillation on the ground.^[23]^[94] In the interest of safety, however, it is best to notify the pilot before performing defibrillation.

Patient Combativeness

Patients may be combative to the point that they pose a threat to the safety of the flight and crew. An uncontrollable patient may cause sudden shifts in aircraft balance or may strike a crew member or important flight instruments or equipment. Such patients should be properly restrained in advance. If sedation is necessary, a careful neurologic examination documented beforehand is essential. Useful agents include diazepam (5 to 20 mg intravenously) or shorter-acting agents, such as midazolam (2 to 10 mg intravenously or intramuscularly.) Paralyzing agents, such as pancuronium, vecuronium, and succinylcholine, have the advantage of not altering the sensorium, but they require airway control with ET intubation.^[90] In addition, it is necessary to sedate a patient who is paralyzed to facilitate intubation and transport.

Endotracheal Intubation

ET intubation may be difficult to perform while airborne, especially in a confining cabin, and should be done before departure if possible. This is especially true in trauma victims with head injuries and in burn victims who have carbonaceous sputum or hoarseness. Special techniques are available to supplement standard methods of intubation, including a lighted stylet, ET tubes with controllable tips, and digital intubation. Sedation or pharmacologic paralysis may be necessary. Of 106 aeromedical transport programs in the United States that reported using neuromuscular blocking agents, 39 use them to facilitate intubations, and 67 use them once a patient is intubated to manage combativeness and ensure airway patency.^[79] Induction of paralysis before intubation in the aeromedical setting is controversial. One study reported a 96.6% success rate using succinylcholine to facilitate intubation, with 3.4% of patients requiring an emergency surgical airway.^[66] Besides the need for surgical airway if intubation is unsuccessful, concerns exist about cervical spine manipulation during intubation in the paralyzed patient, unrecognized esophageal intubation in a nonbreathing patient, and the relative contraindications to the use of succinylcholine in certain patients. As shorter-acting nondepolarizing paralytic agents (e.g., mivacurium) are developed, this adjunct to airway and combativeness control in the aeromedical setting will be studied further.^[51]

In some flight programs, nonphysician crew members are taught to perform emergency cricothyrotomy. Although occasionally lifesaving, this procedure is often difficult to perform and should be undertaken only as a final method to secure an emergency airway.

Thrombolysis

The air transport of patients with acute myocardial infarction often involves thrombolytic therapy. Because bleeding is a major adverse effect of thrombolytic agents, one study investigated whether air transport resulted in a higher incidence of bleeding complications compared with a similar cohort of patients given thrombolytic drugs who were transported by ground ambulance. The study concluded that helicopter transport of patients with acute myocardial infarction after initiation of thrombolysis is comparatively safe and without a clinically significant increase in bleeding complications.^[34]

Flight Safety

Because aeromedical transport involves medical care delivered in a hostile environment, the patient and crew are at risk of injury or death in the event of a mishap. Flight crew training must emphasize safety. The pilot is ultimately responsible for the safety of the aircraft's occupants and is trained not only to operate the aircraft skillfully and safely, but also to provide necessary safety instructions and guidance to crew members and passengers. Safety practices vary depending on the type of aircraft but include common guidelines.

Approaching the Aircraft.

Helicopters with turning rotor blades must be approached only from the front and sides and only while under pilot observation ([Figure 27-13](#)). The tail rotor must be given wide berth, especially on helicopters with rear doors. It is advisable to station a crew member in a safe position to direct approaching individuals away from the tail rotor. Shutting down the helicopter's engines completely, when the situation allows, is prudent before patient loading and unloading. Approaching in a crouched position minimizes the risk of contact with the rotor blades should a sudden gust of wind or movement of the aircraft cause them to dip. Loose clothing and debris should be secured ([Box 27-5](#)).

Fixed-wing aircraft should be approached with similar precautions regarding propellers. This is especially important in aircraft with access doors in front of the wing and engine nacelles. Engine shutdown on the side of entry enhances safety of loading and unloading.

Figure 27-13 Helicopter safety. **A**, Safe approach zones. **B**, The proper way to approach or depart a helicopter.

Safety Belt Use.

The use of safety belts (preferably with shoulder harnesses, especially in helicopters) is an important safety measure. Certain patient care activities (e.g., ET intubation, CPR), however, may be impossible to perform with safety belts secured. The design and selection of aircraft and interior configurations should allow maximal access to the patient with the crew members properly restrained. Throughout the flight the crew members and patient should remain restrained as much as possible in smooth air and at all times in rough air. Movement inside the cabin affects aircraft balance. An aircraft loaded near its aft CG limit may exceed its limits if a crew member moves to a new position within the cabin. Changes in position should be preceded by consultation with the pilot. Light aircraft are sensitive to turbulent air, and appropriate precautions must be taken to avoid being injured from sudden motion.

Proper Use of Aircraft Equipment.

Crew members must be familiar with all aircraft equipment they may be required to operate in flight or in an emergency. This includes all aircraft doors, fire extinguisher, communications equipment, oxygen equipment, and electrical outlets. In addition, the crew must be familiar with emergency shutdown procedures. Finally, before takeoff, door security must be confirmed by a crew member familiar with the operation of the door.

Box 27-5. HELICOPTER SAFETY

DO:

Approach and depart downhill.

Use crouched position.

Approach after visual contact and approval from pilot.

Await direction of flight crew.

Approach from the front or the sides.

Secure area first of people and then of loose debris.

DON'T:

Approach or depart uphill.

Use tall intravenous poles or other objects.

Use loose sheets or clothing.

Smoke tobacco within 50 feet.

Run near the aircraft.

Drive a vehicle within 30 feet.

Shine headlights or flashlights toward the aircraft.

In-Flight Obstacle Reporting.

An extra pair of eyes can be invaluable to a pilot in a busy airspace or on a scene approach complicated by trees and electrical or phone wires. Primarily important in VFR conditions, assistance with obstacle identification can enhance the safety of the mission;

however, flight should not occur under conditions in which obstacle reporting by a crew member is essential to safety, since the person must then divide attention between patient care and obstacle reporting.

Ground Coordination and Control.

Enthusiastic rescue personnel or curious onlookers may approach the aircraft in a hazardous manner. Flight crew members must be able to communicate with ground units during the landing phase to ensure adequate scene preparation; they may be required to perform crowd control while on the ground. This requires directing individuals away from the rotor blades, propellers, or other hazardous equipment at the scene. If loading or unloading the patient while the rotors or propellers are still turning ("hot loading" or "hot off-loading") is necessary, special precautions must be undertaken for ground crews, the flight crew, and the patient.

Emergency Procedures.

All crew members should memorize and routinely practice emergency procedures.

667

These procedures should address in-flight fires, electrical failures, loss of pressurization, engine failure, emergency landing with and without power, precautionary landing away from an airport, and other in-flight emergencies.

Survival.

An emergency or precautionary landing away from an airport necessitates survival before rescue arrives. Under adverse environmental conditions and with injured victims, survival may depend on specific actions by the crew. The crew should be proficient in emergency egress from the aircraft, including escape after crashes and water landings, especially in helicopters. After water landings, helicopters usually roll inverted and sink rapidly. Helicopter "dunker" training is required for all military helicopter crews. The crews are strapped into a simulated helicopter fuselage and lowered rapidly into a pool, simulating a semicontrolled water landing. The fuselage then rolls inverted and the crew must open emergency exits and egress the simulator. This type of training has been shown to save lives in helicopter water crashes. All crew members should be trained in the use of emergency signaling devices, such as ELTs, flares, signal fires, and ground emergency signals. Survival skills should be taught to all crew members, including advanced first aid, building emergency shelters, fire starting, and obtaining water and food from the environment.

Aeromedical Accidents.

Attention continues to focus on EMS helicopter accidents. Statistics from 1986

estimated a rotor-wing accident rate of 17.65 with 5.88 fatalities per 100,000 transports.^[35] Aviation accident rates are typically reported in relation to flight hours. EMS fatalities therefore amounted to 6.0 per 100,000 flight hours, compared with 3.3 for the helicopter industry in general. The EMS rate subsequently declined, however, with 3.0 accidents per 100,000 transports reported in 1991 ([Figure 27-14](#)).^[74] ^[88]

From 64% to 84% of EMS accidents result from pilot error, approximately 23% from mechanical causes, and 3% from unknown causes.^[19] Of accidents caused by pilot error, adverse weather was a contributing factor in 67% ([Table 27-9](#)).^[17] In all, two thirds of fatal weather-related accidents occur at night, and 86% of all fatal accidents occur at night or in marginal weather conditions ([Table 27-10](#)).^[20] Only 35% to 40% of all EMS helicopter flights occur at night. The most common phase of flight for weather-related accidents was en route (86%), with 14% occurring on departure and none on approach ([Table 27-11](#)).

Only 5% of fatal EMS helicopter accidents occur in flights to or from the scene, although such flights account for 24% of EMS helicopter missions.^[21] When scene-related accidents occur, they result in fatalities 9% and injuries 35% of the time, suggesting a low-energy impact vs. an en route crash. Causal factors related to scene accidents include wire and obstacle strikes (70%),

Figure 27-14 Aeromedical helicopter accident rate, 1972 to 1991. (From Preston N: *J Air Med Transport* 11:14, 1992.)

TABLE 27-9 -- Major and Primary Causes and Severity of Aeromedical Accidents, 1972 to 1989

	PERCENTAGES		
	1972–1985	1987–1988	1989
MAJOR CAUSES			
Weather	30	30	17

Night marginal	10	48
TOTAL	21	100

From Collett HM: Hosp Aviat 5(11):15, 1986.

loss of control (18%), and mechanical failure (12%). The landing phase is involved in scene-related accidents in 41% of cases, whereas the take-off phase is involved in 59%. Because 40% of scene-related accidents occur at night and approximately 40% of helicopter EMS flights occur at night, scene accidents do not appear more hazardous at night than in the day. Single-engine helicopters have more often been involved in engine failure accidents (77%) than have twin-engine craft (the two types are approximately equal in number in the EMS industry).

Recommendations for enhancing safety include instituting stringent guidelines to limit

flights at night or in adverse weather, increasing pilot proficiency training, and reducing pilot fatigue and workload factors. Decisions on the appropriateness of air transport regarding utilization and weather should be based on general protocols that are not subject to the emotional turmoil of a medical crisis.^[10] The trend in the industry has been toward twin-engine helicopters for an increased margin of safety from engine failure accidents.

In addition, for dedicated EMS helicopter flights, a statistically strong relationship exists between the ability to fly under IFR and a lower accident rate.^[56] The Association of Air Medical Services considered the question of whether all helicopters should be required to have IFR capability when it published its voluntary standards for rotor- and fixed-wing aircraft. This was not mandated because of the tremendous expense and because many programs were unlikely to comply.^[58]

Ground to Air Signaling.

It is best to have radio communication between the ground party and the helicopter crew. This may not be possible, however, and hand signals may be needed to communicate. Standard hand signals are used by military rescue personnel for communication between a deployed rescue swimmer and the helicopter ([Table 27-12](#)). These same signals can be used while on land. To acknowledge the signals, the hoist operator gives a thumbs up or the pilot flashes the rotating beacon.

TABLE 27-12 -- Swimmer to Helicopter and Ground to Air Signals

INTENTION	ACTION
Deploy medical kit	Arms above head, wrists crossed
Situation OK	Thumbs up
Lower rescue cable with rescue device attached	Arm extended over head, fist clenched
Lower rescue cable without rescue device attached	Climbing-rope motion with hands
Helicopter move in/out	Wave in/out with both hands
Cease operations	Slashing motion across throat
Deploy litter	Hands cupped, then arms outstretched
Personnel secured, raise cable	Vigorously shake hoist cable or thumb up; vigorous up motion with arm
Team recall	Circle arm over head with fingers skyward

Landing Zone Operations.

The ideal helicopter landing zone is a wide, flat, clear area with no obstacles in the approach or departure end. Vertical landings and take-offs can be done, but it is safer for the helicopter to make a gradual descent while flying forward. Higher altitudes and higher temperatures require larger landing zones. The center of the landing zone can be marked with V, with the apex pointing into the prevailing wind. Any obstacles can be marked with brightly colored, properly secured clothing.

The size of the landing zone depends on the weather conditions, type of helicopter involved, altitude, temperature, and types of obstacles in the area. Small helicopters such as the Jet Ranger can usually land safely in a 60 × 60-foot landing zone. Larger helicopters such as the Bell 412 require a 120 × 120-foot zone.^[95] Large military helicopters may require even greater landing zones. In general, pilots prefer the largest, flattest piece of ground they can find. The condition of the ground (e.g., loose snow, dust, gravel) should be communicated to the pilot before the final approach. Before the helicopter lands, all loose clothing and equipment should be secured. During approach, no personnel or vehicles should move on or near the landing zone.

Once the helicopter is on the ground, it must be approached only from the front and side, and then only while under direct observation of the pilot. The aft portion of the aircraft and areas around the tail rotor must

be avoided at all times. Some helicopters (e.g., BK-117) have rear doors for loading and unloading patients, and ground personnel should wait for directions from the crew before approaching the rear area.

If the ground is uneven or slopes, all personnel should approach and depart from the helicopter on the downslope side. It is safest to load the patient into the helicopter with the engines off and the rotors stopped ("cold load"). If the patient must be loaded with the engines on and blades turning ("hot load"), eye and ear protection should be worn by all personnel approaching the helicopter, including the patient. A safety person should be assigned to prevent anyone from inadvertently walking toward the tail rotor.

Once the patient is loaded, all personnel should leave the landing zone, take cover, and stay in place until the helicopter has departed. It is best to be off to the side, not directly in the take-off path.

Hoist Operations.

If the helicopter is not able to land and has a rescue hoist installed, hoist operations may be the only means of evacuating the patient. In most circumstances a helicopter crew member rides the hoist down to the site to rig the survivor into the rescue device and to

oversee the hoist operation, using the following guidelines:

Do not touch the hoist, rescue device, or cable until after it has touched the ground (or water). Helicopters can build up a very powerful static electricity charge that will be grounded through whatever the hoist touches first. This has been known to knock rescuers and survivors off their feet.

Once the rescue device and cable have touched the ground, put the patient into the rescue device, taking care to keep the hoist cable clear of all personnel. Do not allow the hoist cable to loop around any personnel or around the rescue device, since serious injury is possible when the cable slack is taken up.

Make sure that the patient is properly secured in the rescue device, with all safety straps tightened.

When the patient is secured, move away from the rescue device and signal "up cable."

If the rescue device is a basket (Stokes) litter, use a tag line with a properly installed weak link to prevent the litter from spinning during the hoist.

Night Operations.

Night helicopter rescue operations are considerably more dangerous than daylight operations. In most cases it is best to delay helicopter insertion or extraction operations until daylight. If this is not possible, however, night missions can be done safely with careful planning and coordination between the helicopter and ground party. The same rules of daylight helicopter operations apply to night operations, but with extra care taken to ensure that all personnel understand their roles.

In night operations it is virtually mandatory to have radio communications between the ground and the helicopter. "No-comm" night operations should only be attempted by personnel specially trained and experienced in these techniques. The landing zone should be clearly marked and the pilot allowed to make the approach. All personnel should stay clear of the landing zone until the pilot has made a safe landing.

Personnel approaching the landing zone should have a small light or reflective material attached to their outer clothing so they can be clearly seen. The minimum number of people should approach the helicopter, and a safety observer is mandatory to keep the ground team together and clear of the tail rotor and rotor blades.

The landing zone should be as large as possible, preferably at least 50% larger than a daylight landing zone. Any obstacles should be clearly marked with light-colored streamers, small lights, or even light-colored clothing. The landing zone can be illuminated with flashlights at the corners, with another flashlight at the center point. These flashlights should be pointed at the ground, not into the air; flashlights pointed at the helicopter during landing and take-off may distract or momentarily blind the crew. If flashlights are not available, small fires can be used to illuminate the edges of the

landing zone, although the helicopter can scatter burning embers for many meters.

If crew members are using night vision equipment, lights must never be flashed at the helicopter. Even the amount of white light from a small flashlight may be sufficient to overload the night vision equipment, functionally blinding the crew.

Dispatch and Communications.

The dispatch center is the focal point for communications during aeromedical transport operations. Dispatchers receive incoming requests for service; obtain necessary information relative to the launch decision: coordinate the interaction between essential parties; "scramble" the flight crew; assemble and maintain necessary information regarding destination, weather, local telephone numbers, and frequencies; follow the progress of the flight; input data into the system database; and communicate with ground EMS units and hospitals. Communication may occur through a combination of methods: land telephone lines into a dispatch switchboard, hospital-EMS net transceiver, discrete frequency transceiver (communications with aircraft), or walkie-talkie radios. Familiarity with the EMS system and EMS communications is essential for successful dispatch.

Flight following is an important part of aeromedical safety and involves tracking the position of the aircraft during a mission by plotting the location according to reports from the pilot at 10- to 15 minute intervals. If an accident or in-flight emergency occurs, the dispatcher

is soon aware and can initiate SAR to a precise location, which enhances the chances of survival.

APPROPRIATE USE OF AEROMEDICAL SERVICES

Aeromedical transport combines skilled treatment and stabilization capability with rapid access to definitive care, but not without risk, and at high cost (\$1 to \$2 million per year for a program, or about \$2000 per transported patient, which is approximately 400% higher than ground transport).^[13] However, the comparative risk of aeromedical transport must be placed in perspective against the risk of patient death from nonreferral or from less timely ground transport with limited medical capability en route.

Although not proved, advanced provider skill levels during prehospital care are considered beneficial, especially in severely ill or injured patients.^[49] In rural and wilderness environments, advanced life support (ALS) services may be made more readily available by EMS helicopters. This is especially true in areas that are difficult or impossible to reach by ground.

The speed of access to definitive care is another consideration in choosing the mode of transport. In isolated rural or wilderness locations, a helicopter may be the only means of expedient access. Prolonged victim extrication allows time for a helicopter to arrive at the scene, decreasing total transport time and thereby increasing the advantage of helicopter transport.

Patient comfort also must be considered, especially on long transports over rough roads. Although a helicopter moves in three dimensions, fore and aft acceleration is usually steady, without the starting and stopping motions present during ground transport. However, helicopters typically travel within 914 m (3000 feet) of the ground's surface and are more subject to turbulence than are high-flying fixed-wing aircraft.

Whether aeromedical transport reduces mortality when compared with ground transport has not been determined definitively. An uncontrolled national multicenter study of trauma patients transported by helicopter showed a 21% reduction in mortality from that expected based on predictions from the Trauma Score-Injury Severity Score (TRISS) methodology and national normative trauma outcome data.^[8]

A similar study using the TRISS methodology compared actual mortality with helicopter vs. ground transport and showed a 52% reduction from expected mortality when patients were transported by air, vs. no reduction in expected mortality when transport occurred by ground.^[7] Another study using TRISS methodology found a benefit of aeromedical transport only in patients with severe trauma (a probability of survival less than 90%).^[11]

In 1990 the Association of Air Medical Services (AAMS) issued a position paper on the

appropriate use of emergency air medical services. In 1992 these recommendations were accepted by the California Medicaid provider as reasonable criteria for the use of air medical transport. In a review of 558 consecutive patient transports, 98% had met at least one of the AAMS criteria.^[71]

The risk of aeromedical transport can be placed in perspective if the overall risk of death using ground transport, estimated from the trauma score, is compared with the risk when patients are transported by air. Assuming a reduction in risk of between 21% and 52% when transport is by air, the additional risk of death from crashes (6 per 100,000 transports, or 0.006 per transport) is negligible in comparison to the benefits. This is probably true, however, only for patients with moderate to severe, but nonmortal, injuries (i.e., trauma scores between 5 and 14). Those having minor injuries, with near 100% likelihood of survival, are unlikely to gain additional benefit; those having mortal injuries, with little hope of survival, are unlikely to be saved by any means attempted or employed.

The decision to transport a patient by air requires judgment and a realistic appraisal of the risks. A patient should be transported by air only if he or she is so ill that transport is necessary; if ground transport is unavailable, delayed, or unable to reach the patient; or if aeromedical transport would reduce the risk of death by permitting more rapid access to definitive care, providing greater medical skill en route, or both.

SUMMARY

It has been estimated that since aircraft took to the sky to assist in the emergency transport of sick and injured patients, more than 1 million have been transported over 100 million miles. With a conservative estimate of mortality reduction of even 10%, close to 100,000 patients may owe their lives to the speed and skill provided by aeromedical transport teams.^[47]

Chapter 28 - Wilderness Survival

Warren D. Bowman

This chapter examines the human body's requirements for homeostasis and how they can be satisfied in a wilderness environment where little oxygen, food, or water may be available and where extremes of heat or cold may exist. The requirements are similar whether the individual becomes lost with few resources during a simple day hike or whether injury occurs or severe environmental conditions develop during a well-planned wilderness expedition. Although improvisation and living off the land are mentioned, *anticipation*, *prevention*, and especially *preplanning* are much more important and form the core of this discussion. As an example taken from Antarctic exploration, Roald Amundson's style of thorough preparation and the use of well-tested equipment should be emulated rather than Robert Scott's intuitive and untested approach.^[12]

The outcome of an encounter with severe environmental stress varies with the type, magnitude, and duration of the stress and with the stressed subject's resources. These resources include the state of acclimatization; physical integrity, particularly conditioning and the presence of illness or injury; experience; equipment and the ability to improvise intelligently; and such intangibles as "backcountry common sense" and the will to survive. The recommendations in this chapter are based on personal experience, the opinions of survival experts, research, and analysis of actual survival situations. General principles are emphasized, but "tricks of the trade" may hold the key to life or death. Unfortunately, most of the lay literature emphasizes tales of misfortune, hazardous adventures, and mindless bravado in the face of unnecessary hardships brought on by errors of the participants, while great deeds go unrecorded or forgotten because the experience and competence of the adventurers kept catastrophic, "newsworthy" experiences to a minimum. In the words of Corneille, "To vanquish without risk is to triumph without glory."^[6]

Increased leisure time and growing interest in outdoor activities place more people into settings where survival situations may develop. The cross-country skier, winter mountaineer, and winter camper may be exposed to extremes of cold and storms. The expeditionary mountaineer may explore regions where winter exists year-round and where ambient oxygen is low. The desert traveler may be exposed to extremes of heat

and the tropical traveler to extremes of both heat and humidity. Passengers in aircraft, seacraft, or land vehicles may be stranded in almost any type of environment. A common thread in the development of life- or limb-threatening emergencies is the insistence on traveling during storms and other stressful environmental conditions, when more prudent persons would stay put in a comfortable bivouac. Excuses for this include reaching a predetermined but not essential goal on time so that others will not worry. Physicians who participate in wilderness recreation or treat adventurers need to be aware of the physiologic and psychologic impacts of environmental stress and how related deleterious effects can be prevented and treated.

The knowledgeable traveler should plan for unexpected situations using preventive aspects of survival. This includes being familiar with weather forecasts, strategizing worst-case scenarios, carrying emergency items, avoiding solo travel in isolated areas, and leaving notice of the projected route and expected time of return. With good planning, deteriorating weather or an injury-forced bivouac becomes more of an inconvenience than a life-threatening ordeal. However, chance plays a part in survival. Serious but unforeseen hazards can occur, or environmental stresses can be so severe that survival is impossible regardless of preparations. Anyone who ventures into wilderness must accept the possibility, however remote, of death or serious injury.

For survival the body requires a constant supply of oxygen, a core temperature regulated within relatively narrow limits (about 24° to 42° C [75° to 107° F]), water, food, and self-confidence, faith, and will to live. For comfort and optimum performance, body temperature must be close to normal, and the body must be rested, well nourished, in top physical condition, and free from disease and injury. The most immediate of these requirements are maintenance of body integrity (through accident prevention) and regulation of body temperature. Dehydration, starvation, and exhaustion make temperature maintenance more difficult and interfere with the rational thought and agility required to prevent accidents. Insufficient oxygen becomes a contributing factor at extreme altitude or in such mishaps as suffocation caused by avalanche burial or carbon monoxide (CO) poisoning from cooking in an unventilated shelter. Abundant food and water are of little value to a hypothermic person with insufficient clothing and shelter or to the victim of heatstroke, even though lack of food and water eventually weaken and

kill an otherwise healthy individual. Lack of self-confidence, faith, and the will to live may cause an attitude of panic and defeatism that prevents a person from taking timely survival actions, such as conserving energy, preparing shelter, or lighting a fire. Poor physical conditioning or the presence of illness or injury may interfere with the body's ability to produce heat by shivering or to lose heat by sweating and increasing skin perfusion, which can hamper wood gathering, shelter building, and other necessary actions.^[4]

The most important organ for survival is the *human brain*, since voluntary actions such as preparedness, regulation of energy expenditure, adjustment of clothing, and seeking

shelter are more important than involuntary mechanisms of adaptation to environmental stress.

OXYGEN

As a human ascends from sea level, the body is subjected to increasing cold, decreasing oxygen, increasing solar radiation, and decreasing atmospheric pressure. For every 305 m (1000 feet) of altitude gain, the ambient temperature drops by about 2.2° C (4° F), the barometric pressure drops by about 20 mm Hg (0.1 mb/m), and the amount of ultraviolet (UV) radiation increases by about 5%. The percentage of oxygen in the atmosphere remains constant, but the partial pressure of oxygen diminishes with altitude so that at 3077 m (10,000 feet) it is only two-thirds that at sea level and at 5488 m (18,000 feet) only half.^[3]

During acute exposure to high altitude the effects of hypoxia initially can cause fatigue, weakness, headache, anorexia, nausea, vomiting, dyspnea on exertion, insomnia, and Cheyne-Stokes respirations (see [Chapter 1](#)). These symptoms are probably present to some degree in everyone who goes rapidly from sea level to 2462 m (8000 feet) or above. The clinical effects of hypoxia are often difficult to distinguish from those of cold, high winds, dehydration, and exhaustion. Serious degrees of acute mountain sickness (AMS) are unusual below 3692 to 4308 m (12,000 to 14,000 feet) but have been reported in trekkers as low as 2308 m (7500 feet). In Yellowstone National Park, mild AMS is not infrequently seen in visitors at just over 1829 m (6000 feet). At any height, oxygen in ambient air may be prevented from reaching the cellular level because of interruption of normal transport pathways, generally by illness or injury. Examples of this in the wilderness include the following^[4] :

1. Insufficient oxygen in inspired air in avalanche burial, near drowning, or living in a poorly ventilated snow cave
2. Upper airway obstruction from a facial injury, blockage by the tongue in an unresponsive patient, or aspiration of foreign material
3. Interference with proper lung function caused by pneumonia, pulmonary edema, pulmonary hemorrhage, pulmonary contusion, atelectasis, hemothorax, pneumothorax, or chest wall injury
4. Circulatory insufficiency caused by myocardial infarction, pericardial tamponade, shock, or pulmonary embolism
5. Interference with ventilatory control after injury to the respiratory center or hyperviscosity-induced cerebral infarction
6. Interference with the oxygen-carrying capacity of the blood from anemia or CO poisoning

The emergency and definitive treatments of such conditions follow standard techniques detailed elsewhere in this book and include the administration of oxygen, if available. CO poisoning is probably a greater hazard than is generally appreciated. Many famous polar explorers, including Byrd, Andree, and Stefansson, were killed by or had narrow

escapes from the effects of stoves operated in tightly enclosed living areas.^[20]

REGULATION OF BODY TEMPERATURE

Humans are called *homeotherms* because as warm-blooded animals they maintain a body temperature that varies within very narrow limits despite changes in environmental temperature. In *poikilotherms*, or coldblooded animals, body temperature varies with that of the environment. Homeothermy is necessary to support the enzyme systems of the human body, which function best at 37° to 37.5° C (98.6° to 100° F). The human body can be viewed as a heat-generating and heat-dissipating machine where internal temperature is the net result of opposing mechanisms that tend to increase or decrease body heat production, increase or decrease body heat loss, and increase or decrease addition of heat from the outside. Through these mechanisms the internal body temperature usually can be regulated successfully despite ambient temperatures that vary more than 55° C (100° F) from the coldest to the hottest seasons in temperate climates.

Basal body heat production occurs at about 50 kcal/m² /hr. This can be increased by muscular activity (involuntary [shivering] and voluntary), eating, inflammation and infection (fever), and in response to cold exposure. Shivering can increase heat production up to 5 times the basal rate and vigorous exercise up to 10 times. Cold exposure increases hunger, the secretion of epinephrine, norepinephrine, and thyroxine, and semiconscious activity such as foot stamping and dancing in place. Eating provides not only needed calories but also the temporary increase in basal metabolic rate that occurs during digestion alone (specific dynamic action, or SDA). The SDA of protein is five to seven times higher than that of fat and carbohydrate and lasts longer. However, the onset of the SDA is much faster with carbohydrate than with protein or fat. Therefore the person who is cold inside a sleeping bag at bedtime should eat carbohydrate, and to stay warm all night, protein.

675

Figure 28-1 Line chart showing windchill and state of comfort under varying conditions of temperature and wind velocity. The numbers along the left margin of the diagonal center

block refer to the windchill factor, that is, that rate of cooling in kilocalories per square meter per hour of an unclad, inactive body exposed to specific temperatures and wind velocities. Windchill factors above 1400 are most hazardous.

In hot weather, body heat production can be decreased by slowing muscular activity and avoiding foods with a high SDA.

In cold weather, heat can be added to the body by close exposure to a fire or other heat source, such as sunlight, and by ingesting hot food and drink. In hot weather, external heat addition can be decreased by staying in the shade, wearing clothing that blocks the sun's rays, and avoiding hot objects and hot food and drink.

The body loses heat to the environment by conduction, convection, evaporation, radiation, and respiration. It may gain heat from the environment by the same mechanisms (except for evaporation). The relative importance of these mechanisms depends on temperature, humidity, wind velocity, cloud cover, insulation, contact with hot or cold objects, sweating, and muscular exercise. With a resting body in still air at 21° C (70° F), radiation, conduction, and convection account for 70% of total heat loss, evaporation for 27%, and urination, defecation, and respiration for only 3%. During work, however, evaporation may account for up to 85% of heat loss.^[4]

It is useful to think of the body as composed of a core (heart, lungs, liver, adrenal glands, central nervous system, and other vital organs) and a shell (skin, muscles, and extremities). Most of the adjustments in response to cold or heat exposure occur in the shell. They are designed to maintain a relatively constant core temperature; in below-freezing weather, these adjustments may predispose parts of the shell to frostbite and other types of localized cold injury.

The importance of avoiding travel and seeking shelter during storms and extreme cold cannot be overemphasized. The additive chilling effect of wind when added to cold is impressive. Windchill charts ([Figure 28-1](#)) show the relationship between actual temperature,

TABLE 28-1 -- Fiber Characteristics of Natural and Synthetic Fibers

FABRIC	SPECIFIC GRAVITY* (RATIO TO WATER)	THERMAL CONDUCTANCE‡ (cal/m²)	EVAPORATIVE ABILITY‡	WICKING ABILITY	MOISTURE REGAIN§
Wool	1.32	2.1	Low	Moderate	17
Cotton	1.54	6.1	Low	High	7.9

Nylon	1.14	2.4	High	Low	4
Polyester	1.38	2.4	High	Low	1
Acrylic	1.15	2.4	High	High	1
Polypropylene	0.91	1.2	High	High	5

Modified from Davis AK: Nordic skiing—a scientific approach, Minneapolis, 1980, University of Minnesota.

*The lower the specific gravity, the better the insulating ability.

†The lower the thermal conductance, the slower the flow of heat from the body.

‡The higher the evaporative ability, the shorter the amount of time a fiber will be wet, that is, in a reduced insulative state.

§Moisture regain is the amount of moisture a fiber can absorb before feeling wet.

wind velocity, and "effective" temperature at the body surface. "Windchill" refers to the *rate* of cooling; the actual temperature reached is no lower than it would be if wind were absent (unless evaporation of liquid is occurring from the body surface). The increase in heat loss as the wind rises is not linear; rather, it is roughly proportional to the *square root* of the wind speed.

At moderate ambient temperatures the body's core temperature is kept stable by constant small adjustments in metabolic rate, muscular activity, sweating, and skin circulation. When the body is chilled, automatic and semiautomatic mechanisms increase internal heat production by slightly increasing the metabolic rate, by shivering, and by semiconscious activities (e.g., foot stamping) and reduce heat loss by diminishing sweat production and shell circulation. The person has a strong urge to curl up in a ball, thereby reducing the body's surface area. At the same time the brain tells the body to decrease heat loss by adding insulation and wind protection, to seek shelter, and to increase heat gain by increasing muscular activity, building a fire, seeking sunlight, and eating.^[4]

When the body overheats, these actions are reversed. The body increases heat loss by increasing circulation to the skin and extremities and increasing sweating. These mechanisms require more water, which stimulates the thirst response. Heat production is decreased because of a feeling of sluggishness and languor, leading to a reduction in physical activity and in the amount of heat produced by muscles. The brain tells the body to decrease heat gain and increase heat loss by providing shelter from the sun, removing clothing, and fanning oneself.

COLD WEATHER SURVIVAL

Body temperature in a cold environment is maintained by decreasing heat loss, increasing internal body heat production, and adding heat from the outside. The most efficient of these methods is conservation of body heat by decreasing heat loss, generally by using clothing and shelter.

Decreasing Heat Loss

Heat loss from conduction and convection can be prevented by interposing substances of low thermal conductivity, such as clothing made of good insulating materials, between the body and outside air. Clothing creates a microclimate of warmed, still air next to the skin surface. Clothing's value depends on how well it traps air, the thickness of the air layer, and whether these qualities are reduced by wetting ([Table 28-1](#)). Traditional insulating materials are wool, down, foam, and older synthetics such as Orlon, Dacron, and polyester. Wool retains warmth when wet because of moderately low wicking action and a unique ability to suspend water vapor within its fibers without affecting its low thermal conductance. It can absorb a considerable amount of water without feeling wet but is heavier than synthetics, itchy, and more difficult to dry. Its toughness and durability, however, make it a good choice for garments subject to hard wear, such as trousers, mittens, and socks. Cotton, particularly denim and corduroy, is a poor insulator. It dries slowly because of low evaporative ability; high thermal conductance is further increased by wetting. Cotton has no place in the backcountry in cold weather.

Orlon, acrylic, and polyester were developed to duplicate the properties of wool without wool's higher cost. They traditionally have been used in hats, sweaters, and long underwear. They are almost as warm and not as itchy as wool, and they evaporate moisture better. A number of newer fabrics are woven from fibers that have lower thermal conductance, greater insulating ability, and better wicking action

than traditional fibers. Examples include polypropylene and treated polyesters, such as Capilene, Thermax, and Thermastat. Polyester is also made into pile and fleece, which are light, dry easily, trap air well, and stay warm when wet because the fibers do not absorb water. Examples are Polartec, Borglite, Polarplus, and Synchronia. Fibers used as fillers in quilted garments include hollow synthetic fibers designed on the principle of reindeer hair, such as Hollofil II and Quallofil. Microfibers that provide good insulating ability with less bulk include Thinsulate, Thermoloft, and Thermolite. One of the newest

microfibers, Microloft, is supposed to be warmer than down at the same weight. New synthetics come on the market frequently—consult trade journals and "gear" issues of outdoor magazines.

The "layer principle" of clothing is effective in preventing overheating and chilling. Multiple layers of clothing provide multiple layers of microclimate. Layers are added as necessary to prevent chilling or subtracted to prevent excessive perspiration. Since water conducts heat 25 to 32 times faster than air at the same temperature, clothing wetted by perspiration or water may cause rapid heat loss from conduction and evaporation. The need to add or subtract layers should be anticipated before chilling or heavy perspiring occur.

Clothing should be easily adjustable, sweaters should be of the zipper or cardigan type, and outer layers should be cut full enough to allow expansion of inner layers to their full thicknesses. Zippers in the axillary and lateral thigh areas are useful for ventilation.

Loss of heat from convection can be prevented by wearing windproof outer garments of nylon, tightly woven cotton-nylon blends, or water-resistant laminates such as Gore-Tex. Typical examples include a parka with hood and a pair of windproof pants (regular or bib style) or ski warm-up pants.

The loss of heat from infrared radiation can also be prevented by insulation, emphasizing proper covering for body parts with a large surface area/volume ratio. The uncovered head can dissipate up to 70% of total body heat production at an ambient temperature of -16°C (5°F), partly because the body does not reduce blood supply to the head and neck as it does to the extremities in cold weather. High heat loss through radiation during cold nights can be decreased by sleeping in a tent or under a tarp instead of in the open. Coverage for the head, ears, hands, and feet should not restrict circulation. Developed initially for skiers, the "neck warmer," or "neck gaiter," can be pulled up over the back of the head to form a hood or up over the lower face to form a mask.

Heat loss from the respiratory tract can be diminished by avoiding overexertion and overheating with excessively heavy breathing. When it is extremely cold, inspired air can be warmed by pulling the parka hood out in front of the face to form a "frost tunnel."

Heat loss from conduction occurs by direct contact with a colder object. Sitting on a pack, foam pad, log, or other object of lower heat conductivity is preferable to sitting in the snow or on a cold rock. At low temperatures, bare skin freezes to metal. This can be avoided by wearing light gloves when handling metal objects. Gasoline or other liquids with freezing points lower than that of water can cause frostbite if accidentally poured on the skin at low temperatures. During bivouacs in snow shelters, contact with the snow can be avoided by using a foam pad or improvising a mattress of evergreen boughs, grass, or dry leaves. In cold or windy weather an injured person needs windproof insulating material under as well as over and around the body.

Heat loss from conduction and evaporation can be lessened by avoiding wetting and by changing to dry clothes or drying out quickly when wet. Ideally, outer clothing should be

windproof, should not collect snow, and should shed water but not be waterproof, since waterproof garments prevent evaporation of sweat. Newer fabrics, such as Gore-Tex, are suited for this and for outermost layers.

Dressing for Cold Weather

Anyone who ventures outdoors in cold weather should have enough clothing, either on the body or in the backpack, for the most extreme environmental conditions likely to be experienced.

First Layer

LONG UNDERWEAR.

Wool is still an excellent choice for long underwear but is expensive and may be difficult to find. Merino wool is less itchy. Polypropylene, acrylic, and the newer polyesters may be preferable because of their lower cost, good insulating ability, and good evaporative ability (see [Table 28-1](#)). Again, fabrics containing cotton should be avoided. Synthetics tend to retain body odor more than wool after washing.

SOCKS.

One or two pairs of moderate to heavy wool or wool/nylon blend socks are excellent, preferably with an additional pair of light polypropylene socks worn underneath next to the skin. At least one spare pair of the wool socks should be carried.

THIN GLOVES (GLOVE LINERS).

Light polypropylene, wool, silk, or fingerless wool or pile gloves are useful for moderately cold conditions or when finger dexterity is required, as in adjusting ski bindings. Polyester/Lycra gloves provide a tighter but more stretchable fit to enhance fine finger movements.

Second Layer

SHIRT.

Shirts should be made of light, soft wool or a suitable synthetic such as acrylic and should have long

sleeves. Large breast pockets with buttons or Velcro are handy to carry items such as sunglasses and a compass. Shirts should open completely in front or at least have a

half-zipper. A turtleneck feature protects the neck, as do neck warmers and mufflers, which can be pulled up to protect the lower face.

PANTS.

Wool or pile pants are best and should have pockets that are easily accessible for hand warming. Pile pants should have reinforcements at the knees and buttocks and a zipper or Velcro fly for males. Full or partial lateral leg zippers are convenient.

FOOT GEAR.

The type of boot chosen depends on the type of activity and the expected environmental temperatures. For moderate temperatures, sturdy leather climbing boots made of full-thickness leather, 6 to 8 inches in height with rubber lug soles and roomy enough to accommodate the desired numbers of socks, are ideal. Boots made of leather and fabric such as Gore-Tex are lighter and suited for trail hiking but are not as durable for rough terrain.

Boots must be long enough so that the toes do not strike the front of the boot during downhill walking. They should be laced firmly enough that the heel does not move up and down, but not so tightly that circulation is restricted and the toes cannot be wiggled easily.

For colder temperatures, double boots are preferable. These can be all-leather boots or can have outer shells of plastic or nylon with inner boots of felt or foam. All-leather versions are becoming difficult to obtain. The Canadian type of shoe-pak (e.g., Sorel) with a removable inner felt liner is a good choice for light snowshoeing and other nontechnical outdoor activities in the cold. Special double ski boots are available for ski touring, Telemark skiing, and ski mountaineering, depending on whether three-pin or mountaineering ski bindings are used.

HAT.

Hats should be of the stocking variety, made of wool, pile, Orlon, polypropylene, or wool-polypropylene, and large enough to cover the ears. A small bill feature is desirable to shade the eyes. "Bomber" caps with bills and pull-down earflaps and "Andean" caps with ear coverings are popular. Some arrangement should be provided to protect the face from cold wind, as with a balaclava configuration or a separate face mask. A useful combination is a ski hat with a neck warmer that can be pulled up to cover most of the lower face.

Third Layer

PARKA.

The parka can be a standard ski or mountain parka filled with down, Dacron, Quallofil,

Thinsulate, or other lofting material. A more versatile combination is two separate garments: a pile jacket plus a Gore-Tex shell. For snow camping a pile jacket with a thin outer layer of nylon (three-season, squall, or warm-up jacket) may be preferred because, unlike an uncovered pile jacket, it does not collect snow when worn without the shell. The shell should have a hood with a drawstring, a two-way zipper with an overlying weather flap closed with snaps or Velcro, a cloth flap to protect the chin from the metal zipper pull, armpit and/or lateral chest zippers for ventilation, and at least four outer pockets plus one or two inside pockets to contain frequently needed items (e.g., gloves, compass, map, sunglasses, neck warmer). Outer pockets should be located where they can be reached while wearing a backpack with a fastened waist belt. The shell should be fingertip length unless bibs are worn.

Pockets with horizontal openings may close with Velcro, but those with vertical openings should close with zippers. Because the parka is anchored by the shoulders, when using one hand it is generally easier to pull a vertical zipper down than up. In some brands of parkas, vertical zippers are pulled *down* to close the pockets; in other brands they are pulled *up*. I prefer the *down* type because the danger of losing pocket contents from difficulty closing a zipper is worse than any delay from difficulty opening a zipper.

For ventilation, there should be zippered openings at the armpits. These should be large enough so the parka can be converted into a vestlike garment during warm conditions by inserting the wearer's arms through the openings and tucking the sleeves inside the parka. Since these zippers usually perform more easily when pulled from the distal to the proximal direction, this direction should close them, since increasing wind protection is usually more urgent than decreasing it (freezing is more dangerous than sweating).

WIND PANTS.

These should be light and water repellent; Gore-Tex is a good choice. Long, zippered side openings are useful to permit donning pants without removing boots, as well as for ventilation and access to inner pants pockets.

HAND GEAR.

One of the more serious and still unsolved cold weather problems is how to keep fingers warm while leaving them unhampered enough to do work. Mittens are warmer than gloves since fingers that touch each other warm each other, but even thin mittens do not allow delicate finger movements. An important part of the cold finger solution is to prevent core cooling and compensatory extremity vasoconstriction by addressing core temperature stabilization through exercise, eating, and wearing enough layers on the trunk.

A common strategy is to wear a pair of thin gloves of polypropylene, silk, thin wool, or polyester-Lycra inside a wool or pile mitten covered with a windproof and water-resistant

glove shell. For delicate finger work, the gloved hand is removed from the mitten, the work done as fast as possible, and the hand returned to the mitten. However, since insulating materials insulate in both directions, when inside a warm mitten, cold fingers wearing gloves will not rewarm as fast as cold, bare fingers. Therefore another solution is to use bare fingers, which will perform faster than gloved fingers, returning them to warm mittens periodically until the task is done. This is not practical, however, when working with metal in very cold weather. Another approach is to keep a pair of gloves warm in a pocket and put them on after removing the hands from mittens. Polyester-Lycra gloves are easier to don than many other types of thin gloves.

Excellent three-layer mitten sets include windproof shells with leather palms and two sets of removable pile mittens, at least one of which is fastened with Velcro. Another good system is a thin glove liner inside a heavy wool (Dachstein, ragg, or wool-polypropylene) mitten inside a Gore-Tex shell. An option that gives more finger dexterity in moderately cold conditions is a polypropylene glove liner inside a fingerless wool glove inside a shell. However, more layers result in more difficulty working with the hands. Shells should have easily accessible "nose warmers" of pile or mouton on the backs, should be long enough to cover the wrists, and should have palms of soft leather or sticky fabric for securely holding ice axes and ski poles.

GAITERS AND OVERBOOTS.

Gaiters, which are long nylon tubes that cover the lower leg and upper part of the boot, are designed to keep snow, sand, and gravel out of boots and socks. They extend upward to just below the knee, open at the side or in front with a zipper or Velcro, and have a strap that fits under the boot sole to keep them snug on the boots and a drawstring at the top to hold them up. Gaiters with a front opening closed by a wide Velcro strap are easiest to don and doff. Shorter versions that extend to just above the ankle are adequate for summer mountaineering and may be preferable for cross-country skiers who need access for tightening boot buckles before descents.

High-altitude mountaineering requires special insulated overboots or lined gaiters.

Fourth Layer.

The previous three layers are usually worn on the body. A fourth layer should be easily available in the pack. This should include quilted or pile pants and jacket (or vest).

RAIN GEAR.

In moderate climates or in spring conditions when rain and wet snow may be encountered, outer garments of Gore-Tex or similar material should be used. For maritime climates and during seasons of heavy rain, it may be better to have two separate sets of outer garments: a light, thin, windproof nylon jacket and pants and a waterproof (coated nylon) jacket and pants.

Vapor Barrier Systems.

Waterproof garments and sleeping bag liners close to the skin can prevent saturation of outer clothing and sleeping bags with sweat and the resulting reduction in insulating value. Sweating is reduced, and body water requirements are decreased. Vapor barriers seem to work better in very cold weather than at moderate temperatures. A light garment of polypropylene or similar material should be worn next to the skin, with the waterproof garment over this. Persons with hyperhidrosis and those who dislike clammy skin may object to a vapor barrier system.

Shelter

Everyone who spends time in the wilderness should practice the construction of several types of emergency survival shelters. The function of a shelter is to provide an extension of the microclimate of still, warm air furnished by clothing and to contain heat generated by the body, a fire, or other heat source. A properly designed shelter should permit easy and rapid construction with simple tools and should give good protection from wind, rain, and snowfall. The type and size of shelter depend on the presence or absence of snow and its depth, on natural features of the landscape, and on whether firewood or a stove and fuel are available. If external heat cannot be provided, a shelter must be small and windproof to preserve body heat.

Small trees, branches, thick grass, leaf piles, small caves, and snow holes under downed trees or dense evergreens can be used. If possible, a shelter should be constructed in the timber to provide protection from the wind and access to firewood. Generally, shelters partway up the side of a ridge are warmer than those in a valley, since cold air tends to collect in valleys and basins during the night. Exposed, windy ridges above the timberline are cold. Areas exposed to flooding (drainages, dry river beds), rockfalls, or avalanches and under dead trees or limbs should be avoided. If open water is available, the camp may be located nearby, although in nonsurvival conditions, camps should be at least 200 feet from bodies of water. To avoid drifting snow, tents and shelters should be located with the entrance at right angles to the prevailing winds.

TABLE 28-2 -- Thermal Conductivity of Various Substances

SUBSTANCE	CONDUCTIVITY*	TEMPERATURE MEASURED (° C)
Air	0.006	0
Down	0.01	20
Polyester (hollow)	0.016	

Polyester (solid)	0.019	
Snow (old)	0.115	0
Cork	0.128	30
Sawdust	0.14	30
Wool felt	0.149	40
Cardboard	0.5	20
Wood	0.8	20
Dry sand	0.93	20
Water	1.4	12
Brick	1.5	20
Concrete	2.2	20
Ice	5.7	0

*Conductivity is the quantity of heat in gram calories transmitted per second through a plate of material 1 cm thick and 1 cm² in area when the temperature difference between the sides of the plate is 1° C.

Figure 28-2 Natural shelter.

Snow is a good insulator ([Table 28-2](#)). Its heat conductivity is 1/10,000 that of copper and somewhat better than wool felt, so snow shelters may be warmer than other types of constructed shelters as long as the inhabitants remain dry. Contact with the snow or cold ground is avoided by using a foam pad, dry leaves, grass, or (in survival conditions only) a bed of evergreen boughs.

Natural Shelters.

Caves and alcoves under overhangs are good shelters and can be improved by building wind walls with rocks, snow blocks, or brush. A fire should be built in such a way that heat reflects onto the occupant. The fire should be 5 to 6 feet from the back of the shelter, with a reflector wall of logs or stones on the opposite side of the fire; the occupant should sit between the fire and the back of the shelter ([Figure 28-2](#)).

In deep snow, large fallen logs and bent-over evergreens frequently have hollows under

them that can be used as small caves. Cone-shaped depressions around the trunks of evergreens ("tree wells") can be improved by digging them out and roofing them over with evergreen branches or a tarp. A fire built to one side of such a shelter will reflect its heat off the snow toward the occupant. Ventilation must be adequate,

681

and the fire should not be positioned under snow-laden branches.

Constructed Shelters.

When no snow is available, shelters can be built of small trees, branches, brush, and boughs. A tarp can be rigged into a lean-to shelter. In cold weather the most satisfactory form is a lean-to with two sides closed with brush, a fire at the open front, and a wall of logs or stones on the far side of the fire to reflect heat into the lean-to's interior ([Figure 28-3](#)). Walls or roofs of brush, branches, or broad leaves should be thatched (i.e., each layer should overlap the one below it).

Snow Shelters.

If snow shelters become too warm, the walls will be wet and the roof will drip. A useful rule of thumb is that persons inside a snow shelter should be able to see their breath at all times.^[24]

SNOW TRENCHES.

A snow trench is the easiest and quickest survival snow shelter and the one least likely to make the diggers wet. It can be dug in most areas that are flat or on slight to moderate inclines as long as the snow is 3 feet or deeper or can be piled to that depth. A 4 × 6-foot trench can be dug in 20 minutes, one end roofed over with a tarp or boughs, and a fire built at the opposite end ([Figure 28-4](#)).

If a large tarp and a stove are available, a trench can be dug that is as comfortable as a snow cave and will hold two or three people. The object is to keep the maximal amount of snow around and over the trench. The trench is dug as narrow as possible at the surface while still providing sufficient room to shovel; a suitable size for the top is 4 feet wide and 8 feet long. It is undercut at the back and sides so that the bottom is 6 to 7 feet wide and 9 to 10 feet long ([Figure 28-5](#)). A narrow entrance

Figure 28-3 Lean-to shelter. Sides should be closed with brush or snow and a fire

built in front.

helps contain heat and can be closed with a small plastic sheet or a pack. Four or more skis or small tree trunks are laid from side to side over the top of the trench, with ski poles or branches interwoven at right angles. A tarp is then laid on top of these and snow piled around its edges to hold it down. In very cold weather the entire tarp can be covered by a layer of snow; at least 8 inches is needed for proper insulation. When the entrance is closed, a small stove and the occupants' body heat will raise the interior temperature to -4° to -1° C (25° to 30° F). Higher temperatures should be avoided so that clothing and bedding will not become wet from melting snow.

Above the timberline in deep, wind-packed snow, a similar trench can be roofed with snow blocks that are laid horizontally, set as an A-frame, or laid on skis ([Figure 28-6](#)). Chinks between the blocks are caulked with snow.

SNOW CAVES.

Although a small snow cave large enough for one person can be dug with a ski or cooking pot, it is much better to have a shovel. Two shovels are best: a medium-sized general-purpose aluminum scoop

Figure 28-4 Emergency snow trench. **A**, Pit is dug and overlaid with skis and poles. **B**, Tarp is placed over the skis and secured with snow and heavy objects.

682

Figure 28-5 **A**, Three-person snow trench. **B**, Completed trench the morning after a heavy snowfall.

shovel and a small, straight shovel (French type) to use while excavating the interior of

the cave. The site is a large snow drift such as found on the lee side of a small hill. Areas in avalanche zones are avoided (see [Chapter 2](#)). The entrance is dug just large enough to crawl through and is angled upward toward the sleeping chamber ([Figure 28-7, A](#)), which should be large enough for a stove and two occupants lying side by side. After the entrance is dug with the scoop shovel, the digger crawls inside, lies supine, and uses the straight shovel to excavate the chamber until room is sufficient to move around and use the larger scoop shovel. A ventilation hole as large as a ski pole basket is cut in the roof over the cooking area. A cave large enough for two persons takes several hours to dig. Pine branches or other natural material are used to cover the floor if a sleeping pad is not available. Since the diggers tend to become wet, water-resistant or waterproof jackets

683

Figure 28-6 A, Above-timberline snow trench. **B**, Completed snow trench the morning after a heavy snowfall.

and pants should be worn. A faster method is to excavate a large entrance so there is more room to dig, then partly fill in the entrance hole with snow blocks cut with a shovel or snow saw ([Figure 28-7, B and C](#)).

SNOW DOMES.

When the ground is flat or the snow cover is shallow, snow can be piled into a large dome 6 to 7 feet high and left to harden for a few hours ([Figure 28-8](#)). A low entrance is dug on one side, and from there the interior is carved out to make a dome-shaped room large enough to sleep three people. A ventilation hole is cut in the roof over the stove.

IGLOOS.

Igloos are the most comfortable arctic shelters but require time, experience, and some engineering skill. They are not recommended for the novice but may be worth the effort if the party will be stranded for any length of time. Igloos require one or ideally two

684

Figure 28-7 A, Snow cave entrance. B, Snow cave partly closed with snow blocks. C, Interior of snow cave.

snow saws and snow of the proper consistency. Windblown snow in a treeless area is best; otherwise a large area of snow can be stamped well and left to harden over several hours. To mark the diameter of the igloo, a ski pole is held by the handle and the body turned so that the pole basket makes a large circle. This will outline the

Figure 28-8 A, Preparing a snow dome. B, Completed snow dome.

base of an igloo suitable for three people. Cutting some of the snow blocks from inside this circle will lower the floor so that fewer blocks are required for the dome.

At least two persons are needed, one to cut and carry the blocks and the other inside the igloo to lay the blocks. The blocks should be about 18 inches wide, 30 inches long, and 8 inches thick. They are laid in a circle leaning in about 20 to 30 degrees toward the center of the igloo, with the sides trimmed for a snug fit. The tops of the first few blocks in the first circle are beveled so that a continuous line of blocks is laid, with the first few blocks of each succeeding circle cocked upward ([Figure 28-9](#)). A common error is not to lean the blocks inward enough, resulting in an open tower instead of a dome. Gaps are caulked with snow. The dome should be 5 to 6 feet high inside and can be closed with a single capstone of snow. The entrance is dug as a tunnel under rather than through the edge of the igloo, preventing warm air from escaping.

Tents and Bivouac Sacs.

Tents are generally comfortable and dry but in very cold weather are not as warm as snow shelters. They are preferable to snow shelters at mild temperatures, during damp snow conditions at temperatures above freezing, or when the snow cover is minimal. Bivouac sacs are carried by climbers on

Figure 28-9 A to C, Stages of igloo construction. D, Building an igloo, southeast ridge of Mt. Foraker. E, Double igloo for a party of five.

long alpine-style climbs or for emergencies. They are usually made of Gore-Tex or waterproof fabric and hold one or two persons. Many modern packs have extensions, so when used with a cagoule or anorak (roomy, knee-length, hooded pullover garment), they form an acceptable bivouac sac.

Increasing Internal Body Heat Production

Internal body heat production can be increased voluntarily by raising the level of muscular activity and by eating. To obtain maximal heat production from exercise, the body should be well fed and in peak physical condition. This is particularly important for persons with sedentary jobs who participate in vigorous outdoor sports and for rescue personnel who may be subject to severe, unplanned, and prolonged physical stress. A suitable physical conditioning program should develop both aerobic and motor fitness. The goal of aerobic exercise is efficient extraction of oxygen from alveolar air. This is best developed by rhythmic endurance exercises such as running, cross-country skiing, cycling, swimming, and using exercise bicycles and Nordic skiing simulators. The most effective activities are those that exercise lower and upper extremities simultaneously. Exercise should be vigorous enough to produce a heart rate of 75% of the age-related maximum ($0.75 \times [220 \text{ minus the participant's age}]$) for at least 15 minutes 4 days a week. Motor fitness, which includes strength, power, balance, agility, and flexibility, is developed by vigorous competitive team sports, selected calisthenics, and weight-lifting exercises.

Providing External Heat: Fire Building

The ability to build a fire under adverse conditions is an essential skill that should be practiced by persons

Figure 28-10 Stages of building a fire. **A**, Select a spot out of the wind. Start by placing tinder, such as small, dry evergreen twigs, in a lean-to fashion against a larger branch. **B**, Add a layer of kindling (larger dry branches and split sticks) over the tinder, being sure that air can reach each piece. **C**, Insert a lighted match, candle, or cigarette lighter into the base of the lean-to. **D** and **E**, Add larger pieces of kindling and fuel (large sticks and pieces of split wood) as the fire catches well. Keep the fire small so that you can get close to it.

who engage in outdoor activities ([Figure 28-10](#)). Necessary equipment includes a sturdy knife, a candle, and waterproof matches. In addition, a tube of chemical fire starter (available in most outdoor stores) is highly recommended, especially for wet climates.

To burn, a fire needs air, but not too much air. The fire site should be out of the wind behind a rock or log or in a snow pit. If the fire is built on bare ground, all flammable material such as moss and grass should be cleaned off by scraping the ground surface down to mineral soil over an area at least 3 feet in diameter. If snow is too deep to be removed down to bare ground, the fire should be built on a platform of green logs.

Building a fire requires three types of combustible material: tinder, kindling, and fuel. *Tinder* is any type of finely divided, high flammable material. It must be dry. Examples include grass and leaves, inner bark of birch trees, shavings from dry sticks, cotton balls, small sticks, and fine grades of steel wool. The most readily available natural material is the small dry twigs found on the lower, dead branches of evergreens. If the outer wood of small branches is wet, it can be shaved off, or the branches can be split lengthwise into several thinner lengths with a sturdy knife to expose the dry core. The tinder is arranged in lean-to form by placing it against a larger branch, smallest sticks on the bottom and larger ones on top, separated just enough so that

687

air can reach each piece. To conserve matches, one match should be used to light a candle or segment of fire starter, which in turn lights the tinder. The flame should be placed under the middle of the lean-to of tinder so that lower, smaller pieces will set fire to higher, larger pieces.

Kindling is larger material, usually larger pieces of dead branches and large branches that have been split lengthwise with a knife. Once the tinder is burning well, these larger pieces of dry wood are added.

Fuel is the largest material, usually branches and sections of dead tree trunks several inches or more in diameter. These should be split if an ax is available. Standing dead

wood is preferable to wood lying on the ground, and wood that has lost its bark to wood with bark, because both will be drier and less rotten than their alternatives. Fuel is added after the kindling is burning well.

Several times more fuel than the predicted need should be collected. When dead branches are gathered, only those that snap loudly when broken off should be selected. If no ax or saw is available, the fire can be built next to a large, downed log, which may catch and burn for several days. Long, dead sections of trees can be shortened by laying them across a fire so that when they burn through, two shorter sections result. Fires generally should be kept small, both to conserve wood and to allow them to be approached more closely. The wood supply should be protected from rain and snow.

A fire can be started without matches by using an automobile cigarette lighter or batteries and steel wool. A "wire" can be made by twisting and pulling out a fine-grade (e.g., 4-0) steel wool. This will catch fire if the ends are touched to the positive and negative terminals of two fresh C or D batteries in tandem. A fire starter can be made by stripping the insulation from the middle of a wire and wrapping the bare portion 7 to 10 times around a dry stick. If the two ends of the wire are touched to the terminals of an automobile battery, the wire will become red hot and the stick will ignite (the wire should be long enough that the flame is not close to the battery, where it could ignite hydrogen gas produced by the battery).

When scraped hard with a file or knife blade, commercial "metal matches" made of magnesium will produce showers of sparks that will ignite tinder such as fine steel wool, cotton, or small dry shavings.

Food

For optimum performance, the human body requires a daily supply of calories, carbohydrate, protein, fat, minerals, and vitamins. Carbohydrates supply calories and are essential for replacement of muscle glycogen. If diet is inadequate, body carbohydrate and fat stores and finally tissue protein will be depleted to provide calories for heat and energy. Carbohydrate in the form of liver and muscle glycogen is used up first, then fat is used at a steady rate until gone. Protein is used rapidly at first, then more slowly, and finally rapidly again just before death. ^[9]

A moderately active 70-kg (154-pound) male normally requires the food equivalent of 2800 kcal/day, but if exercising in cold weather, he may require more than twice this amount. Protein intake should be at least 65 g/day, and carbohydrates should make up 60% to 70% of the diet.

Although most persons in a survival situation worry more about food than anything else, food is usually less important than shelter or water because a person can survive for weeks without food, even in cold weather. Enough water must be available, however, and energy expenditure must be kept to a minimum. Most wilderness parties carry adequate supplies of food; problems arise if food is exhausted, lost, or contaminated. Bare ridges, high mountains above timberline, and dense evergreen forests are difficult places to find wild food, even in summer. Success is more likely on river and stream

banks, on lake shores, in margins of forests, and in natural clearings. Since in most cases the amount of wild food found by an untrained individual will not provide enough calories to replenish the energy expended in searching for it, it is important *always to carry extra food for emergencies*.

The following general rules about wilderness edibles have many exceptions, so no unfamiliar wild food should be eaten except in extreme circumstances (see [Chapter 48](#) and [Chapter 49](#)):

1. All wild foods except fruits and berries should be cooked. This will make them more palatable, more digestible, and safer to eat.
2. Persons who spend time outdoors should know the edible plants and animals of familiar areas. Similar species are often found in similar though unfamiliar areas.
3. Plants to avoid include mushrooms and other fungi, buttercups, plants with umbrella-shaped flowers, wild beans and peas, all unknown berries except blue and black ones, all bulbs except those with an onion odor, and all plants with milky or colored sap or shiny leaves. Compound berries (e.g., raspberries, blackberries, thimbleberries, salmonberries) are safe to eat.
4. No one should eat large quantities of a strange plant food without first tasting it.
 - A. Touch the plant's sap or juice to the inner forearm or tip of the tongue.
 - B. If no ill effects occur, boil plant parts in two 5-minute changes of water. Place 1 teaspoon of the resulting material in the mouth for 5 minutes, and chew but do not swallow it. If a

*References [\[2\]](#) [\[7\]](#) [\[16\]](#) [\[17\]](#) [\[19\]](#) [\[22\]](#) [\[23\]](#) [\[26\]](#) .

- burning, nauseating, or bitter taste results, immediately spit it out. If no unpleasant effect occurs, swallow it and wait 8 hours.
- C. If no ill effects (e.g., nausea, cramps, or diarrhea) occur after 8 hours, eat 2 tablespoons and wait an additional 8 hours.
 - D. If no ill effects occur at the end of this period, consider the plant edible.
5. All land mammals, birds, and birds' eggs can be eaten. The entire carcass, both fat and lean, should be eaten, except for canine, seal, and polar bear livers. Crustaceans below the high-tide mark, mollusks, insects, reptiles, and some amphibians can be eaten. Salamanders and frogs should be skinned; toads should be avoided altogether. Fish, crustaceans, and mollusks should be eaten promptly because they spoil quickly. Fish and meat can be preserved by drying. Black mussels, mollusks with cone-shaped shells, Pacific reef fish, "puffers," fish eggs or entrails, and any fish that looks "ugly" should be avoided (see [Chapter 54](#)). Any fish with an unpleasant odor, pale slimy gills, flabby skin, flesh that remains pitted when pressed on, or sunken eyes should be avoided, as well as all aquatic life during a red tide.
 6. Edible parts of wild plants may include roots, leaves (especially young leaves), stems (usually require peeling), shoots, buds, grass seeds, inner bark (aspen, cottonwood, birch, willow, lodgepole pine, Scotch pine), nuts, and berries (except

as noted in 3).

Figure 28-11 Snare loop. **A**, Simple snare loop. **B**, Locking device for a wire snare loop.

Animal Food.

Mammals and birds can be trapped, snared, or shot. Some, such as spruce hens and porcupines, can be clubbed. Fish can be hooked, speared, or trapped. To secure this type of food, however, the hunter must locate the prey. On land this is done by searching for signs such as trails, droppings, burrows, dens, and bedding areas. Carnivore dung usually contains hair and bone; herbivore dung has indigestible plant parts. Trails lead to feeding and watering places. Successful hunting requires patience, skill at stalking, and knowledge of animal behavior. The best times to hunt are at dawn and dusk as animals are moving to or from their bedding areas.

Small animals can be snared or trapped. Snares should be baited or located on a game trail at a place where the animal has no choice but to enter the snare. This can be a naturally narrow or a prepared area. The mouths of dens and burrows are good places to set snares. Gloves should be worn during snare construction to minimize human scent. Snare loops can be made from any type of bare wire or improvised from strips of green bark, cord, shoelaces, or clothing strips. Light, strong wire such as 28-gauge piano wire is best. A small loop is tied at one end of the wire, and the main loop is made by feeding the other end through the small loop ([Figure 28-11, A](#)). The main loop is adjusted to catch the animal around the neck and to fit the expected size of the prey (e.g., three fingers in width for squirrels, fist sized for rabbits). Snares using loops are effective because the animal almost always lunges forward, tightening the loop around its neck. A locking device should be included to prevent the wire loop from loosening after the animal is trapped ([Figure 28-11, B](#)). Snares should be set at midday when animals are bedded down. The trapper approaches the area at a 90-degree angle to the trail, sets the snare, and backs away, keeping downwind from the animal's expected location and not walking on the game trail. Natural surroundings should be disturbed as little as possible. Snares and traps should be checked twice daily. In general, one animal is caught for every 15 snares set.

Many different types of traps have been invented; most include a trigger arrangement that is baited or located so that it releases when disturbed by the animal's movement. Trigger release allows a counterweight to pin the animal or a bent sapling to straighten and hoist it off the ground ([Figure 28-12](#)).

Figure 28-12 A, Figure-4 deadfall. B, Twitch-up snare.

Figure 28-13 A, Split-shaft fish spear. B, Fish trap.

Birds can be caught with snares or baited fishhooks.

Fish can be taken with hook and line, traps, and spears. Emergency survival kits should contain several hooks and a long length of line. Insects, smaller fish, worms, shellfish, or meat can be used as bait, or lures can be improvised from pieces of brightly colored cloth, feathers, or bits of shiny metal. In open streams the best places to fish are pools below falls and behind rocks. Locating fish is more difficult in the winter, when they retreat into the deep parts of lakes. Holes can be cut in the ice of frozen lakes. The best time to fish is early morning or dusk. An effective fish spear is the split-shaft type ([Figure 28-13, A](#)), which has two toothed jaws held apart by an easily dislodged trigger. A spear works best if it is used to pin a fish against the bottom or bank so the fish can be grasped with the hands before it works loose.

In streams, fish traps can be made by using rocks or vertical willow branches to build an enclosure with a funnel-shaped opening, the narrow end extends

690

well into the enclosure ([Figure 28-13, B](#)). The trap should be located so that the water current drives fish into the wide end of the funnel. Another type of trap can be made by tying the neck and sleeves of a T-shirt closed, placing the shirt with the tail propped open in the water at the downstream end of a pool where fish have been seen, and chasing the fish into the shirt.

Another way to catch large fish (at least 10 inches long) is by "tickling."^[17] ^[23] This involves crawling slowly upstream along a stream bank, feeling underneath the bank and under nearby logs for fish. They are usually found lying still with their heads pointed upstream. If a fish is felt, the person moves the hand slowly forward, grasps the fish at the gills, and flips it onto the bank. Tickling fish and constructing and using fish traps are difficult in winter.

Plant Food.

Edible plants ([Figure 28-14](#)) are common in mountain meadows and even in forests, although considerable energy may be needed to dig up or gather plant material. This is

especially true during the winter months, when gathering roots and berries may require

Figure 28-14 Edible wild plants. **A**, Pine cone. **B**, Acorns. **C**, Wild onion. **D**, Dandelion.

removing snow from large areas and digging in frozen ground. Tender new needles of pines and other conifers are edible, although not very tasty. Pine nuts are found in pine cones, which can be picked from trees. All pine nuts are edible and high in caloric value but are so small in some species that it is impractical to gather them. The gatherer should look for unopened cones, scorch them over a fire, and split them by pounding with a rock. The nuts are removed and roasted. Acorns are another good source of food; they should be boiled for an hour with three changes of water to remove the bitter tannic acid. Cattails and arrowheads can be found in low-lying, marshy areas and lake shores. In spring the sheathed top spike of the cattail can be boiled and eaten and the sprouts eaten raw. Pollen from the blooming flower spike can be used as flour. Although fibrous, the roots contain much starchy material and can be boiled or roasted. Arrowhead tubers are boiled or roasted for 30 minutes and eaten after peeling.

Dandelions, woolly louseworts, wild onions, elk thistle, and bistort can sometimes be found under the snow in mountain meadows. The roots of all these

691

plants are edible and nourishing but should be boiled. Many bulbs are poisonous, however, and only those with an onion odor should be eaten. The young leaves and shoots of ferns can be boiled and eaten, and the leaves of mountain sorrel can be eaten raw. Wild rose hips are edible. Elk thistle stems are edible if peeled and boiled. Young dandelion roots and leaves can be eaten; older ones should be boiled in several changes of water to remove the bitter taste. The inner bark of aspen, cottonwood,

Figure 28-14 E, I, Elk thistle. **F**, Fern. **G**, Arrowhead. **H**, Bistort. **I**, Cattail.

birch, willow, lodgepole pine, and Scotch pine is edible.

Berries, such as huckleberries, raspberries, crowberries, cranberries, bearberries (Kinnikinnick), salmon-berries, and thimbleberries can sometimes be found under or over the snow and are edible ([Figure 28-15](#)).

Certain types of lichen can be eaten. Iceland moss should be boiled for an hour, reindeer moss boiled or roasted, and rock tripe dried and then boiled.

692

Figure 28-15a Edible berries. **A**, Blueberry. **B**, Blackberry. **C**, Cranberry.

Cooking.

As noted, all wild foods except fruits and berries should be cooked. Cooked food is usually more appetizing, easier to chew, more digestible, and safer because cooking destroys microorganisms. Hot food also helps maintain morale.

A large metal container, preferably a pot with a bale (see [Appendix A](#)), is indispensable to heat water and other liquids. Since cooking over a fire will cover the outside with soot, a stuff sack is useful to store the pot. Since it can tip over easily, the pot should not be placed directly on burning wood but on two firm rocks or green logs with fire in between. Rocks from a stream or dry wash should not be placed near a fire, since steam from internal moisture can cause an explosion. A pot can also be hung over the fire on a sturdy green stick, one end of which is supported by a forked stick driven into the ground and the other end anchored by rocks.

Most types of wild food can be cooked successfully by boiling, and the cooking water retains the food's fat and natural juices. This water should be consumed as well.

693

Figure 28-15b D, Crowberry. E, Bearberry. F, Salmonberry.

Meat and fish can be roasted on a spit made from a green tree branch or can be fastened to a flat rock or the flat surface of a split log tipped on edge to face the fire.

Water

Water constitutes about 60% of the body weight of an average young adult male; the value for a female is slightly lower. The percentage of water tends to decrease with age. In a sedentary adult, normal daily water loss includes about 1400 ml of urine, 800 ml through the skin and lungs, and 100 ml in the stool, for a total of 2300 ml daily. Since about 800 ml of water per day is contained in food and 300 ml produced by metabolism, a minimum daily intake of 1200 ml is necessary in a temperate climate at sea level to avoid dehydration.^[9] In a hot dry climate, at high altitude, or with exertion, insensible losses and sweating increase considerably, so fluid intake should be increased proportionally. Monitoring urine output determines whether intake is adequate; 1 to 1.5 L of light-colored urine should be excreted per day. Adding fruit flavors and making hot drinks improve the palatability of water. Electrolyte drinks and salt tablets are generally unnecessary in cold weather, since the electrolytes lost in sweat are easily replaced by a normal diet. When water supplies are limited, overexertion is avoided and sweat "rationed."

Almost all surface water should be considered contaminated by animal or human wastes, with the possible exception of small streams descending from

Figure 28-16 A, Emergency snowshoe. B, Detail of snowshoe binding.

untracked snowfields or high, uninhabited areas. At altitudes below 5488 m (18,000 feet), simply bringing water to a boil will kill *Giardia* cysts and most harmful bacteria and viruses. Water can also be disinfected by filtration or addition of chemicals (see [Chapter 51](#)).

At subfreezing temperatures and in locations above the snow line where liquid water is difficult to find, snow or ice must be melted to obtain water. This requires a metal pot (which should be included in every survival kit), fire-starting equipment, and wood for

fuel. The time and effort required and decreased thirst in cold weather favor development of dehydration under survival conditions.

Whenever open water is encountered, individuals should drink their fill of disinfected water, then top off all canteens. Each evening, enough snow is melted to provide water for supper plus a full canteen, which is placed in the bottom of the sleeping bag to keep it from freezing and is ready for use during the night or for making breakfast in the morning. Before leaving camp in the morning, melted snow provides everyone with at least a full canteen for the day. Melting ice or hard snow is more efficient than melting light, powdery snow. To avoid scorching the pot, the snow is melted slowly, or water is heated in the bottom of the pot before adding snow. On warmer sunny days, snow can be spread on a dark plastic sheet to melt.

Emergency Snow Travel

Travel in deep snow is almost impossible without skis or snowshoes. Even though travel may be unwise for other reasons, wilderness foot travelers in both subarctic and temperate latitudes should know how to improvise snowshoes from natural materials in case they are stranded by a late- or early-season snowstorm. Emergency snowshoes ([Figure 28-16, A](#)) can be made from poles that are 6 feet long, $\frac{3}{4}$ to 1 inch thick at the base, and $\frac{1}{4}$ inch thick at the tip, and sticks $\frac{3}{4}$ inch thick and 10 inches long.^[2] Twelve long poles and 12 short sticks are needed. For each snowshoe, six long poles are placed side by side on the ground, and the middle point of the poles is marked. One short stick is lashed crosswise to the tail (base) of the poles, and three short sticks are lashed side by side just forward of the midpoint of the poles where the toe of the boot will rest. Two sticks are lashed where the heel of the boot will strike the snowshoe. The tips of the six poles are tied together. Each binding ([Figure 28-16, B](#)) is made of a continuous length (about 6 feet) of nylon cord, preferably braided, since it will eventually fray. The midpoint of the cord is positioned at the back of the boot above the bulge of the heel. Each end of the cord is run under the three side-by-side short sticks at the side of the boot, then up and across the boot toe so that it crosses the other end on top of the toe, forming an X. Then each end is looped around the cord running along the opposite side of the boot, and the ends are brought around the back of the boot heel. The cord is pulled tight around the boot, and the ends are tied together at the lateral side of the heel.

On walking the tip of the snowshoe should rise, the boot heel should rise, and the boot sole should remain on the snowshoe.

Snow travelers should avoid stepping close to trees (because of funnel-shaped "tree wells" around tree trunks), large rocks (because of weak snow or moats around them), and overhanging stream banks. The person who falls into a stream or lake should roll repeatedly

in powdery snow to wick the water from clothing, brushing the snow off each time. A fire completes the drying process.^[2]

Stalled or Wrecked Vehicles

Persons stranded in automobiles or downed airplanes can survive using the equipment in the vehicles. Survivors should *stay with the vehicle* rather than go for help, since a vehicle is much more visible to rescuers than is a person. Floor mats and upholstery can be used for insulation, but it is much better to have a vehicle survival kit containing extra clothing and blankets (see [Appendix D](#)).

Automobiles.^[25]

In cold weather, drivers should keep their vehicles in the best possible mechanical condition, using winter-grade oil, the proper amount of radiator antifreeze, deicer fluid for the fuel tank, and windshield antifreeze for the cleaning fluid. Windshield wiper blades that are becoming worn should be replaced. A combination snow brush and ice scraper should be available, and a can of deicer is useful on frozen door locks and wiper blades. Snow tires, preferably studded (illegal in some states), are desirable, but chains should be carried as well. All-wheel drive or four-wheel drive is optimal, and front-wheel drive superior to rear-wheel drive. The battery should be kept charged, the exhaust system free of leaks, and the gas tank full (drive on the upper half of your tank). A cell phone or citizen's band radio is useful. The marooned driver should tie a brightly colored piece of cloth to the antenna and at night should leave the inside dome light on to be seen by snowplow drivers and rescuers (headlights use too much current). If necessary for heat, the motor and heater can be run for 2 minutes each hour (after checking to see if the exhaust pipe is free of snow). To avoid CO poisoning, a downwind window is cracked 1 to 2 inches. Reusable CO detectors are available and can be carried in the survival kit. One or two large candles should be carried to provide heat and light if the gasoline supply runs out. Two candles can raise the interior temperature well above freezing.

Airplanes.

Airplane fuselages are poorly insulated. Unless a stove is available, survivors are usually better off constructing a shelter than can be heated with a fire (as described earlier), outside but near the aircraft. Batteries and cigarette lighters can be used as fire starters. Oil and gasoline can be used as fuel if poured over a container full of dirt or sand.

HOT WEATHER SURVIVAL

Environmental conditions predisposing to serious heat stress can be found in most temperate zone regions during the summer months and in the tropics year-round. The amount of heat stress is proportional to both temperature and relative humidity; thus a tropical jungle environment with a relatively lower temperature and higher humidity can be as dangerous as a drier desert environment with a relatively higher temperature. Serious heat illness occurs when endogenous heat production plus exogenous heat gain forces the core temperature to dangerous levels (more than 40° to 46° C [104° to 105° F]) despite the body's cooling mechanisms. These mechanisms include involuntary cutaneous vasodilation, sweating, and voluntary mechanisms, such as seeking shelter from the sun, avoiding excess insulation and heat-producing physical activity, and replacing lost fluids and electrolytes (see [Chapter 10](#)).

The body adapts better to heat and altitude than to cold. It acclimatizes to heat by increasing the blood volume, dilating skin blood vessels, and improving cardiac efficiency so as to carry more heat from the body core to the shell. The process of acclimatization takes about 10 days, during which the subject starts to perspire at a lower temperature, the volume of perspiration increases, and the perspiration contains fewer electrolytes.

The following discussion emphasizes survival in a desert environment (see also [Chapter 29](#)).

Practical Methods for Adjusting to Hot Weather^[4]

Heat loss by conduction, convection, and radiation can be increased by exposing the maximum amount of skin to the circulating air. This should be done only when in the shade; when in the sun, skin should be completely protected by clothing. Wearing clothing when exposed to hot sun also reduces water loss by reducing sweating. Because heat loss and sweating may be impaired by sunscreens, a good compromise is to cover the face and hands with a sunscreen having a high sun protection factor (SPF) number and to wear a long-sleeved shirt and long trousers of tightly woven, loose-fitting, light-colored (preferably white) cotton. Avoid T-shirts, which have an SPF of only 5 to 9. Special clothing with an SPF of 30 or greater is available (e.g., Solumbra). If desired, ventilation holes can be cut at the axillae and groin. Hydration is maintained by drinking adequate fluids, some of which can contain electrolyte supplements. Optimal hydration maintains blood volume and shell circulation and supports the sweating mechanism. Enough water *must* be carried or be available in the field. Water bottles should be wrapped with clothing to insulate them and buried in the backpack.

The layer principle of clothing is recommended in the desert as well as in cold weather. Layers can be taken off during the heat of the day and added at night when the dry desert air cools rapidly. Since high winds and sandstorms occur frequently in desert areas, a

wind-resistant parka and pants are desirable; since rains occasionally occur as well, the garments should also be water repellent.

Because of its high thermal conductivity, poor insulating ability, and good wicking ability, cotton—which is avoided in cold weather—is the fabric of choice for hot weather clothing. Clothing should be loose to promote air circulation.

Before exposure to prolonged or strenuous hot weather exertion, individuals should allow time for acclimatization.

Heat gain from the environment can be minimized by using clothing to protect the head and body from the direct rays of the sun. A hat with a wide brim or a Foreign Legion-style cap with a neck protector and ventilation holes in the crown is recommended. A neck protector can be improvised from a large bandana by placing it on the head with the point just above the forehead, bringing the two tails around in front of the ears, tying them under the chin, and then replacing the hat.

Travelers should seek shelter during the hottest part of the day. Caves and overhangs can be used, but gulleys and other dry watercourses should be avoided because of the danger of flash floods. A sun shelter can be made by suspending a tarp from brush or cacti or by laying the tarp on a framework of poles. Travelers who become stranded in a vehicle should lie *under* it. Because desert air is much cooler a foot above or a few inches below the ground surface, the desert traveler should lie on a platform or in a scooped-out depression rather than directly on the ground.

Direct contact with the hot ground and other hot objects, particularly hot metal, should be avoided. Sturdy hiking or climbing boots should be worn to protect the feet, not only from the hot ground but also from sharp rocks, the spines of cacti, and snakes. Gaiters should be worn or improvised from strips of cloth to keep sand and insects out of boots and socks. The hands should be protected with leather gloves. Rest periods should be taken in the shade rather than in the direct sun. High-quality sunglasses should be used to protect the eyes; if necessary, sunglasses can be improvised from a piece of cardboard or wood with a narrow slit cut for each eye.

Body heat production can be minimized by avoiding muscular exertion during periods of high heat and humidity. Persons should travel only early in the morning, late in the evening, or at night.

Desert Survival¹

About 20% of the earth's land surface is made up of desert. Desert areas average less than 25.4 cm (10 inches) of rainfall annually. Deserts range from barren sand or gravel plains without a living plant for a hundred miles to areas of grass and thorny bushes that can support camels and goats. Despite lack of moisture, many plants and animals have adapted to the hot, arid environment and are able to thrive in many deserts.

Deserts heat up rapidly during the day, but because of low humidity and the low specific heat of the ground, they cool rapidly at night. Daily temperature ranges may be as great as 55° C (100° F).^[26] These temperature changes produce alternate expansion and contraction of rocks, causing them to break up into smaller and smaller fragments and eventually to form gravel or sand. Lack of rainfall reduces the eroding effect of water, so wind and wind-borne sand are the most important agents of erosion. When the rare rains occur, water tends to run off rather than sink into the ground, and flash floods may occur; dry watercourses (arroyos, wadis, dry washes) are familiar features. Sudden weather changes are common; desert travelers in the fall, winter, and spring should be prepared for cold as well as hot weather. Dust storms and strong solar glare can be hazardous.

Southerly deserts may be hot year-round, whereas northern ones may have four recognizable seasons. Desert temperatures as hot as 134.4°F in the Sahara at Azizia and 134°F in Death Valley, California, have been recorded.^[16] At such temperatures, the ground can become so hot that feet may be burned through shoes, and serious burns can result from touching exposed metal.

Desert plants have developed special characteristics that enable them to conserve water and survive long periods of drought. Some have extensive root systems that quickly absorb rainfall moisture, and others have exceptionally long roots that reach down to the water table. Many plants are dormant during the hottest season; others have thick external coverings that resist evaporative losses. Some are able to store water during wet seasons to allow survival through dry periods. Desert animals forage and hunt during the cool of the evening and night, resting in cool places during the day.

Food.

Natural food is difficult to obtain in true deserts but is less important than water. A survivor can live several weeks without food if water is available. More natural food is available in the deserts of the American Southwest than in Old World deserts, such as the Sahara and Gobi ([Figure 28-17](#)).

No plant with milky juice should be eaten. All cactus fruits are edible, and the leaves of flat-leaved cacti (e.g., prickly pear) can be peeled and eaten, preferably after boiling. Wild cherries, wild celery, wild currants, wild onions, acacia beans, and piñon nuts are found in some areas. Grass seeds and the soft part of grass stalks are edible. Kangaroo rats, jerboas, rabbits, prairie dogs, lizards, tortoises, snakes, and insects, particularly

locusts,

TABLE 28-3 -- Expected Days of Survival at Various Environmental Temperatures and with Varying Amounts of Available Water

(Not Available)

From Adolph et al: Physiology of man, New York, 1947, Interscience.

are all edible. Small mammals and birds can be trapped or snared as described previously. If firearms are available, larger animals such as antelope, deer, foxes, and badgers can be procured and leftover meat dried in the sun.^{[\[16\]](#) [\[22\]](#) [\[23\]](#)} If water is limited, however, it is wise to base the diet on carbohydrate rather than protein, since more water is required to excrete the waste products of protein in the urine.

Water.

There is no substitute for water in the desert, although a person can prolong life in a survival situation by decreasing water loss. Waterholes and oases are rare in deserts. They occasionally may be located by watching the behavior of animals and birds, which travel toward water at dawn and dusk. Animal trails tend to lead to water and may be joined by other trails and become wider as they approach it. Birds may circle before landing at a waterhole, especially in the morning. A pool of water with no animal tracks or droppings may be poisonous. Muddy and dirty water should be filtered through cloth, and all water should be treated chemically or by filtration or boiling before drinking (see [Chapter 51](#)). Persons should not drink urine or water from a vehicle radiator (which contains glycols). Table 28-3 (Table Not Available) shows the expected days of survival

in the desert in relation to the amount of water available.

A useful device for producing potable water is a solar still ([Figure 28-18](#)). The materials needed include a 6 × 6-foot piece of sturdy, clear plastic sheeting (preferably reinforced with duct tape in the center), a shovel, a 6- to 8-foot piece of surgical tubing, a 1-quart plastic bowl, duct tape, and a knife. A cone-shaped hole about 3 ½ feet in diameter and 18 to 20 inches deep should be dug in a low area where water would stand the longest after a rain. With the surgical tubing taped securely to its bottom, the bowl is placed in the center of the hole. The plastic sheet is positioned loosely on top of the hole and weighted with a fist-sized rock in the center so that it sags into a cone whose apex is just above the bowl. Crushed desert vegetation is placed inside the hole to provide additional moisture, preferably barrel and saguaro cactus parts. Unknown or possibly poisonous plants are avoided. Dirt and rocks are piled around the rim on top of the plastic sheet to seal the edges of the hole. Urine can be placed inside the hole in an open container. Contaminated surface water can also be purified inside a solar still, but water from a vehicle radiator should not be used because the glycols will distill along with the water.

The still is not opened once it starts operating. It will produce 1 pint to 1 quart of water per 24 hours without added urine or vegetation and up to 4 quarts with it. The surgical tubing is used to suck water from the bowl periodically as it collects.

If vegetation is plentiful, another type of solar still can be made from a large, clear plastic bag. ^[21] On a slope, a hole several feet in diameter is dug with a craterlike rim surrounded by a moat that drains downhill into a small hole. The bag is centered on the large hole with its edges over the moat and its mouth downhill at the small hole. An upright stick is placed

699

Figure 28-18 Solar still.

inside the bag in the middle and clean rocks along the crater rim inside the bag to keep the bag anchored and ballooned out. Duct tape reinforces the bag where the stick tents it. After the bag is filled with vegetation, its mouth is tied shut. The vegetation should not touch the sides of the bag or spill into the part of the bag that is over the moat. The warmth of the sun causes water to evaporate from the vegetation and condense on the inside of the bag, run down into the part of the bag that is over the moat, run downhill toward the mouth of the bag, and collect in the part of the bag's neck that is in the small hole. Survivors open the mouth of the bag and pour out the water as needed.

NAVIGATION

Even if in a familiar area, backcountry travelers should always carry a compass, map, and altimeter. Prior training and experience in map reading and compass use are necessary.^[13] The best type of compass for the layperson is the Swedish Silva compass, designed to be used in the sport of orienteering. The compass is always followed even if at odds with "gut feelings" about direction. Topographic maps are available at most outdoor stores in both the 7.5- and 15-minute series.

Global positioning system (GPS) units are small, electronic devices that can plot a traveler's position by receiving signals from satellites. Although very useful, especially in poor visibility, they are expensive and battery dependent, require at least three satellites in the unobstructed sky above, and need experience to translate their output into a position on a map.^[5] The backcountry traveler should be expert with map and compass before considering a GPS unit.

Travelers who lose or forget their compass should still be able to find directions (see [Chapter 73](#)). At night, north can be found by identifying the Big Dipper (Northern Hemisphere only) and following the "pointers" (farthest stars on the bowl of the dipper) to the North Star (Polaris), the most distal star in the handle of the Little Dipper, which is located about halfway between the Big Dipper and the W-shaped constellation Cassiopeia. On a sunny day a nondigital watch set to standard time can be used to find direction. When the hour hand is pointed toward the sun, south will be one-half of the shorter of the two distances between the hour hand and 12 o'clock.

WEATHER FORECASTING^[5] ^[11] ^[15] ^[18] ^[27]

Travelers entering the backcountry must check expected weather conditions. Modern weather forecasting, because of radar, satellite technology, and other advanced techniques, is accurate but not infallible. Local and national radio and television networks broadcast local and regional reports hourly. The Weather Channel has multiday forecasts and is also available on the Internet at www.weather.com. The best source of up-to-date local weather information is the National Weather Service, which broadcasts

700

24 hours a day at frequencies from 162.400 to 162.550 MHz on very-high frequency (VHF) FM. Multichannel radios with a weather band receive these frequencies, and inexpensive, lightweight radios receive only these frequencies.

When evaluating avalanche conditions, travelers must know the weather conditions over the previous few days as well. The U.S. Forest Service provides information on avalanche conditions in many mountainous areas, especially in western states (see [Chapter 2](#)).

Since weather information from outside sources is usually impossible to access in a wilderness environment, the wilderness traveler should be able to predict weather to some extent. This requires a knowledge of both local weather patterns and basic meteorology, particularly the significance of cloud patterns, wind directions, barometric pressure changes, and temperature changes. Backcountry weather forecasting is an inexact science, however. In Michael Hodgson's words, "Predictions relative to weather are only educated guesses, never statements of fact. Always be prepared for the worst."^[11]

The major factors that influence weather are solar radiation, the components of the atmosphere (especially water vapor), topography, physical properties of large water bodies and land masses, and the effects of the earth's daily and yearly rotation on the amount of solar radiation that reaches each part of the earth.

The earth's atmosphere is constantly in motion. The primary motion is basically circular, involving vertical upward motion as air is heated at the equator, then horizontal motion of this warm air toward the poles where it cools, descends, and moves back toward the equator to replace heated, upward-moving air. If the earth did not rotate, this circular

motion would be in a north-south direction. The earth's rotation, however, causes the direction of movement to be deflected to the right (in the Northern Hemisphere), so the movement becomes more west to east (Coriolis effect) in the temperate zone (area between Tropic of Cancer and Arctic Circle). Because the earth's surface is covered unevenly by land masses, water bodies, and polar ice, and because these regions are heated irregularly as the earth rotates on its axis, systems of moving cold and warm air masses are formed. Cold, moist air masses tend to form over cold (polar) seas and warm, moist air masses over warm seas. Cold, dry air masses tend to form over cold (polar) land and warm, dry air masses over warm land. The polar regions have large, stable areas of cold, high-pressure air (polar highs), and the equatorial regions (between 10 degrees south and north of the equator) have a large area of stable, warm, moist, and low-pressure air (doldrums).

Atmospheric pressure in air masses depends on their temperature: higher in cold air masses and lower in warm air masses. Winds are caused by air moving from a high-pressure to a low-pressure area; the greater the pressure difference, the higher the wind speed.

Each air mass, which may cover hundreds to thousands of square miles of the earth's surface, is nearly homogenous for temperature and humidity. In the northern temperate zone, air masses generally move from west to east; in North America, exceptions include cold, relatively dry air masses that move south from northern Canada in the winter and warm, moist air masses that move north from the Gulf of Mexico in the summer.

Cold air masses move faster than warm air masses (25 to 35 mph vs. 10 to 20 mph). The boundaries between air masses are called *fronts*. Frontal air is generally unstable and frequently an area of violent weather. A cold front is an area where heavy, cold air is displacing lighter warm air, frequently by coursing under it. A warm front is an area where lighter, warm air is replacing a retreating mass of heavier, cold air.

Warm, low-pressure air masses are called *lows*, or *cyclones*; cold, high-pressure ones are called *highs*, or *anticyclones*. Since air flows from areas of high pressure to areas of low pressure, lows are characterized by winds blowing from their edges toward their centers and highs by winds blowing from their centers toward their edges. The Coriolis effect causes winds in the Northern Hemisphere to move in a clockwise direction from the center to the periphery in a high and in a counterclockwise direction from the periphery to the center in a low. Understanding these principles can help the traveler interpret shifting wind directions as highs and lows pass.

Weather within an air mass is controlled by its moisture content, the relationship between land surface and air mass temperatures, and terrain features such as up or down slopes. Precipitation can occur in either a high or a low but is more common in a low. The amount of moisture in a mass of air can be described as the air's *relative humidity*, or the amount of water vapor in the air compared with the amount it could hold at its current temperature without condensation occurring. Warm air can hold more water vapor than can cold air. The term *dew point* refers to the temperature at which the relative humidity becomes 100% and the water vapor in air starts to condense. Since

the temperature drops about 2.2° C (4° F) for every 305 m (1000 feet) of ascent (1.6° C [3° F] if moist, 3° C [5.5° F] if dry), rising air cools and descending air warms. Water vapor in rising air will condense when the air cools to its dew point, producing fog, clouds, and precipitation.

The wilderness traveler should be able to identify the different types of clouds and know their significance. Clouds are divided into four types based on

701

Figure 28-19 Different types of clouds. (Modified from Woodmencey J: *Reading weather, Helena, Mont, 1998, Falcon.*)

level, form, and association with precipitation ([Figure 28-19](#) and [Figure 20](#)). The highest clouds are *cirrus* clouds, which develop above 6000 m (20,000 feet). These ice-crystal clouds frequently appear thin, veil-like, and delicate. The feathery ones are called "mare's tails." The sun shines brightly through cirrus clouds. Middle-level clouds (2000 to 6000 m [6500 to 20,000 feet]) have the prefix *alto-* (e.g., *altocumulus*). Low-level clouds (2000 m or below) have the prefix *strato-* or suffix *-stratus* (e.g., *stratocumulus*, *nimbostratus*). These terms are also used to indicate clouds in sheets or layers at high altitudes (e.g., *altostratus*, *cirrostratus*).

Clouds of high vertical development (500 to 18,200 m [1600 to 60,000 feet]) are the larger types of cumulus clouds frequently associated with heavy precipitation. Developing ones that ascend to 9100 m (30,000 feet) are called *cumulus congestus* with billowing tops resembling cauliflowers. The largest ones rise to 18,200 m (60,000 feet) or above, are called *cumulonimbus*, and have anvil-shaped tops. Both types have darkening bases. Because of these clouds' height, precipitation falls long distances through supercooled water droplets. Depending on conditions, hail, soft hail (*graupel*), or huge snowflakes may result.

The prefix *nimbo-* or suffix *-nimbus* indicates that a cloud is associated with precipitation. The term *cumulus* refers to any clouds that present as large or small groups of separate fluffy masses (e.g., *cirrocumulus*, *altocumulus*, *cumulus fractus*, depending on their altitude). *Cumulus humilis* refers to the middle-level, white, cottony clouds with white bases seen in fair weather.

In the inland parts of North America, the worse winter weather (blizzards) is associated

with moving masses of warm air (lows) and the worst summer weather (severe thunderstorms) with rising masses of warm air and moving masses of cold air (highs).

There are two types of thunderstorms, both associated with cumulonimbus clouds (thunderheads). *Frontal* thunderstorms result when an arriving cold front slides under a warm air mass. *Air mass* thunderstorms consist of two subtypes. *Orographic* thunderstorms result when moist air is forced up over a mountain range, causing thunderstorms on the windward side. *Convective* thunderstorms result from rising vertical currents of air caused by heating of ground or water by solar radiation. These are the typical afternoon or early-evening thunderstorms, which may be accompanied by tornadoes when severe.

An advancing warm front bringing precipitation has a predictable series of lowering, darkening cloud formations: scattered cirrus, sheets of cirrostratus, sheets of altostratus, then nimbostratus. Precipitation can begin with the appearance of either altostratus or nimbostratus clouds. The combination of cirrus clouds followed by cirrostratus and altostratus clouds usually predicts precipitation within 24 to 48 hours. Cumulus congestus and especially cumulonimbus clouds indicate thunderstorms.

The wilderness traveler can anticipate weather to a limited extent by using a thermometer and altimeter (or barometer), noting the wind direction, and identifying clouds. Some digital watches have altimeter and barometer features. Both measure air pressure, but the altimeter registers higher as altitude increases (pressure drops) and the barometer registers higher as pressure rises. While traveling in mountains, barometer and altimeter readings will change as altitude changes, regardless of a low or high pressure area. In the evening, however, the movable arrow on an aneroid altimeter can be set or the altitude (or barometric pressure) recorded. The next morning the evening reading is compared with the morning reading. Most severe winter storms are accompanied by an altimeter rise of 150 to 240 m (500 to 800 feet). A rapid altimeter rise (barometer drop) may signify high winds or a short severe storm and a slow steady altimeter rise (barometer drop) a long storm. A rapid altimeter drop (barometer rise) may also mean high winds.

Measuring and recording the air temperature several times daily (remembering that normal temperature drops with increased altitude) can confirm an advancing

Figure 28-20 A and B, Cirrus. C, Altocumulus lenticularis. D and E, Altostratus. F, Altocumulus. G, Nimbostratus. H, Cumulus humilis.

703

Figure 28-20 I, Cumulus congestus. J, Cumulonimbus.

low or high when coordinated with other observations. If a low is moving directly toward you, the wind will shift so that it is blowing from the southeast or south (Northern Hemisphere). If the wind comes from the southwest or west, the low is passing north of you; if from the northeast or east, it is passing south of you. An easy way to check this is to stand with your back to the wind. The low-pressure area will be in front of you and to your left.^[5] As a front passes, the wind will gradually shift 180 degrees.

The shores of large bodies of water have characteristic wind patterns because of the difference in warming and cooling rates of water and land. As the land warms, breezes begin to blow from water to shore in the morning. As the land cools, breezes begin to blow from land to water in the evening. Since cloud patterns are always changing, they must be observed at regular intervals throughout each day in order to develop the ability to predict their meanings with any confidence.

Mountain Weather

Mountain weather is more unpredictable than weather in lower, flatter country. Winds frequently blow up and down mountain valleys regardless of their orientation because of the funnel effect of the valley and temperature differentials caused by solar radiation. The funnel effect may also cause heavy snowfalls at passes or the higher ends of valleys.

On a sunny day the sun warms mountaintops and high slopes first, the warm air rises, and winds blow up the slope. In the evening, the tops and high slopes cool first, the cool air descends, and winds blow down the slope. Glaciers and large snowfields produce significant cool, down-slope winds. Except on the clearest days, mountaintops may have clouds over them or nearby because of up-slope winds that carry moist air high enough to reach its dew point. In the summer, mountains warm up during the morning and early afternoon, creating cumulus congestus and cumulonimbus clouds that produce thunderstorms, lightning, and hail. Therefore the standard recommendation for

summer climbers is to arise early and reach the summit before noon.

Lightning usually precedes rain in a thunderstorm and can strike up to 5 miles away from the storm. Distance is estimated by counting the seconds between the lightning flash and the first noise of thunder; 5 seconds equals 1 mile (see [Chapter 3](#)).

Precipitation is frequently heavy on the windward side of large mountain ranges; the leeward sides are usually much drier and in low areas may be desert. Stationary lens-shaped clouds (altocumulus lenticularis) are frequently seen near mountaintops in windy weather and signify high winds at the summits. High winds also produce long snow plumes from summits and ridges. The summit wind speed will be about twice the valley wind speed.^[27]

Winds blowing at right angles to a mountain range tend to concentrate at any gaps or passes in the range, creating high winds due to the Venturi effect. Warm winds on down slopes in the winter (Chinook or foehn winds) are produced when cool, dense air blowing over mountaintops loses its moisture as precipitation on the windward side; the drier air then warms rapidly as it descends on the lee side. These warm winds can melt snow rapidly.

Weather is more stable at certain times of the year than others, but the times vary by geographic area. For example, in the northern Rocky Mountains the best times to hike or climb in the summer are the last week of July, all of August, and the first week in September. The best time to ski, tour, or climb in the winter is February. In Alaska the best climbing weather in winter is during February and in spring and summer from April through June. In the Himalaya and Karakorum Mountains, the best climbing weather is immediately before and after the summer monsoon (a seasonal, northward flow of warm, moist air from the Indian Ocean).

The principal value of understanding weather signs is in predicting severe, life-threatening storms and providing adequate time to seek shelter or the option to stay put rather than try for a summit. Travel in severe weather, especially above timberline, should never be undertaken casually.

Summary of Backcountry Weather Forecasting

1. Blue sky, a few cirrus or cumulus humilis clouds, cold temperatures, low to medium winds, and a steady or dropping altimeter are predictors of good weather.
2. A lowering cloud pattern (cirrus followed by cirrostratus, altostratus, and nimbostratus), rising temperatures, wind freshening and shifting to blow from the southeast or south, and an altimeter rise of 152 to 244 m (500 to 800 feet) indicate a possibly severe winter storm.
3. Building cumulus congestus clouds changing to cumulonimbus clouds indicate probable thunderstorms and possible hail. A thunderstorm is frequently heralded

- by a rush of cold air (cold front).
4. Signs that a severe winter storm is abating include clouds thinning, cloud bases rising, temperature falling, altimeter dropping, and winds shifting to blow from the north or northwest.

SANITATION

Adherence to proper habits of cleanliness and sanitation is as important in the wilderness as at home.^[4] The hands are washed with biodegradable soap after urinating and defecating, before cooking and eating, and before dressing open wounds. If soap is unavailable, snow or the cleanest available plain water is used. Dishes and pots are washed with hot water, avoiding soap. Waste water is scattered over a wide area and never dumped into a body of water. Bathing and washing clothes should be done at least 60 m (200 feet) from bodies of water, using water in a container. Gloves, preferably rubber (impermeable) ones, are worn when handling moist animal or human tissues.

Campers should dig and defecate in a "cathole" at least 8 inches deep, 6 inches wide, downhill, and at least 60 m from camp, water sources, or snow to be melted for water, covering feces completely with dirt. No camp should be within 60 m of a lake or stream, which is 70 to 80 normal steps for most adults.

Travelers should urinate on rocks or dirt, not on green plants. When sleeping in a tent or snow shelter, a 500-ml wide-mouth polyethylene bottle can be used as a urinal to avoid going outside, especially at night. Special funnels to use with the bottle are available for women.

PSYCHOLOGIC ASPECTS OF SURVIVAL

Dealing with the psychologic aspects of survival is as important as confronting physical and environmental factors. As mentioned previously, the dangerous mindset that keeps a person continuing on a hazardous course, such as completing a climb or reaching a distant campsite despite conditions that would make a more prudent person bivouac or turn back,^[8] is a recurring scenerio. In a survival emergency, a person with adequate oxygen, a stable body temperature, shelter, water, and food may still die if unable to withstand the psychologic stress. Conversely, persons have survived amazing hardships with little more than a strong determination to live. Individual reactions, however, cannot be predicted in advance. Groups faced with unexpected emergencies testify that courage and leadership appear in unexpected places.

If persons possess the necessary skills and have at least a minimum of survival equipment (see [appendix](#) to this chapter), the odds are strongly in their favor. Medical personnel have the advantage of being trained to suppress panic. Fear and surrender are normal reactions that must be opposed by whatever psychologic tools are available. In some cases, religious faith or the desire to rejoin loved ones have been credited with survival.

Anxieties that paralyze action include fear (of the unknown, being alone, wild animals, darkness, weakness, personal failure, discomfort, suffering, and death) and panic. Panic, the uncontrolled urge to run away from the situation, interferes with good judgment, resulting in inappropriate actions, such as abandoning weaker companions, dividing the party, and discarding vital survival equipment. Useless flight saps available energy, leads to exhaustion, and hastens death.

Other psychologic reactions include apathy and the normal desires to be comfortable and to avoid pain.^[23] Apathy is giving up, a state of indifference, mental numbness, surrender, and unwillingness to perform necessary tasks. The person shows resignation, quietness, lack of communication, loss of appetite, fatigue, drowsiness, and withdrawal. Apathy in one's self is overcome by faith in abilities and equipment and belief in survival and the possibility of rescue. Apathy in others is combated by communicating plans and positive feelings about resources and outcomes to them, and including all group members in planning and survival activities.

Comfort is not essential to survival. Severe discomfort from injuries, illnesses, thirst, hunger, excessive heat or cold, sleep deprivation, and/or exhaustion is inevitable in a survival situation and must be tolerated in order to live. There are many accounts of adventurers who have survived many days with severe injuries

such as open fractures because of the will to live, or who have dragged themselves for miles despite multiple injuries to find help.

Providing an ill or injured party member with psychologic support is important. This includes appearing calm, unhurried, and deliberate yourself while trying to encourage optimism, patience, and cooperation. A person with a minor injury or illness should be encouraged to self-evacuate, accompanied by at least one healthy party member. When a person with a severe injury or illness needs to be evacuated, the party must decide whether to use the resources at hand or to send for help. The decision will depend on the weather, party size, training, available equipment, distance, type of terrain involved, type of injury or illness, victim's condition, and availability of local search and rescue groups, helicopters, and other assistance. Unless the weather is excellent, the party strong and well equipped, the route short and easy, and the victim comfortable and stable, the best course of action generally is to make a comfortable camp and send the strongest party members for help. A written note should include each victim's name, gender, age, type of injury or illness, current condition, and emergency care; the party's resources and location (preferably map coordinates); and names, addresses, and telephone numbers of relatives. The victim who must be left alone should have an adequate supply of food, fuel, and water.

As soon as you realize that you are lost, stop, sit down in a sheltered place, calmly go over the situation, and make an inventory of your survival equipment and other resources. If it is cold or becoming dark, start a fire and eat if you have food. Take out your map or draw a sketch of your route and location based on natural features. Unless you know your location and can reach safety before dark, prepare a camp and wait until morning. Do not allow yourself to be influenced by a desire to keep others from worrying or the need to be at work or keep an appointment. Your life is more important than anyone else's peace of mind.^[10]

If you are alone and unquestionably lost, and especially if injured, you must decide whether to wait for rescue or attempt to walk out under your own power. Almost always, it is better to use the time to prepare a snug shelter and conserve strength if rescue is possible. If you decide to leave, mark the site with a cairn or bright-colored material such as surveyor's tape, leave a note at the site with information about your condition, equipment, and direction of travel, and then mark your trail. These actions will aid rescuers and enable you to return to the site if necessary. Travel should never be attempted in severe weather, desert daytime heat, or deep snow without snowshoes or skis. If no chance of rescue exists, prepare as best possible, wait for good weather, and then travel in the most logical direction.

SIGNALING

Besides radios, cell phones, and other electronic equipment, signaling devices are either auditory or visual. Three of anything is a universal distress signal: three whistle blasts, three shots, three fires, or three columns of smoke. The most effective auditory device is a whistle. Blowing a whistle is less tiring than shouting, and the distinctive sound can be heard farther than a human voice. An effective visual ground-to-air signal device is a glass signal mirror, which can be seen up to 10 miles away but requires sunlight. Smoke is easily seen by day and a fire or flashlight by night. On a cloudy day, black smoke is more visible than white; the reverse is true on a sunny day.

Black smoke can be produced by burning parts of a vehicle, such as rubber or oil, and white smoke by adding green leaves or a small amount of water to the fire.

Ground signals (e.g., SOS, HELP) should be as large as possible—at least 3 feet wide and 18 feet long—and should contain straight lines and square corners, which are not found in nature. They can be tramped out in dirt or on grass or can be made from brush or logs. In snow the depressions can be filled with vegetation to increase contrast.

Many pilots do not know the traditional 18 international ground-to-air emergency signals, which have been replaced with the following five simple signals adopted by the International Convention on Civil Aviation^[23] :

V I require assistance

X I require medical assistance

N No

Y Yes

? Am proceeding in this direction

Air-to-ground signals include the following:

Message received and understood: rock plane from side to side.

Message received but not understood: make a complete right-hand circle.

When using cell phones, radios, and other electronic devices, persons should move out of valleys and gulleys to higher elevations if possible. Operational pay phones in campgrounds closed for the season or other facilities can be used to call for help. Most will allow 911 or another emergency number to be dialed without payment, but carrying the right change and memorizing your telephone credit card number are recommended.

PROTECTION FROM WILD ANIMALS

Although persons in a survival situation often worry about wild animal attacks, these are rare. Many wild animals flee when confronted with a shouting, moving human. Exceptions include polar bears, grizzly bears,

706

moose, bison, cougars, jaguars, wild pigs, elephants, lions, tigers, water buffalo, leopards, wolverines, females with young (e.g., bears, moose, elk, deer), rabid mammals, and feral dogs and cats (see [Chapter 41](#) , [Chapter 42](#) , [Chapter 43](#)). Polar bears, some grizzly and black bears, the great cats, and crocodiles may hunt humans as food. Venomous snakes, insects, arachnids (e.g., scorpions and ticks), and marine animals are also a concern (see [Chapter 33](#) , [Chapter 34](#) , [Chapter 35](#) , [Chapter 36](#) , [Chapter 37](#) , [Chapter 38](#) , [Chapter 39](#) , and [Chapter 60](#) , [Chapter 61](#) , [Chapter 62](#)).

The only effective weapon against large mammals and reptiles is a high-powered rifle, although pepper spray may discourage an attacking bear. Improvised weapons such as a spear tipped with a hunting knife, are useless.

Food should not be kept in a shelter or backpack during the night. All food should be placed in a nylon bag and hung between two trees on a high line. Above the timberline, small rodents such as mice may gnaw holes in expensive tents to reach food inside, so all food should be bagged and hung on a line between two high boulders.

In desert and other snake or scorpion country, travelers should avoid walking barefoot, especially at night, and should not place hands, feet, or other body parts in uninspected places. Desert campers should carry tents with floors and tightly zipped doors. Those sleeping outside should shake out clothing, footgear, and bedding before using them.

In warm weather, insect repellent should be carried and used liberally.

HOW TO PREPARE FOR A POSSIBLE SURVIVAL SITUATION

Basic survival equipment and skills for those interested in wilderness travel should include the following:

1. Practice physical conditioning and healthful habits. Avoid alcohol, tobacco, and "recreational" drugs.
 2. Develop the ability to swim well.
 3. Learn how to use a map and compass and find directions without a compass.
 4. Be able to build a fire under adverse conditions.
 5. Have a working knowledge of local weather patterns and be able to use an altimeter, thermometer, cloud forms, and wind directions to predict storms. Avoid exposure to meteorologic hazards, such as blizzards and lightning strikes.
 6. Be familiar with the special medical problems of the type of wilderness involved. For example, for cold weather and high-altitude travel, be familiar with the prevention, diagnosis, and treatment of hypothermia, frostbite, and altitude illnesses. Travel in the desert and tropics requires familiarity with tropical infections, snakebites, tropical skin diseases, and heat illness. Understand basic principles of prehospital emergency care and the improvisation of splints and bandages.
 7. Carry a survival kit containing equipment appropriate for the topography, climate, and season (see appendices to this chapter).
 8. Be able to construct appropriate types of survival shelters.
 9. Acquire a working knowledge of the characteristics of natural hazards and how to predict and avoid them. These include forest fire, lightning strike, avalanche, rockfall, cornice fall, flash flood, white water, deadfall, storms of various kinds, and the hazardous animals and plants of the area of travel.
 10. Read and analyze accounts of survival experiences (see Suggested Readings). ^[1]
^[12] ^[14]
 11. Be aware of the psychologic aspects of a survival situation and of errors in judgment that can lead to a survival emergency.
 12. Know the edible plants and animals of the area of projected travel, as well as the poisonous or venomous species. Basic hunting, trapping, and fishing skills are valuable.
 13. Never travel alone. Always let responsible persons know your destination and expected time of return, and do not fail to notify these persons of your return to avoid unnecessary rescue attempts. After you leave, avoid changing destination and time plans except in unusual circumstances. Failure to follow these guidelines has led to many unsuccessful searches.

APPENDIX A

Everyone should develop the habit of carrying at least a Swiss Army knife and matches in a waterproof container when away from paved roads.

Sample Basic Wilderness Survival Kit

This kit is carried in a small backpack, with a capacity of 3200 to 4000 cubic inches.

Shelter-building equipment:

- Plastic or nylon tarp (not a "space blanket")

- ? inch braided nylon cord, 50 to 100 feet

- Folding saw

Fire-building equipment:

- Waterproof matches

- Candle

- Fire starter (substitute: camera film)

- Sharp, sturdy hunting knife (e.g., folding Buck knife with 4-inch blade)

Signaling equipment:

- Pencil and small notebook

- Whistle

- Card with ground-to-air signals

Two sets of correct change for pay phone

Signal mirror, preferably glass with sighting device

Flashlight (or preferably headlamp), with spare batteries and bulb

Other:

Compass

Map

Nondigital watch

Metal pot with bale and sack to store it

Metal cup with handle

Spoon

Toilet paper

Sunburn cream

Lip balm with high SPF number

Spare socks (used as spare mittens in emergency)

Emergency food

First-aid kit

Sunglasses

Canteen (full)

Water disinfection equipment: chemicals or filter

Insect repellent (in season)

Repair kit, adapted to type of travel (e.g., ski, snowshoe, kayak):

Leatherman type of tool (or Swiss Army knife) small pliers with wire-cutting feature, small crescent wrench

Small screwdriver with multiple tips

Picture wire

Fiberglass tape

Duct tape

Steel wool for shimming

Assorted nuts, bolts, and screws

Additional considerations:

Altimeter

Thermometer (plastic alcohol type clipped to loop on outside of pack)

Spare eyeglasses

Swiss Army knife with scissors

Fishhooks and line

No. 28 piano wire for snares

Cellular telephone (if service available)

GPS locator

.22-caliber rifle and ammunition

Surveyor's tape

Cigarette lighter

APPENDIX B

Sample Winter Survival Kit

Basic survival items from [Appendix A](#)

Spare clothing for severe weather: at least four layers total, including spare mittens

Snow shovel: small grain-scoop type with detachable handle

Optional items:

- Piece of Ensolite or Therm-a-Rest mattress

- Sleeping bag

- Gore-Tex bivouac sac

- Stove and fuel

- Light ax

- Snow saw

APPENDIX C

Sample Desert Survival Kit

Basic survival items from [Appendix A](#)

Fold-up steel shovel with short handle

Items for construction of four solar stills:

Four sheets of clear plastic, 6 × 6 feet, reinforced in center by cross of duct tape

Four pieces of surgical tubing, 6 to 8 feet long

Four 1-quart plastic bowls

5-gallon water jug, full

1-liter wide-mouth bottle for use as urinal

Spare sunglasses

Heavy leather gloves

Citizen's band radio

Light rifle or target pistol with ammunition

APPENDIX D

Vehicle Cold Weather Survival Kit (see [Chapter 69](#))

Sleeping bag or two blankets for each occupant

Extra winter clothing, including boots, for each occupant

Emergency food

Waterproof matches

Long-burning candles, at least two

First-aid kit

Spare doses of personal medications, if any

Swiss Army knife

Three coffee cans with lids, for toilet

Toilet paper

Citizen's band radio or cell phone

Flashlight with extra batteries and bulb

Battery booster cables

Extra quart of oil (place some in hubcap and burn for emergency smoke signal)

Tire chains

Snow shovel

Tow chain, at least 20 feet long

Small sack of sand

Two plastic water jugs, full

Tool kit

Gas line deicer

Flagging, such as surveyor's tape (tie to top of radio antenna for signal)

708

Signal flares

Long rope (e.g., clothesline) to act as safety rope if you leave car in blizzard

Carbon monoxide detector

Ax

Folding saw

Full tank of gas

APPENDIX E

Minimal Equipment for Survival First-Aid Kit (see [Chapter 69](#))

Cravats, at least two

Rubber gloves

Roll of 3-inch Kling (self-adhering roller bandage)

Roll of 2-inch adhesive tape (waterproof preferred)

2-inch rubberized bandage (Ace or Coban)

Small prepackaged bandage strips

Nonadhering sterile gauze pads

Sterile compresses

20-ml syringe and needle or splash shield for irrigating wounds

Steel sewing needle (can be part of sewing kit)

Single-edged razor blade

Thermometer (low readings for cold environments)

Nonprescription analgesic of choice (e.g., acetaminophen, ibuprofen)

Prescription analgesic of choice (e.g., APAP with codeine, 30 mg; APAP with propoxyphene, 100 mg)

Diphenhydramine, 25- or 50-mg capsules

Small bottle or package of swabs of povidone-iodine solution 10%

Duct tape, fiberglass strapping tape (for improvising litters and splints; carried in repair kit); other splinting materials can usually be improvised using ski poles, ice axes, hammers, branches, and parts of backpacks or vehicles

Splinter forceps

Persons who are taking regular medications, such as asthmatics and diabetics, should carry emergency supplies of their medicines in addition to regular supplies; anyone who has had an anaphylactic reaction should carry an emergency epinephrine kit (EpiPen or Ana-Kit)

Physicians may take additional items, such as injectable epinephrine, an injectable narcotic, and skin glue

Other considerations (for longer trips):

Drug for nausea and vomiting (e.g., prochlorperazine or promethazine suppositories)

Drug for diarrhea (e.g., loperamide)

All-purpose antibiotic (e.g., ciprofloxacin)

Topical ophthalmic ointment (e.g., gentamicin)

Chapter 29 - Jungle Travel and Survival

John B. Walden

Persons who venture into the tropical rainforest step into an exotic and mysterious environment that can be unforgiving. Preparedness makes the difference between misery and pleasure.

TROPICAL ENVIRONMENT

In these forests lies a virtually limitless supply of excitement, joy and wonder to be encountered in new illuminations on the constructs and workings of life on earth.^[23]

Tropical rainforests, located between the Tropic of Cancer (23°27' N latitude) and the Tropic of Capricorn (23°27' S latitude), are regions with at least 4 inches of precipitation per month and a mean annual monthly temperature exceeding 24° C (75° F) without any occurrence of frost.^[10] Facts and figures fail to capture the essence of tropical rainforests and their extraordinary biologic diversity. Seen from the air, the forest stretches from horizon to horizon in a vast green carpet. In season the crowns of trees in full blossom dot the landscape with vivid splashes of red, orange, and yellow. Sizable streams may be hidden beneath the emerald canopy. Rivers, usually muddy yellow or black, snake through the forest; early-morning or late-afternoon sun transforms these braided rivers into glistening, mirrorlike strands of liquid silver.

Observed from the forest floor, the jungle is entrancing. In virgin, deep forest, all is muted and shadowy save for random shafts of light that stream down to spotlight labyrinths of oddly shaped branches and spectacularly colored flowers. Shrubs and herbaceous plants are scarce in forest away from the flood plain, so it is relatively easy to walk undisturbed. The dimness is occasionally disrupted by areas bathed in bright light from larger holes in the canopy caused by a recently fallen tree, sandy beach, or cutting and burning by humans. It is in these sunlit areas that the traveler encounters the lush and nearly impenetrable wall of foliage portrayed in adventure films. The tidy "textbook" division of vegetation into distinct tiers is somewhat arbitrary and not easily confirmed, even by experts.^[27]

In addition to upland *terra firme* forests, lowland forests remain submerged for several months each year. Such forests, or *várzeas*, make up only a small percentage of forested land but are infinitely more fertile than their nonflooding and nutrient-poor counterparts.

Despite environmental differences within the jungle, the basics of travel remain the same.

TRIP PREPARATION

Reading

National Geographic^[3] and Wilson^{[35] [36]} provide an excellent introduction to people, places, and biodiversity issues. *The Emerald Realm*^[10] is a superb overview of the world's tropical forests. The references at the end of this chapter offer insights into the complex inner workings of the moist tropical forest.^{[1] [26] [27]} The books by Kritcher^[20] and Forsyth et al^[14] are especially helpful.

Trips into the rainforest should be scheduled for the dry season, because trails are more serviceable for trekking at that time. Information on weather patterns can be obtained from agencies of national governments, anthropologists, missionaries, and the excellent series *World Survey of Climatology*.^[31]

Attitude

In selecting participants, experienced expedition leaders look for a sense of humor; the ability to see the bright side in difficult times may be an asset more valuable than physical conditioning. Houston^[18] and others have discussed the role of humor as a predictor of success. Erb^{[11] [12]} noted that successful or failed participation in wilderness ventures also is a significant predictor.

A number of expedition leaders privately note that two individuals who have a sexual relationship often form a team within a team, to the detriment of the expedition as a whole.

Conditioning

Indigenous peoples in jungle regions are almost always slender. After trekking with large numbers of non-indigenous men and women in equatorial regions, I have observed that overweight or powerfully built individuals, particularly men, seem to fare the worst, especially with heat-related illness. Achieving an ideal weight is beneficial on the trail.

Although being in good shape is sensible, a person need not be an elite athlete to trek through the jungle and enjoy the experience. Good leg strength, acquired by training with stair-climbing exercise machines, offers appropriate preparation.

To keep up with native porters and guides, the prospective expedition member should

at a fast pace. Once in the jungle, travelers should imitate the energy-saving, fluid rhythm of local inhabitants.

Because trekkers frequently encounter single-log bridges, a well-developed sense of balance is desirable. Walking on the rails of train tracks or on curbs may help in preparation. To adapt to the specific situations, trekkers should go to the woodlands and practice walking on logs. Head stability is important. Equilibrium can be enhanced by avoiding brisk head movements and by employing the "gaze-anchoring" technique of tightrope walkers. The person fixes the gaze on a spot near the end of the log and does not stare down at the spot just ahead of the feet.^{[2] [6]} Special cleats (Covell) should be considered for crossing log bridges that are high off the ground, long, and slippery. The cleats can be snapped on quickly before crossing a log bridge and promptly snapped off at the other end.

IMMUNIZATIONS

Travelers to rainforest regions should protect against the following diseases by vaccination or with prophylactic medications:

1. Diphtheria, tetanus
2. Hepatitis A, hepatitis B
3. Measles, mumps, rubella
4. Polio
5. Rabies
6. Typhoid
7. Yellow fever (in certain regions of tropical Africa and South America)
8. Malaria

Malaria is prevalent throughout the tropics. Before travel to malarious areas, appropriate prophylaxis is needed. Updated information on the risk of malaria in various regions may be obtained through the International Travelers' Hot Line service at the Centers for Disease Control and Prevention (877-FYI-TRIP, www.cdc.gov). *The Medical Letter on Drugs and Therapeutics* issue on parasitic diseases, published every 2 years, is an excellent source for current recommendations on preventing and treating malaria (see [Chapter 66](#)).

Persons traveling into remote regions of Amazonia where Indian groups live in isolation should receive yearly influenza vaccinations to reduce the likelihood of inadvertently transmitting disease to these high-risk native inhabitants. Protection against meningococcal disease should be considered where circumstances warrant.

Medical Kit

The Wilderness Medical Society points out that it is inappropriate to pack medications and equipment when no team member has the knowledge or experience to use them safely.^[19] The following items for a basic medical kit ([Box 29-1](#)) are adequate for personal use in the rainforest setting (see [Chapter 69](#)):

1. Bismuth subsalicylate (Pepto-Bismol tablets) is an effective over-the-counter preparation for preventing and treating common traveler's diarrhea. It also is useful for heartburn and indigestion. Pepto-Bismol tends to turn the tongue and stools black.
 2. Diphenhydramine hydrochloride (Benadryl, 50-mg capsules) is safe and effective as an antihistamine, for motion sickness, and as a nighttime sleep aid.
 3. Ciprofloxacin hydrochloride (Cipro, 500-mg tablets) is highly active against the important bacterial causes of enteritis, including *Escherichia coli*, *Vibrio cholerae*, *Salmonella*, *Shigella*, *Campylobacter jejuni*, *Aeromonas*, and *Yersinia enterocolitica*.
 4. Clotrimazole and betamethasone dipropionate (Lotrisone) cream has antifungal properties and a steroid for rashes.
 5. Epinephrine autoinjector (EpiPen/EpiPen Jr.) provides for emergency treatment of severe allergic reactions to insect stings, foods, or drugs.
 6. Ibuprofen (600-mg tablets) is a good choice for mild to moderate pain from such problems as menstrual cramps, rheumatoid arthritis, and osteoarthritis. It also lowers elevated body temperature caused by common infectious diseases.
 7. Ketorolac (Toradol, 60-mg for injection) provides good short-term relief for moderate to severe pain. It is preferred over narcotics only because it is less likely to cause problems with customs officers and police.
 8. Lidocaine hydrochloride may be required as a local anesthetic agent for relief of the excruciating
-

pain resulting from stingray envenomation and conga ant or caterpillar stings. It should be infiltrated into and around the wound area using a dental aspirating syringe and 25-gauge needle. Lidocaine carpules (used by dentists) are protected and easy to carry and use in the rainforest.^[16]

9. Metronidazole (250-mg tablets) is excellent for treating giardiasis, acute amebic dysentery, and *Trichomonas vaginitis*.
10. Mupirocin (Bactroban) ointment 2% should be immediately applied to burns, abrasions, lacerations, and ruptured blisters, which can rapidly become infected in the tropics.
11. Permethrin 5% cream and 1% shampoo should be applied before returning home by travelers who have been in close contact with heavily infested tribal peoples. Many natives, especially in the tropics of Central and South American, are infested with scabies and head lice.
12. The SAM splint is lightweight, waterproof, reusable, and not affected by temperature extremes.

13. Sulfacetamide sodium (Sodium Sulamyd) ophthalmic solution 10% is excellent for treating conjunctivitis, corneal ulcers, or other superficial ocular infections.
14. Sunscreen is essential in open areas such as rivers or jungle clearings. Sunscreens designated "waterproof" retain their full sun protection factor (SPF) rating for longer periods during sweating or water immersion than do products designated "water resistant." Opaque formulations are excellent for the nose, lips, and ears. Visitors to the tropics should wear lightweight, long-sleeved shirts and a wide-brimmed hat when exposed to the sun for prolonged periods (see [Chapter 14](#)).
15. Tramadol hydrochloride (Ultram, 50 mg tablets) is used for moderate to severe pain.

Box 29-1. MEDICAL KIT FOR JUNGLE TRAVEL

Bismuth subsalicylate tablets (48)

Diphenhydramine hydrochloride 25- or 50-mg capsules (15)

Ciprofloxacin hydrochloride 500-mg tablets (20)

Clotrimazole and betamethasone dipropionate cream (60 g)

Epinephrine autoinjector (2)

Ibuprofen 200- or 600-mg tablets (30)

Ketorolac 60-mg single-dose syringe (2)

Lidocaine hydrochloride carpules (3)

Metronidazole 250-mg tablets (21)

Mupirocin ointment 2% (30 g)

Permethrin 5% cream (60 g)

Permethrin 1% shampoo (2 oz)

SAM splint (1)

Sulfacetamide sodium ophthalmic solution 10% (15 ml)

Permethrin 1% shampoo (2 oz)

SAM splint (1)

Sulfacetamide sodium ophthalmic solution 10% (15 ml)

Sunscreen (4 oz) (2)

Tramadol hydrochloride 50-mg tablets (20)

Box 29-2. GEAR FOR JUNGLE TRAVEL

Trail shoes (1 pair)

Camp boots (1 pair)

Covell cleats

Socks (3 pairs)

Hat (1)

Pullover garment (1)

Shirts

 Long sleeved (2)

 Short sleeved (2)

Pants (2 pairs)

Umbrella

Whistle

Zipper-lock bags

 Gallon size (5)

 Quart size (5)

 Pint size (5)

Common sense dictates supplementary items. Women on long trips might add miconazole vaginal suppositories to treat yeast infections; older men might take a 16 French catheter and sterile lubricating jelly for dealing with problems from prostatic hypertrophy. The fingers may swell rapidly during vigorous activity in the rainforest. To eliminate the possible need for emergency removal, all rings should be removed before jungle trekking.

Gear

The goal is to travel as light as possible. The more stuff that is packed, the greater is the likelihood of breakdowns, complications, and misery. The items mentioned have withstood the test of time over years of long-distance tropical trekking ([Box 29-2](#)).

Gear must hold up under difficult jungle travel conditions that include heat, wetness, and mud. No line of advertised gear is ideally suited for the traveler in the tropics. In the United States, L.L. Bean, Inc. (www.llbean.com) and Recreational Equipment, Inc. (REI) (www.rei.com) are good sources for equipment that is usually satisfactory for the tropics (see [Chapter 69](#)).

Footwear.

Since feet absorb more punishment than any other part of the body, suitable footwear is the most important item of gear. This is one area where a person absolutely must not carry inferior equipment. If the feet cannot go, nothing can go.

Military-style "jungle boots" are unsuitable for serious, long-distance trekking. After an hour of hard walking through streams and muddy trails, blisters will form on every surface of the foot and the skin will peel off in sheets, bringing a jungle trip to a premature end. Furthermore, safely crossing log bridges and mossy, slime-covered river rocks is almost impossible in these boots.

Two pair of shoes are needed: one suitable for the wet, slippery conditions imposed by the trail and another that meets the need for dryness and comfort in camp.

TRAIL SHOES.

The following features are desirable in trail shoes:

1. Uppers that hit just above or just below the ankles. Some people choose a high-cut design, reasoning that the extra height gives some added snake protection.
2. Extra protection over the big toe. Rubber or leather toecaps prevent the big toe from being severely battered and bruised.
3. Moderately deep-tread outsoles. Traction on rugged and muddy terrain is important. Running shoes with hard, "high-impact" soles should not be worn because they become slippery on wet logs or river rocks.
4. Quick drying time. Uppers of Cordura nylon and split leather, in addition to resisting abrasion and being aerated, dry rapidly in the sun. Even though hiking shoes usually become soaked within minutes on the trail, it is a psychologic boost to start each day with dry shoes. Since jungle travelers can be in waist-high water while on the trail, waterproof shoes with Gore-Tex liners are not essential.
5. Snagproof design. Shoes or boots with "quick-lace" steel hooks should be avoided; vines and weeds become tangled around the metal hooks, causing the wearer to stumble and pulling the laces untied. Shoelaces should always be double knotted.
6. Light weight
7. Well broken in

CAMP BOOTS.

Footwear needs are different in camp where the trekker wants dry feet. Shoes, although excellent for the trail, are not suited for camp. A boot that comes to midcalf keeps mud off the feet and pants. Rubber remains an excellent material for keeping water away from the feet. Rubber lug soles provide traction. When rubber-soled boots are worn, however, extreme caution is needed when crossing bridges and walking on rocks. Camp boots should be light weight, since they must be carried in a pack on the trail. Discount stores usually carry lightweight, lug-soled rubber boots that meet the criteria for jungle camp boots.

OTHER OPTIONS.

The lightweight, comfortable, mesh/neoprene fabric "water" shoes popular for beach and sailboarding activities may have a place on river trips when substantial time will be spent in dugout canoes or rubber rafts.

Thongs and open-toe sandals are fine for most towns and cities in the tropics, but in certain jungle regions such as the Amazon Basin, exposed feet invite hordes of biting insects.

The jungle traveler must never go barefoot. Plant spines and glass can puncture the feet, and larvae of ubiquitous parasites such as hookworm and *Strongyloides* can enter through the skin. The burrowing jigger flea, *Tunga penetrans*, is a serious pest and can be avoided by wearing shoes.

SOCKS.

Cotton or thin synthetic socks should be worn in the jungle to decrease the risk of blisters from wet trail shoes, to reduce insect bites (particularly from no-see-ums), and to lessen the risk of lacerations from sawgrass.

Clothing.

In many countries military green or camouflage-style clothing is strictly contraindicated. This is particularly true in military dictatorships or in remote border regions. To be mistaken for a guerilla or foreign infiltrator by the military, police, or security (undercover) forces can lead to harassment, detention, or worse.

HAT.

For protection from radiant heat and objects falling in the forest, the traveler should wear a lightweight, light-colored hat that has a medium or wide brim. It need not be waterproof but should be made of material that can be wadded up. A useful feature is a fastener on each side to snap the brim up for traveling on the trail. A pith helmet, widely regarded as affectatious, is fine for open savanna and river trips, but on the trail, branches make it impractical.

PULLOVER.

Drenching rain may leave a person feeling chilled and uncomfortable, particularly when traveling mainly by canoe or raft. Chilling generally is not a

problem when hiking on the trail so long as the person keeps moving. A Dacron

polyester fleece pullover such as L.L. Bean's Polarlite Pullover, REI's Polarlite Sweater, or a Patagonia pullover will keep a person warm. Wet garments should be wrung out so that they continue to offer thermal protection. Professional white-water boatmen working in tropical regions generally pack a polyester outerwear garment.

SHIRTS.

Two light-colored, ultralightweight, long-sleeved cotton shirts should be taken. At the end of the day, the trail shirt should be washed and rinsed so that it will be ready, although perhaps still damp, the next morning. The second shirt can be used in camp or as a spare for the trail. Expensive synthetic shirts guaranteed to wick away moisture are poor jungle trail shirts, and make the person sweaty and sticky.

In camp, if no-see-ums and mosquitoes are few, a lightweight, short-sleeved cotton shirt is practical. Two should be packed. A four-pocket style called the *guayabera*, favored by men throughout Latin America and the Caribbean, is ideal. La Casa de Las Guayaberas (Naroca Plaza, 5840 SW 8th St., Miami, FL 33144; 305-266-9683; fax 305-267-1687) has an exceptional selection of short- and long-sleeved *guayaberas*; be sure to specify 100% cotton.

PANTS.

Two pairs of ultralightweight, light-colored cotton pants are needed. One pair is worn on the trail during the entire trip. Trail pants should be washed often. The other pair is worn around camp and in towns along the way. Jeans become waterlogged as soon as they become wet and are totally unsuitable for tropical trekking. Although synthetic shirts are unsuitable, nylon Supplex pants can substitute for cotton on the trail. Mangrove Sanded Supplex pants (Sportif, 800-776-7843) hold up well, are quick drying, have a built-in mesh brief, and meet criteria for comfort on the trail. Pants with zip-off legs to create instant shorts should be avoided.

UNDERGARMENTS.

Underpants and sport bras should be made of cotton.

PONCHO.

An ultrathin waterproof poncho is useful on rafting or canoe trips and in villages but is worthless on the trail.

Bedding

FLANNEL SHEET.

Tropical rainforests become uncomfortably cold between midnight and sunrise. A cotton sheet does not provide enough warmth, a blanket is too heavy, and a summer-weight

sleeping bag retains too much body heat. A flannel sheet sewn together like a mummy bag (40 × 90 inches), but without a taper, provides suitable warmth either in a hammock or on a pad.

Many inhabitants of the tropical forests sleep with their feet near a fire that is tended throughout the night. They have learned that the chill of damp, cool jungle nights can be lessened as long as the feet stay warm. Also, disposable "warm packs" can be wrapped within a sock.

HAMMOCK.

Soft cloth hammocks are too bulky and heavy for trips and begin to smell after a few days. Fishnet cotton hammocks tend to fall apart within hours or days. The so-called camping tent-hammocks or military tent-hammocks are usually bulky, heavy, impossible to sling properly, extremely uncomfortable, hot, unstable, and *never* able to keep the rain out in a heavy tropical downpour.

The nylon Double Hammock sold by Wal-Mart (Model EZ-190 by E-Z Sales Manufacturing, 1432 West 166 St., Gardena, CA 90247) has proved nearly ideal for jungle travel. It is compact, lightweight, durable, and reasonably comfortable. It cannot rot or absorb odors. For easier handling, the ski rope tie-end lines that are sold with the Double Hammock should be replaced with 7/8-inch double-braided rope.

THERM-A-REST.

The Therm-a-Rest foam pad is the choice of expedition organizers throughout the world. It combines the insulating qualities of foam and the cushioning of an air mattress, rolls up to a compact size, and inflates on its own when the valve is opened.

The traveler who will be sleeping on a pad should pack a 1 ½ × 2 ½-yard plastic ground sheet. The sheet should not be placed directly on the jungle floor, where stinging insects and snakes abound. It should be used only in a hut or on an elevated platform. The ground sheet may also be beneficial for temporary rain protection and for keeping bow spray off a person or gear during water travel.

MOSQUITO NETTING.

A mosquito net designed for use with a hammock is basically a rectangular box that is open at the bottom with sleeves at each end panel for the passage of the ropes by which the hammock is slung. Such nets are difficult to find outside the tropics. Fortunately, a serviceable mosquito net can easily be made from "no-see-um netting" (available by request from REI).

Backpacks.

A sturdy, well-designed backpack should be used to carry gear. Reflective material

should be sewn onto the back of each backpack. Iron Horse Safety Specialists (800-323-5889, fax 214-340-7775, e-mail ihss1@aol.com) sells red-orange reflective material for daytime visibility and reflective silver for nighttime reflectivity. On serious jungle treks, porters are present. This frees expedition members to carry much lighter loads.

BACKPACK FOR PORTER.

An internal-frame backpack of 3000 to 4000 cubic inch capacity is a good size. It should have external pockets for quick access to liter-sized water bottles.

Indigenous peoples are accustomed to carrying packs and hauling loads with a strap, known as a *tumpline*, slung over the forehead or chest. Many natives, including Amazonian Indians, dislike using the shoulder straps that come as standard equipment on backpacks. Given enough straps, almost any native porter can quickly rig a satisfactory tumpline on a backpack.

PERSONAL PACK.

A daypack of 1200 to 2000 cubic inch capacity is useful for carrying a camera, snack food, and other gear that must be kept handy. A waterproof liner will keep perspiration from wicking into the bag and wetting everything inside. The pack should have two outside pockets for quick access to liter-sized water bottles.

PACK FOR RIVER TRIPS.

A durable, waterproof "dry" bag, used by river runners, is worth considering, especially if the trip will involve spending days or weeks at a time in dugout canoes or rubber rafts. Most of these packs, however, cannot stand up to the demands of long-distance overland trekking. The straps tend to be uncomfortable and frequently rip out on the trail.

Other Useful Items

ANTIFOGGING SOLUTION FOR EYEGASSES.

Antifog solution, available from dive shops, reduces humidity-induced fogging of glasses.

BATTERIES.

Alkaline batteries should be brought from home. Batteries sold in Third World nations do

not last long and often leak.

BINOCULARS.

The traveler who is an avid bird watcher or enjoys watching butterflies or seeking out orchids high on distant limbs will want to pack a pair of binoculars that are lightweight, compact, shockproof, and waterproof or water resistant.

CAMERA EQUIPMENT.

Older-style cameras with mechanical shutters are reliable in regions of high humidity. Film with an ISO of 200 is ideal for use in the low-light conditions of the jungle and much preferred over slower film.

CAMERA CASE OR BAG.

Hard-bodied Pelican cases are waterproof and virtually indestructible. The silver-gray color cuts down on heat absorption and is preferred in hot climates. The cases are ideal for rafting or canoe trips but bulky for trekking. On the trail, waterproof "dry" bags protect equipment.

CAMP SOAP.

A biodegradable soap should be used. The soap Campsuds works in hot, cold, fresh, or salt water and cleans dishes, clothing, hair, and skin.

CANDLES.

Electricity tends to fail at unpredictable times in small towns and even in cities in Third World countries. Travelers should carry dripless candles, but spring-loaded candle lanterns should be avoided.

CUP AND PLATE.

A large Lexan polycarbonate cup is unbreakable, does not retain taste or odor, and serves the role of cup, bowl, and plate. Travelers who want an actual plate should buy one made of indestructible Melamine.

EAR PLUGS.

Travel in the tropics often involves flying in incredibly loud helicopters, cargo planes, or short takeoff and landing (STOL) aircraft. Sponge ear plugs that roll up and fit in the ear canal offer inexpensive, effective protection against hearing damage.

FISHING SUPPLIES.

For additional "food insurance" the jungle traveler should carry 75 feet of 20-pound-test fishing line, a 12-inch steel leader with swivel, and a few hooks. Breakdown travel rods and spincast reels should be considered for sport fishing or adding fresh meat to the daily provisions. Throughout the tropics, most species of fish find Rat-L-Trap lures, particularly the chrome and blue combination, irresistible.

GARBAGE BAGS.

Four 30-gallon capacity and four 13-gallon capacity large plastic garbage bags can hold clothes, bedding, and other items that must stay absolutely dry and can keep dirty boots isolated from clean items in the backpack.

HEADLAMP.

Battery-operated headlamps offer hands-free convenience at night for reading or going to the latrine. They should shine at least 10 hours on a set of batteries.

INFLATABLE CUSHION OR PILLOW.

A small, durable, cloth-covered inflatable cushion is recommended for sitting in a dugout canoe or aluminum boat.

INSECT REPELLENT.

To repel mosquitoes, flies, ticks, chiggers, fleas, and gnats (but not no-see-ums), insect repellent should contain 15% to 30% diethyl-toluamide (DEET). Formulations should not contain higher than 30% DEET, often called "jungle juice." These may pose health hazards (see [Chapter 32](#)).

Technique is critical when applying insect repellent. Before dressing, the person should spray the ankles, lower legs, and waist. After the socks are put on, a band should be sprayed around the top; a band should also be sprayed around both pant legs to midcalf. A light spray to the shirt, front and back, may also help. The

hands should be sprayed, rubbed vigorously, and run through the hair. Some repellent should be dabbed on the face, neck, and ears, carefully avoiding the eyes; contact lens wearers should be especially vigilant when applying insect repellent.

No-see-ums, which are tiny gnats that abound throughout the tropics of the Americas,

are the most common source of insect annoyance in many regions. They are active at sunset and attack humans emerging from jungle streams. No-see-ums cannot bite through even the thinnest cloth and are usually inhibited by Skin So Soft (SSS, Avon). (SSS is not effective against ticks, fleas, flies, and chiggers and offers little protection against mosquitoes.) SSS should be applied liberally and often to the wrists, knuckles, bare ankles, face, ears, and scalp. Men with full beards seem to be especially troubled by tiny gnats and may benefit by applying small amounts of SSS to the beard area.

LAMINATED MAP.

Accurate maps exist for most regions on earth. From the best map available, travelers should laminate photocopied portions that are relevant to a particular itinerary (see Rescue Strategies).

MACHETE.

A machete is the single essential tool for jungle survival and for the many tasks in camp and on the trail that require steel with a sharp edge. It is hazardous to use a machete in the rain or when cutting wet grass, however, since the weapon may fly out of the hand. Also, when cutting brush, the person often encounters sawgrass. The resulting skin lacerations, which are not noticed at the first because sawgrass is razor sharp, may take a week or two to heal. Because of the risks involved, an experienced individual should be in charge of transporting and using the machete.

MATCHES OR CIGARETTE LIGHTER.

Waterproof, windproof Hurricane Matches light when damp and stay lit for several seconds even in the strongest wind. Many jungle travelers prefer a butane cigarette lighter.

ORGANIZER BAGS.

See-through organizer bags help reduce clutter and minimize the risk of misplacing small items.

PEN.

The Fisher Space Pen (Fisher Pressurized Pen, 711 Yucca St., Boulder City, NV 89005) writes upside down without pumping, under water and over grease, and in hot and cold temperature extremes. It has an estimated shelf life of over 100 years.

POCKET TOOL.

A favorite pocket tool for the outdoors enthusiast is the Swiss Army knife. The Leatherman Super Tool is recommended for jungle travel and survival and features

needle-nosed pliers and 12 locking implements.

POLY BOTTLES.

Essential gear includes two quart- or liter-sized wide-mouth water bottles made of high-density polyethylene or Lexan polycarbonate. A 2-ounce, heavy-duty poly bottle comes in handy for carrying a salt and pepper mixture to add flavor to boiled plantains and yucca.

RAZOR OR BATTERY-OPERATED SHAVER.

Both men and women should carry lightweight disposable razors. Most men find that lightweight, AA battery-operated shavers give two shaves a day for up to 2 weeks before requiring a change of batteries.

SPOON.

Knife-spoon-fork sets are unnecessary. With a knife blade, a good tablespoon made of either Lexan polycarbonate or stainless steel is sufficient for eating.

SPORT SPONGE.

A camp towel, made of microporous material, is lightweight, compact, and superabsorbent; it replaces the cotton towel. With the Cascade Designs Pack Towel or similar brand, the body and even hair can be dried much more quickly than with a traditional towel.

SUNGLASSES.

Sunglasses should be polarized with full ultraviolet light protection. Many travelers prefer sunglasses with red-tinted lenses. Because red is the complement of green, these lenses make the jungle foliage stand out intensely and sharply, with enhanced contrast and depth of field. Retainers hold eyeglasses securely during vigorous activity.

TOILET PAPER.

American toilet paper is much softer than that purchased in Third World countries. The traveler should never wipe with jungle leaves.

UMBRELLA.

A collapsible umbrella is useful in tropical cities and in remote villages when walking from hut to hut. It also offers excellent protection from the sun on canoe or raft trips. The umbrella should be reflective silver, not heat-absorbing black.

WHISTLE.

A high-quality plastic whistle can be used to signal in case someone strays off the path.

ZIPPER-LOCK BAGS.

Heavy-duty zipper-lock freezer bags are excellent for organizing medicines, toiletries, and other small objects. Bring five each of the gallon, quart, and pint sizes.

COPING WITH THE JUNGLE ENVIRONMENT

A visit to the rainforests of the New World tropics can be either a sublime experience or a hellish ordeal.^[14]

Wetness

The superhumid lowland rainforest receives up to 400 inches of rain a year; in contrast, Indiana averages

716

about 40 inches. In the higher elevation cloud forest, dense cloud cover throughout the year is accompanied by constant mist or drizzle. In such heat and high humidity, people become mentally fatigued as a result of being constantly wet. Fortunately, travelers can use basic strategies for coping with the physical and psychologic burden of wetness. Wetness is as much a state of mind as a physical condition.

Dryness while trekking or working during the day is not a requisite for physical or mental health. Wetness does not equate with illness, significant discomfort, or dampened spirits. People can tolerate being wet throughout much of the day if they know that they have a dry change of clothes to wear in camp and that they will be dry at night. In addition to the psychologic benefits, being dry at night means that maceration is less likely to develop in intertriginous areas.

Bedding and clothing can be protected from moisture by careful wrapping in plastic garbage bags. Despite all efforts, however, certain "dry" items eventually become damp or accidentally soaked. Wet articles should be spread out on shrubs and bushes. They will dry within 2 hours in full sun. Myiasis caused by the tumbu fly, *Cordylobia anthropophaga*, of sub-Saharan Africa can be avoided by hanging clothing to dry in bright sunlight, never on the ground. Clothing dried over a wood fire absorbs odors that do not wash out.

Health Issues

Health Risks.

The subject of the tropics causes many people to think about tropical diseases such as

filariasis and animals such as the candirú (see later discussion). Malaria, hepatitis, and motor vehicle accidents are the three leading health problems in most tropical regions. Tropical travelers who venture off the path may be exposed to bodily harm and serious diseases, such as leishmaniasis, onchocerciasis, and Chagas' disease. Bouts of diarrhea or other annoyances will likely occur, regardless of the extent of precautions taken, but death is unlikely.

Duration of Travel and Emotional Response.

Cashel et al^[5] examined the mood pattern of participants on a wilderness course and noted a high level of confusion, fatigue, anger, depression and tension on day 4. After 2 to 3 weeks of travel in remote areas, the general health of expedition participants deteriorates as a result of insect bites, falls, and noxious plants. Inexperienced trekkers may quickly tire of unfamiliar food and miss usual comforts. Experienced leaders therefore prefer to limit expeditions to 3 weeks.

Preventing Heat-Related Illness.

The following guidelines may help prevent heat-related illness (see [Chapter 10](#) and [Chapter 11](#)).

1. Before undertaking long-distance trekking in the tropics, acclimatize by spending at least 5 days in a hot, humid environment and engaging in moderate daily exercise. This acclimatization will be lost within a week if not maintained.^[15]
2. Avoid alcohol and certain drugs. Medications such as β -blockers, anticholinergics, and diuretics increase the likelihood of heat-related illness and should be avoided if possible.
3. Wear ultralightweight, light-colored, and loose-fitting cotton clothing and a wide-brimmed hat.
4. Whenever possible, have a native porter carry all gear.
5. Maintain adequate hydration. Before setting off on the trail, drink a liter of disinfected water. A half hour later, drink a second liter. One hour after the second liter, drink a third, then consume approximately 1 L every 2 to 4 hours while on the trail.

Heat cramps, often severe, tend to occur when large amounts of water are ingested without adequate salt replacement. Oral rehydration salts (ORS), in premeasured packets added to a liter of disinfected water, provide an ideal balance for replacing lost electrolytes. Trekkers should drink at least 1 L of water containing ORS before setting out on the trail and a second liter after especially strenuous days. ORS packets are distributed by the World Health Organization and UNICEF but are difficult to obtain commercially overseas. In the United States, oral rehydration therapy packets may be obtained from Cera Products (888-237-2598) and Jianas Brothers (816-241-2880).

Sport beverages, such as Gatorade, help maintain adequate electrolyte balance but not as well as ORS. Salt tablets are not recommended because they are gastric irritants

and may even delay acclimatization because of aldosterone suppression. [15]

Unexpected Isolation

Various factors contribute to unexpected isolation in the jungle, such as inclement weather, mechanical problems, or political turmoil that shuts down public transportation. Many people respond with anger and irritability, which can be devastating to group dynamics. Travelers should accept the situation and use the additional time to appreciate the tropical forest, take photographs, or read paperback books.

It helps to shift out of gear mentally and allow the intellectual machinery to idle. Nearly everyone has the experience of driving for hours and arriving at a destination with virtually no recollection of the trip. The same can be accomplished in the village setting, lying around on a hammock. The hours and days pass surprisingly quickly, akin to cruising in a sailboat with no engine. The person learns patience and develops an appreciation that the rhythms of nature are not governed by the ticking of a clock. Unexpected isolation allows many visitors to experience the biospheric cadence.

717

Figure 29-1 Construction of mosquito netting for use with a hammock: sleeve hole = 88 inches in circumference; small hole = 18 inches in circumference; smallest holes (for supporting sticks) = 4 inches in circumference.

Camp Life

Shelter.

Natives rarely spend the night in makeshift shelters, and it is usually best to use existing dwellings for a hammock or sleeping pad. Common courtesy governs their placement or sleeping pad inside the hut of a native. Travelers should ask about taboo spots before bedding down.

When huts are not available for use, a tarpaulin provides satisfactory shelter from the rain. Rip-stop polyethylene tarps (8 × 10 feet) are lightweight and waterproof. Coated nylon tarps are also acceptable but must be sealed with a product such as Seam Grip.

[Figure 29-1](#) illustrates a typical method of erecting a tarp. First, a thick line is run between two trees 7 to 8 feet off the ground and cinched tight. The long axis of the tarp is centered over the rope, and a rope attached to the middle grommet on each end is

tied to the tree. The corner grommets are tied to available trees, bushes, or strong clumps of grass; a tie-down in the middle on each side is also helpful. The sides of the roof should be made high enough to enter and exit conveniently but not so high that driving rain can come in at an angle.

Once the tarp is up, the hammock ropes are run through the sleeves of the mosquito net. Then the hammock is slung. It should be suspended high enough that it will not sag to the ground during the night as it naturally gives under an adult's weight. Next, the mosquito net is suspended. The ropes running from tree to tarp, from tree to mosquito net, and from tree to hammock should be sprayed with DEET-containing insect repellent to keep ants and other pests from using the ropes as trails. Finally, a few broad leaves (banana leaves or heliconia) folded at the spine are draped over the bare rope extending from the tree to the tarp to keep rain from running down the tarp and hammock ropes.

Knowledge of two knots is needed for slinging a hammock. These knots always hold and always come undone quickly without jamming. The *half hitch* is used to tie the hammock to a horizontal beam, as follows ([Figure 29-2](#)):

1. Pass the working end of the rope around the object to which it is to be secured.
 2. Pass the working end of the rope around again without crossing over itself.
-

718

3. Bring the end over and around the standing part and through the loop that has just been created. You have just made a half hitch.
4. Make a second half hitch below the first half hitch.
5. Pull tight.

Figure 29-2 Half hitch knot.

The *camel hitch* is used to tie the hammock to a vertical post secure, as follows ([Figure 29-3](#)):

1. Make three turns around the vertical pole.
2. Bring the working end up and over the turns.
3. Make a turn at the top and pass the end back under itself.
4. Make a second turn at the top and pass the end back under itself.

Weather conditions can change in minutes, and travelers must be prepared with adequate shelter. The use of a tent as shelter in the tropical rainforest is not recommended.

Food.

Solitary travelers or small groups usually do not need to pack large amounts of food. Edibles are always available in areas inhabited by friendly natives. As a general rule, food is safe to eat if it is peeled, cooked, or boiled.

Figure 29-3 Camel hitch.

Figure 29-4 The palm grub is a favorite delicacy.

Travelers in the tropics must be open to eating local food. Most creatures are edible, such as boiled caiman (alligator), cooked capybara (a 50-kg rodent), or roasted palm grubs (larvae of *Rhynchophorus*). Raw palm grubs, up to 5 inches long, are tasty and a favorite of Amazonian Indians ([Figure 29-4](#)). They are eaten by slashing open the thin integument with the thumbnail, extracting and discarding the intestinal tract, placing the opened skin to the mouth, and sucking out the turgid contents.

In addition to palm grubs, more than 20 species of edible insects, including ants and termites, are collected year-round by the people of Amazonia. ^[9] Large hairy spiders 10 inches in diameter, *Theraphosa leblondi*, are often roasted on an open fire. After the barbed hairs are singed off, the spider is placed in the embers; it has a shrimplike taste.

Indians of the Americas have perfected the art of smoking fish and meat so that they remain safe to eat for long periods. It is common to see huge hunks of tapir meat or slabs of 100-pound catfish resting on racks, coal black from the smoking process.

The tropics have an abundance of flora as food. The yard-long heart of palm is cool and delicious when

eaten in its raw state or may be included in a soup spiced with tropical herbs. Familiar tropical fruits include papaya, mango, pineapple, and passion fruit (*Passiflora*). Many New World fruits have no name in English and generally have not found their way into the world market, such as chirimoya, guanabana, pitahayas, naranjilla, uchuva, tamarillo, zapote, sapotilla, and badea.^[22] ^[25] ^[34] The boiled fruit of the peach palm, *Bactries gasipaes*, is nutritious and flavorful.

The banana and its cousin, the plantain, provide a large percentage of the total caloric intake of natives in the American and African tropics. Curiously, in many native villages it is difficult to find the sweet, finger-length bananas and the common yellow bananas exported from tropical countries. The green plantain features prominently in the daily fare of inhabitants of the tropics. The plantain has little taste and is exceptionally dry.

Yucca (manioc or cassava), *Manihot esculenta*, is a staple source of carbohydrate nutrition throughout the Americas and much of tropical Africa. The two kinds of yucca, "sweet" and "bitter," are the same species but differ in their distribution and amount of a poisonous constituent, a cyanogenic glycoside, in the root.^[30] Sweet and bitter yucca cannot be easily distinguished; one must know which variety was planted. Sweet yucca, common in the eastern lowlands of the Andean countries of Colombia, Ecuador, and Peru, is eaten after the bark containing the toxic substance is peeled off and the root boiled. In bitter yucca the poison is more concentrated and distributed throughout the root, so it must be extracted before consumption. Amerindians use an apparatus called the *tipiti* to express the poisonous juice from the peeled and grated flour of manioc roots.

Travelers in a large group should carry dried, packaged foods, since the host village might not be able to provide sufficient foodstuffs or travelers might pass through isolated and uninhabited regions. Packaged foods should also be carried by travelers in regions where natives are unfriendly.

Dried instant food only needs water to make a meal. A few selections should be tried before a large supply for field use is ordered. It is not necessary to add hot water to all packaged foods; adding disinfected, ambient-temperature water produces acceptable results for most foods. Drawbacks to prepackaged foods include expense, space, and disposing of the empty foil packages.

I carry the following supplemental food items for 2- to 3-week treks into remote but inhabited jungle regions: one 2-ounce heavy-duty poly bottle filled with salt and pepper mixed half and half, a few pounds of rice, a tin of long-keeping butter (or oil) for cooking the rice, a few tins of tuna or sardines packed in tropical hot sauce, and several Power-Gel energy packets for trail snacks. Hard caramels can be given to porters after long or difficult passages.

Potable Water.

Potable Aqua (tetraglycine hydroperiodide 16.7%) tablets are recommended for disinfecting water because they are easy to use and have proved effective in killing bacteria, viruses, and most parasite cysts (see [Chapter 51](#)). Water filters are not recommended for purifying jungle water; they clog with silt and must be cleaned frequently. If a water filter is used, it should be fitted with a good pre-filter to catch the excess silt.

Jungle Hazards

The following hazards are common in the wilderness jungle setting or thought to be common. Other chapters provide additional insights and viewpoints, particularly with respect to treatment.

Arthropods

ANTS.

The conga ant, *Paraponera clavata*, 1 to 1 ½ inches long, is the terror of the American tropics. The bite of these large black ants can produce intense pain and fever for up to 24 hours, which provides the Spanish name *veinte-cuatro* (twenty-four). Fortunately, they are conspicuous because their large, shiny black bodies tend to stand out against foliage. Special caution is needed when ducking under or climbing over trees, where ants are often found. A conga bite requires strong pain medication and perhaps the injection of lidocaine at the bite site.

Travelers should avoid touching trees and bushes. Many plants in the tropics provide a home and food for ants, which provide aggressive defense of the plants.

Fire ants are common throughout the tropics and subtropics. Their bite causes discomfort but not excruciating pain. Characteristic pustular lesions in crops often result from fire ant stings.

CHIGGERS.

Chiggers, a form of mite, are a problem throughout equatorial regions. Whereas temperate-climate chiggers may cause mild discomfort for a few days, the tropical chigger sets up an inflammatory and allergic reaction that often persists for weeks.

In the South American tropics, chiggers are found in grassy fields, such as jungle airstrips and yards around mission compounds. Walking through chigger-infested areas without protection could leave a person covered with chigger bites. After a few days the victim begins to itch mildly. As the days pass, the itching intensifies, seems to come in

waves, and may change its focus.

Prevention is the best treatment. Areas known to be infested with chiggers should be avoided when possible. Spraying shoes or boots and lower pant legs with repellent containing DEET is highly effective. Pretreatment of clothing with permethrin has been recommended. Travelers in the American tropics should *never* walk through grassy areas in shorts.

JIGGER FLEA.

Tunga penetrans, the jigger flea or chigoe, originally found in South and Central America, has now spread to East and West Africa and India. The fertilized female flea enters the feet through cracks in the soles, between the toes, and around the toenails. The female swells to the size of a pea and may be readily identified as a white papule with a central pit, through which the female extrudes excrement and eggs. When eggs are ripe for release, intense itching causes scratching that helps release large numbers of flea eggs. Incomplete removal of the jigger frequently results in complications caused by secondary infection. A simple extraction technique virtually eliminates complications. Open the skin over the nest of eggs with a surgical blade. Fold back the flaps, remove the easily identified egg sac, and with tweezers, remove the head of the female flea, which can be seen once the egg sac has been removed. Wash the area with hydrogen peroxide.^[16]

MYIASIS.

Myiasis (skin infestation by fly larvae) is common in many regions of sub-Saharan Africa (the tumbu fly, *Cordylobia anthropophaga*) and Central and South America (the human botfly, *Dermatobia hominis*). The victim finds an itchy swelling that slowly enlarges into a lesion with a single breathing pore from which bubbles clear or slightly bloody drainage. Later, movement is felt under the skin as the developing larva wriggles around.

Removing the larvae before they emerge on their own is generally advised. Surgical excision, however, should be undertaken with caution because accidental rupture of the larval tegument can lead to secondary infections. Various methods to close off the breathing pore so the larva will emerge on its own include application of bacon fat, meat, chewing gum, or petroleum jelly.

SCORPIONS AND SPIDERS.

Stinging scorpions and venomous spiders are common throughout the tropics and provide another reason to exercise caution before sitting down or placing a hand on logs, bushes, or the ground.

VENOMOUS MOTHS, BUTTERFLIES, AND CATERPILLARS.

The larvae and adults of a number of moths (genus *Hylesia*) and butterflies bear venomous hairs that may cause skin eruptions. A rash may result from direct contact with the adults or larvae or by windblown hairs. Direct contact with certain Amazonian caterpillars can cause disabling pain.

In the Amazon tropics, noxious smoke from burning garbage (e.g., plastic wrappers) may cause tree-dwelling caterpillars to loosen their hold on overhead branches and rain down on unwary campers.

Treatment of lepidoptera envenomation may require injection of lidocaine at the site of intense pain and administration of analgesics, antihistamines, and corticosteroids ([Chapter 36](#) and [Chapter 37](#)). Moth hairs may be removed with sticky lint removers used for clothing.

WASP AND BEE STINGS.

Sudden, intense pain from the sting of certain species of tropical wasps and bees can be so severe that it knocks the victim to the ground as though hit with an electric shock. Perfumes and brightly colored or flower-patterned clothing should be avoided.^[19] Bird watchers should not venture too close to the hanging nests of yellow-rumped caciques and oropendolas, because wasps are invariably associated with these nests.

Fish

STINGRAY.

The stingray, a flattened, cartilaginous cousin of the shark, may be encountered buried just beneath the surface of the bottom ooze in tropical rivers and streams throughout the Amazon Basin, Africa, and Indo-China. Rays inflict injury by lashing upward with the caudal appendage, driving one or more retroser-rated venomous spines deep into the victim's foot, ankle, or lower leg. This produces agonizing pain, often accompanied by headache, vomiting, and shortness of breath. After the initial phase of envenomation, tissue necrosis may develop. Wearing shoes or boots when wading in water does not always prevent a stingray from jabbing its barb into the foot or leg. Prevention lies in shuffling the feet along the bottom so that the ray will have enough warning to glide away safely (see [Chapter 60](#)).

ELECTRIC EEL.

The so-called electric eel (actually an eel-shaped fish) is encountered from Guatemala to the La Plata River in South America and is especially common in the Amazon region. A person can drown after being stunned by a jolt from this fish.

Electric eels are said to prefer deep water. Inhabitants of regions heavily infested with eels report a slight tingling sensation when one is close. No practical way exists to prevent these shocks.

CANDIRÚ.

The candirú is a toothpick-sized parasitic catfish that inhabits Amazonian waters and may invade the urethra of urinating humans. Orifice penetration by the wily candirú can be prevented by wearing a tight bathing suit and not urinating underwater. Native methods of dislodging these fish from the urethra include drinking a tea made from the green fruit of the jugua tree, *Genipa americana* L. Vitamin C (2 to 5g) may serve the same purpose⁴¹ (see [Chapter 62](#)).

PIRANHA.

Although no human deaths have been documented, piranha have nipped off the fingertips of canoeists dangling their hands in the water.

Mammals

721

BATS.

Vampire bats are found throughout Mexico, Central America, and South America, especially in areas that have large cattle ranches. Sleeping humans are unaware of the presence of a feeding bat; the phlebotomy is painless. Both vampire and fruit bats carry rabies. Sleeping under mosquito netting prevents bat bites. The risk of rabies can be reduced by prophylactic human diploid cell rabies vaccine.

DOGS.

Most native groups keep dogs for hunting. Populations with a history of recent tribal warfare often keep packs of dogs close by as an early warning system. These semiwild dogs should be treated with caution; threatening them may cause immediate attack, since they are not easily intimidated. When approaching huts or villages, the traveler should allow porters to deal with the dogs first.

Dogs intent on biting often adopt particular behavior patterns. The dog protecting its territory crouches low, straightens its back and tail, emits a deep guttural growl, and stares fixedly at a specific part of the person's anatomy. Such behavior indicates imminent attack and a sharp blow to the nose may be necessary. Freezing in place may

prevent an attack, and direct eye contact should be avoided.

JAGUARS.

Jaguar attacks are rare. Recommendations are based on advice for avoiding a cougar attack. Increase your apparent size by raising your arms above the head and waving an object such as a backpack or stick, or opening a jacket. Yell, shout, whistle, or speak loudly and forcefully in a low, deep tone of voice. Back away slowly; do not turn your back and run.^[8]

Reptiles

SNAKES.

Snakebites are rare; 450,000 hours of field work at sites in Costa Rican rainforests were documented without a single snakebite.^[7]

Most poisonous snakes tend to blend into their surroundings, and nonnatives rarely see them. The most effective protection is putting a jungle-reared guide in front on the trail. Natives almost always spot a poisonous snake and can quickly dispatch it.

Snakes are often encountered along the shoreline of rivers and small streams. Particular caution is needed when hiking in such areas or when disembarking from a canoe or rubber raft. In the forest the hiker should always step onto a log and then step away from it. The log should *not* be straddled; snakes often are encountered where the log makes contact with the jungle floor. Since many venomous snakes in the tropics are heat seeking and hunt at night, caution is needed.

Anacondas (water boas) feature in the folklore of all native cultures in the regions of Amazonia where these enormous snakes (up to 30 feet long) live. These non-poisonous

Figure 29-5 Needle-sharp spines ring the peach palm.

snakes kill by looping coils around prey and then tightening the coils, suffocating the victim. Anecdotal reports of anacondas attacking and swallowing humans, particularly children and women bathing at the edge of jungle streams, are unconfirmed.

ALLIGATORS AND CROCODILES.

Although they appear torpid lying in the sun, alligators and crocodiles can move

amazingly fast. Humans cannot outswim or outrun a charging crocodile.

Bites should be treated with thorough cleaning of the wound, surgical debridement if necessary, tetanus prophylaxis, and an appropriate antibiotic. A study of the oral flora of 10 alligators captured in Louisiana revealed various aerobic and anaerobic organisms responsive to trimethoprim-sulfamethoxazole.^[13]

Plants

ARMED OR SPINE-BEARING PLANTS.

Spine-bearing trees abound in forested areas of the tropics. The peach palm (*Bactris gasipaes*), a tall, slender palm whose heart and fruit mesocarp are prized by natives, is found from Nicaragua to Bolivia. The trunk of this tree is ringed with needle-sharp spines ([Figure 29-5](#)). Peach palms often grow alongside trails. Contact with this palm can result in penetration of spines deep into the flesh. Spines that enter a joint space may require surgical extraction. Secondary infection and inflammation often occur.

HALLUCINOGENIC PLANTS.

Jungle-dwelling tribes throughout Central and South America use hallucinogenic plants. Powerful drugs, such as ayahuasca (*Banisteriopsis*), *Brugmansia*, the virola snuffs, and yopo (*A. peregrina*), are used by shamans seeking the truth.^[28] ^[29] ^[30] These powerful intoxicants should be avoided.

SAWGRASS.

In many regions of the tropics, sawgrass is an ever-present nuisance. This scalpel-like blades of this

Figure 29-6 Poison-dart frog.

grass can slice into exposed skin. Even when treated with antibiotic ointment, the lacerations often take 1 to 2 weeks to heal. Hikers should avoid sawgrass; special care is needed when working with a machete.

Miscellaneous Hazards

POISON-DART FROGS.

Poison-dart frogs, tiny, brilliantly colored species in the genus *Dendrobates*, may be encountered in Central America and Northern South America ([Figure 29-6](#)). *Phyllobates terribilis* secretes a toxin from its skin so powerful that a lethal dose could be absorbed if enough secretion entered an open wound. It is wise to avoid all contact with brilliantly colored frogs, caterpillars, and snakes.

FALLING TREES.

Tropical trees do not have deep roots and often fall in relatively modest winds. In many regions of the world, risk of snakebite is significantly lower than the risk of injury or death from falling trees. In the forest, hammocks should be slung away from large trees. Travelers setting up camp should always look up at the branches of any trees near camp; although the base of the tree may appear sound, higher areas may be rotted.

FORDING RIVERS.

The hiker should never attempt to cross a fast-flowing or deep river with a pack on his back. Regaining footing in a rapidly moving current can be difficult. Unless experienced in crossing such streams, the traveler should take the hand of a native guide or porter.

LOG BRIDGES.

On frequently used trails, natives generally place a single log across creeks, ravines, and swampy areas. These log bridges may be up to 20 feet high and 75 feet long. Good balance is essential. Because a backpack impairs balance, a porter should carry it across.

MERCURY CONTAMINATION.

Travelers to the Amazon Basin should be aware of the serious, widespread contamination of waterways by mercury that gold miners (*garimpeiros*) use to process their ore. Although most manufacturers of portable water treatment and filtration systems do not specifically claim to remove mercury, any activated carbon system should reduce the risk. The manufacturers of SafeWater Anywhere, (www.safewateranywhere.com), a 1-L squeeze-bottle filter, cite 99.25% mercury removal. Travelers should exercise caution in choosing rivulets as a source of potable water in areas where mercury contamination is known or suspected.

RISING RIVERS.

Streams, particularly narrow ones bounded by vertical banks, can rise 20 feet in a few hours as a result of intense rains. Camp should not be set up on an island or beach in a small canyon during the rainy season. A cloudburst in the headwaters can send a wall of water rushing downstream, even though it may be a clear, moonlit night at the campsite.

Traveling with Children in the Tropics

The following guidelines should be considered when trekking with children in the tropical forest:

1. Do not attempt a daylong hike. Unlike indigenous children, others cannot hike all day in the humid tropical forest. Preadolescents should hike only 1 to 2 hours; for children aged 12 to 16 can hike 2 to 3 hours. Do not subject a child to jungle trail conditions unless the child has had extensive experience hiking in temperate climates.
2. Do not attempt difficult or dangerous trails.
3. Avoid trekking during the rainy season.
4. Keep the child well hydrated.
5. Provide proper footwear (running or hiking sneaker-type shoes or boots with an adequate tread). Avoid leather boots.
6. Keep the child ahead of you and behind a native guide. Children should not be out of sight on the trail.
7. When wading across rivers, have an adult native guide hold the child's hand.
8. *Always* have children wear a properly sized life vest while rafting, taking canoe trips, or crossing deep, swift, or wide rivers.
9. Do not allow a child to carry any equipment in a daypack other than 2-L bottles of drinking water.
10. Ensure that routine vaccinations are up to date. Special vaccinations, such as yellow fever and typhoid should be considered for certain jungle areas. Hepatitis A vaccine is recommended. Antimalarials are indicated.

Any child who plans to visit the tropics should be a strong swimmer. Many natives begin swimming in infancy

and are accustomed to deep or rapidly flowing water that would be extremely hazardous to visiting children. Swimming holes are often located in the swift-flowing outer loop of jungle rivers, where depths may reach 6 feet or more within a yard of the shoreline.

SURVIVAL

Every year, inexperienced people enter the jungle and become lost. After a person ventures only a mere few yards into the forest, especially jungle that has been cleared and is now a tangle of secondary growth, everything begins to look the same. *To avoid becoming lost, travelers should always have an experienced guide when traversing unfamiliar territory.*

Tribal peoples of the world's tropical forests have an uncanny ability to find their way and arrive at the desired destination, even after days of travel. They can always find food and water and, if necessary, rapidly construct a shelter or a weapon.

Occasionally, travelers are left behind on the trail by indigenous guides. Unintentional desertion occurs when trekkers hire natives who have had no experience with neophytes. Realizing that their charges cannot keep up on the trail, the guides run ahead and sit down to rest, not knowing that others cannot navigate the trail alone. Travelers who want to avoid being left behind on the trail should hire a guide who is experienced in traveling with nonnatives. Suitable guides and porters can usually be identified with the help of a village leader, local school teacher, village health worker, missionary, or anthropologist.

Rescue Strategies

For individuals in a jungle survival situation, lifesaving items include a large-scale map, a global positioning system (GPS) unit, some form of electronic voice communication, and a machete. Topographic maps are available from numerous international and national mapping agencies. Satellite images with extraordinary resolution are available from Space Imaging (1-800-232-9037) or the U.S. Geological Survey (Eros Data Center 47914, 252 ND St., Sioux Falls, SD 57198-0001; 1-800-252-4547; edcwww.cr.usgs.gov).

Small, lightweight GPS units display precise latitude, longitude, and altitude. Such information is extremely useful for navigation and for communicating one's location to rescue aircraft. Newer units quickly lock onto satellites and are more likely to work under the jungle canopy.

Canoeists, rafters, or trekkers contemplating an expedition into largely uninhabited and unexplored regions should consider buying a compact emergency position-indicating radio beacon (EPIRB). The 406 MHz EPIRB units offer a reliable method of alerting various rescue services via a global satellite system. These units should be activated

only in a true emergency when lives are at risk.

Hand-held satellite phones are available for worldwide communication. Although currently expensive to purchase and operate, their potential to provide rescuers with precise GPS location makes these lightweight phones worthy of serious consideration for inclusion for wilderness travel.

Lightweight, hand-held, very-high-frequency (VHF) aircraft transceivers are excellent for emergency communications. Visitors to remote areas should know the radio frequencies used by rescue aircraft. VHF transceivers are line-of-sight instruments, so they are most useful when aircraft are overhead without objects, such as trees or mountains, between the hand-held unit and the aircraft. In many regions of the world the Mission Aviation Fellowship (MAF) provides air service to remote airstrips in small villages. If assistance is needed, a hand-held radio transmitter can be used to call an MAF short take-off and landing (STOL) aircraft.

Bush pilots appreciate having information on the condition of seldom-used airstrips. A crude but acceptable device can be constructed to measure airstrip hardness ([Figure 29-7](#)). Cut a pole exactly 2 inches in diameter and approximately 6 feet long. Starting exactly 6 inches from one end, taper that end to a point. Lash a cross-member on the pole, and have a person weighing approximately 170 pounds stand with assistance on the cross-member. Make a map of the strip, noting the depth to which the pointed end of the pole sinks into the earth at several dozen sites. Communicate this information to the pilot by radio. If the pole goes in only 2 inches in most areas, the strip is considered ideal; 2 to 4 inches is marginal; penetration beyond 4 inches indicates that the airstrip is unsuitable for landing and take-off.

If rescue is not feasible, the traveler should continually move downstream at a fast pace.

Inhabited areas usually have a trail running alongside a stream. The trail may veer away from the stream where natives have cut a path to connect two villages. Marking the trail every 10 yards with a machete makes it easier to return to the starting point. To avoid confusion, the traveler should mark trees only on one side of the trail.

Where human paths are in frequent use, identifying a trail is fairly easy. Seldom-used trails or any trail traversed during times of optimal plant growth may be extremely difficult for the nonnative to identify and follow. Even under adverse circumstances, however, there are clues to trail identification. Paradoxically, concentrating only on the actual foot path will almost certainly cause you to lose sight of the trail. Think of the jungle trail not as a track on the ground but as the intestinal lumen of "some gigantic leafy creature,"^[17] with vertical margins, often an overhead horizontal boundary, and sometimes a visible path beneath the

Figure 29-7 A, Young man sharpening a stick to a point. B, Lashing a cross-member to a pole. C, Standing on the pole to take measurements of the depth of penetration into the airstrip.

Figure 29-8 Log flotation device. A, Two lightweight logs are tied together. B, Device in action.

feet. Diagonally sliced saplings or neatly severed branches indicate someone has used a machete. There is a particular reflectivity off the ground where humans have trod; this reflectivity is the best way to follow a trail at night. These trail-finding clues are often so subtle that you may *sense* the trail rather than *see* it. Game trails meander and are narrower than human trails.

In the jungle setting, navigation with a compass for a distance of more than 200 yards is fraught with hazard. Travelers should not attempt to cut overland if lost, inexperienced, or on their own unless a significant landmark is visible or sounds of humans or domesticated animals, indicating a settlement, are clearly heard.

A raft may be constructed by lashing logs together with rope or tough, pliable jungle vines. Balsa trees (*Ochroma pyramidale*), encountered throughout much of Amazonia, make the best rafts. Balsa is often found growing alongside rivers and has the following characteristics: tall, columnar trunk with branches and leaves bunched at the top, which gives the tree a "skinny" look; beige or gray-beige trunk; bark that is smooth but tends to flake, giving it a mottled appearance; and broadly heart-shaped, more or less three-lobed leaves. The key feature of balsa wood is its remarkably light weight. Bamboo also can be used to construct a first-class raft.

A log flotation device may be constructed by tying together two balsa logs or other lightweight wood placed 2 feet apart ([Figure 29-8](#)).^[32]

A "brush" raft may be made by placing buoyant vegetation within clothing or a poncho. Dry leaf litter ("duff") or plants such as water hyacinth may be used.^[32]

Food

Food is readily available in inhabited regions. Even abandoned villages yield enough fruit and vegetables on which to survive. Throughout the tropical world, bananas and the large plantain "cooking banana" are ubiquitous. Root crops such as taro, yams, and yucca should be sought. Yucca roots should be shredded or pounded and then boiled to release their toxic compounds. As an extra precaution, the wet pulp should be flattened into a "pancake" and cooked on a grate to eliminate any remaining volatile hydrogen cyanide gas.

All land crabs, mammals, birds, freshwater fish, turtles, snakes, and lizards are edible but should be cooked first to eliminate parasites. It is virtually impossible to kill game without firearms. In inexperienced hands, traps and snares are not effective. Much better results are obtained from fishing (see [Chapter 28](#)).

Water

Water may be made safe by boiling or using chemical disinfectants, such as Potable Aqua tablets. Drinkable water may be found in lianas, often called "water vines," throughout jungle regions. Vines that contain water are fairly easy to identify because they tend to resemble the "grapevines" of North American forests and have rough, scaly bark. These vines may be several inches thick and contain surprising amounts of clear water. Vines that do not contain drinkable water tend to have smoother bark and, when cut, exude sticky, milky liquid. Travelers should *not* drink from vines that contain milky, latex-like sap; this substance is poisonous. Maximal amounts of water are collected from water-bearing vines if the first cut is high on the vine and the second cut is lower on the vine near the ground. When the water stops flowing from the cut section, cutting approximately 6 inches from the opposite end will start the flow again.

Water may be trapped within sections of certain types of green bamboo. Bamboo that contains water makes a sloshing sound when shaken. Water also may be obtained from green bamboo stalks by bending a stalk over, tying it down, and cutting off the top. Water dripping from the severed tip can be collected in a container during the night ([Figure 29-9](#)).^[32]

Large amounts of water can be found in the voluminous natural cisterns formed by the cuplike interiors of epiphytes (air plants), such as bromeliads. The water should be strained through a cloth.^[32]

Figure 29-9 Bamboo can be a source of water.

Water may be collected from a banana or plantain plant by cutting the plant approximately 1 foot above the ground and scooping out the center of the stump into a bowl shape. The hollow thus formed fills immediately with water. The first two fillings have a bitter taste and should be dipped out. The third and subsequent fillings are drinkable. A banana plant can furnish water in this fashion for several days ([Figure 29-10](#)).^[32]

In coastal regions, unripe (green) coconuts provide adequate supplies of refreshing milk. The milk of mature coconuts has a laxative effect and should be avoided.

Shelter

Abandoned, temporary shelters previously constructed by natives on hunting expeditions seem to attract particularly aggressive, large biting spiders and stinging ants. Also, venomous snakes may be attracted to rodents residing in these abandoned shelters. It is often preferable to take the extra time to set up a new camp than to risk encountering venomous insects, arachnids, and snakes.

In an emergency a proper shelter can be constructed using only plant materials. [Figure 29-11](#) illustrates the basics of constructing a sleeping platform and lean-to. A shingled covering can be made quickly and easily from long, broad banana or heliconia leaves. Tropical palms provide a more substantial roof but require more time and skill in construction. After selecting a suitable ground-hugging species or chopping down a slender tall palm (palm trees with spines often provide the best fronds), each frond is separated into halves by grasping

Figure 29-10 Water collected from a banana plant.

it at the distal end, separating the leaves as though parting hair down the middle, and splitting the frond in two with a quick jerk ([Figure 29-12](#)). The halves should be overlapped like shingles and secured to the roof framework.

It is much easier to construct an adequate shelter using a tarpaulin (see Camp Life).

Psychology of Survival

Travelers reared on movies and novels depicting the horrors of the Amazon may have irrational fears of being lost or stranded in the jungle. Visible daytime threats worsen with the onset of darkness, when perception becomes distorted. Travelers incapacitated by fear may throw away survival items or may flee from rescuers.

Strategies that can increase travelers' confidence in survival include the following:

1. Previous jungle experience. It is helpful to begin tropical excursions in the structured setting of small-group travel. Ecotours, particularly in Costa Rica and Ecuador, offer a combination of rainforest trekking and cross-cultural experience.
2. Survival manuals. Military experts and others provide insights from decades of experience.^[32] ^[33]
3. Information on the tropical rainforest. Familiarity with exotic plants and animals lessens the likelihood of fear while increasing awareness of potential utility in a survival situation. The anthropological literature is replete with first-person accounts by anthropologists who have lived under trying circumstances with minimally contacted tribal populations throughout the tropics.
4. Classic accounts of adventure and survival. The Adventure Library (800-754-8229) offers an excellent series of survival epics.^[21]
5. Courses in wilderness-oriented skills. The National Outdoor Leadership School (NOLS, 307-332-5300, www.nols.edu) teaches wilderness-oriented skills and leadership in a core curriculum stressing safety and judgment, leadership and team work, outdoor skills, and environmental studies.
6. Traveling with a machete, the one indispensable tool. A map, compass and a GPS unit are other recommended items.
7. Taking stock. The traveler facing a wilderness crisis assess a situation analytically and rationally before planning the course of action. *Having survival skills is important; having the will to survive is essential.* ^[33]

Chapter 30 - White-Water Medicine and Rescue

Eric A. Weiss

Rivers have what man most respects and longs for in his own life and thought—a capacity for renewal and replenishment, continual energy, creativity, cleansing.

John M. Kauffman, *Flow East*

Rafting, canoeing, and kayaking have become the third largest outdoor recreation industry in the United States.^[34] Over 19 million people canoe and kayak each year, and more than 57 million enjoy rafting.^[6] Combined participation in river sports is growing at a rate of 15% annually.^[35] ^[43] Kayaks and rafts are also used by law enforcement officers, park rangers, and game wardens to patrol and manage their territories.^[29] New equipment designs have opened up more difficult rivers for exploration and commercial recreation.

It is not surprising that the number of river-related accidents and deaths has also increased dramatically. The American Canoe Association reports that approximately 130 white-water fatalities occur each year.^[43] This chapter examines the unique and dynamic hazards associated with rivers and white-water paddling. Safety equipment, accident prevention, common injuries, environmental hazards, medical management, and swift water rescue are also reviewed.

HISTORICAL PERSPECTIVE

White-water boating as a recreational activity began in the United States in earnest during the late nineteenth century when adventurers attempted to emulate Major Wesley Powell's Colorado River expedition by rowing boats down many of the West's large rivers.^[24] These heavy wooden boats were replaced by inflatable rafts after World War II, when surplus neoprene assault boats and life rafts became available for civilian use.^[3] In 1966, fewer than 500 people boated the Colorado River through the Grand Canyon in an entire year. Recently, the figure exceeded 500 per day.^[24]

Rafting did not become popular in the eastern United States until the early 1960s. In 1968, commercially guided raft trips were offered for the first time on the New River in West Virginia.^[45] The Chattooga River in Georgia attracted many rafters after the movie *Deliverance* was filmed there in 1971. The Youghiogheny River in Pennsylvania and the South Fork of the American River in northern California have become the two most heavily rafted rivers in the country.

Technologic advances have revolutionized river running. Electronically welded plastic has largely replaced rubber as the primary material used in raft construction, making the vessels lighter, stronger, and easier to repair. Self-bailing rafts, introduced in 1983, are now ubiquitous and provide greater maneuverability, allowing rafters to run rivers previously considered too difficult and dangerous. Unfortunately, greater mobility has been paralleled by an increase in the number of accidents occurring far from medical care.

A major innovation in kayaking was the development of the plastic kayak, first manufactured in 1972 by the Holloform Company ([Figure 30-1](#)).^[45] Kayaks had been previously constructed from resinous materials, such as fiberglass and Kevlar, which were more fragile and less likely to "broach," or wrap around rocks. Paddlers were reluctant to run steep, rocky rivers for fear of breaking their boats. Most recreational white-water kayakers are now made of molded polyethylene plastic, which does not break apart and has the potential to fold when broached or pinned, trapping the paddler. Kayakers with "indestructible" boats are pushing the limits of navigable rivers. Even Niagara Falls has been successfully run by a kayaker!

The enormous popularity of rafting and kayaking has led to exponential growth of professional guide services. In 1990, 35 million people were taken down U.S. rivers by commercial companies.^[43] Faced with increased competition, guide services have been leading inexperienced clients with little formal training and few practical skills into difficult and dangerous rivers ([Figure 30-2](#)). In the summer of 1988, five U.S. executives died after their raft flipped on the Chilco River in British Columbia. One of the survivors was

reported to have said, "We looked at white water as sort of a roller coaster ride."^[41]

MORBIDITY AND MORTALITY

There is a paucity of data that document the relative risk of white-water-related activities. In Colorado, fewer people die while engaged in rafting, canoeing, and kayaking than in climbing, bicycling, and skiing. Figures compiled by the Colorado Department of Public Health and Environment showed that 69 people died in climbing or hiking accidents, 36 while bicycling and 32 while snow skiing during a 3-year period ending in 1995. Rafting, canoeing, and kayaking incidents, by comparison, resulted in 19 fatalities ([Table 30-1](#)).

Figure 30-1 River rescue. The plastic kayak has revolutionized white-water sports. (Courtesy Paul Auerbach, MD.)

Figure 30-2 Class V commercial rafting on the Chattooga River, Georgia. (Courtesy Robert Harrison, Whetstone Photography.)

A retrospective analysis of injury reports submitted by commercial rafting outfitters to the West Virginia Division of Natural Resources from 1995–1997 revealed a total of 200 injuries with a resulting overall injury incidence rate of 0.263 per 1000 rafters. The average age of injured persons was 33.14 years, 53.3% were male, and 59.8% had previous rafting experience.^[47]

TABLE 30-1 -- Recreational Fatalities in Colorado, 1993–1995 (252 deaths were the result of recreational activities)

ACTIVITY	RANK	FATALITIES
Climbing/hiking	1	69
Bicycling	2	36
Snow skiing	3	32
Swimming	4	25
Canoeing/kayaking/rafting	5	19
Horseback riding	6	18
Boating/water skiing	7	13
Fishing	8	11
Hunting	9	6

Data from Colorado Department of Public Health and Environment.

The body parts most frequently injured during rafting mishaps are the face (33.3%), including the eye (12.1%), mouth (6.6%), other facial parts (5.1%), nose (4.5%), and teeth (4.0%), followed by the knee (15.3%), arm/wrist/hand (11.6%), and other parts of the leg, hip, or foot (10.5%). The most common injury types are lacerations (32.5%), sprains/strains (23.2%), fractures (14.9%), contusions/bruises (9.8%), and dislocations (8.2%). Most injuries occur in the raft as a result of collisions among passengers, being struck by a paddle or other equipment, or entanglement of extremities in parts of the raft.^[47] Because most injuries occur in the raft and involve the face, accident-preventive measures include attaching face protection to paddling helmets and carrying fewer passengers per raft.

EQUIPMENT

The dynamic and unpredictable nature of rivers can turn any mishap into a tragedy. For this reason, the initial mission of white-water medicine is to emphasize safety and accident prevention.

According to the U.S. Coast Guard's boating accident statistics, the most common factor contributing to white-water-related deaths is failure to wear a personal flotation device (PFD, or life jacket).^[43] Exposure to cold river water can stimulate respiratory and cardiovascular reflexes, making it difficult for a swimmer to keep his or her head above water (maintain freeboard) (see [Chapter 8](#)).^[25] The Coast Guard is charged with regulating and testing life jackets and classifies PFDs into five types. Of these, only two types are commonly used in white-water sports.

The type III PFD, a vest-type jacket favored by most paddlers, permits greater mobility and comfort. The Coast Guard requires that type III PFDs have a minimum of 15 ½ pounds of flotation (lift). Because most

adults effectively weigh between 10 and 12 pounds in the water, this allows at least 3 ½ pounds of effective required buoyancy.

Type V PFDs are used by commercial outfitters because they provide greater flotation and are constructed asymmetrically with over half of the jacket's flotation distributed in the front. This is supposed to turn an unconscious wearer face up. Although this may be true in calm water, it does not work reliably in swift water.

A PFD should fit snugly and not ride up over the head when a person is in the water. Because even a well-fitting life jacket can be pulled off by turbulent water, some manufacturers now include crotch straps as an added safety feature. Testifying before a congressional subcommittee, the president of the National Transportation Safety Association cited the Chilco River accident to support his contention that crotch straps be made mandatory on all white water-use life jackets. Several survivors reported that their life jackets rode up over their heads and did not keep their faces above water.

Life jackets with built-in rescue harnesses, pioneered by the Europeans, are now widely available in the United States. A typical harness system uses seat-belt webbing threaded through a metal retainer, then run into a plastic cam-lock buckle with a toggle.

The toggle allows the user to find the buckle in white water. To release the system, the user pulls the toggle, opening the buckle and allowing the webbing to slip through the retainer and release. A D-ring mounted on the back of the jacket provides a point for clipping in a rope ([Figure 30-3](#)). This quick-release belt allows the wearer to attempt a strong swimmer rescue but also to get free of the tethering line quickly in an emergency.

Beyond flotation, life jackets have other benefits that make them highly useful in wilderness settings. Their insulating properties help prevent hypothermia. The closed-cell foam flotation material acts as thoracic padding during falls on slippery rocks or when swimming rapids after exiting the craft. Life jackets also make excellent improvised splints; they can be fashioned into cervical collars, cylindrical knee braces ([Figure 30-4](#)), or padded ankle stirrups.

The American Whitewater Affiliation (AWA) safety code recommends the use of helmets at all times in kayaks and canoes, and in rafts and other craft when attempting rapids of class IV or greater difficulty. Surveys have shown that head trauma after capsizing comprises 10% to 17% of all kayaking accidents.^{[29] [44]}

Another vital piece of safety equipment is a rope, which should be readily accessible and secured in a manner that facilitates rapid deployment and prevents entanglement. Throw ropes for river use should float, have a certain amount of dynamic stretch, and not absorb water. Self-contained throw bags have virtually replaced

Figure 30-3 A, Life jacket with built-in rescue harness. **B** and **C**, A quick-release buckle allows the wearer to release the tether when necessary. It is essential for swiftwater use.

coiled ropes for river use and generally hold about 50 to 75 feet of 1/2-inch polypropylene rope inside a nylon stuff sack. Newer styles can be attached to life jackets for rapid access. They can also be thrown to rescuers by a paddler who is pinned or broached. Commercial outfitters and

Figure 30-4 A paddler wearing a type III life jacket around his knee as an

improvised knee immobilizer to help stabilize a sprained knee.

large groups of rafters should carry at least one 300-footlong static rope to be used for Telfar lowers, Tyroleans, and other rescue situations where mechanical advantages are used.

Knives should be readily accessible. Fixed blades are preferable to folding ones unless the folded blade can be opened easily with one hand. Double-edged blades can cut in two directions and thus require minimal handling in precarious situations. Some modern knives designed for kayakers feature serrated edges that can cut through plastic boats during entrapment.

Whistles should be worn so paddlers can alert others that an accident has occurred. Paddlers are often spread out over the course of a rapid, and yelling over the roar of the water is usually a frustrating and fruitless endeavor.

Placing adequate barriers between the human body and the environment is of paramount importance in aquatic sports. Functional, insulated clothing should be considered a mandatory safety item to prevent hypothermia. Cotton is a poor choice for river wear; it loses all of its insulating properties when wet and dries slowly. Newer synthetics such as polypropylene and polyester pile absorb no more than 1% of their weight in water and maintain thermal insulating qualities when wet.^[27] When combined with a nylon or Gore-Tex paddling jacket, a synthetic underlayer provides effective protection from cold and wind.

Wet suits, previously considered to be optimal garments for paddlers in extreme conditions, are stiff and somewhat constricting.^[4] The dry suit, with tight-fitting latex seals at the wrist, ankle, and neck, is the new "gold standard" for cold water boating. By sealing water out and preventing evaporative heat loss, the dry suit can keep a paddler warm even during winter conditions.^[17]

Overheating is occasionally a problem with dry suits. Recently a dry suit contributed to profound and unexpected hyperthermia in a kayaker who had suffered a submersion injury in cold water.^[4]

RIVER HAZARDS

The International Scale of River Difficulty grades rivers and rapids into classes I to VI. An American version of this rating has been adopted by the AWA for most U.S. rivers ([Box 30-1](#)).^[42] Some western rivers use the Grand Canyon System, which rates rapids on a scale from 1 to 10. Neither scale is a truly objective standard; individual and regional variations are common, and the margin of difficulty for a particular rapid may differ significantly for kayaks and rafts. Unfortunately, important safety parameters, such as water temperature, remoteness, and evacuation potential, are not taken into consideration.

The difficulty of a river generally increases with the volume of flow and the average gradient. The volume of water in a river is usually expressed as a measure of cubic feet per second (cfs). It is the amount of water moving past a certain point during a given period of time. The volume of a river can be determined by multiplying the width by the depth times the speed of the current. As the water level rises, its speed and power increase exponentially, raising the difficulty of most rapids.^[3] Occasionally, however, a rapid becomes easier as the added water submerges hazardous obstacles. Gradient is the amount of drop between two points and is expressed as feet per mile. The steeper the gradient, the faster the water moves.

Not all water flows downstream. The most common upstream flow is an eddy, which is created when water flows around an obstacle. The water piles up higher than the river level on the upstream side of the obstacle, while the water on the downstream side is lower. Water flows around the obstacle then back toward it to fill in the low spot. The line between the upstream and downstream current is the eddy line. Eddies are one of the most important features of the river for boat maneuvering and rescue. Exiting the main current by pulling into an eddy allows the paddler to stop the descent and safely scout the next rapid. It also provides a location for a paddler to set up rescue for his or her companion upstream.

Hydraulics, also known as holes, reversals, rollers, suck-holes, and pour-overs, are the most common hazards in rivers. A hydraulic is created when water flows over an obstacle, causing a depression that produces a relative vacuum within which the downstream water recirculates ([Figure 30-5](#)). The water below a hydraulic is typically very aerated and presents a white, foamy appearance. Rafts and kayaks can be turned upside down by the force of a hydraulic, and if the reversal currents are strong enough, crafts and people can become trapped in the recirculating flow. When proceeding into a rapid that contains a hazardous hydraulic,

Figure 30-5 Recirculating currents created by a hydraulic. Water and "swimmers" are released downstream beneath the surface.

one of the group should preset a rope below the hole to facilitate rescue.

Box 30-1. AMERICAN VERSION OF THE INTERNATIONAL SCALE OF RIVER DIFFICULTY

CLASS I: EASY

Fast-moving water with riffles and small waves. Few obstructions, all obvious and easily avoided with little training. Risk to swimmers is slight; self-rescue is easy.

CLASS II: NOVICE

Straightforward rapids with wide, clear channels that are evident without scouting. Occasional maneuvering may be required, but rocks and medium-sized waves are easily avoided by trained paddlers. Swimmers are seldom injured, and group assistance, although helpful, is seldom needed.

CLASS III: INTERMEDIATE

Rapids with moderate, irregular waves that may be difficult to avoid and can swamp an open canoe. Complex maneuvers in fast current and good boat control in tight passages or around ledges are often required; large waves or strainers may be present but are easily avoided. Strong eddies and powerful current effects can be found, particularly on large-volume rivers. Scouting is advisable for inexperienced parties. Injuries while swimming are rare; self-rescue is usually easy, but group assistance may be required to avoid long swims.

CLASS IV: ADVANCED

Intense and powerful but predictable rapids requiring precise boat handling in turbulent water. The advanced river may feature large, unavoidable waves and holes or constricted passages that demand fast maneuvers under pressure. A fast, reliable eddy turn may be needed to initiate maneuvers, scout rapids, or rest. Rapids may require "must" moves above dangerous hazards. Scouting is necessary the first time down. Risk of injury to swimmers is moderate to high, and water conditions may make self-rescue difficult. Group assistance for rescue is often essential but requires practiced skills. A strong Eskimo roll is highly recommended.

CLASS V: EXPERT

Extremely long, obstructed, or violent rapids that expose a paddler to above-average danger. Drops may contain large, unavoidable waves and holes or steep, congested chutes with complex, demanding routes. Rapids may continue

recommended.

CLASS V: EXPERT

Extremely long, obstructed, or violent rapids that expose a paddler to above-average danger. Drops may contain large, unavoidable waves and holes or steep, congested chutes with complex, demanding routes. Rapids may continue for long distances between pools, demanding a high level of fitness. Eddies may be small, turbulent, or difficult to reach. At the high end of the scale, several of these factors may be combined. Scouting is mandatory but often difficult. Swims are dangerous and rescue is difficult, even for experts. A very reliable Eskimo roll, proper equipment, extensive experience, and practiced rescue skills are essential for survival.

CLASS VI: EXTREME

Class VI runs exemplify the extremes of difficulty, unpredictability, and danger. The consequences of errors are very severe, and rescue may be impossible. For teams of experts only, at favorable water levels, after close inspection and taking all precautions. This class does not represent drops believed to be unrunnable but may include rapids that are only occasionally run.

From Safety code of the American Whitewater Affiliation, Phoenicia, NY, 1989, American Whitewater Affiliation.

Hydraulics release water downstream from beneath the surface. This may be the only avenue of escape for a swimmer. Escape from a strong hydraulic may require a person to stay submerged and to resist the urge to return immediately to the surface. Surfacing too early can result in recirculation. Fortunately, most hydraulics eventually release people regardless of what action they take.

734

Novice paddlers often misjudge the force of hydraulics. It is not the height of the drop that generates the recirculating power but rather the shape and angle of the obstruction, combined with water volume and adjacent eddy currents. A "smiling" hydraulic has its outer edges curving downstream, so that the recirculating water feeds out into the main current and is thus easier to escape. In a "frowning" hydraulic, the outer edges curve back upstream into the center of the hydraulic, making escape much more difficult.

Low-head dams or weirs form massive hydraulics with enormous recirculating potential. Unlike natural hydraulics, these human-made structures form hydraulics all the way across the river, leaving no escape routes. In the Binghamton Dam disaster of 1975, a 13 ½-foot Boston whaler with a 20-horsepower engine was pulled into a hydraulic while attempting a rescue, resulting in the deaths of three firefighters. ^[39]

Undercut rocks are boulders or ledges that have been eroded just beneath the water surface. These usually occur on geologically older rivers. They can be difficult to recognize and pose significant risks for entrapment and drowning, even in class II

rapids.

The potential for entrapment can also occur when swimmers attempt to stand up and walk in swift-moving currents. A foot can become wedged in an undercut rock or between rocks beneath the surface, causing the victim to lose his or her balance and fall face down into the river ([Figure 30-6, A](#)). With the foot entrapped,

Figure 30-6 A, Attempting to stand up in shallow water can produce foot entrapment in an undercut rock. **B**, Proper way to swim while in a rapid.

the victim cannot regain an upright or even face-up position. This type of mishap has caused drownings in water less than 3 feet deep.

A swimmer in a rapid should assume a supine position, with feet at the surface and pointed downstream to serve as shock absorbers. This position minimizes the potential for both foot entrapment and head and neck trauma ([Figure 30-6, B](#)).

Strainers are obstacles, such as fallen trees, bridge debris, or driftwood lodged between rocks or jutting out from the shore, that allow water to pass through (sieve effect) while trapping the swimmer or boater. Flooded rivers, a favorite of expert boaters, often develop many new strainers as riverbank debris is washed into the flow. In the summer of 1987, five paddlers drowned when their raft struck a large strainer on Canada's Ellaho River.^[41]

Negotiating a strainer requires special tactics. The safest option for the swimmer is to swim aggressively into the strainer head first rather than feet first, and then attempt to climb over the debris ([Figure 30-7, A](#)). Approaching a strainer feet first may lead to underwater entrapment ([Figure 30-7, B](#)).

Human-made hazards can also pose a threat to river runners. Bridge pilings, submerged automobiles, dams, and low-hanging power lines can pin or injure boaters.

A broach occurs when a boat wraps sideways around an obstacle or when both bow and stern become stuck on separate obstacles simultaneously. Common obstacles

Figure 30-7 A, Proper approach to a strainer. **B**, Incorrect approach to a strainer.

735

include boulders, trees, bridge pilings, and ledges protruding from canyon walls. Drowning can occur if the paddler leans upstream away from the obstacle and flips upside down while still broached or if the boat collapses and entraps the victim ([Figure 30-8](#)).

Figure 30-8 Broach.

Figure 30-9 1, Vertical pin. 2, Pitchpole pin.

A vertical pin happens when a kayaker plunges over a drop and the end of the boat becomes trapped between rocks beneath the surface. The force of the water can fold a plastic kayak over on itself, trapping the occupant upside down beneath the surface ([Figure 30-9](#)).

A survey of 365 members of the AWA revealed that 33% of serious kayaking incidents and 41% of open canoeing mishaps involved either pinning or broaching ([Table 30-2](#)).^[44] In a separate survey of 500 paddlers between 1989 and 1993, 42% of kayaking fatalities resulted from vertical pins, broaches, or entrapments in strainers.

Kayak construction can have important safety implications in both broach and pin situations. The force of the current against the deck of the boat or back of the paddler can make it impossible for the victim to extract his or her legs and escape. Boat makers

have developed kayaks with larger cockpits that make it easier to raise the knees out and escape the craft. Transverse bulk-head-type

TABLE 30-2 -- Serious White-Water-Related Incidents

INCIDENT	NUMBER	PERCENTAGE OF ACCIDENTS

Figure 30-10 Safety Deck system, which offers an emergency exit for a kayaker in distress.

foot braces have replaced pedal-type braces to prevent the kayaker from being shoved forward in the boat. This feature ensures the escape potential offered by larger cockpits. One of the compromises of the larger cockpit, however, is that the sprayskirt is more likely to come off in turbulent water.

Another safety feature, the Safety Deck System (Outdoor Safety Systems, Princeton, NJ), uses a manually releasable foredeck section that can be jettisoned by the paddler for emergency exit ([Figure 30-10](#)). During normal use, this deckplate is securely fastened to the boat and does not alter its shape or performance. The Safety Deck System has been tested extensively with positive results, but unfortunately its cost has precluded commercial development.

SUBMERSION ACCIDENTS

Almost all fatalities on rivers result from submersion. Each year the River Safety Task Force of the American Canoe Association compiles accounts of drownings and other accidents. Every 3 years it publishes the *River Safety Report*, which chronicles and analyzes these accidents.^{[39] [40] [41] [43]}

Most submersion fatalities occur after paddlers unexpectedly swim from their boats or become trapped in them underwater. The exact cause of drowning often remains unclear and is inexplicably blamed on immersion hypothermia. Although hypothermia induces impaired judgment and coordination and may be an important contributing factor, immersion hypothermia is probably never the sole cause of death.^[46] Studies by Hayward and others have shown that seminude subjects are able to maintain normal core temperatures for 15 to 20 minutes in 10° C (50° F) water.^{[19] [20]} Continuous immersion for up to 1 hour would be required to produce profound hypothermia.^[20]

Cold water immersion precipitates drowning by three other mechanisms. Sudden cold water immersion produces profound cardiovascular and respiratory responses. Reflex sympathetic output can markedly increase blood pressure and heart rate, resulting in lethal arrhythmias.^{[16] [25] [26]}

An immediate and involuntary gasp occurs after cold water immersion. This is followed by hyperventilation.^[8] Pulmonary ventilation increases up to fivefold because of increased tidal volume and respiratory rate.^[38] The initial gasp can result in aspiration of water and laryngospasm. Hyperventilation produces respiratory alkalosis with resultant muscle tetany and cerebral hypoperfusion.^[8] This response can increase the risk of drowning in a person struggling to maintain an airway freeboard in rough water.

The respiratory stimulation produced by cold water immersion significantly decreases breath-holding duration.^[21] This fact has enormous implications for kayakers who must hold their breath while attempting to roll up a boat after flipping upside down. This probably accounts for the unexplained swims by expert kayakers who sometimes fail to right themselves after flipping in cold water.

Peripheral cold water-induced vasoconstriction exacerbates rapid cooling of muscles and nerves in the extremities, resulting in loss of strength and coordination.^[38] The ability to swim, maintain freeboard, avoid obstacles, and climb from the river may be greatly impaired.^[28] Even when the air temperature is warm, paddlers running cold water rivers should wear sufficiently insulated clothing.

The combination of hyperventilation and muscle dysfunction can be lethal for a swimmer

in rough water. A PFD helps but does not prevent even small waves from submerging a swimmer's head.^[15] These dangers make imperative the need to preset safety systems in significant rapids and rescue swimmers first. Unfortunately, paddlers have drowned when their companions chased after equipment, assuming that the swimmer could climb out of the river without assistance.^{[40] [42]}

Safety kayaks with enhanced buoyancy are recommended on commercial raft trips, since they provide additional flotation for clients who fall overboard.

Although some maintain that the respiratory and cardiovascular reflexes can be abolished by repeated exposure of the face to cold water, there are currently no scientific data to support this theory of acclimatization.

TRAUMA

A survey of commercial raft clients revealed that the most common significant injury was a sprained or fractured ankle.^[45] Ironically, these injuries usually occur out of the water when persons walk on loose, wet, and slippery rocks during scouting and portaging or when entering

737

or leaving the river. Ankle and other lower extremity injuries also occur on the river when rafters are tossed onto each other in rapids.

Kayakers are prone to ankle injuries from forced dorsiflexion or inversion when the bow of the boat hits an obstruction. The feet are held against the narrow horizontal braces while the heels are pushed underneath, or the entire ankle is inverted. European- and some American-designed kayaks with bulkhead foot braces have reduced this problem.

Management of foot and ankle injuries should begin with ice, elevation, and compression to reduce swelling. Cold river water is usually substituted for ice. Compression wrapping is important after icing to prevent swelling from reflex vasodilation. Splinting is important to reduce pain and edema and to limit exacerbation of the injury during evacuation. Pneumatic splints, still carried by many raft companies, provide adequate support and compression but are prone to overinflation when heated by the sun. Zippers often malfunction when they rust or jam with sand. Neurovascular integrity must be checked frequently with an air splint. Ankle splints can be improvised from life jackets, kayak float bags, articles of clothing, or a SAM splint.

Strains are common in white-water sports. Researchers at Dalhousie University in Halifax, Nova Scotia, analyzed dynamic electromyographic potentials of the various muscle groups used in kayaking and then correlated them with videotaped sequences.^[32] Muscles used most often in kayaking that are prone to strain injury are shoulder extensors (latissimus dorsi, teres major, pectoralis major), medial scapula rotators (rhomboides major and minor, pectoralis minor), lateral scapula rotators (pectoralis minor, serratus anterior), shoulder flexors and horizontal adductors (anterior deltoides, pectoralis major, coracobrachialis), elbow extensors (triceps), and spine erector muscles. Any training program for kayakers needs to emphasize conditioning of these muscle groups.

Back strain afflicts rafters, kayakers, and canoers. Rafters are prone to back injuries

while portaging, pushing stuck rafts off rocks, and carrying the crafts to and from the river. Raft guides are notorious for suffering back strain when pulling capsized customers, who often weigh more than they do, back into the rafts. Kayakers and canoers injure their backs lifting water-laden boats and loading their crafts onto automobile roofs. Sitting for prolonged periods with legs extended and minimal back support leads to muscle fatigue in kayakers, compounding the potential for injury.

Repetitive dorsiflexion of the wrist required to operate an offset (feathered) kayak paddle produces tendinitis and synovitis.^[31] A paddle constructed with a 75- to 80-degree offset instead of the traditional 90 degrees can reduce wrist stress. Aspirin or nonsteroidal

TABLE 30-3 -- Common White-Water-Related Injuries, 1980–1991 (N = 85)

INJURY TYPE	NUMBER	PERCENTAGE OF INJURIES
Shoulder dislocation	14	16.5
Near drowning	11	12.9
Fractures	15	17.6
Head and neck	6	7
Hypothermia	4	4.7
Leg injuries	11	12.9

Figure 30-11 High brace maneuver.

antiinflammatory agents ingested 30 minutes before paddling, combined with ice application afterward, may be beneficial. Wrist supports provide limited relief.

The injury most often associated with kayaking is anterior shoulder dislocation. Various surveys have placed its incidence in kayakers at 10% to 16%, making it the second most common white-water-related injury ([Table 30-3](#)).^{[5] [30] [44] [45]} The maneuver most notorious for precipitating this injury is the high brace. Often used while supporting the kayaker in a hydraulic, surfing on a wave, or rolling the kayak upright after a flip, the high brace entails abduction of the humerus, with external rotation of the glenohumeral joint ([Figure 30-11](#)). If the arm becomes extended behind the midline plane of the body

by the force of the current, the triad of abduction, external rotation, and extension of the shoulder can stretch or rupture the glenoid labrum and capsule, resulting in anterior subluxation or dislocation.^[37] The paddle acts as a lever to increase the force on the glenohumeral joint.

To minimize the risk of shoulder dislocation, the preferred method of bracing is the "low brace," in which the arm is held in internal rotation and close to the body (adduction). Although initially awkward for the novice paddler, this bracing maneuver is inherently stronger and more versatile because it allows backpaddling out of a hydraulic. Exercises that strengthen the rotator cuff and deltoideus, triceps, and pectoralis muscles reinforce the glenohumeral joint.

The paddler with a dislocation is usually aware that something has gone wrong and holds the extremity away from the body, unable to bring the arm across the chest.^[37] The shoulder may appear square because of anterior, medial, and inferior displacement of the humeral head into a subcoracoid position.

Although on-scene reduction of shoulder dislocations is controversial, immediate relief of pain, curtailment of ongoing injury, and subsequent ability to function more actively in evacuation are strong reasons to do it. Several techniques have been advocated for reduction.^[36] The key element is rapid initiation, since the longer a shoulder remains dislocated, the more difficult the eventual reduction becomes. Relocation is often delayed because river corridors rarely afford rapid access to a flat and comfortable area upon which to place a victim in the supine or prone position, a requirement for most techniques.

For river and other wilderness settings, reduction is facilitated by using a technique in which the victim is standing or sitting ([Figure 30-12](#)). As soon as the diagnosis is made, the victim bends forward at the waist while the rescuer supports the chest with one hand. With the other hand, the rescuer grabs the victim's wrist and applies steady downward traction and external rotation. While maintaining traction, the rescuer can slowly flex the shoulder by moving it in a cephalad direction until reduction is obtained. If two rescuers are available, one should support the victim at the chest while the other pulls countertraction and flexion at the arm. Scapular manipulation by adducting the inferior tip using thumb pressure and stabilizing the superior aspect of the scapula with the cephalad hand may augment reduction ([Figure 30-13](#)).^{[33] [36]}

Shoulder reduction can also be done while the victim is sitting. Grab the victim's forearm close to his or her elbow with both hands and, with the elbow bent at 90 degrees, pull steady downward traction on the arm. After about a minute of sustained traction, slowly raise the entire arm upward until reduction is complete. Gingerly rotating the forearm outward while pulling traction may facilitate reduction. If a second rescuer is present, scapular manipulation can be performed simultaneously as described above.

Another relocation technique uses the victim's life jacket to allow one rescuer to apply both controlled traction and countertraction.^[11] This technique requires

Figure 30-12 Weiss technique for shoulder relocation with the victim standing. **A**, The rescuer supports the victim's chest with one hand and pulls down and forward **(B)** with the other hand.

that the victim be supine, with room for the rescuer to sit adjacent to the dislocated shoulder. The rescuer then slides his or her foot and leg through the life jacket's arm opening, under the neck, and out through the jacket's head opening. The rescuer's leg functions as a head rest, while the foot braced against the opposite shoulder strap of the life jacket provides countertraction. Holding the forearm of the affected side with the elbow bent at 90 degrees, the rescuer slowly leans back to apply traction while the leg exerts countertraction. The life jacket allows countertraction force to be distributed across the victim's

739

Figure 30-13 If two rescuers are available, scapular rotation to assist shoulder relocation can be performed while the second rescuer pulls the arm down and forward. The inferior top of the scapula is pushed medially.

Figure 30-14 Using a life jacket to assist in countertraction for shoulder

relocation.

chest. External and internal rotation can be applied to the humerus during traction to facilitate reduction ([Figure 30-14](#)).

One should always monitor circulation and motorsensory function to the wrist and hand before and after attempting a shoulder reduction. To prevent a recurrent

Figure 30-15 Shoulder harness for support after shoulder dislocation.

dislocation, the kayaker's arm should be splinted across the chest with a sling or swath or by safety pinning the sleeve of the arm across the chest. If circumstances preclude exiting the river without further kayaking, the shoulder can be partially stabilized by wrapping an elastic or neoprene wrap around the torso and involved arm to limit abduction and external rotation ([Figure 30-15](#)).

Head, facial, and dental trauma are more common in kayakers and decked canoeists than in rafters because of the potential for flipping upside down while still in the craft. Minor abrasions, lacerations, and contusions are common; serious head injury with loss of consciousness is rare. Head and facial trauma can be minimized by wearing a protective helmet and tucking forward, instead of leaning backward, while rolling.

Spine fractures have been reported in kayakers and canoers.^{[40] [41] [43]} Cervical spine injuries have occurred in kayakers in conjunction with head trauma sustained after flipping upside down. Vertical compression fractures of the thoracolumbar spine have occurred from

axial loading when a kayaker landed flat after paddling over a waterfall. One kayaker was rendered paraplegic after landing on his back on rocks while attempting to negotiate a waterfall.^[43] Fortunately, his companions recognized the injury and kept him supported on minicell blocks from their kayaks until a backboard could be obtained.

Significant visceral and musculoskeletal injury can occur when a swimmer is sandwiched between a downstream boulder or obstruction and the upstream craft that has been exited. Swimmers should always stay upstream of their craft.

Many kayakers suffer abrasions and contusions to the fingers and knuckles while hanging upside down after flipping. Oar frames, oars, paddles, and the metal ammunition boxes used to keep supplies dry can all inflict injury when rafts are capsized or paddlers are tossed about in turbulent water.

Blisters on the hands are a frequently reported problem in paddling surveys.^[45] Kayakers develop them at the metacarpophalangeal (MCP) joint of the thumb along the ulnar aspect. Common sites of blister formation in rafters and canoeists are the proximal palmar surfaces of the MCP joints. Taping and moleskin application reduce the incidence of this potentially incapacitating problem.

INFECTIONS

Blisters, abrasions, and lacerations are always at increased risk for infection in an aquatic environment. Maceration from prolonged immersion in water and exposure to atypical pathogens are contributing factors.

An outbreak of *Staphylococcus aureus* skin infections among raft guides in Georgia and South Carolina nearly led to the demise of two rafting companies.^[19] Sharp grommets on the thwarts of the rafts had caused repeated lower extremity abrasions. The causative organism was cultured from rafts up to 48 hours after use. Daily raft disinfection enabled the companies to remain in operation.

Otitis externa (swimmer's ear) is a common problem among paddlers. Water exposure to the ear canal macerates the epithelium and elevates the normally acidic pH of the canal, predisposing the ear to infection.^[12] The bacteria most commonly cultured are *Pseudomonas aeruginosa*, *Proteus vulgaris*, and *Staphylococcus* species.^{[12] [23]} Antibiotic eardrops with or without hydrocortisone are widely available and very useful. Irrigation of the canal with commercially available solutions containing acetic acid and alcohol helps prevent infection by lowering the pH and drying the canal.^[23] The drops should be applied after each outing (see [Chapter 63](#)).

Recent publicity given to water contamination by *Giardia lamblia* has been reinforced by statistics from the Centers for Disease Control and Prevention, which report

Figure 30-16 *Giardia lamblia* trophozoite seen by methylene blue wet mount staining under oil (1000×). The finding of cysts or trophozoites in a patient with diarrhea is sufficient to make a tentative diagnosis of giardiasis.

Giardia organisms to be the most common pathogenic intestinal parasite in the United States (see [Chapter 51](#) and [Chapter 52](#)). *Giardia* cysts abound in mountain streams and rivers once considered to be sources of pristine water ([Figure 30-16](#)). They persist in very cold water and have no detectable taste or smell. Rivers are contaminated by animals that defecate in or near the water. Studies by the Wild Animal Disease Center at Colorado State University, Ft. Collins, Colorado, have identified more than 30 animal species as *Giardia* carriers.

Paddlers who travel to foreign countries should seek information on local endemic diseases and relevant prophylactic measures. White-water rafting and kayaking in Third World countries subject paddlers to unusual aquatic-related infections. This is exemplified by a report of schistosomiasis in rafters returning from Ethiopia.^[22] Schistosomiasis is endemic in large areas of Africa, South America, and the Caribbean and is transmitted to humans who swim or come into contact with fresh water containing the larval stage. Paddlers who return from endemic regions should be screened with serologic testing, since up to 50% of infections are asymptomatic.^[31]

Malaria has been reported in rafters returning from New Guinea, and both leptospirosis and hepatitis have stricken kayakers venturing to Costa Rica.^[2] In the United States, pulmonary blastomycosis was reported among canoeists in Wisconsin.^[7]

ENVIRONMENTAL HAZARDS

Although hypothermia is rarely the cause of death among white-water paddlers, hypothermia-induced impairment of judgment and coordination is a significant contributing factor in many fatalities and accidents.^{[18] [28] [39] [40] [41]} The paddling season usually begins in

741

early spring when air temperatures are cool and snow melt-swollen rivers run extremely cold. Paddlers with rusty skills are more prone to frequent swims and the effects of cold water immersion. Many rivers, especially in the western United States, are controlled by dams that release water from far beneath the surface and thus remain cold year round. Placing adequate barriers between the human body and the environment and carrying adequate food and waterproof matches are of paramount importance.

Another common environmental affliction suffered by paddlers is rhus dermatitis from poison oak or poison ivy. Most cases occur during spring paddling when the vines are potent but the characteristic leaves have not yet appeared. Barrier creams such as StokoGard Outdoor Cream and Tecnu Ivy Shield can be used by individuals highly sensitive to the plants. After plant contact occurs, the oil may be removed from the skin by washing within 30 minutes.^[13] A commercial product, Tecnu Oak and Ivy Cleanser, can remove oil from the skin for up to 8 hours after exposure. Any solvent may help remove some of the urushiol oil from the skin. Gasoline, paint thinner, acetone, and rubbing alcohol have all been reported to be effective. Unfortunately, these products can also be irritating to the skin

Treatment of rhus dermatitis consists of oral antihistamines and systemic corticosteroids. A 2-week course is needed to prevent recurrence of the rash (see [Chapter 47](#)).^[13]

Sunburn and the effects of chronic exposure to solar radiation are compounded by water's ability to reflect up to 100% of ultraviolet radiation (UVR), depending on the time of day. Sand can reflect up to 17% of harmful UVR. Most rivers are situated in mountains, where UVR increases 4% to 5% with each additional 305 m (1000 feet) of altitude.^[9] Sunscreens must be applied frequently because they are prone to wash off in the water. Zinc oxide and other barrier creams are more resistant to water and are preferable on areas of intense exposure, such as the nose and lips. Paddlers with fair

skin should consider using gloves to protect the hands from UVR exposure.

Eye protection from UVR is often overlooked or avoided by paddlers because sunglasses frequently fog while on the river. Application of Dawn dishwashing soap to the lenses prevents fogging for up to 30 minutes. Polarizing lenses reduce glare off the water, but the polarizing feature does not in and of itself filter UVR and infrared radiation.

Venomous snakes, especially pit vipers, along with scorpions, spiders, and fire ants, are frequently encountered by river enthusiasts and should be considered potential hazards. Paddlers should know appropriate first-aid measures for envenomations.

Paddlers commonly consume wild foliage, which may produce severe illness. In one published report, six rafters were poisoned and one of them died after eating water hemlock, *Cicuta douglasii*.^[31]

SWIFT WATER RESCUE

Time is the most important factor in river rescue and often precludes the use of technical rope-based systems. Experience and an understanding of river dynamics are essential.

The most common rescue scenario involves a swimmer who has exited the craft. The victim may be moving downstream at 5 to 10 miles per hour in the middle of a large river. Since the dynamic nature of swift water does not often allow time for a shore-based rescue system to be established, many white-water rescues are made from a raft, canoe, or kayak. Rafts should stay close together in rapids to render mutual aid. Throw bags can be used directly from the raft to rescue swimmers, or the victim may often be reached with an outstretched arm and a paddle. A swimmer should be pulled back into the raft by grabbing the shoulder straps on his or her life jacket and then leaning backward into the raft to pull the person in. The swimmer can assist by pulling up on the frame, D-ring, or hand line as he or she is being pulled in.

Kayaks can be used to rescue swimmers in midcurrent. The kayak is also an excellent platform to provide additional flotation for a swimmer who is trying to maintain freeboard in rough water. The most common method of rescuing swimmers with kayaks is to have them grab the bow or stern "grab loop" of the boat and then tow them to safety. The loop is usually sized so that it is easy to grab yet will not admit an adult-sized hand. The swimmer can also grab onto the back of the cockpit rim and pull his or her torso onto the back deck. This gets the swimmer out of the cold water and reduces the likelihood of injury from rocks.

Boogie Boards originally developed for use in the ocean surf have been modified for rescue use on rivers. Rescue Boards are larger and come with two sets of handles—one for the rescuer and one for the victim. The boards add a substantial amount of flotation to a rescue swimmer and, when used with swim fins, can provide a maneuverable platform for reaching and picking up a victim.

The latest craft to be adapted to swift-water rescue is the personal watercraft, or Jet Ski. Introduced in 1987, these machines have become increasingly popular with professional rescue agencies. Since they lack an exposed propeller, personal watercraft are safe for swimmers and can negotiate shallow rivers. They can be maneuvered upstream in rapids, and turn within a short radius. Newer versions, adapted for rescue, can tow a backboard or litter device behind them and are quite stable.

Rescue from entrapment requires a higher level of skill and often presents greater

potential risk to the

742

Figure 30-17 Strong swimmer rescue.

rescuer. The method used depends on whether the victim can maintain adequate freeboard. If the entrapment site is accessible, direct contact with the victim is quickest and most effective. A rescuer may wade to the entrapment site or reach it by boat if there is a stable site to exit the craft. When wading, the rescuer should use a paddle for support. Start by facing upstream, with legs slightly wider than shoulder width. Reach out, turn the paddle blade parallel to the current, and plunge it into the water. Just before the blade hits bottom, turn it sideways to the current. The force of the onrushing water will pin it to the bottom. The paddle and your two legs form a tripod, which is more stable than your legs alone. Move slowly across the current, facing upstream, moving only one of these three points at a time. The river downstream should be scouted for hazards before entering and, if possible, a rope thrower should be stationed downstream in the event the rescuer loses footing.

A strong swimmer rescue is the next quickest method but entails significant risk to the rescuer ([Figure 30-17](#)). The rescuer is tethered to a rope that provides added stability against the force of the current. If a quick-release harness is not available, a loose loop of rope can be passed under the rescuer's armpits.

A tag line rescue should be considered if the victim cannot be reached directly. A tag line is a rope stretched across the river downstream that is then brought upstream to the victim ([Figure 30-18](#)). Getting the line across the river sometimes constitutes an insurmountable obstacle. If the river is narrow, it may be possible to throw the line across. Otherwise, it can be ferried across by a boat or team of swimmers. During a ferry, as much of the rope as possible should be kept out of the water to avoid drag.

Figure 30-18 Tag line.

Figure 30-19 Two throw bags connected with a carabiner to make a tag line.

There are two types of tag lines ([Figure 30-19](#)). A floating tag line has a life jacket or some other flotation device attached to the middle to keep the rope on the surface, which helps support the victim. A snag tag is a weighted line submerged and walked upstream to

743

Figure 30-20 Submerged snag tag.

snare a foot or other body part that has been trapped under the surface. A snag tag can be made by joining together two throw bags filled with rocks ([Figure 30-20](#)).

APPENDIX: White-Water First-Aid Kits

The following variables should be considered when designing a white-water first-aid kit: remoteness and accessibility of the river, Third World travel conditions, the number of people the kit will need to support, preexisting medical conditions; and space and weight restrictions. When assembling a kit, the following components are generally recommended for rafting and kayaking:

Rafting Kit

Waterproof dry bag or Pelican box

Cardiopulmonary resuscitation mouth shield (CPR-Microshield)

Hypothermia/hyperthermia thermometer

Bandage scissors

Fine-point tweezers or forceps

Temporary dental filling (Cavit)

Glucose paste

Irrigation syringe with 18-gauge catheter

Povidone-iodine solution

3M surgical stapler (1 stapler holds 25 staples)

Dermabond tissue glue

Wound closure strips (Steri-Strips)

Tincture of benzoin

Polysporin ointment

Moleskin

Latex or non-latex (hypoallergenic) gloves

Antiseptic towelettes

Safety pins

Waterproof matches

Accident report form and pencil

Large garbage bag

4 x 4-inch sterile dressings

8 x 10-inch trauma pad or Bloodstopper dressing

Eye pads

Nonadherent dressing (Xeroform or Aquaphor)

Triangular bandage

3-inch conforming gauze bandage

3-inch elastic bandage with Velcro closure

1-inch x 10-yard surgical tape

Duct tape (can be wrapped around the paddle shaft)

Strip and knuckle bandages

Cotton-tipped applicators

Aloe vera gel

Diphenhydramine capsules

Cortisone cream

Acetaminophen tablets

Ibuprofen tablets

Eardrops

Prophylactic eardrops (mixture of rubbing alcohol and white vinegar)

Treatment eardrops (Cortisporin Otic Suspension)

Epinephrine injectable or EpiPen

Prochlorperazine suppository

Diazepam or midazolam

Oxycodone

Oxymetazoline (Afrin) nasal spray

Antibiotics (trimethoprim/sulfamethoxazole, ciprofloxacin, cephalexin)

744

Sunscreen (sun protection factor [SPF] 15 or higher)

Insect repellent

Iodine tablets

Tampons

Tea bags

Kayaking Kit

Waterproof dry bag or small Pelican box

Cardiopulmonary resuscitation mouth shield

Hypothermia/hyperthermia thermometer

Scissors

Fine-point tweezers or forceps

Small surgical stapler (3M) or Dermabond Glue

Wound closure strips

Tincture of benzoin

Polysporin ointment

Latex or non-latex (hypoallergenic) gloves

Antiseptic towelettes

Safety pins

Waterproof matches

Accident report form and pencil

3 × 3-inch sterile dressings

Nonadherent dressings

2-inch conforming gauze bandage

Duct tape

Strip and knuckle bandages

Cotton-tipped applicators

Diphenhydramine

Acetaminophen

Ibuprofen

Prophylactic eardrops

Epinephrine

Prochlorperazine suppository

Diazepam or midazolam

Oxycodone

Sunscreen

Insect repellent

Iodine tablets

APPENDIX: Universal River Signals

Stop: Potential hazard ahead. Wait for "all clear" signal before proceeding. Form a horizontal bar with your outstretched arms. Those seeing the signal should pass it back to others in the party. ([Figure 30-21](#) .)

Help/Emergency: Assist the signaler as quickly as possible. Give three long blasts on a whistle while waving a paddle over your head. ([Figure 30-22](#) .)

All Clear: Come ahead (in the absence of other directions, proceed down the center). Form a vertical bar with your paddle or one arm held high above your head. Paddle blade should be turned flat for maximum visibility. To signal direction or a preferred course through a rapid around an obstruction, lower the previously vertical "all clear" by 45 degrees toward

Figure 30-21 Stop signal.

Figure 30-22 Help/emergency signal.

Figure 30-23 All clear signal.

the side of the river with the preferred route. Never point toward the obstacle you wish to avoid. ([Figure 30-23](#) .)

Chapter 31 - Cave Rescue

Steve Hudson
Loui H. Clem

A cave can be one of the most hostile environments a rescuer can enter. Not only must a cave rescuer be adept at managing the unique challenges of functioning in the cave environment, he or she must also manage a unique set of rescue problems relating to rescuer safety, equipment, logistics, access and extrication, and mission support. A cave rescue should never be undertaken without qualified cave rescuers on scene. In addition, the incident commander must be familiar with or seek the advice of someone who is familiar with the unique challenges of the cave environment.

The time to learn about caving is not as a medic on a cave rescue. If there is any chance that you will encounter a cave rescue as part of your profession or avocation, time spent familiarizing yourself with caves and caving techniques may be lifesaving.

ENVIRONMENT

Any natural opening in the earth large enough to enter is considered a cave. Human-made mines and tunnels are not caves. Although these often seem similar to caves, their entry often requires special skills and equipment different from those for caves. Caves take many forms, including sinkholes, cracks, sumps, siphons, springs, pits, and caverns. Caves are formidable places, dark and dangerous. Running, seeping, or standing water originally formed most caves, so water is a major part of many cave environments. As caves become less active hydrologically, they may dry up. Some caves are so dry that dust induces respiratory problems in visitors.

Temperature extremes are likely. Caves tend to be at the mean ground temperature of the area. For the most part, U.S. continental caves run from cool to cold. Very warm climates sport warm caves, whereas alpine mountain caves measure close to freezing temperatures and may even contain ice. Tropical and desert caves can be so hot that cavers must wear lightweight garments to explore, but more common is the problem of hypothermia from sitting around underground waiting for the next assignment or struggling in cold and wet passages. It is not uncommon to be supine or prone in 4-inch deep, 13° C (55° F) water with one's back pressed against cold rock, facing a stiff breeze.

Caves can be fragile, often heavily decorated with mineral formations that have formed over thousands of years. Cavers try to protect these formations whenever possible by avoiding walking on or touching delicate areas or otherwise altering the cave. Even the natural oils rubbed off of human hands can alter growth of an active formation. The caver's motto, "leave nothing but footprints, take nothing but pictures, and kill nothing but time," extends to rescue operations. Everything brought in must be packed out at the end of the operation. An abandoned flashlight battery can leach its chemicals and poison the cave-adapted life-forms found in a cave passage.

PERSONAL SAFETY

Whether entering a cave for exploration or for rescue purposes, personal gear requirements are tailored to caving. Clothing should be appropriate to the environment. Caves can be wet, dry, dusty, cold, warm, or a combination of these. Wind can exist in passages because of temperature and pressure differentials between the cave and the outside air, and chill factor becomes a significant consideration. Undergarments should provide the necessary thermal layers, while outerwear provides a protective barrier against the elements.

A mountaineering type of helmet, with a nonelastic "three point" chin strap that keeps it planted properly on the head, is a must. The helmet protects against impact with the hard and often sharp rock of cave ceilings and walls in tight or low passages and offers rockfall protection. It is also a convenient mounting platform for the required light source.

It takes only one episode of trying to navigate in the complete darkness underground to understand why no fewer than three light sources should be carried by each person in a cave. Rescuers underground without functioning lights become other subjects to be rescued. Electric lights are preferred, but carbide lamps may also be used. At least two of these lights should be helmet mountable for hands-free operation, each with sufficient "burn time" capacity or spare batteries to travel in and out of the cave. If carbide lamps are used, care should be taken when working close to victims because it is easy in tight spots to forget that the light on your head is an open flame that can quickly burn anything with which it comes in contact. For this reason, most cave rescuers prefer electric lights.

Many cavers find gloves useful for both thermal insulation and protection against sharp rocks and sticky

mud. If the cave has vertical components, leather-palmed gloves are necessary for rope work.

Cave mud is slippery and adheres to everything. It makes walking and scrambling through a cave dangerous. Lug sole boots provide the best traction, and stiff leather uppers help protect feet against sharp rocks. For small passages or "crawlways," a set of durable kneepads is a wise adjunct.

As in any remote environment, the caver should be self-sufficient and able to care for at least himself for an extended period. This requires replacement batteries or carbide, fresh water for drinking, food for energy, a basic first-aid kit, and extra insulation, such as extra thermal layers and a hat that can be worn under the helmet. Cavers often store a folded trash bag in the suspension of their helmets, to be used as an emergency shelter from wind and water, among other possibilities. An additional challenge for the extended cave visit is the requirement to pack out whatever is packed in, including human waste. Strong, leak-proof plastic containers are useful for that purpose.

Use a small, durable pack to carry extra gear. Carry what is needed and no more. Keep in mind that the pack will be alternately carried, pulled, pushed, and dragged through cave passages of different sizes, so things such as straps and external attachments will become an impediment to maneuverability.

Not all caves have vertical drops, but for those that do—or when in doubt—carry a lightweight seat and chest harness, rack or figure-8 descender, and an ascending system. One or two 20-foot sections of 1-inch tubular webbing come in handy for an extra step-up or to construct a quick belay or hand line.

EQUIPMENT

The amount of equipment used during a cave rescue is prodigious. Each person entering the cave must have at least the minimum complement of personal gear. Ropes and hardware are utilized nearly as quickly as they can be produced; items that are difficult to find, such as hard-wired field-phones or cave radio systems, become necessities.

Ropes used underground are usually of the static kernmantle variety. The tougher the sheath, the better the rope. Adequate carabiners, anchor materials, and other hardware should be available for rigging. If multiple locations must be rigged for raising, lowering, or traversing, the best possible scenario is to have enough gear to rig each site individually. Having to derig a system, sort the gear, carry it past the proceeding litter, and rerig another system can be time consuming and a recipe for disaster. Even a small cave might require multiple sites rigged for safe patient extrication. Prebagged packages of gear for specific common rigging tasks are often useful. Include anchor webbing, ample carabiners, pulleys, prussiks, belay devices, lowering devices, and rope grabs as required to set up one site per bag.

Although most cave evacuations require litter transport, evaluate the situation carefully to determine whether a litter is really necessary. A properly stabilized "walking wounded" caver can be helped out of a cave in short time and with little manpower. Put that same person into a litter, and the number of rescuers and hours to the hospital goes up exponentially! If litter transport is deemed necessary, the next difficult decision is which litter (or litters) to use. On any given evacuation, this selection requires a fine balance of requirements. Maneuvering a bulky litter through narrow cave passages can be a challenging proposition. In larger caves, or where a vertical raise is required, basket litters are the best choice. Plastic-bottomed versions are preferable over steel and mesh versions, allowing the option of dragging the litter where necessary. In tighter caves, drag-sheet types of litters, such as the wraparound Sked, provide low-profile advantages but are less comfortable and protective for the victim. Occasionally, a cave is so restrictive that even the length of such a litter is problematic, and a short board, such as a KED or OSS, is the only alternative. It is not unheard of to begin the carry in a tight section of a cave using a OSS, add a Sked once the passage opens up a bit, drop the Sked into a full basket litter for ease of carrying in a large walking passage, then drop all the way back to the OSS to negotiate a tight entrance passage.

When choosing a litter and victim packaging, take comfort into account. Although rescuers are working up a sweat, the victim lying in the litter can be extremely cold. Thermal layers are a necessity and include a sleeping bag, vapor barrier, and moisture barrier to keep the victim dry. The victim should have adequate head and face protection and, if the environment will become vertical at any point, a harness.

Anticipate transport time; evacuation can take days, so extra warmth and padding may be needed.

A reasonable first-aid kit should contain writing materials for recording victim condition, basic medications, airway management tools, bandages, cervical collars, and splints. Sealing each item in plastic helps keep out cave grit, and the entire kit can be packaged in a largemouth bottle or other watertight, durable container.

Because of extended times involved in reporting caving accidents and responding to and accessing injured cavers, most victims are either very stable or dead. The upshot is that advanced life support (ALS) skills and equipment are generally not required. Dragging a defibrillator into the cave with your first-aid kit is for the most part unjustified. This is fortunate, since the effect of cave mud and water would render all but the sturdiest military models ineffective. Newer semiautomatic defibrillators may fare better.

748

The cave environment is no more friendly to even simple interventions such as intravenous (IV) infusions. In most cases, hanging a gravity-operated IV is not an option, so positive pressure infusion methods must be used. Further, consideration must be given to methods for keeping the insertion point clean, and care taken not to interrupt flow while negotiating tight passageways.

LOGISTICS

Logistics of an underground rescue are complicated at best and a nightmare if not managed well. Lack of easy communication, limited access, extended time, and difficulty in obtaining rest for teams all contribute to complexity.

Communication is essential to keep rescuers from becoming lost, to issue instructions, and to distribute nutrition. Various hard-wired field-phone systems are available for use in cave rescue, but generally only well-established teams have access to these. A relatively new development is the availability of special low-frequency cave radios that can transmit voice through dense rock and soil. Without such systems, message runners are indispensable. A group of swift, agile, safe, and well-trained cavers—and a method for keeping them rested and nourished—is invaluable.

A team of rescuers sent into a known location can take hours or most of a day to reach the victim. It is logistically impractical for these rescuers to carry sleeping bags and food to allow rest and recovery before starting their work assignment. Keeping rescuers rested, fed, watered, and warm many hours away through a challenging cave rescue requires an incident management team that can predict the needs of the underground workers hours before they themselves realize the need.

Whether or not a communication system is available, establishment of a control point at or near the cave entrance(s) is critical. Entrance control should be established as soon as rescuers arrive at the cave. All personnel and equipment entering or leaving the cave should be recorded into a log kept by entrance control. This log becomes invaluable hours later to determine when teams should be replaced, if someone is still in the cave, and who carried in what piece of missing vital gear.

The Incident Command System (see [Chapter 24](#)), or a modified version of it, provides the best framework for managing cave rescue personnel, by performing required functions while maintaining a reasonable span of control. Generally, the functions required on a cave rescue are similar to those required on any other rescue, although the specific means of accomplishing the functions will vary.

There should always be one person in command of an operation. This is the foundation of creating accountability and organization, which are the keys to efficiency and safety. The incident commander assesses the incident, activates resources, determines the strategy, and approves the plan for the operation. Other functions vital to success are planning, operations, logistics, and finance. The incident commander may have one or more people to assist, or he or she may be responsible for several of these functions. Someone must plan strategies, supervise the operation, take care of the physical needs

of the rescuers and the required equipment, and track the resources used.

CAVE ACCESS

Gaining access to the caver victim is a matter of overcoming an array of obstructions inherent in the cave. Merely to move a few hundred feet through a cave might require rappelling, crawling on one's belly, and squeezing through cracks in the rocks while dragging equipment, climbing over large rocks, swimming, and slithering through mud.

The total darkness of a cave is confining to some, and even this simple matter can quickly become a major obstacle. Noncaver responders may have psychological inhibitions, such as fear of the dark or confined spaces. In no case should a rescuer ever be pushed beyond his or her comfort level in accessing a victim. Claustrophobia can cause panic and severe dysfunctional behavior.

Other factors inherent to the cave include temperature variables, wetness, and restrictive cave passages. Certain large or weak personnel and/or bulky and heavy equipment might be physically incapable of getting through these tight spaces.

If the cave rescue requires raising or lowering a victim, or traversing the victim over horizontal rope lines, persons skilled in cave rigging should be responsible for building the systems. Rigging in caves is an art because of anchoring difficulties, directional changes, tight squeezes, and minimal working surface. Details on cave rigging and professional training can be acquired through the National Cave Rescue Commission, a nonprofit organization that teaches courses in cave rescue techniques and management.

Many vertical drops in caves are overhung at the top, preventing the caver access to a wall while descending and ascending the rope. In cases where the roped drop has the rope running against a wall, it can be advantageous to place anchors at points throughout the length of the drop. This "rebelay" method allows multiple people to ascend/descend simultaneously, lessens rope wear points, and provides the added safety of having a shorter rope length to protect for each anchor. Practice at crossing rebelays is essential before attempting to enter a cave thus rigged. The caver must be able to essentially transfer from one free-hanging rope to another while hanging in midair. This is easy to do with the correct

equipment setup and practice but not so easy when the technique is tried for the first time underground on the way to a medical emergency.

Usually, single rope techniques are used, especially where a free-hanging drop is involved. This means that just one rope is put over the side for the rescuer to ascend or descend. The use of an additional belay line not only requires additional personnel but might prove more hazardous if the two lines become entangled.

In the United States, the most common cave ascending systems are the Mitchell system and various renditions of the ropewalker system. These are both efficient means of ascending and can easily be mastered with practice. The frog system, popular in other countries, requires more climbing effort but is easier to use when ascending past rebelay in the system. It is imperative that an ascending system be fitted to the user. Some rigs work better for tall, lean frames, and others work best for heavier body types. All rescue personnel entering a vertical cave should have their own personally fitted rope climbing system and must have practiced climbing in that system in a safe practice area.

Large holes or boulder slopes inside the cave may best be negotiated by using a highline traverse. Highlines often require great amounts of time to set up properly but can shave away hours of litter movement time by passing above difficult cave terrain that otherwise would present many challenges for a litter carried by hand. Use of a highline is most practical when it is known in advance that there will be sufficient time for rigging. The decision to take the time to rig a traverse should be made based on these three factors: the time it will take to move the victim to the obstacle you want to be traversed, the time necessary to rig the highline, and the time that will be saved by using the highline to move the victim over the obstacle.

HAZARDOUS ATMOSPHERES

One often-overlooked hazard to cavers is the ambient atmosphere. Most caves in the United States breathe naturally either from changes in barometric pressure or from the chimney effect of multiple entrances. Some caves have small rooms that have so little airflow that a few cavers can quickly consume most of the oxygen. Buildup of gases CO, CO₂, methane, and/or hydrogen sulfide is not uncommon in caves. Instances of gasoline seeping into caves from underground storage tanks have been recorded. If poor air quality is suspected, use of an air monitoring device is essential. It is possible to enter a cave containing high levels of unhealthy gases, but only with appropriate caution. In such cases, it is advisable to solicit participation of the local hazardous materials emergency response team.

With the assistance of a hazardous materials or confined space rescue team, "bad air" in caves can be mitigated in several ways. One way is to release compressed air into the cave, forcing good air in and bad air out. Success of this method is limited, and because of the massive amounts of air in a cave, this method is slow at best. If this method is used, entrants should carry an air monitor, since "pockets" of bad air may remain trapped in parts of the cave. Another option is to release oxygen into the cave. Although this can speed the air exchange process somewhat, it has its own disadvantages. In addition to being difficult to accomplish, it is possible to elevate the oxygen level in the cave to that of deleterious combustion. Exhaust fans offer a reasonable method, although care must be taken to prevent generator exhaust from entering the cave.

If necessary, rescuers can be equipped for entry with surface-supplied air with bail-out bottles, self-contained breathing apparatus, or rebreathers. Each of these has advantages and disadvantages, but all are difficult to manage in the cave environment and thus should be avoided if possible. Pre-event training and practice in the safe use of any of this equipment is imperative before entering an atmosphere that is hazardous for breathing.

Other airborne hazards, such as histoplasmosis and rabies, are not detectable by air monitor. If these hazards are suspected, no rescuer should enter the environment without an appropriate filter mask and other personal protective equipment.

Water and caves are usually closely associated. Created by water, caves are a natural deposit for overflow or drainage from a variety of sources. Many caves can flood with little or no warning, and a recreational caver or rescuer caught in a flooding cave is in mortal danger.

Flooding is usually associated with heavy rains, which can cause diffuse seepage over a large area of the cave or a high flow into sinkholes. Occasionally, sinking streams can carry floodwater. In some parts of the world, entire rivers disappear underground, flow through caves, and resurface miles away. A flood crest from many miles upstream can pass through these caves without warning.

Flood-prone caves are generally identifiable by their makeup. Cave walls coated with thick mud can be an indication that flooding is not unusual in that section of the cave, and extra caution is warranted. Bedrock cave walls with gravel deposits at key points in the cave, and debris lodged in the ceiling can also be warning signs.

Becoming trapped in a flooding cave is not desirable, but it is survivable. If possible, find a high point in a wide passage, downstream of any major constriction, and wait out the flood. It is also possible, with enough advance warning, to remove a sediment dam downstream that may otherwise cause water to back up into your "safety zone." It is seldom wise to attempt to swim, either upstream or down.

For a rescuer called to assist cavers trapped in a flooded cave, entering the torrent is not wise. If the location of the trapped victims is known, it may be possible to use (or make) another entrance from which to evacuate them.

If entry through the main entrance is necessary, it is imperative that the water level be controlled before entry. Methods of accomplishing this goal vary depending on the situation. Often, it may be enough to simply wait out the flood and let the water level subside naturally. If the water level is still on the rise, however, or if the source remains constant, additional measures may be warranted. Keep in mind that water is a powerful force, and any plan should be engineered by professionals.

One of the simplest diversion methods is to broaden the flood crest so that less of it flows into the cave. Water can be diverted using sandbags, hay bales, or dirt or by digging channels. If this is not possible or feasible, one may be able to lower the water level by digging through debris downstream, thereby expediting the exit. Pumping is also an option, although the hazards inherent in this method should be evaluated closely beforehand.

Entering a flooded cave with scuba equipment is a dangerous, last-resort method that should only be attempted by certified cave divers. A scuba entry may be justified if cavers are known to have been entrapped for an extended period of time, if there is a known medical emergency, or if the cave is completely flooded. In these cases, it may be advisable for certified cave divers to enter and assess the condition of entrapped persons, transport survival supplies, or provide medical assistance. Only in the most dire circumstance is it justified to attempt to transport a victim through a flooded

passage.

At a minimum, a scuba entry requires two to three divers, as well as a backup diver. Diving is gear intensive and requires an air compressor, extra tanks, 110-volt electricity to charge dive lights, underwater communications equipment, waterproof bags, full face masks for subjects, water rescue suits, underwater strobe lights, transport cases, and surface personnel to assist with transporting equipment.

VICTIM CARE

As with many remote accidents, the time it takes to report, respond to, and access a caving accident usually means that the victim, if alive, is relatively stable. Although this generalization has exceptions, the treatment issues faced by most rescuers are related to extended transportation times.

Data obtained in *American Caving Accidents* indicate that the leading cause of caving injury is falls, and that hypothermia, fractures, and head injuries top the list of complaints. Unfortunately, spinal injury is invariably present, and this can compound the transportation challenge. The approach to medical care should be similar to any other medical situation, with one notable difference: the victim has suffered an acute injury but will be confined for transport for an extended period. Care, then, will be a combination of acute emergency responses adapted for a victim who is, for all practical purposes, bedridden.

Once the victim has been stabilized and packaged, the assessment process should continue throughout the evacuation. It is best if one medical person can stay with and monitor the victim throughout the evacuation.

Hypovolemia is a common complaint, so establishing an IV early in the intervention can be useful. Take measures to ensure that rescuers will be able to maintain IV access and manage the supplies throughout the evacuation, and infuse only fluids not contraindicated by head or other injury. If the victim is alert and oriented, fluid administration will increase the need to urinate, so take this into consideration. As best as possible, maintain communication with the victim, encouraging him or her to flex muscles to maintain good circulation. Allow the victim to assist in care as much as possible.

Availability of ALS and drug therapy is useful on extended transports, so it is helpful to have strong rapport with the local medical authorities should complex treatment become necessary.

CONCLUSION

Never underestimate a cave rescue. Caves are unique environments, and entry should not be attempted without appropriate technical training and preparation.

The advantage to any rescue group of establishing a good working relationship with local cavers cannot be overemphasized. These are the persons with knowledge of the caves; with the training, equipment, and experience to handle the obstacles and the environment; and who already feel at ease underground. They could prove to be your most valuable resource for a successful cave rescue. Many cavers have taken extensive training in cave rescue techniques and are members of organized cave and cliff rescue teams. The first step to finding cavers is to contact a local chapter, or "grotto," of the National Speleological Society, the largest cave exploration, education and science-oriented organization in the United States. Contact them at:

National Speleological Society
2813 Cave Avenue
Huntsville, AL 35810
nss@caves.org
<http://www.caves.org/>

Given the unique underground environmental and topographic conditions, nothing can replace formal training in cave rescue techniques and specific cave rescue problems and solutions. Persons interested in enhancing their training should get in touch with the National Cave Rescue Commission (NCRC). The NCRC conducts week-long cave rescue seminars and weekend orientations across the United States. Contact them at the address above as the National Cave Rescue Commission of the National Speleological Society or at: <http://www.caves.org/io/ncrc/>

Chapter 32 - Protection from Blood-Feeding Arthropods

Mark S. Fradin

BLOOD-FEEDING ARTHROPODS

Of all the hazards, large and small, that may befall the outdoor enthusiast, perhaps the most vexatious comes from the smallest perils—blood-feeding arthropods. Mosquitoes, flies, fleas, mites, midges, chiggers, and ticks all readily bite humans. The resulting bites may, at best, result only in minor annoyance; at worst, arthropod bites may transmit to humans multiple bacterial, viral, protozoan, parasitic, and rickettsial infections ([Box 32-1](#)). Mosquito-transmitted diseases alone will be responsible for the deaths of one out of every 17 people currently alive.^[108] This chapter reviews the arthropod species that bite humans and discusses various options for personal protection against nefarious insects.

Mosquitoes (Family Culicidae)

Mosquitoes are responsible for more insect bites than any other blood-sucking organism. Mosquitoes are found all over the world, except in Antarctica. These two-winged insects belong to the order Diptera. There are 170 species of mosquitoes in North America and more than 3000 species worldwide. Anopheline, or malaria-transmitting, mosquitoes can be distinguished by their resting position on the skin, characteristically appearing with the bodies raised high, almost as if standing on their heads. Most other species, in contrast, rest with their bodies parallel to the skin surface ([Figure 32-1, A](#)).

Mosquitoes vector more diseases to humans than do any other blood-feeding arthropod. Mosquitoes transmit malaria to 300 to 500 million people each year, resulting in as many as 3 million deaths per year.^[99] They vector multiple arboviruses to humans, including several forms of encephalitis, epidemic polyarthritis, yellow fever, and dengue fever (see [Chapter 66](#)). Mosquitoes also transmit the larval form of the nematode that causes lymphatic filariasis.

Only female mosquitoes bite, requiring a blood-protein meal for egg production. Male mosquitoes feed solely on plant juices and flower nectar. Mosquitoes feed every 3 to 4 days, consuming up to their own weight in blood with each feeding. Certain species of mosquitoes prefer to feed at twilight or nighttime; others (such as the aggressive Asian tiger mosquito, *Aedes albopictus*) bite mostly during the day. Some mosquito species are zoophilic (preferring to feed on animals, including birds, reptiles, mammals, and amphibians), whereas others are anthropophilic (preferring human blood). Members of the genera *Anopheles*, *Culex*, and *Aedes* are the most common biters of humans. In some mosquitoes, seasonal switching of hosts provides a mechanism for transmitting disease from animal to human.

Mosquitoes rely on visual, thermal, and olfactory stimuli to help them locate a blood meal.^{[5] [6] [12] [18] [38] [49]} For mosquitoes that feed during the daytime, host movement and dark-colored clothing may initiate orientation towards an individual. Visual stimuli appear to be important for in-flight orientation, particularly over long ranges, whereas olfactory stimuli become more important as a mosquito nears its host. Carbon dioxide and lactic acid are the best-studied attractants. Carbon dioxide serves as a long-range attractant, luring mosquitoes at distances of up to 36 m (118 feet).^{[36] [37] [102]} At close range, skin warmth and moisture serve as attractants.^{[5] [12]} Volatile compounds, derived from sebum, eccrine and apocrine sweat, and/or the cutaneous microflora bacterial action on these secretions, may also act as chemoattractants.^{[55] [69] [95]} Floral fragrances found in perfumes, lotions, soaps, and hair-care products can also lure mosquitoes.^[30]

There can be significant variability in the attractiveness of different individuals to the same or different species of mosquitoes.^{[15] [50]} Men tend to be bitten more readily than women, and adults are more likely to be bitten than children.^{[50] [73]} Heavilyset people are more likely to attract mosquitoes, perhaps because of their greater relative heat or carbon dioxide output.^[83]

During the day, mosquitoes tend to rest in cool, dark areas, such as on dense vegetation, or in hollow logs, tree stumps, animal burrows, and caves. To complete their life cycle, mosquitoes also require standing water, which may be found in tree holes, woodland pools, marshes, or puddles. To minimize the chances of being bitten by mosquitoes, campsites should ideally be situated as far away from these sites as possible.

Blackflies (Family Simuliidae)

At 2 to 5 mm in length, blackflies^{[3] [8] [21] [39] [48]} ([Figure 32-1, B](#)) are smaller than mosquitoes. They have short antennae, stout humpbacked bodies, and broad wings.

Blackflies are found worldwide. The adults are most prevalent in late spring and early summer and are most likely encountered

755

near fast-running, clear rivers or streams, which they require to complete their life cycle. Unlike most mosquitoes, blackflies tend to bite during the daytime. They primarily use visual cues to locate a host. Dark moving objects are particularly attractive, but carbon dioxide and body warmth also serve as attractants. Only the female bites, taking up to 5 minutes to feed. Blackflies may be present in swarms, inflicting numerous bites on their victims.

of their hosts. They often crawl under clothing or into the hair to feed. The insect's mouthparts are used to tear the skin surface, producing a pool of blood from which the fly feeds. Blood loss from the bite site often persists after the blackfly has departed. The resulting intensely pruritic, painful, and edematous papules are typically slow to heal. Rare systemic reactions, including fever, urticaria, anaphylaxis, and even death, have been reported after blackfly bites. Although these flies are not known to transmit disease to humans in North America, in the tropics, blackflies are vectors of the parasite *Onchocerca volvulus*, which causes river blindness.

Midges (Family Ceratopogonidae)

Also known as *no-see-ums*, *sand gnats*, *sand fleas*, and *flying teeth*, biting midges^{[3] [8] [21] [39] [48]} are small (less than 2 mm), slender flies with narrow wings ([Figure 32-1, C](#)). Their small size makes them difficult to see, and they can pass readily through common window screens. Biting midges may be found worldwide. They breed most commonly in salt marshes but may also be found in freshwater wetlands. Despite their inconspicuous size, female midges are aggressive biters, frequently attacking in swarms and inflicting multiple painful and pruritic bites within minutes. Midges often crawl into the hair before biting. Depending on the species, midges may bite during the day or at nighttime. Their activity is greatest during calm weather, declining as wind speed increases. Biting midges are not known to transmit disease in North America.

Tabanids (Family Tabanidae)

The family Tabanidae ([Figure 32-1, D](#)) includes horse-flies, deerflies, greenheads, and yellow flies.^{[3] [8] [21] [39] [48]} These insects are relatively large (10 to 20 mm) robust fliers, with numerous species worldwide. Tabanids breed in aquatic or semiaquatic environments, with a life cycle of over a year. They are able to fly for miles and rely primarily on vision to locate a host by movement. These flies are most active on warm, overcast days. Only the females bite, using scissorlike mouthparts to create within the skin a bleeding slash, which is slow to heal. Despite their size, these flies usually bite painlessly, but the resulting reaction can include intense itching, secondary infection, and, rarely, systemic reactions, such as urticaria or anaphylaxis. Since the adult fly usually only lives about a month, and only one generation emerges per year, the potential season for being bitten is fortunately relatively short. In the United States, deerflies have been shown to be capable of transmitting tularemia to humans; in Africa, the deerfly may vector the filarial parasitic worm, *Loa loa*.

Sand Flies (Family Psychodidae)

Sand flies^{[3] [8] [21] [25] [39] [48]} are tiny (2 to 3 mm), hairy, and longlegged flies, with multisegmented antennae and a characteristic V-shape to the wings when at rest ([Figure 32-1, E](#)). Only female sand flies are blood-feeders, feeding mostly during calm, windless nights, and resting during the day in animal burrows, tree holes, or caves. Most

sand fly bites tend to occur on the face and neck.

In tropical and subtropical climates, sand flies have been shown to vector multiple cutaneous, mucocutaneous, and systemic diseases, including bartonellosis and three forms of leishmaniasis. The only sand fly-transmitted disease in the United States has been cutaneous leishmaniasis, reported in Texas.

Tsetse Flies (Family Glossinidae)

Tsetse flies^{[3] [8] [21] [39] [48]} are found only in tropical Africa. They are 7 to 14 mm long, yellowish-brown, with wings that fold over their backs, giving them the appearance of honeybees at rest ([Figure 32-1, F](#)). Both genders bite, feeding in daytime on a wide variety of mammals, including humans. Tsetse flies seem to rely primarily on vision and movement to identify their hosts. Their bites may cause petechiae or pruritic wheals. Tsetse flies vector African trypanosomiasis (sleeping sickness).

Stable Flies (Family Muscidae)

Stable flies^{[39] [48]} resemble common houseflies and are most often encountered in coastal areas. Unlike a housefly, which rests with its body parallel to the surface, a stable fly rests with its head held higher than its posterior ([Figure 32-1, G](#)). Both male and female stable flies are vicious daytime biters, requiring a blood meal every 48 hours to survive. If disturbed, they will attempt to feed multiple times, preferring to bite the lower extremities. Horses and cattle are the preferred hosts, but hungry stable flies will readily bite humans. These flies have knifelike mouthparts that they use to puncture flesh before pumping up the blood. Stable flies breed in decaying vegetation and in herbivore manure and are frequently found congregated on sunny walls. Stable fly bites are generally self-limited. They are not known to transmit disease to humans.

Kissing Bugs (Family Reduviidae)

Kissing bugs^{[3] [8] [21] [26] [39] [48]} (assassin bugs) are large (10 to 30 mm in length) insects with cone-shaped heads, overlapping wings, and an alternating pattern of orange and dark brown stripes on the lateral abdomen ([Figure 32-1, H](#)). Kissing bugs get their name from a tendency to bite around the human mouth, but they may also bite other parts of the body. Both male and female reduviids bite, requiring a blood meal to mature through five nymphal growth stages. Reduviids are nocturnal feeders, attracted to their hosts by warmth, carbon dioxide, and odor. During the day, they rest in trees or indoors in crevices of house walls and ceilings. Kissing

bug bites are initially painless, but frequent exposure to the bites can produce erythema, edema, and pruritus at the bite sites. More importantly, kissing bugs are the vector for *Trypanosoma cruzi*, the causative agent of Chagas' disease, which has been reported in Central and South America, as well as in the southwestern United States.

Fleas (Family Pulicidae)

Adult fleas^{[3] [8] [21] [39] [48]} are small (2 to 6 mm), wingless insects, with three pairs of powerful legs that enable them to jump distances of up to 30 cm ([Figure 32-1, J](#)). Hungry fleas of both genders feed on the nearest warm-blooded animal, without clear host preference. Fleas usually move around, probing and biting several times, resulting in grouped lesions of pruritic papules. Fleas are capable of transmitting sylvatic plague and murine typhus.

Chigger Mites (Family Trombiculidae)

Trombiculid mites^{[3] [8] [21] [39] [48]} ([Figure 32-1, J](#)) may be found worldwide. Commonly known as *chiggers*, *redbugs*, or *harvest mites*, these reddish-yellow insects are readily encountered in damp, grassy, and wooded areas, especially along the margins of forests, where they may number in the thousands. Only the tiny (less than 0.2 mm) larval stages are parasitic, feeding on mammals, birds, reptiles, and amphibians. Chiggers are most active in the summer and early autumn. They usually infest humans by crawling up the shoes and legs, preferring to attach to skin at areas where the clothing fits tightly, such as at the top of socks or around the elastic edges of underwear. Chiggers do not burrow into the skin or actively suck blood. Rather, they pierce skin with their mouthparts and secrete a proteolytic salivary fluid that dissolves host tissue, which they, in turn, suck up. If undisturbed, chiggers may feed for several days before dropping off. In humans, this rarely occurs because the larvae usually cause enough irritation that they are dislodged by scratching. The host response to chigger bites is brisk, often leading to intensely pruritic, bright red 1- to 2-cm nodules. In Asia, chiggers may serve as vectors of scrub typhus. Rickettsial pox is also transmitted by a mite bite.

Ticks (Families Ixodidae and Argasidae) (See [Chapter 33](#))

Ticks^{[3] [8] [21] [39] [48] [105]} are classified as hard ticks (family Ixodidae) and soft ticks (family Argasidae) ([Figure 32-1, K](#) and [L](#)). Hard ticks are so named because of the presence of a sclerotized plate, or scutum, that covers part of the body. Both types of ticks may be found worldwide, but hard ticks are more commonly encountered in North America. Hard ticks are usually found in weedy or shrubbed areas, along trails, and at forest boundaries, where mammalian hosts, such as deer, are plentiful. Soft ticks are more resistant to desiccation than are hard ticks. Soft ticks thrive in hot and dry climates and are commonly found in animal burrows or caves.

Both genders are bloodsuckers. Soft ticks are nocturnal and feed rapidly, in just a few minutes. Hard ticks most commonly feed during the day and may feed on a single host for days. Ticks are unable to fly or jump. Hard ticks climb vegetation and "quest," waiting passively for hours or days, forelegs outstretched, until they detect the vibration or carbon dioxide plume of a passing host. When they encounter fur or skin, they climb onto the host and then crawl around in search of an appropriate location on which to attach and feed. The attachment bite is usually painless.

People in suspected tick habitats should check clothing frequently for the presence of ticks. If multiple ticks are seen on clothing, they are most easily removed by trapping them on a piece of cellophane tape, or by rolling a sticky tape-type lint remover across them; hundreds of small ticks can be easily removed by this method.

Attached ticks are more difficult to remove. Tick mouthparts are barbed, and some species of tick also secrete a cement that firmly anchors the tick into the skin. Erythema, pruritus, and edema are commonly seen at the site of a tick bite. Improper partial removal of the mouthparts may initiate a long-lasting foreign body reaction, leading to secondarily infected lesions that are slow to heal, or granuloma formation that may persist for months. (For a discussion of the best method for tick removal, see [Chapter 33](#).)

After the tick is removed, the bite site should be cleansed with soap and water, or an antiseptic, and hands should be washed. It may be prudent to save the tick, in case later identification becomes necessary. Prompt removal of attached ticks will greatly reduce the likelihood of disease transmission. Laboratory studies of attachment times for *Borrelia burgdorferi* (Lyme disease)-infected ticks showed that transmission of the spirochete rarely occurred if the tick was attached for less than 48 hours. ^[79] ^[80] ^[81] ^[82] ^[104] ^[105]

In the United States, soft ticks of the genus *Ornithodoros* are capable of transmitting to humans the *Borrelia* spirochete that causes relapsing fever. Three genera of the hard ticks Ixodidae transmit disease to man: *Ixodes* (which vectors Lyme disease, babesiosis, and tick paralysis), *Dermacentor* (vectors tularemia, Rocky Mountain spotted fever, ehrlichiosis, Colorado tick fever, and tick paralysis), and *Amblyomma* (vectors tularemia, ehrlichiosis, and tick paralysis).^[71] ^[105] Larval, nymph, and adult ticks may all transmit disease during feeding. Transovarial transmission also enables female ticks to directly infect their offspring.

PERSONAL PROTECTION

Personal protection against insect bites may be achieved in three ways: avoiding infested habitats, using protective clothing and/or shelters, and applying insect repellents.

Habitat Avoidance

Avoiding infested habitats reduces the risk of being bitten. Mosquitoes and other nocturnal bloodsuckers are particularly active at dusk, making this a good time to be indoors. To avoid the usual resting places of biting arthropods, campgrounds should ideally be situated in areas that are high, dry, and open, as free from vegetation as possible. Attempts should be made to avoid unnecessary use of lights, which attract multiple insects.

Physical Protection

Physical barriers can be extremely effective in preventing insect bites, by blocking arthropods' access to the skin. Long-sleeved shirts, socks, long pants, and a hat will protect all but the face, neck, and hands. Tucking pants into the socks or boots makes it much more difficult for ticks or chigger mites to gain access to the skin. Light-colored clothing is preferable, since it makes it easier to spot ticks and is less attractive to mosquitoes and biting flies. Ticks will find it more difficult to cling to smooth, closely-woven fabrics (e.g., nylon).^[98] Loose-fitting clothing, made out of tightly woven fabric, with a tucked-in T-shirt undergarment is particularly effective at reducing bites on the upper body. A light-colored, full-brimmed hat will protect the head and neck. Deerflies tend to land on the hat instead of the head, and blackflies and biting midges are less likely to crawl to the shaded skin beneath a hat brim.

Mesh garments or garments made of tightly woven material are available to protect against insect bites. Head nets, hooded jackets, pants, and mittens are available from a number of manufacturers in a wide range of sizes and styles ([Box 32-2](#)). Mesh garments are usually made of either polyester or nylon and, depending on the manufacturer, are available in either white or dark colors. With a mesh size of less than 0.3 mm, many of these garments are woven tightly enough to exclude even biting midges and ticks. As with any clothing, bending or crouching may still pull the garments close enough to the skin surface to enable insects to bite through. One manufacturer (Shannon Outdoors, Louisville, Ga.) addresses this potential problem with a double-layered mesh that reportedly prevents mosquito penetration. Although mesh garments are effective barriers against insects, some people may find them

uncomfortable during vigorous activity or in hot weather.

760

Figure 32-2 A to C, Protective shelters. D, Bed nets. (A, C, and D courtesy Wisconsin Pharmacal Co.; B courtesy Long Road Travel Supplies.)

Lightweight insect nets and mesh shelters are available to protect travelers sleeping indoors or in the wilderness ([Figure 32-2](#)). The effectiveness of insect nets or shelters may be enhanced by lightly spraying them with a permethrin-based contact insecticide, which provides weeks of efficacy after a single application.

Repellents

For many people, applying an insect repellent may be the most effective and easiest way to prevent arthropod bites. The quest to develop the "perfect" insect repellent has been an ongoing scientific goal for years and has yet to be achieved. The ideal agent would repel multiple species of biting arthropods, remain effective for at least 8 hours, cause no irritation to skin or mucous membranes, possess no systemic toxicity, be resistant to abrasion and wash-off, and be greaseless and odorless. No presently available insect repellent meets all of these criteria. Efforts to find such a compound have been hampered by the multiplicity of variables that affect the inherent repellency of any chemical. Repellents do not all share a single mode of action, and different species of insects may react differently to the same repellent.^[88]

To be effective as an insect repellent, a chemical must be volatile enough to maintain an effective repellent vapor concentration at the skin surface but not evaporate so rapidly that it quickly loses its effectiveness. Multiple factors play a role in effectiveness, including concentration, frequency and uniformity of application, the user's activity level and overall attractiveness to bloodsucking arthropods, and the number and species of the organisms trying to bite. The effectiveness of any repellent is reduced by abrasion from clothing; evaporation and absorption from the skin surface; wash-off from sweat, rain, or water; and a windy environment.^{[34] [50] [51] [67] [68] [86]} Each 10° C (18° F) increase in ambient temperature can lead to as much as 50% reduction in protection time.^[51] Presently available insect repellents

NOTE: Some manufacturers give only the concentration of the *m*-isomer; others list total concentrations of all DEET isomers. Technical grade 100% DEET is 95% *m*-isomer and 5% other isomers.

do not "cloak" the user in a chemical veil of protection; any untreated exposed skin can be readily bitten by hungry arthropods.^[67]

CHEMICAL DEET.

N,N-diethyl-3-methylbenzamide (previously called *N,N*-diethyl-*m*-toluamide), or DEET, remains the gold standard of presently available insect repellents. DEET has been

registered for use by the general public since 1957. It is a broad-spectrum repellent, effective against many species of crawling and flying insects, including mosquitoes, biting flies, midges, chiggers, fleas, and ticks. The United States Environmental Protection Agency (EPA) estimates that about 30% of the U.S. population uses a DEET-based product every year; worldwide use exceeds 200 million people annually. [112] [114] Decades of empirical testing of more than 20,000 other compounds has not led to the release of a superior repellent. [17] [47] [53] [84] [91] [111]

DEET may be applied directly to skin, clothing, mesh insect nets or shelters, window screens, tents, or sleeping bags. Care should be taken to avoid inadvertent contact with plastics (such as wrist watch crystals and glasses frames), rayon, spandex, leather, or painted and varnished surfaces, since DEET may damage these. DEET does not damage natural fibers, such as wool and cotton.

In the United States, DEET is sold in concentrations from 5% to 100% in multiple formulations, including lotions, solutions, gels, sprays, and impregnated towelettes and wristbands ([Table 32-1](#)). As a general rule,

higher concentrations of DEET will provide longer-lasting protection. For most uses, however, there is no need to use the highest concentrations of DEET. Products with 10% to 35% DEET provide adequate protection under most conditions. In fact, most manufacturers, responding to consumer demand, have recently begun to offer a greater variety of low-concentration DEET products. The American Academy of Pediatrics currently recommends that DEET-containing repellents used on children contain no more than 10% DEET. [35] [100] Persons adverse to applying DEET directly to their skin may get long-lasting repellency by applying DEET only to their clothing. DEET-treated garments, stored in a plastic bag between wearings, maintain their repellency for several weeks. [15]

Products with a DEET concentration over 35% are probably best reserved for circumstances in which the wearer will be in an environment with a very high density of insects (e.g., a rain forest), where there is a high risk of disease transmission from insect bites, or under circumstances in which there may be rapid loss of repellent from the skin surface, such as under conditions of high temperature and humidity or rain. Under these circumstances, reapplication of the repellent will likely be necessary to maintain its effectiveness.

Two companies (3M, Minneapolis, Minn., and Sawyer Products, Tampa, Fla.) manufacturer extended-release formulations of DEET that make it possible to deliver long-lasting protection without relying on high concentrations of DEET. 3M's product, Ultrathon, was developed for the U.S. military and is currently exclusively sold to the public through Travel Medicine, Inc. (Northampton, Mass.; 800-872-8633). This acrylate polymer DEET formulation, when tested under multiple different environmental/climatic field conditions, was as effective as 75% DEET, providing up to 12 hours of greater than

95% protection against mosquito bites.^{[2] [41] [54] [72] [94] [96]} Sawyer Products' controlled-release 20% DEET lotion traps the chemical in a protein particle that slowly releases it to the skin surface, providing repellency equivalent to a standard 50% DEET preparation, lasting about 5 hours.^[28] Preliminary data suggest that about 50% less of this encapsulated DEET is absorbed when compared with a 20% ethanol-based preparation of DEET.^[27]

Given its use by millions of people worldwide for 40 years, DEET continues to show a remarkable safety profile. In 1980, as part of the EPA Registration Standard for DEET,^[112] over 30 additional animal studies were conducted to assess acute, chronic, and subchronic toxicity; mutagenicity; oncogenicity; and developmental, reproductive, and neurologic toxicity. The results of these studies neither led to any product changes to comply with current EPA safety standards nor indicated any new toxicities under normal usage. The EPA's Reregistration Eligibility Decision (RED),^[114] released in 1998, confirmed that the Agency believes that "normal use of DEET does not present a health concern to the general U.S. population."

Case reports of potential DEET toxicity exist in the medical literature and are fully reviewed by Fradin.^[32] Fewer than 40 cases of significant toxicity from DEET exposure have been documented in the medical literature over the last four decades; over three quarters of these resolved without sequelae. Many of these cases involved long-term, excessive, or inappropriate use of DEET repellents; the details of exposure were frequently poorly documented, making causal relationships difficult to establish. These cases have not shown a correlation between concentration of the DEET product used and the risk of toxicity.

The reports of DEET toxicity that raise the greatest concern involve 14 cases of encephalopathy, 13 in children under age 8 years old.^{[20] [24] [32] [44] [45] [64] [75] [76] [120]} Three of these children died, one of whom had ornithine carbamoyl transferase deficiency, which might have predisposed her to DEET-induced toxicity.^{[44] [45]} The other children recovered without sequelae. The EPA's analysis of these cases concluded that they "do not support a direct link between exposure to DEET and seizure incidence."^[114] Animal studies in rats and mice show that DEET is not a selective neurotoxin.^{[75] [89] [112]} Even if a link between DEET use and seizures does exist, the observed risk, based on DEET usage patterns, would be less than one per 100 million users.^[114]

The EPA has issued guidelines to ensure safe use of DEET-based repellents.^[114] Careful product choice (most often of a DEET concentration of 35% or less), judicious use, and common-sense application will greatly reduce the possibility of toxicity. Conservative use of low-concentration DEET products is most appropriate when applying repellents to children. Guidelines for properly applying insect repellents are given in [Box 32-3](#).

Questions regarding the safety of DEET may be addressed to the EPA-sponsored National Pesticide Telecommunications Network, available each day from 6:30 AM to 4:30 PM Pacific Standard Time at (800) 858-7378 or via their website at <http://ace.orst.edu/info/nptn/>.

SKIN-SO-SOFT PRODUCTS.

Skin-So-Soft Bath Oil (Avon, New York, N.Y.) received considerable media attention several years ago when it was reported by some consumers to be effective as a mosquito repellent. When tested under laboratory conditions against *Aedes aegypti* mosquitoes, Skin-So-Soft Bath Oil's effective half-life was found to be 0.51 hours.^[87] In one study against *Aedes albopictus*, Skin-So-Soft Oil provided 0.64 hours of protection from bites and was 10 times less effective than 12.5% DEET.^[96] Skin-So-Soft Oil has been found to be somewhat effective against biting midges, but this effect is felt to be a result of its trapping the insects in an

763

oily film on the skin surface.^[66] It has been proposed that the limited mosquito repellent effect of Skin-So-Soft Oil could be due to its fragrance or to the presence of diisopropyl adipate and benzophenone in the formulation, both of which have some repellent activity.^[10] ^[53]

Box 32-3. GUIDELINES FOR SAFE AND EFFECTIVE USE OF INSECT REPELLENTS

For casual use, choose a repellent with 10% to 35% DEET. Repellents with 10% DEET or less are most appropriate for use on children.

Use just enough repellent to lightly cover the exposed skin; do not saturate the skin.

Repellents should be applied only to exposed skin and/or clothing. Do not use under clothing.

To apply to the face, dispense into palms, rub hands together, and then apply thin layer to face.

Young children should not apply repellents themselves.

Avoid contact with eyes and mouth. Do not apply to children's hands to prevent possible subsequent contact with mucous membranes.

repellents themselves.

Avoid contact with eyes and mouth. Do not apply to children's hands to prevent possible subsequent contact with mucous membranes.

After applying, wipe repellent from the palmar surfaces to prevent inadvertent contact with eyes, mouth, and genitals.

Never use repellents over cuts; wounds; or inflamed, irritated, or eczematous skin.

Do not inhale aerosol formulations or get them in eyes. Do not apply when near food.

Frequent reapplication is rarely necessary, unless the repellent seems to have lost its effectiveness. Reapplication may be necessary in very hot, wet environments because of rapid loss of repellent from the skin surface.

Once inside, wash off treated areas with soap and water. Washing the repellent from the skin surface is particularly important under circumstances in which a repellent is likely to be applied for several consecutive days.

If you suspect you are having a reaction to an insect repellent, discontinue its use, wash the treated skin, and consult a physician.

Adapted from United States Environmental Protection Agency, Office of Pesticide Programs, Prevention, Pesticides and Toxic Substances Division: Reregistration Eligibility Decision (RED): DEET (EPA-738-F-95-010), Washington, DC, 1998, EPA.

Avon Products, Inc. makes no claims about its bath oil being an effective repellent. They currently manufacturer Skin-So-Soft Bug Guard, which contains 0.10% oil of citronella

as the active ingredient. In July 1999, Avon introduced a new chemical-based insect repellent to the U.S. market, IR3535, or ethyl-3-(*N*-butylacetamido) propionate, which can be found in Skin-So-Soft Bug Guard Plus. The limited data presently available to the public on this repellent show that, although it is more effective than most botanical-based repellents, it does not match the overall efficacy of DEET.^[22]

Botanical Repellents.

Thousands of plants have been tested as sources of insect repellents. Although none of the plant-derived chemicals tested to date demonstrate the broad effectiveness and duration of DEET, a few show repellent activity. Plants with essential oils that have been reported to possess repellent activity include citronella, cedar, verbena, pennyroyal, geranium, lavender, pine, cajeput, cinnamon, rosemary, basil, thyme, allspice, garlic, and peppermint.^{[7] [16] [23] [40] [53] [85]} Unlike DEET-based repellents, botanical repellents have been relatively poorly studied. When tested, most of these essential oils tended to show short-lasting protection, lasting minutes to 2 hours. A summary of readily-available plant-derived insect repellents is shown in [Table 32-2](#) .

CITRONELLA.

Oil of citronella was initially registered as an insect repellent by the EPA in 1948. It is the most common active ingredient found in "natural" or "herbal" insect repellents presently marketed in the United States. Originally extracted from the grass plant *Cymbopogon nardus*, oil of citronella has a lemony scent.

Conflicting data exist on the efficacy of citronella-based products, varying greatly depending on the study methodology, location, and species of biting insect tested. One citronella-based repellent was found to provide no repellency when tested in the laboratory against *Aedes aegypti* mosquitoes.^[10] However, a field study of the same product showed an average of 88% repellency over a 2-hour exposure. The product's effectiveness was greatest within the first 40 minutes after application and then decreased with time over the remainder of the test period.^[107] All Terrain Co. (Encinitas, Calif.; 800-246-7328) produces a citronella-based lotion in which the essential oil has been encapsulated into a beeswax matrix, which slowly releases it to the skin surface, prolonging its efficacy. In laboratory testing against *Aedes aegypti*, this product provided complete protection for the first 2 hours, and 77% protection 4 hours after application.^[43]

In general, studies show that citronella-based repellents are less effective than DEET repellents. Citronella provides a shorter protection time, which may be partially overcome by frequent reapplication of the repellent. In 1997, after analyzing available data on the repellent effect of citronella, the EPA concluded that citronella-based insect repellents must contain the following statement on their labels: "For maximum repellent effectiveness of this product, repeat applications at one hour intervals."^[113]

Citronella candles have been promoted as an effective way to repel mosquitoes from one's local environment. One study compared the efficacy of commercially available 3% citronella candles, 5% citronella incense, and plain candles to prevent bites by *Aedes*

species mosquitoes under field conditions. ^[62] Subjects

TABLE 32-2 -- Botanical Insect Repellents

MANUFACTURER	PRODUCT NAME	FORM(S)	ACTIVE INGREDIENT

	Double Strength	Oil	Citronella oil 10%, peppermint oil 2%

near the citronella candles had 42% fewer bites than controls who had no protection (a

statistically significant difference). However, burning ordinary candles reduced the number of bites by 23%. There was no difference in efficacy between citronella incense and plain candles. The ability of plain candles to decrease biting may be due to their serving as a "decoy" source of warmth, moisture, and carbon dioxide.

The citrosa plant (*Pelargonium citrosum* "Van Leenii") has been marketed as being able to repel mosquitoes through the continuous release of citronella oils. Unfortunately, when tested, these plants offer no protection against bites.^[11] ^[70]

BLOCKER.

Blocker is a "natural" repellent that was released to the U.S. market in 1997. Blocker combines soybean oil, geranium oil, and coconut oil in a formulation that has been available in Europe for several years.^[115] Studies conducted at the University of Guelph, Guelph, Ontario, Canada, showed that this product was capable of providing over 97% protection against *Aedes* species mosquitoes under field conditions, even after 3 ½ hours of application. During the same time period, a 6.65% DEET-based spray afforded 86% protection, whereas Avon's Skin-So-Soft citronella-based repellent gave only 40% protection.^[59] A second study showed that Blocker provided a mean of 200 ± 30 (SD) minutes of complete protection from mosquito bites.^[60] Blocker also provided about 10 hours of protection against biting blackflies; in the same test, 20% DEET only gave 6 ½ hours of complete protection.^[61]

EUCALYPTUS.

A derivative (*p*-menthane-3,8-diol, or PMD) isolated from oil of the lemon eucalyptus plant has shown promise as an effective "natural" repellent.^[16] This repellent has been very popular in China for years and is currently available in Europe under the brand name Mosi-guard. In field tests against anopheline mosquitoes, PMD showed repellency comparable with 50% DEET.^[109] PMD required more frequent reapplication than DEET to maintain its potency but was significantly more effective than 50% citronella oil.^[13] ^[110] Release of PMD-based repellents awaits final EPA approval in the United States.

Efficacy of DEET vs. Botanical Repellents.

Limited data are available from studies that directly compare plant-derived repellents with DEET-based products. Available data proving the efficacy of "natural" repellents are often sparse, and there is no uniformly accepted standard for testing these products. As a result, different studies often yield varied results, depending on how and where the tests were conducted. In general, when compared with "natural" products, DEET-based repellents

Figure 32-3 Average protection times—DEET vs. botanical repellents. A, DEET 6.65%; B, DEET 4.75%, C, soybean oil 2%, geranium oil, coconut oil; D, citronella oil 0.1%; E, citronella oil 5%, cedarwood oil, eucalyptus oil, peppermint oil; F, prickly pear extract 40%; G, citronella oil 0.05%; H, DEET 9.5%, impregnated into a wristband.

demonstrate longer-lasting effectiveness. In a laboratory study against *Aedes aegypti* mosquitoes, two commercially available "natural" repellents containing citronella (and other plant-derived essential oils) demonstrated no repellent effect, even when applied at twice the concentration that would typically be expected to be used.^[10] In the same study, DEET-based repellents (at various concentrations) provided at least 2 hours of protection.^[10] Another study comparing "natural" repellents with low-strength DEET products, conducted under carefully controlled laboratory conditions with caged mosquitoes, demonstrated a dramatic difference in effectiveness between several currently marketed insect repellents. Low-concentration DEET lotions (under 7%) consistently proved to be more effective than any of the tested "natural" repellents in their ability to prevent mosquito bites^[19] ([Figure 32-3](#)).

Alternative Repellents.

There has always been great interest in finding an oral insect repellent. Oral repellents would be convenient and would eliminate the need to apply creams to the skin or put on protective clothing. Unfortunately, no effective oral repellent has been discovered. For decades, lay literature has made the claim that Vitamin B₁ (thiamine) works as a systemic mosquito repellent. When subjected to scientific scrutiny, however, thiamine has unanimously been found not to have a repellent effect on mosquitoes.^[52] ^[117] The U.S. Food and Drug Administration (FDA), prompted by misleading consumer advertising, issued the following statement in 1983: "There is a lack of adequate data to establish the effectiveness of thiamine or any other ingredient for OTC (over the counter) internal use as an insect repellent. Labeling claims for OTC orally administered insect repellent drug products are either false, misleading, or unsupported by scientific data."^[29] Tests of over 100 ingested drugs, including other vitamins, failed to reveal any that worked well against mosquitoes.^[106] Ingested garlic has also never proven to be an effective deterrent.

Insecticides

Permethrin.

Pyrethrum is a powerful, rapidly acting insecticide, originally derived from the crushed dried flowers of the daisy *Chrysanthemum cinerariifolium*.^[9] Permethrin is a human-made synthetic pyrethroid. It does not repel insects but instead works as a

contact insecticide, causing nervous system toxicity, leading to death, or "knockdown," of the insect. The chemical is effective against mosquitoes, flies, ticks, fleas, lice, and chiggers. Permethrin has low mammalian toxicity, is poorly absorbed by the skin, and is rapidly metabolized by skin and blood esterases.^{[46] [119]}

Permethrin should be applied directly to clothing or to other fabrics (tent walls^[90] or mosquito nets^[63]) and not to skin. Permethrins are nonstaining, nearly odorless, resistant to degradation by heat or sun, and will maintain their effectiveness for at least 2 weeks, through several launderings.^{[92] [97]}

The combination of permethrin-treated clothing and skin application of a DEET-based repellent creates a formidable barrier against biting insects.^{[42] [54] [101]} In an Alaskan field trial against mosquitoes, subjects wearing permethrin-treated uniforms and a polymer-based 35% DEET product had greater than 99.9% protection (1 bite/hr) over 8 hours; unprotected subjects were bitten an average of 1188 bites/hr.^[58]

Permethrin-sprayed clothing also proved very effective against ticks. One hundred percent of *Dermacentor occidentalis* ticks (which carry Rocky Mountain spotted fever) died within 3 hours of touching permethrin-treated cloth.^[56] Permethrin-sprayed pants and jackets also provided 100% protection from all three life stages of *Ixodes dammini* ticks, the vector of Lyme disease.^[98] In contrast, DEET alone (applied to the skin) provided 85% repellency at the time of application; this protection deteriorated to 55% repellency at 6 hours, when tested against the Lone Star tick *Amblyomma americanum*.^[103] *Ixodes scapularis* ticks, which may transmit Lyme disease, also seem to be less sensitive to the repellent effect of DEET.^[93]

Permethrin-based insecticides available in the United States are listed in [Table 32-3](#) . To apply to clothing, spray each side of the fabric (outdoors) for 30 to 45 seconds, just enough to moisten it. Allow the fabric to dry for 2 to 4 hours before wearing it. Permethrin solution is also available for soak-treating large items, such as mesh bed nets.

Reducing Local Mosquito Populations

Consumers may still find advertisements for small ultrasonic electronic devices that are meant to be carried on the body and claim to repulse mosquitoes by emitting

TABLE 32-3 -- Permethrin Insecticides

MANUFACTURER	PRODUCT NAME	FORM(S)	ACTIVE INGREDIENT
--------------	--------------	---------	-------------------

Coulston Products Easton, Penn. (610) 253-0167	Duranon	Aerosol and pump sprays	Permethrin 0.5%
	Perma-Kill	Liquid concentrate	Permethrin 13.3%
Sawyer Products Tampa, Fla. (800) 940-4464	Permethrin Tick Repellent	Aerosol and pump sprays	Permethrin 0.5%
United Industries Corp. St. Louis, Mo. (800) 767-9927	Cutter Outdoorsman Gear Guard	Aerosol spray	Permethrin 0.5%
Wisconsin Pharmacal Co. Jackson, Wisc. (800) 558-6614	Repel Permanone	Aerosol spray	Permethrin 0.5%

"repellent" sounds, such as that of a dragonfly (claimed to be the "natural enemy" of the mosquito), male mosquito, or bat. Multiple studies, conducted both in the field and laboratory, show that these devices do not work.^{[4] [14] [31] [57]} Likewise, mass-marketed backyard bug "zappers," which use ultraviolet light to lure and electrocute insects, are also ineffective: mosquitoes continue to be more attracted to humans than to the devices.^[74] One backyard study showed that of the insects killed by these devices, only 0.13% were female (biting) mosquitoes.^[33] An estimated 71 to 350 billion beneficial insects may be killed annually in the United States by these devices.^[33] Newer technologies, utilizing more specific bait, such as a warm, moist plume of carbon dioxide, as well as other known chemical attractants, may prove to be more successful in luring and selectively killing biting insects. Pyrethrin-containing "yard foggers" set off before an outdoor event can temporarily reduce the number of biting arthropods in a local environment. These products should be applied before any food is brought outside and should be kept away from animals or fish ponds. Burning coils that contain natural pyrethrins or synthetic pyrethroids (such as d-allethrin or d-transallethrin) can also temporarily reduce local populations of biting insects.^{[65] [118]} Some concerns have been raised about the long-term cumulative safety of using these coils in an indoor environment.^{[1] [78]}

Wood smoke from campfires can also reduce the likelihood of being bitten by mosquitoes. The smoke's ability to repel insects may vary depending on the type of wood or vegetation burned.^{[77] [116]}

Integrated Approach to Personal Protection

An integrated approach to personal protection is the most effective way to prevent arthropod bites, regardless of where one is in the world and which species of insects may be attacking. Maximum protection is best achieved through avoiding infested habitats and using protective clothing, topical insect repellents, and permethrin-treated garments. When appropriate, mesh bed nets or tents should be used to prevent nocturnal insect bites.

DEET-containing insect repellents are the most effective products currently on the

market, providing broad-spectrum, long-lasting repellency against multiple arthropod species. Insect repellents alone, however, should not be relied on to provide complete protection. Mosquitoes, for example, can find and bite any untreated skin and may even bite through thin clothing. Deerflies, biting midges, and some blackflies prefer to bite around the head and will readily crawl into the hair to bite where there is no protection. Wearing protective clothing, including a hat, will reduce the chances of being bitten. Treating one's clothes and hat with permethrin will maximize their effectiveness, by causing "knockdown" of any insect that crawls or lands on the treated clothing. To prevent chiggers or ticks from crawling up the legs, pants should also be tucked into the boots or stockings.

The U.S. military relies on this integrated approach to protect troops deployed in areas where arthropods constitute either a significant nuisance or medical risk. The Department of Defense's Insect Repellent System consists of DEET applied to exposed areas of skin, and permethrin-treated uniforms, worn with the pant legs tucked into boots, and the undershirt tucked into the pant's waistband. This system has been proven to dramatically reduce the likelihood of being bitten by insects.

Persons traveling to parts of the world where insect-borne disease is a potential threat will be best able to protect themselves if they learn about indigenous insects. Protective clothing, mesh insect tents or bedding, insect repellent, and permethrin spray should be carried. Travelers would be wise to check the most current Centers for Disease Control and Prevention (CDC) recommendations about traveling to countries where immunizations (e.g., against yellow fever) or antibiotic prophylaxis (e.g., against malaria) should be undertaken before departure.

The CDC maintains these recommendations on its website at www.cdc.gov/travel/index.htm, or by telephone at (888) 232-3228. An excellent summary of information on issues relating to travel health can also be found at www.tripprep.com. This website culls its information daily from the CDC, the *Morbidity and Mortality Weekly Report*, the World Health Organization, and the U.S. State Department.

Chapter 33 - Tick-Borne Diseases

Douglas A. Gentile
Jason E. Lang

Ticks are familiar pests to those who frequent wilderness or rural areas. They inhabit forests, marshes, deserts, steppes, mountains, and high meadows and have few natural enemies. Most feed on an extremely wide range of hosts, including humans. Ticks are most noted for their high nuisance potential, but they are also efficient vectors for a large number of zoonoses. In fact, ticks transmit a greater variety of infectious agents than any other group of arthropods and run a close second to mosquitoes as vectors of human disease worldwide.^[142] In the United States, ticks outrank even mosquitoes as vectors, and tick-borne illnesses constitute an important infectious disease problem, particularly in wilderness and other outdoor recreational areas.

Ticks belong to the class Arachnida, which also includes spiders and scorpions, and they are closely related to mites. Taxonomists divide ticks into two major families: Ixodidae (hard ticks) and Argasidae (soft ticks). Argasid ticks are covered with a leathery integument, and the capitulum (head) is subterminal and not visible from above. Ixodid ticks possess a hard, shield-like scutum, which covers the entire dorsal surface in males but only the anteromedial portion in females ([Figure 33-1](#)). The head of ixodid ticks is anterior and visible from above.

Hard ticks have three feeding stages: larva, nymph, and adult. If molting through all stages occurs on the same host, the tick is referred to as a one-host tick. Most Ixodidae are three-host ticks, with each stage feeding on a different host. Hard ticks feed on mammals, reptiles, and birds, and virtually all feed slowly over the course of days. Most take a single adult blood meal, and engorgement with blood is a prerequisite to egg laying. Females may ingest more than 50 times their body weight in blood and other fluids. Ixodid ticks transmit all the major tick-borne diseases in North America, with the exception of relapsing fever.

A typical ixodid life cycle is illustrated by *Dermacentor andersoni*, a major vector for Rocky Mountain spotted fever. The tick hatches as a six-legged larva and actively attaches to a small mammal, often a rodent. After feeding for 3 to 5 days, it drops off

and molts to the eight-legged nymph. The nymph hibernates in soil, becoming active again in the spring. After feeding for 4 to 9 days on a larger animal, it again drops off and undergoes a second molt to the adult stage. The mature tick attaches to a third host, on which mating may occur. As with many ticks, *D. andersoni* is capable of surviving for extended periods (more than a year in adults) without a blood meal.

Whereas ixodid ticks are wide ranging, most argasids are nidicolous, or nest loving. Nymph and adult Argasidae generally inhabit the host lair, hiding in cracks and crevices when not feeding. They usually have several nymphal stages (instars), with each stage taking a blood meal. Adults may take several blood meals, feeding rapidly over hours when the host returns.

Although some ticks are host specific, most are opportunists feeding on a variety of hosts. Appendages on the capitulum, the chelicerae, function as piercing and tearing structures, enabling the entire capitulum to be inserted into the host's integument ([Figure 33-2](#)). Retrose teeth on the chelicerae help anchor the tick to the host; many ixodid species also secrete a cementlike substance that seals the wound and further secures the attached tick. Salivary glands secrete an anticoagulant, allowing the tick to ingest the host's blood easily.

Tick Envenomation

Ticks cause human disease either by transmitting microorganisms or by secreting toxins or venoms. The nature of most tick toxins is poorly understood. Many appear to be secreted by the tick salivary glands. Some stimulate potent host immune responses; others appear to have direct tissue toxicity. Clinical effects range from localized reactions to anaphylaxis, paralysis, and death.^[16]

Local reactions vary from formation of a small pruritic nodule to development of extensive areas of ulceration, erythema, and induration. Lesions may be accompanied by fever, chills, and malaise unrelated to infection. The severity of the reaction varies with both host susceptibility and tick species. A granuloma histologically resembling a lymphoma may develop at the site of a tick bite as long as 6 weeks after the tick is removed.^[124] The lesion is believed to be caused by a salivary toxin. Treatment is surgical excision.

Pajaroello Tick Bites

According to local folklore of southern California and Mexico, the bite of the pajaroello tick *Ornithodoros coriaceus* is more feared than the bite of a rattlesnake. In fact, pajaroello bites usually result in a 10 to 30 mm erythematous papule with minimal associated pain and itching. The papule gradually resolves over 3 to 4

Figure 33-1 Female and male *Dermacentor andersoni*, the tick that causes Rocky Mountain spotted fever.

Figure 33-2 Tick anatomy. **A**, Dorsal aspect. **B**, Ventral surface.

771

weeks. Severe local and systemic reactions have been reported but are rare and probably occur in persons sensitized by previous bites. Local erythema, pain, and edema develop rapidly, followed by tissue necrosis and ulceration. Fever, chills, rigors, and hypotension occur rarely. Severe reactions are probably caused by sensitization to a salivary toxin.^[94] ^[114]

Treatment of pajaroello bites includes wound disinfection and administration of tetanus toxoid. The rare severe allergic reaction may require epinephrine, antihistamines, and corticosteroids. When tissue necrosis occurs, excision and primary closure should be considered.

TICK PARALYSIS

As early as 1912, Todd^[336] recognized that paralysis occurred in humans and animals after the bite of certain tick species. Tick paralysis has been observed only sporadically in humans since that time but has occasionally constituted a serious veterinary problem.^[230] Also known as *tick toxicosis*, tick paralysis is an acute, ascending, flaccid motor paralysis that can appear similar to Guillan-Barré syndrome, botulism, and myasthenia gravis. Although uncommon, familiarity with the clinical features of the disease is important, since prompt diagnosis and removal of the tick are curative.

Tick paralysis has been reported worldwide, but most human cases occur in North America and Australia.^[292] ^[360] Forty-three species of ticks, both Ixodidae (hard ticks) and Argasidae (soft ticks), have been reported to cause tick paralysis.^[55] Human cases in North America are usually caused by *D. andersoni* or less often *D. variabilis*, although *Amblyomma americanum* ([Figure 33-3](#)), *A. maculatum*, and *Ixodes scapularis* have also been implicated.^[131] The Pacific Northwest and Rocky Mountain areas account for most cases. In Australia, *Ixodes holocyclus* is primarily associated with the disease, although *I. cornuatus* has been implicated.^[132] ^[135]

Figure 33-3 Lone star tick (*Amblyomma americanum*), implicated in cases of tick paralysis in North America. (Courtesy Sherman Minton, MD.)

Tick paralysis occurs during the spring and summer months (April to June) when nymphs and mature wood ticks are feeding. Children are affected more often than adults, with most cases reported among girls less than 10 years of age. Girls are affected twice as often as boys, probably because ticks on the female scalp are hidden in longer hair.^[4] Men account for most of the adult cases, presumably because of increased occupational and recreational exposure to tick habitats.

Tick paralysis in humans develops 5 to 6 days after an adult female tick attaches, usually to the head or neck (male ticks do not cause paralysis). Initially the victim may be restless and irritable and may complain of paresthesias in the hands and feet. Over the ensuing 24 to 48 hours, an ascending, symmetric, and flaccid paralysis develops with loss of deep tendon reflexes. Weakness usually is initially greater in the lower extremities; within 1 to 2 days, severe generalized weakness may develop, accompanied by bulbar and respiratory paralysis. Some victims develop cerebellar

dysfunction with incoordination and ataxia.^[1] ^[130] Facial paralysis as an isolated finding has occurred in patients with ticks embedded behind the ear.^[226] In uncomplicated cases, fever and chills are absent, and the white blood cell (WBC) count and cerebrospinal fluid (CSF) analyses remain normal.

Resolution of paralysis on tick removal establishes the diagnosis. Laboratory aids to diagnosis are not available. In North America, recovery is rapid after removal of the tick, with most victims showing improvement within hours and complete resolution within several days. Undiagnosed, however, tick paralysis may be fatal; mortality in children was 12% in a large Canadian series.^[271]

Case reports of Australian tick paralysis suggest that it may be more severe than its North American counterpart. Victims often appear more acutely ill. Paralysis may continue to progress for 48 hours after tick removal, and recovery may be prolonged.^[16] ^[17] ^[226] A recent report of six cases in children in Australia however, found little difference in the course between Australian and North American patients.^[132]

A neurotoxic venom secreted from the tick salivary glands during a blood meal causes the paralysis. The venom's mechanism of action appears to produce a conduction block in the peripheral branches of motor neurons, diminishing acetylcholine release at the neuromuscular junction.^[130] ^[215] Electrophysiologic measurements in humans consistently demonstrate slower motor conduction and reduction in muscle action potential amplitude.^[81] ^[212] ^[330] Additionally, the neurotoxin may increase the stimulatory current potential necessary to elicit a response at the motor end plate.^[165] A central effect of the toxin has been postulated to explain the cerebellar dysfunction observed in some patients.

After removal of the tick, treatment is supportive. Tick antivenom from hyperimmunized dogs has been developed for Australian tick paralysis and may be beneficial in victims with severe disease, although they have a high incidence of acute allergy and serum sickness.^[132] ^[226] The most important aspect of treatment is to consider tick paralysis in any victim with ascending paralysis, then search for and remove the concealed tick.

TICKS AS VECTORS

Ticks transmit a wide variety of infectious agents, all of which cause zoonoses. Ticks may act either as amplifiers or as reservoirs for a given agent.^[143] In the agent-tick *amplifier system* the reservoir for the agent is a vertebrate. An immature tick ingests the microorganism while feeding on an infected vertebrate or while feeding concurrently on a vertebrate host with an infected tick. The pathogen replicates in the tick and is passed transstadially, from larval to nymphal to adult stage. The maturing tick transmits the agent to other vertebrate hosts when it feeds. A key epidemiologic feature of this system, transstadial survival of microorganisms, is common in argasid and ixodid ticks but rare in hematophagous insects. This important difference primarily results from the relatively insignificant anatomic changes that occur in the tick during molting.^[143]

In the agent-tick *reservoir system*, the microorganism is passed transovarially from one generation of ticks to the next. The agent replicates within the tick

TABLE 33-1 -- Major Tick-Borne Diseases in the United States

DISEASE	ORGANISM	MAJOR VECTORS	GEOGRAPHIC DISTRIBUTION
Lyme disease	<i>Borrelia burgdorferi</i>	<i>Ixodes scapularis</i> , <i>I. pacificus</i>	Coastal mid-Atlantic, northern West Coast, Wisconsin, Minnesota
Rocky Mountain spotted fever	<i>Rickettsia rickettsii</i>	<i>Dermacentor andersoni</i> , <i>D. variabilis</i>	South-central states, coastal southern states
Relapsing fever	<i>Borrelia hermsii</i> , <i>B. turicatae</i> , <i>B. parkeri</i>	<i>Ornithodoros hermsi</i> , <i>O. turicata</i> , <i>O. parkeri</i>	Worldwide, most often rural western states
Colorado tick fever	<i>Orbivirus</i>	<i>D. andersoni</i>	Rocky Mountain states, California, Oregon
Ehrlichiosis	<i>Ehrlichia chaffeensis</i>	<i>Ixodes scapularis</i> ?	Coastal mid-Atlantic states, northern West Coast, Wisconsin, Minnesota
		<i>Amblyomma americanum</i> ?	South-central states, coastal southern states

Babesiosis	<i>Babesia microti</i>	<i>Ixodes scapularis</i>	Coastal southern New England and mid-Atlantic states
Tularemia	<i>Francisella tularensis</i>	<i>A. americanum</i>	South-central states, Montana, South Dakota

and depends solely on the tick population for survival. The agent may also replicate within the vertebrate host of the tick, allowing amplification of the cycle, thereby increasing the density and prevalence of the microorganism.

[Table 33-1](#) lists the major tick-borne diseases in the United States, where Lyme disease, babesiosis, and ehrlichiosis have only recently been recognized. Lyme disease and babesiosis constitute important infectious disease problems in endemic areas, and Lyme disease is now the most common tick-borne illness in the United States and throughout the world. Tularemia and Rocky Mountain spotted fever are observed throughout the United States and continue to produce significant morbidity and mortality. Tick-borne relapsing fever and Colorado tick fever occur in the western states and are particularly likely to affect campers, hikers, hunters, and others who frequent wilderness areas.

Borrelia Infections

Borreliae are bacteria belonging to the order Spirochaetales, which also includes the treponemes and leptospire. *Borrelia* species can be stained with aniline dyes, including routine blood stains such as Wright and Giemsa; this feature allows easy differentiation from the other two genera. ^[288] Borreliae are helical, actively motile spirochetes, usually 10 to 20 μm long, with three to 10 spirals. ^[102] Strains cannot be differentiated on the basis of morphology but are classified according to specificity of the tick-spirochete relationship, the range of animals susceptible to infection, and cross-immunity. ^[19]

Human *Borrelia* infections occur worldwide, with the possible exception of parts of the southwestern Pacific. ^[102] All are transmitted by hematophagous arthropods. *Borrelia recurrentis* causes an epidemic form of relapsing fever that is transmitted by the human body louse *Pediculus humanus*. A group of closely related *Borrelia* species causes tick-borne or endemic relapsing fever. A third borrelial disease was recognized in 1982 with the identification of *B. burgdorferi* as the etiologic agent of Lyme disease.

Lyme Disease.

An epidemic form of oligoarticular arthritis, originally diagnosed as juvenile rheumatoid arthritis, was recognized in 1975 in the area around Lyme, Connecticut. ^[308] Subsequent clinical observations revealed a complex, multisystem disorder with dermatologic,

cardiac, and neurologic complications. The new disorder was termed Lyme disease.

The rural setting in which most cases occurred, the close geographic and seasonal clustering of cases, and the clinical response to penicillin suggested an arthropod-borne infection. The presence of a distinctive erythematous skin lesion, erythema migrans, preceding the arthritis pointed to a tick vector.^[300] Erythema migrans had been observed in Europe since 1910, where it was associated with the bite of the sheep tick *Ixodes ricinus*.^[5]

Epidemiologic evidence implicated the deer tick *Ixodes scapularis (dammini)* as the likely vector of Lyme disease. In 1982, Burgdorfer and associates^[44] isolated a treponeme-like spirochete, *Borrelia burgdorferi*, from the midgut of *I. scapularis* ticks collected from a known endemic focus of Lyme disease.^[28] Subsequently, sera from nine patients clinically diagnosed with Lyme disease yielded high antibody titers to the spirochetes by indirect immunofluorescence.^[2] Isolation of *B. burgdorferi* from the blood, CSF, and skin lesions of affected patients finally confirmed the spirochetal etiology of Lyme disease.^{[26] [29] [311]}

EPIDEMIOLOGY.

Lyme disease accounts for more than 90% of all reported vector-borne illnesses in the United States. In 1996 a record 16,461 cases were reported from 45 states, resulting in an overall national incidence of 6.2 per 100,000 population, with 91% of cases in eight states^[59] ([Box 33-1](#)).

Nantucket County, Massachusetts, reported the highest county-specific incidence nationally with 1247.5 cases per 100,000. The highest proportion of cases occurred in the age groups 0 to 14 years (3784, or 23%) and 40 to 79 (7694, or 47%), with males making up 53% of the gender-reported cases. About 80% of cases occur from May to August, with peak incidence in July.

A cross-sectional survey of 1200 physicians in Maryland revealed that Lyme disease may be greatly under-reported, with less than 10% of cases meeting the Centers for Disease Control and Prevention (CDC) diagnostic criteria.^{[51] [66]} CDC criteria for Lyme disease include presence of an erythema migrans rash 5 cm or greater in diameter or laboratory confirmation of infection with evidence of at least one manifestation of musculoskeletal, neurologic, or cardiovascular disease. Campbell and associates^[51] also found several fold underreporting using a nine-component deterministic model.

The principal vectors of Lyme disease are several closely related ticks of the genus *Ixodes*. The deer tick *I. scapularis (dammini)* is the best documented vector; its geographic distribution correlates with endemic foci of Lyme disease in the northeastern and Midwestern United States.^{[272] [312] [351]} The range of *I. scapularis* extends from the northeastern United States to the southeastern states. The northern form of *I. scapularis* was originally thought to be a separate species and was named *Ixodes dammini*. Subsequent studies demonstrated mating compatibility and genetic similarity, however, and the two forms are now considered to be the same species.^[19] The southern form of *I. scapularis* appears to be responsible for Lyme disease cases in the southeastern

United States.^[43] ^[232]

Northern *I. scapularis* larvae, abundant in late summer and fall, and nymphs, numerous in spring and summer, are aggressive and parasitize a number of vertebrate species.^[43] The preferred host is the deer mouse *Peromyscus leucopus*, which serves as an important reservoir for *B. burgdorferi*.^[33] ^[289] ^[297] Transovarial transmission in ticks occurs but appears to be unusual.^[40] Adult *I. scapularis* ticks, abundant in spring and fall, have a narrow host range, feeding primarily on deer, which are key hosts in the life cycle of the tick ([Figure 33-4](#)). The high incidence of Lyme disease in the northeastern United States has been linked to increases in the deer population.^[316] ^[363] In some focal endemic areas, up to 60% of *I. scapularis* ticks are infected with *B. burgdorferi*, and tick populations may be high, even on well-kept lawns.^[95]

A third endemic focus in the United States has been identified on the West Coast (California and Oregon),

774

Figure 33-4 Life cycle of *Ixodes scapularis*. The cycle of ixodid ticks typically spans 2 years and includes three blood meals in the spring. The adult female tick releases her eggs, which hatch as six-legged larvae; during the summer, the larvae take a blood meal that lasts approximately 2 days. Larval ticks then enter a dormant phase with cooler fall weather. The ticks then molt in the spring, entering the second phase of their life cycle as eight-legged nymphal ticks. In the late spring or summer, nymphal ticks take a blood meal that typically lasts for 2 to 3 days. The nymphal ticks then molt as eight-legged adults in the fall. The adults mate on white-tailed deer; after mating the male dies, but the female takes one more blood meal before she lays her eggs and dies. (Modified from Habicht et al: *Sci Am* 257:78, 1987.)

where the vector is the western black-legged tick *Ixodes pacificus*, another member of the *I. ricinus* complex. The zoonotic transmission cycle for *I. pacificus* differs from *I. scapularis*, as evidenced by only 1.5% of *I. pacificus* surveyed in northern California and southwestern Oregon being infected with *B. burgdorferi*, a fraction too small to maintain an animal reservoir.^[45] In addition, the major hosts for immature *I. pacificus* are species of lizards, which are not competent hosts for *B. burgdorferi*.^[175] Instead, the enzootic cycle is maintained by a second tick, *Ixodes neotomae*, which does not bite humans.^[18] Up to 15% of *I. neotomae* ticks are infected with *B. burgdorferi*, which is enough to maintain endemic disease. The primary host for *I. neotomae* is *Neotoma fuscipes*, the dusky-footed wood rat, which is a competent reservoir for *B. burgdorferi*.^[37] Larval *I. pacificus* ticks feed on a variety of vertebrates and become infected when they feed on *N. fuscipes*. Transmission to humans may then occur from an infected nymph or adult.

**Box 33-1. INCIDENCE OF LYME
DISEASE, 1996 (RATE PER 100,000
POPULATION)**

Connecticut	94.8
Rhode Island	53.9
New York	29.2
New Jersey	27.4
Delaware	23.9
Pennsylvania	23.3
Maryland	8.8
Wisconsin	7.7

Cases of Lyme disease in states outside the range of *I. scapularis* and *I. pacificus* suggest that additional vectors are involved. Ticks from five genera (*Amblyomma*, *Dermacentor*, *Haemaphysalis*, *Ixodes*, *Rhipicephalus*) and other arthropods, such as mosquitoes, horseflies, and deerflies, are naturally infected with *B. burgdorferi*, but only members of the *I. ricinus* complex appear to be competent vectors for the disease.^[172]^[186]^[214]^[232] Investigators have found an uncultivable spirochete in *Amblyomma americanum* ticks, leading to speculation that a related borrelial species is causing a Lyme disease-like illnesses in the southeastern and south-central United States.

Lyme disease or similar syndromes also occur in Europe, Asia, and Australia. Garin and Bujadoux^[116] in France recognized as early as 1922 that neurologic abnormalities occasionally followed erythema migrans. This symptom complex has been described variously as Bannwarth's syndrome, tick-borne meningopolyneuritis, and meningopolyneuritis. The neurologic features include intense radicular pains, chronic lymphocytic meningitis, and peripheral nervous system involvement, particularly facial palsies. The full description of Lyme disease in the United States has led to the recognition of other erythema migrans-associated manifestations (arthritis and cardiac symptoms) in Europe.^[121]^[261]^[353] Patients with these European diseases (arthritis, carditis, meningoradiculitis) demonstrate increased antibody titers against *B. burgdorferi*.^[156]^[269]^[321]

The established vector for European erythema migrans, *I. ricinus*, is closely related to the common vectors for Lyme disease in the United States, *I. scapularis* and *I. pacificus*, and the major reservoirs in Europe are species of rodents.^[197] Areas of central Europe recently reported that more than 40% of *I. ricinus* ticks are infected by *B.*

burgdorferi.^[323] *B. burgdorferi* isolated from *I. ricinus* shows minor differences from U.S. strains in morphology, outer surface proteins, plasmids, and deoxyribonucleic acid (DNA) homology.^[2] ^[260] ^[298] As a result, *B. burgdorferi* is now divided

Figure 33-5 (Figure Not Available) Time course and frequency of symptoms. Approximately 50% of victims report recent tick bite. The initial stage I symptoms occur in approximately 70% to 80% of infected individuals. Weeks after the initial tick bite the skin, nervous system, and joints are most often affected as the spirochete spreads hematogenously. Stage II symptoms typically begin 4 to 10 weeks after the initial infection and occur in approximately 50% of untreated patients. Stage III typically starts much later, often 1 ½ to 2 years and rarely more than 5 years after initial infection. (Modified from Schmid GP: *Rev Infect Dis* 11(suppl 6):51460, 1989.)

into three strains: *B. burgdorferi sensu stricto*, *Borrelia afzelli*, and *B. garinii*.^[323] North American isolates are limited to *B. burgdorferi sensu stricto*, but all three strains are found in Europe. These strain variations likely account for differences in clinical manifestations and serologic response between North American and European cases.

Lyme disease cases have also been reported from China, Japan, and Russia, where the principal vector is *Ixodes persulcatus*, and from Australia in the Hunter Valley^[320] and along the New South Wales coast.^[198] No ticks of the *I. ricinus* complex have been found in Australia, suggesting that other vectors are likely to be identified.

Spirochetal development in most ticks is limited to the midgut, but the organisms disseminate during feeding and appear in saliva, providing the likely mechanism for disease transmission.^[33] ^[253] This phenomenon also explains the relationship between duration of tick feeding and *B. burgdorferi* transmission. In one study, nymphal *I. scapularis* transmitted *B. burgdorferi* to one of 14 rodents exposed for 24 hours, five of 14 rodents exposed for 48 hours, and 13 of 14 rodents exposed for 72 hours.^[233] A study of persons with tick bites investigated disease progression, as diagnosed by development of erythema migrans, seroconversion on enzyme immunoassay (EIA) and immunoblot, or both. Using the established scutal index to determine length of tick engorgement, investigators found that female and nymph ticks attached for greater than 72 hours were much more likely to induce Lyme disease than ticks attached less than 72 hours.^[287]

Although all three stages of the tick may bite humans, the nymph is primarily responsible for transmission of Lyme disease.^[312] The small size of nymphs accounts for only 30% of patients with Lyme disease recalling a tick bite.

Box 33-2. LYME DISEASE: STAGE I

Incubation: 7–10 days (range, 3–32 days)

Duration: 28 days (range, 1–14 months)

SYMPTOMS (INCIDENCE)

Erythema migrans (60%–89%)

Mild lymphadenopathy (23%)

Low-grade fever (19%–39%)

Mild fatigue and malaise (54%)

Neck stiffness (35%)

Mild arthralgia and myalgia (44%)

CLINICAL MANIFESTATIONS.

Lyme disease is multisystemic and multiphasic. It can be divided into three stages based on chronologic relation to the original tick bite, with different clinical manifestations at each stage (Figure 33-5 (Figure Not Available)). The disorder usually begins as a localized infection with erythema migrans and associated symptoms (stage I; [Box 33-2](#)).^{[120] [218]} Within days to weeks, spirochetes may disseminate through blood or lymph, and neurologic, cardiac, or joint abnormalities may develop (stage II). Finally, chronic, persistent infection (stage III) of the joints, nervous system, skin, or eyes may occur months to years after the onset of Lyme disease. Clinical expression, however, may vary greatly. Incomplete disease presentations occur, and virtually any clinical feature may be present in isolation or recur at intervals, complicating clinical diagnosis.

Although the exact roles of the infecting spirochete, spirochetal antigens, and host immune responses are unclear, tissue invasion and persistence of infection probably cause many later manifestations of Lyme disease. This concept is supported by the isolation of

Figure 33-6 Erythema migrans rash of Lyme disease in a pregnant female. (Paul Auerbach, MD.)

B. burgdorferi from blood, skin lesions (erythema migrans), and CSF.^[28]^[311] The organism has also been identified in the eye,^[314] myocardium,^[190] and synovium.^[285] Patients at all stages of disease respond to appropriate antimicrobial therapy, and early treatment generally leads to an excellent long-term prognosis.

Stage I: early localized.

Erythema migrans is the most characteristic clinical manifestation of Lyme disease ([Figure 33-6](#)). An average of 7 to 10 days (range, 3 to 32 days) after inoculation from a tick bite, *B. burgdorferi* spreads locally in the skin, producing an expanding, annular, and erythematous lesion. Initially a central red macule or papule forms at the site. As the lesion expands, partial central clearing may be seen, particularly in larger lesions, whereas the outer borders remain bright red. The borders are usually flat but may be raised and indurated. The center of some early lesions becomes intensely red and indurated or may even become vesicular or necrotic. In some cases, multiple red rings form within the outside margin, or the central area turns blue before clearing. The lesion often reaches a diameter of 15 cm (range, 3 to 68 cm), increasing in size as much as 1 centimeter per day. Erythema migrans may appear anywhere on the body. In cases with a single erythema migrans lesion, the most common sites include the head and neck region (26%), extremities (25%), back (24%), abdomen (9%), axilla (8%), groin (5%), and chest (3%).^[120] Erythema migrans is usually warm to the touch and often described by the patient as burning, but occasionally as itching or painful.

Constitutional symptoms may accompany erythema migrans but are usually mild and consist of regional lymphadenopathy, fever, and malaise. Fever is usually low grade but can reach 40° C (104° F) and is more common in children than adults. Lymphadenopathy is typically localized, related to the erythema migrans lesion, but can be generalized.

Erythema migrans fades after an average of 3 to 4 weeks (range, 1 to 14 weeks) without treatment; with antibiotics the lesion resolves after several days. Recurrent lesions may develop 1 to 14 months after the initial lesion in victims who do not receive antibiotic therapy, appearing as erythema migrans, secondary lesions, or both. Rarely, evanescent small red circles and blotches may develop. Patients treated with appropriate antibiotics rarely have recurrent skin lesions.^[310]

Retrospective reviews typically note erythema migrans in 60% to 80% of patients with Lyme disease, but a prospective longitudinal cohort study of more than 200 children and an adult prospective population-based study reported erythema migrans in almost 90% of patients. [\[52\]](#) [\[120\]](#) [\[295\]](#)

It is important to differentiate erythema migrans from local tick bite reactions, insect and spider bites, tinea, cellulitis, and plant dermatitis. Unfortunately, only a minority of victims recall a tick bite. Annular erythematous lesions occurring hours after a tick bite represent hypersensitivity reactions, not erythema migrans. In addition, a rash that resolves in 48 hours is unlikely to be Lyme disease. Biopsy of erythema migrans shows dermal and epidermal involvement at the center, but only dermal changes in the periphery, which are findings suggestive of an arthropod bite. [\[310\]](#)

Although erythema migrans is highly suggestive of Lyme disease, it is not pathognomonic. A study of rashes in the southern United States that clinically resembled erythema migrans found little association serologically or microbiologically with *Borrelia burgdorferi* infection. Many of these rashes were associated with bites from the *Amblyomma americanum* tick, which have recently been found to be infected by *Borrelia lonestarii* sp nov. Currently, no known association exists among *A. americanum*, *B. lonestarii*, and a Lyme disease-like illness. [\[50\]](#)

Stage II: early disseminated.

Within days or weeks after infection, the *B. burgdorferi* may spread from the skin to other organs through the blood or lymph. During this stage, spirochetes can be recovered from the blood. *B. burgdorferi* probably spreads initially to all organs, but like its spirochetal cousin *Treponema pallidum* (syphilis), it appears to sequester in certain niches. [\[298\]](#)

During the hematogenous spread of early disseminated disease, the most common manifestation seen is multiple erythema migrans. These annular secondary skin lesions develop in 20% to 50% of patients in the United States. The secondary lesions are generally smaller, migrate less, and lack indurated centers. They may be located anywhere except the palms

and soles. Ten to fifteen percent of patients have more than 20 such lesions; rarely the lesions exceed 100 in number. Blistering and mucosal involvement do not occur; this is an important feature in differentiating the lesions from erythema multiforme. Other skin manifestations include a malar rash (10% to 15%) and rarely urticaria. [\[310\]](#)

Constitutional symptoms typically accompany stage II Lyme disease. Malaise and fatigue are most common, may be severe, and are usually constant throughout the duration of the illness. Often a low-grade and intermittent fever accompanies stage II. In

children, temperature elevations may be constant and can reach 40° C. Tender regional lymphadenopathy in the distribution of erythema migrans or the posterior cervical chains is common, and generalized lymphadenopathy and splenomegaly may occur.^[310] Nausea, vomiting, and sore throat have also been reported. Prominent respiratory and gastrointestinal manifestations should suggest an alternative diagnosis or coinfection.

Symptoms of meningeal irritation predominate in some patients. Severe headaches are typically intermittent and localized. Stiff neck with extreme forward flexion occurs, but Kernig's and Brudzinski's signs are negative. Some patients have evidence of mild encephalopathy with somnolence, insomnia, memory disturbances, emotional lability, dizziness, poor balance, or clumsiness. Dysesthesias, most often of the scalp, may be particularly bothersome.

Musculoskeletal complaints are common. Arthralgias, myalgias, and pain in tendons, bursae, or bones are typically migratory, sometimes lasting only hours in one location. Patients may complain of generalized stiffness or severe cramping pain, particularly in the calves, thighs, and back. Frank arthritis is uncommon in the first several weeks of illness.^[310]

In 10% of patients, symptoms of hepatitis (e.g., anorexia, weight loss, nausea, vomiting, right upper quadrant pain), hepatomegaly, and generalized abdominal pain occur. Anicteric hepatic symptoms usually resolve in less than 1 week but may persist intermittently for several weeks. Respiratory symptoms are generally minor. Conjunctivitis occurs in 10% to 15% of patients.^[310]

During this phase of the illness, Lyme disease might easily be confused with a viral or collagen vascular disease, especially with no preceding skin rash. A distinguishing feature of Lyme disease is that early signs and symptoms are intermittent and rapidly changing. Such a pattern in a victim from an endemic area should suggest Lyme disease.

After dissemination, *B. burgdorferi* typically produces sequestered infection, most often of the nervous system, heart, and joints. Neurologic manifestations develop in 10% to 40% of patients with erythema migrans who are not treated with appropriate antibiotics.^[70] ^[225] Symptoms begin an average of 4 weeks (range, 0 to 10 weeks) after the onset of erythema migrans, usually after a latent period. However, neurologic signs and symptoms may be the presenting manifestations of Lyme disease. In untreated persons, symptoms usually resolve after several months (median duration, 30 weeks).^[225]

Meningoencephalitis is the most common neurologic presentation. Headache, typically fluctuating in intensity, is the predominant symptom. Subtle symptoms of encephalitis include sleep disturbances, poor concentration, memory loss, irritability, emotional lability, and confusional state. Unlike stage I disease, CSF examination in stage II often shows pleocytosis with an average of 100 cells/mm³, predominantly lymphocytic, usually with elevated protein level but with normal glucose level and opening pressure.^[225]

Behavioral or mood disturbances are the second most common symptom reported in children and adolescents with neurologic Lyme disease. Symptoms include fatigue, difficulty concentrating in school, oppositional behavior, irritability, and anxiety.^[23] Despite normal intellects, children with neurologic Lyme disease shows impaired auditory and visual sequential processing.^[32]

Facial nerve palsy develops in 11% of Lyme disease patients and 50% of those with Lyme disease meningitis. It may occur as an isolated finding. Facial paralysis in Lyme disease is similar to Bell's palsy, except that it is bilateral in 25% of cases. When bilateral, facial paralysis develops sequentially, with the opposite side presenting days to weeks after initial involvement. Duration of facial paralysis is from weeks to months, and 99% of patients have nearly complete return of function even if left untreated.^[62]^[227] Involvement of other cranial nerves is unusual.

The third common neurologic manifestation of Lyme disease is radiculoneuritis, including thoracic sensory radiculitis, motor radiculoneuritis in extremities, brachial plexitis, mononeuritis, and mononeuritis multiplex. This syndrome generally presents either as a painful limb, with stabbing, shooting, or burning pains, paresthesias, weakness, and fasciculations, or as an acutely herniated disk. The outcome is generally complete recovery, although a few patients have had residual weakness.^[225] Radiculopathy and peripheral neuropathy are uncommon in children with Lyme disease.^[31]

The triad of meningitis, cranial neuritis, and radiculoneuritis presents a unique clinical picture. However, any neurologic manifestation of Lyme disease may occur alone and may be the presenting manifestation. Other neurologic abnormalities described in association with Lyme disease include chorea, cerebellar ataxia, myelitis, dementia, pseudotumor cerebri, and optic atrophy.^[248]^[250]^[267]

Cardiac abnormalities develop in 4% to 10% of patients with untreated Lyme disease.^[256]^[309] The onset ranges from 3 to 21 weeks after the tick bite. The most common abnormality is fluctuating atrioventricular block, including first-degree, Wenckebach, or complete heart block. More than 80% of patients with documented Lyme carditis have abnormalities of the conduction system.^[223]^[309]

Progression to symptomatic complete heart block may require a temporary transvenous pacemaker. Patients typically report dizziness, palpitations, dyspnea, chest pain, and syncope. Hospitalization with continuous cardiac monitoring is advisable for patients with a second-degree or complete atrioventricular block, as well as for those with first-degree block if the PR interval exceeds 300 milliseconds. Electrophysiologic studies indicate that the block is at the level of the atrioventricular node. The block does not respond to atropine, suggesting a direct effect on the node.^[223]^[256]

Evidence for more diffuse cardiac involvement, most often electrocardiographic (ECG) changes compatible with myopericarditis, is found in about one half of patients with carditis. Radionuclide angiography may show left ventricular dysfunction in some patients, which is seldom clinically significant. Cardiomegaly rarely occurs in U.S. patients, although dilated cardiomyopathy is often reported from Europe.^[286]^[294] Valvular involvement is generally not a feature. At least one death has been linked to cardiac involvement,^[190] but abnormalities usually resolve completely, often within 1 to 2 weeks.^[309] Severe cardiac complications have been described in pediatric patients but are relatively rare.^[120]

In approximately 60% of untreated persons with erythema migrans, arthritis develops an average of 4 weeks and up to 2 years after onset of illness. The typical pattern is brief, recurrent episodes of asymmetric, oligoarticular swelling and pain in large joints, separated by longer periods of complete remission. Arthritis may be monoarticular or migratory, usually one joint at a time, in as many as 10 different joints. Arthritis in a single joint is usually of short duration (median, 8 days) but may persist for months. The knee is most often affected, followed by the shoulder, elbow, temporomandibular joint, ankle, wrist, hip, and small joints of the hands and feet.^[362] Many regard the rheumatologic findings of Lyme disease as primarily a North American phenomenon.^[298]^[324] Frank arthritis with joint swelling usually does not begin until months after onset of illness, and other than the knee, joint swelling is unusual. Inflamed knees are typically more warm and swollen than red or painful. Baker's cysts may develop and rupture, simulating thrombophlebitis. A majority of patients have repeated attacks, averaging three recurrences, which become less frequent and less severe over time.^[302]

In children, arthritis may be more delayed, developing an average of 4.3 months (range, 2 days to 20 months) after onset of illness. Children also often have complete resolution between recurrences, whereas adults more often have chronic effusions and morning stiffness between episodes. In a prospective study of patients with Lyme arthritis confirmed by CDC criteria, 90% had arthritis in at least one knee.^[119] Half the children had only a single episode of arthritis, and half had recurring joint involvement. Most children did well regardless of whether they received antibiotic treatment.

Synovial fluid in Lyme disease is inflammatory, with a median WBC count of 25,000/mm³, predominantly polymorphonuclear leukocytes. Higher counts may simulate septic arthritis.^[146] Complement level is generally greater than one-third that of serum, and protein level ranges from 3 to 8 g/dl. Synovial biopsy reveals hypertrophy, vascular proliferation, and a mononuclear cell infiltrate.^[307] Although *B. burgdorferi* DNA can be detected by polymerase chain reaction (PCR) in the synovial fluid of up to 85% of untreated patients with Lyme arthritis, the organism is rarely cultured successfully from joint fluid.^[221]^[307] After treatment with antibiotics, *B. burgdorferi* DNA can no longer be detected in synovial fluid.

Other reported manifestations of stage II Lyme disease occur much less frequently. Conjunctivitis can be a transient, early ophthalmologic manifestation in disseminated disease. In one patient, iritis progressed to panophthalmitis and unilateral blindness, with spirochetes isolated in the vitreous debris.^[310] Other findings associated with *B.*

burgdorferi infection include adult respiratory distress syndrome (ARDS),^[163] myositis,^[12] and osteomyelitis.^[146]

A solitary borrelial lymphocytoma may develop in patients with Lyme disease from Europe (approximately 1% of cases); it occurs rarely in patients in the United States. This tumorlike nodule is associated with *B. afzelli* and *B. garinii* and is characterized histologically by a dense polyclonal lymphocytic infiltrate with germinal centers in the dermis or cutis. Clinically it presents as a red to dark-blue-red nodule a few centimeters in diameter, most often on the earlobe in children and the nipple in adults. The lesion is often painful or itchy. Onset ranges from 1 to 6 months (mean 1.8 months) after a tick bite. Untreated, borrelial lymphocytoma may persist for many months, but it usually disappears within a few weeks after antibiotic therapy.^[325] In one study the lesion resolved after 6 weeks in 86% of patients after treatment with antibiotics.^[326] Patients with borrelial lymphocytoma are likely to have systemic disease and should be evaluated for neurologic and cardiac involvement.

Stage III: late disease.

Late or persistent infection usually begins a year or more after the onset of erythema

migrans, although patients may present with stage III disease as the initial manifestation of Lyme disease. The skin, joints, and nervous system are most often affected.

Chronic arthralgias and oligoarthritis develop in about 50% of untreated patients.^[306] In about 10% of adult patients with arthritis the knees or other large joints become chronically involved, as seen radiographically. Juxtaarticular osteoporosis, cartilage loss, cortical or marginal bone erosions, and joint effusions may be seen. Features of degenerative arthritis, cartilage loss, subarticular sclerosis, and osteophytosis are found less often.^[175] Patients usually do not have continual joint inflammation for more than several years, and recurrences tend to become progressively milder.^[303] Rheumatoid and antinuclear antibodies are generally absent,^[307] although the incidence of B cell alloantigens DR2 and DR4 appears to be increased in patients with chronic Lyme arthritis.^[301] The chronic form is unusual in children.^[119]

Patients with Lyme disease may develop persistent nervous system involvement months to years after becoming infected. Several distinct but often overlapping syndromes have been described. The best established syndrome is a severe, progressive encephalomyelitis characterized clinically by spastic paraparesis, cerebellar ataxia, cognitive impairment, bladder dysfunction, transverse myelitis, hemiparesis, and cranial neuropathy, particularly of the seventh and eighth cranial nerves.^[3] CSF examination typically shows a lymphocytic pleocytosis and intrathecal production of anti-*B. burgdorferi* antibody. Magnetic resonance imaging of the brain may show abnormalities of the white matter. Among seropositive persons, boys seem to develop

neurologic symptoms more than girls.

Chronic involvement of the peripheral nervous system also occurs in Lyme disease. Patients may have painless distal paresthesias or painful radiculopathy. The distal paresthesias are generally intermittent, are often symmetric, and involve the legs more frequently than the upper extremities. Radicular pain is more frequently asymmetric and may involve the cervical, thoracic, or lumbosacral segments, often in combination. The pain is typically spinal with radiation into the affected limbs or trunk.^[179] Nerve conduction and electromyographic studies suggest a mild axonal polyneuropathy with reductions in motor or sensory nerve conduction velocities and denervation of spinal and limb muscles.^[180] The underlying pathophysiologic mechanism appears to be mononeuritis multiplex.^[105]

Rarely, patients with neuroborreliosis may have strokes, seizures, or severe dementia.^[97] Several syndromes have also been described in which the association with infection by *B. burgdorferi* is less certain. Some patients with serologic evidence of infection develop mild encephalopathy with memory difficulties, depression, mood swings, language disturbances, and fatigue. These patients may or may not have increased intrathecal production of antibodies to *B. burgdorferi*, although some do show improvement with antibiotic treatment.^[179] The syndromes termed postborreliosis disorders are more problematic. After treatment for Lyme disease, many patients note persistent fatigue, sleep disorders, depression, or cognitive difficulties. The cause is unknown, and patients do not respond to antibiotics.^[105]

Acrodermatitis chronica atrophicans is the best example of prolonged latency followed by persistent infection in Lyme disease. Observed primarily in Europe where the causative organism is *B. afzelii*, the dermatitis may develop years after the onset of illness.^[216] ^[298] It begins with an inflammatory phase with bluish red discoloration, often at the site of a previous erythema migrans lesion, preferentially involving the extensor surfaces of the extremities. The inflammatory phase may persist for years or decades, with gradual conversion to atrophy of the skin.^[11] After initial hyperpigmentation, hypopigmentation develops, and eventually the skin becomes frail. One third of patients have an associated (usually sensory) polyneuropathy.

Other, unusual late manifestations of Lyme disease include recurrent hepatitis, myositis, eosinophilic lymphadenitis, and ARDS. Several patients with a history of Lyme disease developed a keratitis similar to syphilitic keratitis years after their initial infection.^[298] Late Lyme disease occurs infrequently in children.^[370]

The roles of persistent infection with *B. burgdorferi* immune mechanisms in late Lyme disease remain unclear. PCR studies show *B. burgdorferi* in joint fluid and CSF of untreated patients with late Lyme disease. After antibiotic therapy, PCR studies may be negative, although inflammation persists within involved joints, especially in patients with HLA-DR4 B-cell alloantigens.^[221] Immune mechanisms may also play a role in chronic neurologic disease.

LYME DISEASE DURING PREGNANCY.

Lyme disease during pregnancy historically has been of considerable concern because other spirochetes, the treponemes, cause significant congenital infection. The risk of fetal and postnatal complications of Lyme disease during pregnancy require further study, but human transplacental transmission of *B. burgdorferi* has been documented.^{[184] [193] [268] [354]} In each case the infant was either stillborn or died shortly after birth; one mother had been treated with oral penicillin for Lyme disease early in pregnancy.^[354] However, fetal infection appears to be rare. In a report of 19 pregnancies complicated by Lyme disease, five had an adverse outcome, although several were minor with no permanent sequelae, and no two outcomes were the same. *B. burgdorferi* infection was not documented in any fetus or neonate, and disease exposure earlier in pregnancy was not associated with

increased adverse outcome.^[193] Serologic surveys in endemic areas also suggest a low but real risk of fetal transmission. One survey of 2014 pregnant women in Westchester County, New York, showed 0.7% seropositivity, with no significant difference in obstetric outcomes between seropositive and seronegative mothers.^[327] In a second report comparing serologic status, 8% of neonates from endemic areas were seropositive for *B. burgdorferi* from cord blood sampling, compared with only 0.8% in infants from nonendemic regions. All neonates with positive serology showed an immunoglobulin (IgG) response, but none had elevated *B. burgdorferi* IgM antibodies. Neonates from the endemic region had fewer malformations but a significantly increased rate of cardiac malformations compared with the non-endemic group.^[361]

Despite the increase in Lyme disease, the risk of adverse outcome during pregnancy remains low. No clear association exists between Lyme disease and congenital anomalies, and no distinct pattern of teratogenicity has been identified. The risk of transplacental transmission appears minimal, and currently, no published data support a congenital Lyme disease syndrome.

Despite the relatively low risk, women who acquire Lyme disease during pregnancy should be treated promptly with antibiotics. A 1996 prospective study of 58 pregnant women with erythema migrans given oral or intravenous (IV) penicillin or ceftriaxone reported only seven adverse outcomes, unrelated and none clearly associated with Lyme disease.^[188] Although no randomized trials have compared oral with parenteral therapy during pregnancy, the American College of Obstetrics and Gynecology (ACOG) recommends oral penicillin or amoxicillin for three weeks in patients with early localized disease or those with recent deer tick bites. For patients with severe acute disease, neurologic sequelae, or chronic disseminated disease, the ACOG recommends IV therapy with penicillin.^[9] Others also recommend IV penicillin, 20 million units/day in divided doses for 10 to 14 days.^[354] In patients allergic to penicillin, erythromycin (500 mg four times daily) is an alternative. Ceftriaxone has also been recommended.^[216] Pregnant or lactating women should not receive tetracyclines.

DIAGNOSIS.

The diagnosis of early Lyme disease is best made using careful consideration of clinical and epidemiologic data. According to the CDC surveillance criteria, the clinical diagnosis includes exposure to an endemic region by a patient presenting with erythema migrans and accompanying generalized symptoms. Diagnosis with early disease does not require laboratory confirmation. However, incomplete cases without erythema migrans may prove difficult to diagnose, presenting as a viral-like illness.^[99] Arthritis or neurologic involvement may develop months after the cutaneous eruption, which the patient may not remember. Most patients do not recall a tick bite. The confirmation of late disease requires clinical evidence of disseminated disease plus laboratory evidence of infection.

Routine laboratory studies add little to the early diagnosis of Lyme disease and should not be used as a screening tool in healthy persons. Most patients have a mildly elevated erythrocyte sedimentation rate (ESR), gamma-glutamyltransferase (GGT), aspartate transaminase (AST, SGOT), and alanine transaminase (ALT, SGPT), and decreased absolute WBC count. Some patients have mild anemia. Immunoglobulins A and G are usually normal, whereas IgM may be elevated, especially in severe and neurologic or arthritic disease.

Positive culture for *B. burgdorferi* is the best laboratory evidence of causality but is difficult to obtain. Skin culture may be useful in patients in whom primary erythema migrans lesions are suspected. Saline lavage-needle aspiration and 2-mm punch biopsy of the leading edge of a suspected erythema migrans lesion obtain spirochetes in 29% and 60% of samples, respectively.^[371] In specialized laboratories, the success rate of skin biopsy may be as high as 80%.^[29] Biopsy from other areas is typically unsuccessful.

Other tests to detect *B. burgdorferi* infection lack sensitivity or are primarily research tools. Direct visualization techniques have yields too low to be clinically useful and are difficult to distinguish from elastin tissue fibers, procollagen fibers, and other artifacts.^[279] Urine antigen testing lacks sensitivity. PCR technology amplifies genomic and nongenomic gene sequences of *B. burgdorferi* from tissue samples and can be used as a surrogate to culture. DNA sequences can be detected in blood, urine, CSF, skin, and synovial fluid of patients with Lyme disease. PCR testing is promising but is not standardized and has large interlaboratory variability. Accordingly, routine use of PCR is not currently recommended for the diagnosis of Lyme disease. This leaves detecting indirect evidence of infection—antibodies to *B. burgdorferi*—as the only practical laboratory aid to diagnosis.

Unfortunately, antibody response to *B. burgdorferi* develops slowly. Serologic studies are usually negative in the first 3 to 6 weeks of illness, particularly in patients with limited manifestations. However, patients with complicated Lyme disease (neurologic, cardiac, or joint involvement) or those in remission typically have elevated specific antibody titers.^[206] ^[279] IgM antibody titers generally peak between the third and sixth weeks after the onset of illness; IgG antibody titers rise slowly and are highest weeks to months later when arthritis is present. Early treatment with antibiotics may blunt or completely suppress antibody formation. Both IgM and IgG antibodies may persist for months or

years after clinical resolution, even after treatment with appropriate antibiotics.^[98] Also, patients with early disseminated

Lyme disease (carditis, meningitis, neuropathy) may be seronegative.

Current methods for detecting antibodies to *B. burgdorferi* include indirect immunofluorescent assay (IFA), enzyme-linked immunosorbent assay (ELISA), and Western blot or immunoblot. In most laboratories, ELISA appears to be the test of choice for evaluation of suspected Lyme disease (89% sensitivity, 72% specificity), although IFA can be comparable when performed by experienced technicians.^[125]^[340] Western blot is often used as the second test in a two-test protocol to increase the specificity of serologic testing by demonstrating the presence of antibodies to epitopes that are unique to *B. burgdorferi*.^[85] Western blot's particular usefulness lies in identifying false-positive results. Because a positive ELISA result is usually statistically defined as a value two standard deviations above the mean, approximately 5% of the normal population will have a "false-positive" result. Consequently, according to the CDC national consensus panel, positive results from serologic testing are significant only if both ELISA and Western blot are positive. False-positive results are also common in patients with other treponemal diseases (syphilis, yaws, and pinta), leptospirosis, relapsing fever, viral infections (varicella), and autoimmune diseases such as systemic lupus erythematosus (SLE).^[206] Patients with Lyme disease, however, do not have positive Venereal Disease Research Laboratories (VDRL) tests. In addition, antibodies directed toward oral flora may cross-react, causing false-positive results.^[206]^[252]

The importance of appreciating the limitations of serologic testing cannot be overstated. Considerable caution must be exercised in interpreting test results. In one study, only 23% of patients referred to the Lyme Disease Clinic at New England Medical Center had active Lyme disease, and a majority of those without Lyme disease had been treated inappropriately with antibiotics.^[304] In this study, the most common reason for lack of response to antibiotics was misdiagnosis. The limitations of laboratory testing in Lyme disease include lack of sensitivity and specificity of serologic tests and considerable interlaboratory and intralaboratory variability in test results.^[274] The persistence of antibodies in patients with past or asymptomatic infection with *B. burgdorferi* also complicates serologic testing. If another illness develops, as occurred in 20% of patients referred to the New England Medical Center clinic, it may be incorrectly attributed to Lyme disease. This is particularly problematic in patients with nonspecific symptoms of chronic fatigue or fibromyalgia, in whom the predictive value of a positive ELISA is low.

The overdiagnosis of Lyme disease has significant health system and patient care implications. In a study of 209 individuals referred to a university-based Lyme disease clinic with a diagnosis of the disease, only 21% met criteria for active Lyme disease, 60% had no evidence of current or previous infection, and 19% had evidence of previous but not active disease. The 79% of patients without active Lyme disease

displayed significant anxiety and stress related to their diagnosis of Lyme disease, used considerable health care resources, and had frequent adverse antibiotic reactions. [249]

Diagnosis of Lyme disease requires careful consideration of epidemiologic and clinical information, supplemented by serologic testing when appropriate. For greatest cost-effectiveness, testing by serologic means should be guided by a patient's pretest likelihood of disease, taking into account exposure history, endemicity, and clinical signs and symptoms. Only 1.2% of tick bites in endemic regions result in erythema migrans. [340] For patients in nonendemic areas and with nonspecific symptoms, the pretest probability of Lyme disease is low, and these patients should not be referred for laboratory testing. Likewise, even patients from endemic areas who only present with nonspecific symptoms (e.g., fatigue, headache, myalgias, arthralgias, palpitations) have a low pretest probability and should not be referred for serologic testing. Serologic testing is most useful in patients with an intermediate pretest probability of having Lyme disease (20% to 80%). Serologic testing should be done in a reference laboratory and confirmed with a Western blot.

In patients from endemic areas who have erythema migrans, serologic tests are not indicated because the pretest probability of Lyme disease is very high; a negative serologic test is likely to be a false negative. Many patients with localized Lyme disease have not developed antibodies at the time of testing, especially if drawn within 2 weeks of symptom onset. These patients should be assumed to have Lyme disease, whether or not serologic tests are positive, and treated empirically. Convalescent titers are not helpful, since early antibiotic treatment may prevent seroconversion. Uncertainty about a lesion being erythema migrans demands careful observation. A lesion that resolves in 1 to 2 days, that does not expand centrifugally, or that is less than 5 cm in diameter is unlikely to be erythema migrans. [118] If Lyme probability appears intermediate after considering the factors of exposure, tick history, and clinical manifestations, the two-step ELISA and Western blot testing is recommended.

Most patients with symptoms of early disseminated or late Lyme disease have positive serologic tests. If clinical and epidemiologic data strongly support the diagnosis of Lyme disease, however, antibiotic treatment is appropriate even with negative findings, since some patients will not have seroconverted. Although patients with symptoms of central nervous system (CNS) involvement often undergo CSF testing for *B. burgdorferi* antibodies, this is not always necessary. [118] The CDC surveillance criteria require diagnostic levels of IgM or IgG antibodies to *B. burgdorferi* in serum or CSF.

Because almost all neuroborreliosis patients have positive serum serologies, CSF testing is not required to diagnose Lyme disease. As noted, a positive test does not establish the diagnosis of Lyme disease but merely indicates that infection has likely occurred in the past. Because immunoglobulins can persist in the serum for years after clinical improvement, serology testing has no role in measuring treatment response. The sensitivity and specificity of T-cell recognition of *B. burgdorferi* antigens are controversial. [298] [340]

In patients with isolated nonspecific symptoms such as chronic fatigue, transient musculoskeletal pain, or difficulty concentrating, Lyme serologic tests should not be performed. These symptoms are rarely if ever the sole manifestation of Lyme disease. The pretest probability of Lyme disease in this situation is so low that a positive test is likely to be a false positive.

TREATMENT.

Most manifestations of Lyme disease will resolve without treatment; however, appropriate antibiotic therapy hastens resolution in all stages of disease and prevents later complications.^{[264] [312]} *B. burgdorferi* is highly sensitive to tetracycline, aminopenicillins, ceftriaxone, and imipenem, both in vitro and in vivo.^{[151] [152] [153]} Alternative antimicrobials include penicillin (unlike *Treponema pallidum*, however, *B. burgdorferi* is only moderately susceptible), oxacillin, chloramphenicol, macrolides, and several newer oral cephalosporins. Both cefixime and cefuroxime appear to have equal efficacy to standard therapy.^{[6] [153]} Cefuroxime axetil and possibly azithromycin have been found comparable with doxycycline in a clinical trial in patients with early Lyme disease.^{[183] [217] [299]} Erythromycin also has good in vitro activity but is not as effective as amoxicillin or doxycycline in vivo. Aminoglycosides, sulfa drugs, first-generation cephalosporins, quinolones, and rifampin have little activity against *B. burgdorferi*. [Table 33-2](#) outlines the current approach to antimicrobial therapy in Lyme disease.

In stage I Lyme disease, amoxicillin and doxycycline are the drugs of choice. Amoxicillin is safe in pediatric and pregnant patients. The recommended duration of therapy is at least 14 days and up to 4 weeks if symptoms persist or recur. Because *B. burgdorferi* is very slow growing, prolonged antibiotic exposure may be necessary to kill the organism.^[6] Also, some treatment failures have occurred with shorter courses of therapy, so many clinicians recommend at least 21 days of therapy. Choosing an antimicrobial agent for early Lyme disease also depends on attainable CSF levels, since *B. burgdorferi* can invade the CNS early in the course of infection, even in the absence of specific neurologic symptoms.^[182] Although some clinicians have used probenecid to increase serum levels of amoxicillin, probenecid may block the entry of beta-lactam antibiotics into brain parenchyma and thus should not be routinely administered.^[368] Oral penicillin and erythromycin are not recommended because they are less effective at preventing late complications (myocarditis, arthritis, meningoencephalitis) than amoxicillin and doxycycline.^[310]

Within the first 24 hours of therapy, 15% of patients develop a Jarisch-Herxheimer reaction (JHR), with worsening fever, rash, malaise, and arthralgias.^{[216] [217] [312]} Treatment for JHR is symptomatic with nonsteroidal antiinflammatory drugs (NSAIDs), and symptoms rarely continue beyond 24 hours from the time of antibiotic administration. Antimicrobials should not be discontinued.

Treatment of early disseminated Lyme disease should be based on the severity of disease. Patients with mild disease, such as facial nerve palsy with normal CSF, first-degree heart block with a PR interval less than 0.30 second, multiple erythema migrans lesions, or early arthritis, can be treated with any of the oral regimens for 3

weeks. In a trial of patients with early disseminated borreliosis without meningitis, a 21-day course of oral doxycycline was equal in efficacy to 14 days of parenteral ceftriaxone.^[75]

Patients with severe disease (evidence of meningoencephalitis or more severe heart block) should be treated with parenteral antibiotics. IV penicillin (meningitis dosage), ceftriaxone (2 g every 24 hours for 2 to 4 weeks), and cefotaxime are all effective in treating CNS involvement (meningitis, cranial neuritis, or radiculoneuritis) in Lyme disease.^{[8] [230] [303]} Ceftriaxone was more effective in some studies than penicillin, and the once-daily dose schedule makes outpatient treatment feasible.^{[73] [74]} Meningitic symptoms usually resolve with therapy in 1 week, although complete recovery of motor deficits may require 7 to 8 weeks.^[306]

No controlled studies have compared oral vs. parenteral therapy for Lyme carditis, and cardiac manifestations of Lyme disease usually resolve within 1 to 2 weeks, even without antibiotic treatment.^[8] However, *B. burgdorferi* can directly invade the myocardium and produce a cardiomyopathy.^[294] Other manifestations of disseminated infection also occur in patients with cardiac involvement.^[239] For these reasons, patients with evidence of cardiac involvement more severe than a first-degree heart block should be treated with IV antibiotics for at least 2 weeks. Such patients should also be admitted for telemetry and possible temporary pacemaker placement if complete heart block develops.

Optimal therapy for Lyme arthritis remains controversial. Several oral and parenteral regimens have been used successfully. A reasonable approach for patients without evidence of neurologic involvement is to use an oral regimen initially.^[308] Four to eight weeks of oral antimicrobial therapy is recommended for acute, intermittent, or chronic arthritis. Generally these patients do well, but treatment failures occur.^[69] If an adequate clinical

TABLE 33-2 -- Antimicrobial Recommendations for Lyme Disease

DRUG	DOSE	DURATION
EARLY LOCALIZED DISEASE		
Adults		
Tetracycline	250 mg po qid	14–28 days
Doxycycline	100 mg po bid	14–28 days
Amoxicillin	500 mg po tid	14–28 days
Cefuroxime	500 mg po tid	14–28 days
Children		

Amoxicillin	50 mg/kg/day po tid	14–28 days
Doxycycline (over 8 yr)	100 mg po bid	14–28 days
Erythromycin	30–50 mg/kg/day po qid	14–28 days
Tetracycline (over 8 yr)	250 mg po qid	14–28 days
Cefuroxime axetil	30–40 mg/kg/day po bid	14–28 days

EARLY DISSEMINATED AND LATE DISEASES*

LATE DISSEMINATED NEUROLOGIC DISEASE†

Adults		
Ceftriaxone	2 g/day IV qd	14–28 days
Cefotaxime	2 g/day IV q8h	14–28 days
Penicillin G	20 million IU/day IV q4h	14–28 days
Children		
Ceftriaxone	75–100 mg/kg/day IV qd	14–28 days (max, 2 g/day)
Cefotaxime	90–180 mg/kg/day IV q8h	14–28 days
Penicillin G	300,000 U/kg/day IV q4h	14–28 days (max, 20 million U/day)

LATE DISSEMINATED ARTHRITIS

Adults		
Amoxicillin	500 mg po qid	28 days

Ceftriaxone	75–100 mg/kg IV/IM qd	14–21 days (max, 2 g/day)
Penicillin G	300,000 U/kg/day IV q4h	14–21 days (max, 20 million U/day)

po, Orally; *IV*, intravenously; *IM*, intramuscularly; *bid*, twice a day; *tid*, three times a day; *qid*, four times a day; *qd*, every day; q4h or, q8h, every 4 or 8 hours.

*For multiple erythema migrans, use treatment for early localized disease for at least 21 days.

For isolated facial palsy, use treatment for early localized disease for at least 21 to 28 days.

†Neurologic involvement limited to an isolated facial palsy should be treated as early disease.

‡For mild cardiac involvement, i.e., first degree atrioventricular block with PR interval less than 0.30 second.

§For second- or third-degree heart block, although no evidence indicates that intravenous is better than oral regimens.

response is not obtained, a parenteral regimen can be tried. Clinicians should keep in mind, however, that the response to antibiotics may not occur for 3 months or longer after completion of therapy.^[239] Treatment can be augmented with NSAIDs.^[216]

In chronic infection (stage III) the outcome after antibiotic treatment is usually favorable, but incomplete resolution is common.^[179] In cases of chronic neuroborreliosis, treatment should consist of at least 28 days of IV antibiotics.^[74] ^[181] Some experts now advise continuation

of treatment for an additional month for late Lyme disease manifestations that do not completely respond to an initial 4-week regimen. In 23 patients with late disease, ceftriaxone had better efficacy than IV penicillin.^[74] One case report suggests β -lactam resistance as a possible cause for suboptimal resolution of disease with penicillin treatment.^[117]

ASYMPTOMATIC TICK BITES.

Patients with asymptomatic tick bites frequently present for care. In one survey, physicians in Maryland reported seeing 11 times as many patients seeking help after "tick bites" than true diagnosed cases of Lyme disease.^[66] Three randomized, placebo-controlled studies have addressed antibiotic prophylaxis for tick bites.^[7] ^[65] ^[277] Patients in the placebo groups developed Lyme disease or seroconversion 1% to 3.4% of the time, despite 15% to 30% of ticks being infected. No patients in the treatment groups developed Lyme disease. A meta-analysis of the three studies concluded that there was no significant difference between the groups and that routine prophylaxis of tick bites is not warranted, even in endemic areas.^[352]

Many physicians do not adhere to this recommendation. Maryland physicians ordered serologic testing in two thirds of patients with asymptomatic tick bite and treated more than half with prophylactic antibiotics.^[109] The major area of concern appears to be patients with tick bites who become infected but do not develop erythema migrans (when the disease is easily treated) then develop the late and more serious

manifestations of Lyme disease. However, the risk of serious late sequelae in untreated patients with a tick bite is extremely low. First, less than 5 % of those bitten by the *I. scapularis* tick in endemic areas become infected. Second, most patients with an identified tick bite remove the tick before it has been attached for the 36 to 48 hours required to transmit an infectious inoculum of *B. burgdorferi*. Finally, 80% to 90% of the few patients who do become infected will develop erythema migrans, which is easily treated.

Physicians should weigh a number of factors related to the likelihood of disease acquisition in deciding whether to treat asymptomatic tick bites with antibiotics. Those factors include species and stage of the offending tick, duration of attachment, geography, and patient factors such as pregnancy. If a decision is made to treat, the literature supports using a 10-day course of amoxicillin or doxycycline.

VACCINE.

The high incidence of Lyme disease and the potential for long-term morbidity have led investigators to focus increasing effort on developing an effective vaccine. Two large trials of vaccines against the outer surface protein A (Osp A) of *B. burgdorferi* have been completed. Efficacy was 49% to 68% after the second dose, increasing to 76% to 92% after three doses. ^[279] ^[317] Both vaccines were administered in three doses at 0, 1, and 12 months. The vaccines appear to work by neutralizing spirochetes in the midgut of the biting tick during engorgement but before transmission of the organism. ^[115] ^[281] One of the vaccines, LymeRix, has received Food and Drug Administration (FDA) approval. The vaccine is recommended for individuals 15 to 65 years of age living in highly endemic areas or those in intermediate areas with extensive work outside in forested, grassy areas.

The Osp A vaccine caused few complications in either trial or in earlier safety trials; the most common side effects were localized pain and tenderness. ^[160] However, these first generation vaccines are not without problems. Because the vaccines are not 100% effective, vaccinated patients can still contract Lyme disease. In recent trials, antibody levels appear to decrease rapidly after vaccination, suggesting the need for boosters to maintain immunity. ^[115] Follow-up studies are required to determine long-range efficacy beyond 20 months, and new vaccine schedules must be devised with the goal of achieving full immunization within one Lyme disease season. The current vaccines are not approved for children under age 15, despite children representing almost one fourth of Lyme disease cases. ^[194] In addition, because antibodies to *B. burgdorferi* proteins react in vitro with cardiac and skeletal muscle proteins, neuronal tissue, hepatocytes, and synovial cells, the FDA advisory committee has urged caution in using the Osp A vaccine in persons with arthritis. Finally, the Osp A vaccines result in a positive ELISA result but a negative Western blot. ^[369] This may lead to confusion if clinicians follow the recommended two-step testing protocol.

Inactivated whole-cell vaccines are effective in laboratory animals and are available for use in dogs. Delays in use of whole-cell vaccines for humans stem from concern that molecular mimicry of whole-cell proteins may lead to immune cross-reactivity and

chronic inflammatory conditions.

Relapsing Fever.

Relapsing fever is an acute borrelial disease characterized by recurrent paroxysms of fever separated by afebrile periods. It occurs in both endemic and epidemic forms ([Table 33-3](#)). The endemic or sporadic form occurs worldwide and is caused by a group of closely related *Borrelia* species. Argasid ticks belonging to the genus *Ornithodoros* and wild rodents both serve as reservoir hosts, but the tick serves as the main vector. [338] The epidemic form of relapsing fever is transmitted by the human body louse; it has not been reported in the United States in recent years.

The *Ornithodoros* ticks that transmit tick-borne relapsing fever (TBRF) act as both vectors and reservoirs for *Borrelia* organisms. Transovarial transmission allows all developmental stages to be potentially infective. The

ticks generally feed at night and attach themselves to the host for a short time, usually less than 1 hour. The bite is seldom painful and frequently goes unrecognized. The ticks

are extremely resilient and may survive for years between feedings.

Ticks ingest *Borrelia* organisms while feeding on an infected vertebrate, most often a rodent. Borreliae enter the tick hemocele and then spread to other tick tissues, including the salivary glands, coxal organs, and reproductive organs. The coxal organs in argasid ticks are specialized tissues for excretion of excess fluids and solutes accumulated during feeding. In some *Ornithodoros* species, the coxal fluid is released near the mouthparts during feeding, allowing transmission of spirochetes to vertebrate hosts. Transmission may also occur through saliva or regurgitated gut contents.^[19] Borreliae remain infective within ticks for many months.^[288]

A high degree of specificity exists between the major strains of relapsing fever *Borrelia* and associated tick vectors. For instance, the three *Borrelia* species found in the United States—*B. hermsii*, *B. turicatae*, and *B. parkeri*—show complete specificity for their respective vectors, which are *O. hermsi*, *O. turicata*, and *O. parkeri*. *B. hermsii* can be transmitted only by *O. hermsi*, not by *O. turicata* or *O. parkeri*. This specificity is used extensively in classification of *Borrelia* species.^[76]

EPIDEMIOLOGY.

Ornithodoros ticks generally inhabit rodent burrows and nests, cracks and crevices in human and animal habitats, caves, and similar locations. Habits and patterns of infection vary between tick species. In parts of Africa, ticks live in the dust and cracks of earthen-floored huts, and sporadic cases are seen throughout the year. In the Middle East, Mexico, and southwestern United States, ticks live in the guano of cave floors, and human infection is often associated with visiting or camping in caves.

The majority of cases of TBRF in the United States are attributed to *B. hermsii*. Its vector, *O. hermsii*, inhabits the coniferous forest biome of the western United States and Canada, where it lives in remains of dead trees and burrows inhabited by mice, rats, and chipmunks. Ticks are carried by rodents into poorly maintained cabins and huts; lodging in such shelters by hikers and hunters is a major factor in acquiring relapsing fever.^[104]^[144] Occasional cases are also caused by *O. turicata* (transmitting *B. turicatae*) in Texas (associated with travel into caves) and adjacent areas of the Southwest; *O. parkeri* (transmitting *B. parkeri*) rarely bites humans.^[143]

TBRF is found throughout most of the world, although endemic areas include Colorado,^[90]^[144] California,^[90] the Pacific Northwest,^[104] southern British Columbia, plateau regions of Central and South America, central Asia, Mediterranean countries, and most of Africa. In California, where reporting of relapsing fever is encouraged, two to 12 cases are reported per year.^[90] Large outbreaks have been reported from Spokane County, Washington,^[333] Colorado,^[338] and the north rim area of the Grand Canyon.^[53] Between 1985 and 1996, the 285 cases of TBRF reported in the United States occurred in California, Colorado, Idaho, Texas, Washington, Arizona, New Mexico, Nevada, Oregon, Utah, and Wyoming.^[338] TBRF is more common in men, presumably because of increased exposure to tick vectors, and occurs primarily during summer months. TBRF is rarely fatal in adults, but in infants less than 1 year of age,

case fatality rates may be 20% or higher. ^[176] ^[288]

CLINICAL MANIFESTATIONS.

The characteristic clinical feature of TBRF is abrupt onset of fever lasting about 3 days (range, 12 hours to 17 days), an afebrile period of variable duration, and then relapse with return of fever and other clinical manifestations. The initial febrile period terminates with rapid defervescence or a "crisis," accompanied by drenching sweats and intense thirst. Febrile periods in TBRF are associated with bacteremia. Resolution of fever occurs when the host develops an adequate antibody response to the spirochete. During

786

afebrile periods the spirochete remains "hidden" in organ tissue and undergoes antigenic conversion to a new serotype. Relapse occurs when the new serotype causes bacteremia.

After being bitten by an infected tick, victims may develop a pruritic eschar at the site of the tick bite, but the lesion is usually absent by the onset of clinical symptoms. After an incubation period of approximately 7 days, victims develop fever, frequently accompanied by shaking chills, severe headache, myalgias, arthralgias, upper abdominal pain, photophobia, cough, nausea, and vomiting. The temperature is usually greater than 39° C (102.2° F), and patients may manifest extreme muscular weakness and lethargy. Splenomegaly develops in approximately 40% and hepatomegaly in 18% of TBRF patients. From 10% to 40% have neurologic involvement, approaching the incidence seen in Lyme disease. The most common neurologic complications are meningismus and facial nerve palsy.^[48] Facial palsy, when present, typically occurs after the second febrile episode and usually resolves within 2 to 9 weeks with or without treatment. Other reported neurologic complications include neuropsychiatric disturbances, encephalitis, peripheral neuropathy, myelitis, and pathologic reflexes. Iritis or iridocyclitis occurs in up to 15% of untreated cases, typically occurring later in the fever course. Formation of adhesions between the iris and anterior lens capsule frequently leads to visual defects. A rash, ranging from a macular eruption to petechiae and erythema multiforme, develops in 25% to 30% of patients.^[288]

Mortality rates have been as high as 40% in some epidemics of louse-borne relapsing fever,^[280] but TBRF is generally self-limited, although clinical features may be severe and prolonged. Neurologic complications generally resolve spontaneously, but severe depression may persist for months. Hemorrhagic complications, pneumonia, ARDS, hepatosplenomegaly, petechiae, or myocarditis may develop rarely.^[77] ^[104] ^[357]

Relapsing fever in pregnancy results in a high incidence of spontaneous abortion,^[288] premature birth, and perinatal morbidity.^[156] Fetal death is probably caused by direct placental invasion by spirochetes, resulting in thrombocytopenia and retroplacental hemorrhage.^[297] Prior studies have linked pregnancy with a more serious maternal

disease course.^[132] ^[205] ^[206] A more recent case-control study, however, found no significant difference in pregnant women's mortality or complications.^[155] Infection in the neonatal period usually occurs by placental transmission and presents as overwhelming sepsis with very high mortality.^[372]

ANTIGENIC VARIATION.

The phenomenon of relapse in TBRF is caused by the ability of borreliae to undergo antigenic variation in an infected host. The organisms are capable of spontaneous conversion to many serotypes. Clinically, defervescence occurs when the dominant serotype is eradicated by interaction with host antibody. Spirochetemia probably persists at undetectable levels during the afebrile period and consists of mixed serotypes. Relapse occurs when a variant population reaches detectable levels. Antigenic variation is under complex genetic control and does not appear to require contact of the organism with host antibody.^[17] ^[322]

DIAGNOSIS.

The clinical diagnosis of TBRF requires thorough knowledge of the epidemiology of the disease and a high index of suspicion. TBRF is uncommon and occurs only sporadically. A history of recent exposure to old cabins, caves, or any rodent-friendly environment suggests the diagnosis. Routine laboratory tests are of little value. The WBC count is usually normal but may be increased or decreased. A left shift is often present. Thrombocytopenia is common but non-specific. The CSF is often abnormal, with a lymphocytic pleocytosis (typically 10 to 2000 cells/mm³), usually with a normal glucose and elevated protein. A false-positive serologic test for syphilis (Wassermann) occurs in about 5% of cases.^[288]

The diagnosis of relapsing fever is confirmed by demonstrating spirochetes on peripheral blood smears. A routine peripheral blood smear (Wright-Giemsa stain) from a febrile patient is initially positive in 70% of cases.^[288] The diagnostic yield can be increased by examining thick smears and by staining with acridine orange using fluorescence microscopy.^[275] Inoculating laboratory animals (rats, mice) with blood and examining blood smears from the animals will also increase the diagnostic yield. The visual yield of spirochetes in peripheral blood smears diminishes with each successive febrile sampling. *B. hermsii* can be cultured in BSK-II medium, with the yield increasing in acutely febrile patients. Serologic tests are difficult to perform and are not yet practical utility.^[338] TBRF is probably underrecognized and underreported and has been misdiagnosed as Lyme disease.^[88]

TREATMENT.

Tetracycline and erythromycin are both effective in treating relapsing fever. A single oral dose of 500 mg of either drug is effective in louse-borne relapsing fever.^[47] However, a 7- to 10-day course (500 mg orally four times a day) is generally recommended in tick-borne disease.^[143] ^[288] For children less than 9 years of age, erythromycin is recommended (30–50 mg/kg/day in four divided doses), with the first dose given

intravenously. The borreliae are also sensitive to penicillin and chloramphenicol, but treatment failures have been reported with penicillin.^[47] Animal studies have shown that early treatment with a β -lactam antibiotic within 24 hours of onset of spirochetemia decreases CNS involvement.^[48]

	<i>E. canis</i>		Worldwide

JHR often occurs after the first dose of antibiotics. In one series, 54% of patients developed a JHR.^[88] It is often severe and may be fatal. The reaction begins with a rise in body temperature and exacerbation of existing signs and symptoms; vasodilation and a fall in blood pressure follow. This complex reaction is mediated in part by products of mononuclear leukocytes. The leukocytes are stimulated by increased contact with antibiotic-altered spirochetes. Neither endotoxin nor complement appears to be necessary in the pathogenesis of JHR.^[46] JHR typically occurs within a few hours of

initial antibiotic dosing and cannot be prevented by prior steroid treatment.

Waiting to begin treatment until the patient is afebrile does not prevent JHR.^[144] Pretreatment with acetaminophen and hydrocortisone results in only a mild reduction of hypotension and does not prevent rigors.^[47] Patients who are receiving the initial dose of antibiotics for relapsing fever should receive an IV infusion of isotonic saline in anticipation of a possible JHR. This is generally sufficient to counteract the hypotension. Lower initial doses of tetracycline or erythromycin may reduce the frequency of JHR.^[144]

Tick-Borne Rickettsial Diseases

Bacteria of the family Rickettsiaceae are small, fastidious intracellular parasites with gram-negative bacterium-like cell walls, typical prokaryotic DNA arrangement, and considerable independent metabolic activity. The six major antigenic groups cause a variety of human diseases worldwide ([Table 33-4](#)). Three are potentially transmissible to humans by ticks: spotted fever group (SFG) diseases, Q fever, and *Ehrlichia* infections. Organisms from the genus *Rickettsia* cause the various spotted fevers. *Coxiella burnetii* is the etiologic agent of Q fever. *Ehrlichia* are intraleukocytic Rickettsiaceae that infect humans and a variety of wild and domestic animals.

Spotted Fever Group Diseases.

Rickettsia of the SFG share intracellular growth characteristics and a group-specific antigen. They are distributed worldwide and, with the exception of *Rickettsia akari* (rickettsial pox), are transmitted by the bite of ixodid ticks ([Table 33-5](#)). Ticks serve as the natural hosts, reservoirs, and vectors for the rickettsiae.^[200] The organisms replicate freely within the tick host and are passed transovarially and transstadially. Amplification of the cycle occurs when uninfected ticks feed on an infected vertebrate host or concurrently with an infected tick.

In most natural vertebrate hosts the SFG rickettsiae induce an inapparent infection with transient rickettsemia. Human infection occurs through accidental intrusion into the natural cycle of infection or when ticks are transferred into human environments. Humans are incidental and "dead-end" hosts not involved in sustaining the life cycle of the organism.

PATHOGENESIS.

The tick-borne SFG diseases share a similar pathogenesis. The usual route of infection is by direct inoculation through the skin through the bite of a tick vector. Infection may also develop after contamination of broken skin with infected tick parts or feces, after blood transfusion from an infected donor,^[356] or through aerosol transmission among laboratory personnel working with pathogenic rickettsiae.^[224]

Local proliferation of rickettsiae probably occurs at the site of the tick bite, and a primary lesion or eschar frequently develops. Regional lymphadenitis may develop

TABLE 33-5 -- Spotted Fever Group Diseases

DISEASE	ETIOLOGIC AGENT	MAJOR VECTOR	GEOGRAPHIC DISTRIBUTION	PRIMARY LESION	USUAL SEVERITY
Rocky Mountain spotted fever	<i>Rickettsia rickettsii</i>	<i>Dermacentor andersoni</i> , <i>D. variabilis</i>	Western Hemisphere	None	Moderate-severe
North Asian tick typhus	<i>R. sibirica</i>	<i>Dermacentor</i> , <i>Haemaphysalis</i>	Europe to Russian Far East	Often present	Mild
Mediterranean spotted fever	<i>R. conorii</i>	<i>Rhipicephalus sanguineus</i> , <i>Haemaphysalis</i>	Mediterranean littoral, South Africa, Kenya, India	Often present	Moderate
Queensland tick typhus	<i>R. australis</i>	<i>Ixodes holocyclus</i>	Australia	Often present	Mild

in the distribution of the eschar, suggesting early lymphatic spread. Rickettsemia is typically present at the onset of clinical illness and persists throughout the febrile period.^[364]

The SFG diseases are characterized by disseminated vasculitic lesions.^[347] The rickettsiae invade, proliferate within, and ultimately destroy capillary and precapillary endothelial cells. In Rocky Mountain spotted fever (RMSF) the organisms spread into larger arterioles and arteries and invade medial smooth muscle cells. Medial necrosis and destruction of the vascular wall may follow. At sites of endothelial cell damage, a perivascular inflammatory response ensues, and platelet and fibrin thrombi tend to form and occlude the vessel lumen. In severe cases, vascular thrombi lead to necrosis of peripheral parts, including fingers, toes, the external ear, and scrotum. Antibodies develop 5 to 7 days after the onset of illness but do not appear to play a significant role in the pathogenesis of the vasculitis.^[366] Immunity develops with clinical recovery, tends to be long lasting, and appears to involve both antibody- and cell-mediated mechanisms.

CLINICAL MANIFESTATIONS AND DIAGNOSIS.

The SFG diseases display similar clinical manifestations, including fever, chills, headache, and myalgias. Three to 5 days after the onset of illness a characteristic maculopapular rash develops on the ankles, feet, wrists, and hands, then spreads centripetally to involve the entire body, including the palms and soles. With the

exception of RMSF, the SFG diseases are generally mild, self-limited illnesses, with deaths seen primarily in elderly or debilitated patients. Untreated RMSF, however, may be severe, with a mortality rate approaching 30%.^[40]

Early diagnosis and treatment virtually eliminate mortality and reduce morbidity in SFG diseases. At the onset of illness, however, signs and symptoms are frequently nonspecific, leading to diagnostic confusion with viral or other infectious diseases.^[158] Rash, the most characteristic feature of the illness, may develop late or, rarely, not at all. Identification of the eschar is helpful, but its presence is variable, and it is always absent in RMSF. Only 60% to 70% of patients recall a tick bite. Laboratory data (e.g., hyponatremia, thrombocytopenia) may provide clues to the diagnosis but are nonspecific. Serologic evidence of infection develops late in the illness. Early diagnosis therefore is based primarily on clinical evidence and relies on the ability to correlate clinical signs and symptoms with epidemiologic features.

Rickettsial infection is confirmed by identification of rickettsiae in tissues (not widely available), by isolation of rickettsiae from infected blood or tissues (difficult and hazardous to laboratory personnel), or by demonstration of antibody rise in paired sera. The widely used Weil-Felix test is based on the unique sharing of polysaccharide antigens between certain *Proteus* strains (OX-19, OX-2) and the SFG rickettsiae. This agglutination test lacks both sensitivity and specificity, however, and should be abandoned if other serologic methods are available. Newer and more sensitive serologic methods include complement fixation, microimmunofluorescence, IFA tests, microagglutination, indirect hemagglutination, and ELISA.^{[63] [157] [231]}

TREATMENT.

Early treatment of the spotted fevers is the most important factor in speeding convalescence and reducing mortality. Antibiotic therapy begun early in the course results in rapid resolution of clinical abnormalities. Tetracycline and chloramphenicol are both very effective, although neither drug is rickettsicidal. The antibiotics inhibit the rickettsiae until an adequate immune response by the patient eradicates the infection. Tetracycline is given orally at a dosage of 25 to 50 mg/kg/day in four divided doses (2 g/day in adults); the dose of chloramphenicol is 50 and 75 mg/kg/day for adults and children, respectively. Appropriate IV doses of both drugs may be substituted. Penicillins, streptomycin, and sulfonamides are ineffective. Treatment

should be continued until the patient is afebrile for 48 hours, or for a minimum of 5 to 7 days. Relapses are uncommon but may be treated with the same drug when they occur.^[366]

Epidemiology.

RMSF is the most common fatal tickborne disease in the United States.^[67] It was first recognized in the northwestern United States in the latter part of the eighteenth century and may have been prevalent even earlier in Native Americans of that region. It has since been identified throughout the Western Hemisphere. Human infections have been reported from all 48 contiguous states except Maine. The disease is also seen in Canada, Mexico, and parts of Central and South America.

A major shift in the demographics of RMSF occurred during the twentieth century. Before 1930 most cases were reported from the Rocky Mountains region of the western United States; in recent years more than 90% of cases have been reported from southern and eastern states. Reported cases in the mountain states have actually decreased more than tenfold, with only 2% of cases between 1981 and 1991 occurring in the Rocky Mountain States.^[199] "Rocky Mountain" spotted fever has thus become somewhat of a misnomer.

In the early 1970s a marked increase in the reported cases of RMSF was seen in the United States, reaching a peak in 1981 of 1192 cases, for an incidence rate of 0.51 cases per 100,000 population. Reported cases have gradually declined since that time, more recently ranging from 600 to 1200 cases reported each year.^[60] Most of this decline has occurred in the South Atlantic states, although they still account for a majority of the cases reported each year. States with the most cases in 1991, for example, were North Carolina (159 cases), Oklahoma (71), Tennessee (58), and Georgia (41).^[58]

The changes in the incidence and endemicity of RMSF have been attributed to cyclic changes in tick populations, changes in the virulence of infecting rickettsiae, and the process of suburbanization.^{[27] [137] [199]} A convincing explanation, however, is still lacking.

RMSF is caused by the gram-negative intracellular bacterium *Rickettsia rickettsii*. The epidemiology of RMSF is determined by the seasonal and geographic distribution of *R. rickettsii*-infected ticks. Many species of ixodid ticks have been implicated as vectors of the disease,^{[40] [173] [199]} but the most important species in the United States are *Dermacentor variabilis*, the American dog tick, and *Dermacentor andersoni*, the wood tick. Ticks of the *Dermacentor* genus are quite hearty, often living up to 5 years and displaying resilience to desiccation, cold, and starvation. Ticks transmitting RMSF outside the United States include *Rhipicephalus sanguineus* in Mexico and *Amblyomma cajennense* in Central and South America.

D. andersoni is the principal acarine host of *R. rickettsii* in the western United States and Canada. It feeds on virtually any available warm-blooded animal. *D. variabilis* is the primary host in the eastern United States and Canada. The domestic dog is the major host of adult *D. variabilis*, but the tick will feed on a variety of large and medium-sized animals. Nymphal and larval *D. variabilis* feed on various mice, voles, and rabbits. Serosurveys have indicated that a broad range of vertebrate hosts are infected with *R. rickettsii*, although not all sustain rickettsemia of sufficient magnitude to transmit the

infection to feeding ticks. *R. rickettsii* occurrence in the United States does not depend on the presence of any given order of mammal.^[199]

Domestic dogs become infected with *R. rickettsii* and may become acutely ill with fever and rash. Dogs probably do not play an important role in the amplification cycle of RMSF but may be important in transporting infected ticks close to humans.^[128] Several studies have shown an association between domestic dogs and RMSF.^{[41] [128] [196]} An infected tick may detach from a dog and complete its engorgement on a human, thereby transmitting *R. rickettsii*. Alternatively, infection through abraded skin or conjunctivae may occur during manual deticking of dogs.^[349]

Transmission by a tick vector delimits the clinical epidemiology of RMSF. It is a seasonal disease occurring when ticks are active; 95% of U.S. cases occur between April 1 and September 30, with most in May, June, and July. Exposure to wooded areas or areas of high grass increase the risk of disease. In southern states the season is longer with more winter cases, although sporadic cases can occur even in cold climates. RMSF also tends to be focally endemic, with a high proportion of cases occurring in small, circumscribed areas. This may be the clinical expression of "islands" of infected ticks.^[196] It is more common in males (60%) and young people (50% less than 20 years of age), who are more likely to be exposed to tick habitats.^{[332] [334]} The demographic group with the highest incidence of RMSF is 5- to 9-year-old children in the mid-Atlantic and southern United States.^{[60] [70]}

Other factors influencing human transmission include the duration of tick attachment and the prevalence of *R. rickettsii* in ticks. Transmission from the tick salivary glands may occur in as short as 6 to 10 hours of tick attachment, although some cases require more than 24 hours. Only a small percentage of ticks, even in highly endemic areas, are infected by Rickettsia. The chance of exposure to *R. rickettsii* from a tick bite ranges from 1 in 2123 in North Carolina to less than 1 in 1500 in Ohio.

Clinical manifestations.

RMSF ranges from mild, even subclinical illness to fulminant disease, with vascular collapse and death occurring within 3 to 6 days of onset.

TABLE 33-6 -- Clinical Findings in Rocky Mountain Spotted Fever

CLINICAL FINDING	PERCENT OF CASES
Fever	99

Clinical manifestations reflect the pathogenesis of the infecting rickettsia. Infection typically is through the skin, with spread occurring primarily by blood and lymphatic channels. The rickettsial species attaches to and invades vascular endothelial and smooth muscle cells using surface exposed protein and rickettsial phospholipase. The rickettsial species multiply intracellularly, becoming cytopathic. Vascular injury often ensues, with activation of clotting factors, extravasation of intravascular fluid, and impaired perfusion. Vascular permeability is elevated, with resultant edema, hypovolemia, and hypoalbuminemia. The incubation period ranges from 2 to 14 days (7-day mean onset); severe disease is associated with a shorter incubation period. Typically the victim has sudden onset of fever and chills, with or without headache, and myalgias. The classic triad of fever, rash, and history of tick exposure is present in only 3% to 18% of persons at the initial physician visit.^[162] The fever is usually high, greater than 39° C (102.2° F) in two-thirds of patients in the first 3 days of illness, and myalgias and headache may be severe. The most characteristic feature, the rash, usually develops 2 to 5 days after the onset of illness. Other signs and symptoms, including abdominal pain, vomiting, diarrhea, confusion, conjunctivitis, and peripheral edema, are common ([Table 33-6](#)). A history of tick exposure is present in 85% of confirmed cases.^[334]

The rash in RMSF results from injury to dermal capillaries and small blood vessels. It typically develops first on the wrists, hands, ankles, and feet 2 to 3 days after disease onset. The rash then spreads rapidly and centripetally to cover most of the body, including the palms, soles, and face. Initially the lesions are pink macules, 2 to 5 mm in diameter, that readily blanch with pressure. After 2 to 3 days the lesions become fixed, darker red, papular, and finally petechial. The hemorrhagic lesions may coalesce to

form large areas of ecchymoses. Necrosis may develop, especially in areas supplied by terminal arteries, such as fingers, toes, nose, ears, and genitalia. Involvement of the scrotum or vulva is a diagnostic clue.^[83]

In its classic form, the rash occurring during the summer months in an endemic area is almost pathognomonic for RMSF. Unfortunately, it is often absent on initial patient presentation, making diagnosis more difficult. The rash is delayed in approximately 10% of patients,^[138] with younger patients generally displaying the rash earlier in the disease course. In an additional 10% to 15% of laboratory-confirmed cases of RMSF, no rash is noted ("spotless" fever).^{[107] [137] [139]} In other patients the rash is evanescent, occurring only with fever spikes. One report indicates a possible actinic nature to the RMSF rash, worsening in sun-exposed areas.^[20]

Neurologic involvement in RMSF ranges from mild headache to serious focal or generalized disorders of cerebral function. Headache is very common. Meningismus occasionally develops but does not correlate well with CSF findings, which may be normal or may show modest protein elevation and pleocytosis of both lymphocytes and polymorphonuclear cells (usually 8 to 35 cells/mm³). Cerebral vasculitis may manifest with focal neurologic deficits, which are quite variable but usually transient. Seizures may develop during the acute phase of the illness but rarely persist.^[125] Lethargy and confusion are common and may progress to stupor or profound coma. Generalized cerebral dysfunction may be secondary to vasculitic lesions, especially in the reticular network of the brainstem, or to toxicity from severe rickettsial infection (fever, hypotension, hyponatremia, and thrombocytopenia with intracranial hemorrhage). Children with RMSF who develop coma have an increased risk of subsequent behavioral disturbances and learning disabilities. One case report describes Guillain-Barré syndrome as a complication of acute RMSF.^{[22] [129] [207] [338]}

Myocarditis is frequently found at necropsy in fatal RMSF; however, the clinical significance of the cardiac involvement is unclear. Pathologic study shows a patchy, interstitial, mononuclear infiltrate that appears to coincide with the distribution of rickettsiae in myocardial capillaries, venules, and arterioles.^[348] Abnormal left ventricular function can frequently be demonstrated echocardiographically in hospitalized patients.^{[103] [191]} Overt clinical manifestations of left ventricular dysfunction are uncommon, however, and hypotension and pulmonary edema are generally attributable to noncardiogenic causes. Cardiac enlargement rarely may be seen on chest radiographs.^{[177] [192]} ECG abnormalities include nonspecific ST-T changes, conduction abnormalities

(primarily first-degree atrioventricular block), and arrhythmias (paroxysmal atrial tachycardia, nodal tachycardia, and atrial fibrillation).^[192] Most patients have complete resolution of cardiac abnormalities with clinical improvement, but persistent echocardiographic abnormalities have been noted.^[191]

Infection of the pulmonary microcirculation by *R. rickettsii* results in interstitial pneumonitis and increased pulmonary vascular permeability. Although pulmonary involvement is not usually a prominent aspect of RMSF, a significant number of patients complain of cough, chest pain, dyspnea, or coryza.^[49] Patchy infiltrates may occasionally be seen on chest radiographs, and noncardiogenic pulmonary edema may develop in severe cases, with potential progression to ARDS.^{[82] [177] [262]}

Gastrointestinal symptoms are common in RMSF and are prominent complaints in some patients. At autopsy, rickettsial vascular lesions are found throughout the gastrointestinal tract and pancreas, although actual necrosis appears to be a rare event.^[240] Occasionally, RMSF presents as an acute abdomen, suggesting appendicitis or cholecystitis.^[350]

In the kidneys a focal perivascular interstitial nephritis is concentrated near the corticomedullary junction. Clinically, however, significant renal involvement is usually caused by prerenal azotemia or acute tubular necrosis after a hypotensive episode.^[329] Monarticular arthritis in the acute phase of RMSF has been reported.^[329]

The major complications of RMSF result from direct vasculitic injury. In late stages of the disease, diffuse vasculitic lesions cause increased systemic capillary permeability, leading to hypovolemia and vascular collapse. Disseminated intravascular coagulation (DIC), acute renal failure, metabolic acidosis, and cardiorespiratory dysfunction may ensue and often presage death. Endothelial leukocyte adhesion molecules and cytokines are thought to play an important role in the pathogenesis of fulminant RMSF. Long-term sequelae include paraparesis; hearing loss; peripheral neuropathy; bladder and bowel incontinence; cerebellar, vestibular, and motor dysfunction; language disorders; and disability from limb amputation.

When death results, it typically occurs after delayed treatment and 8 to 15 days following symptom onset. The exception is with fulminant RMSF, in which death occurs in less than 5 days, with hemolysis the most likely pathogenic cause. Risk factors associated with mortality include elevated serum creatinine, increased AST, increased bilirubin, hyponatremia, thrombocytopenia, and advanced age.^[64]

Diagnosis.

Before antimicrobials were available, RMSF was frequently a fatal disease. Even with effective antibiotic agents the mortality rate remains approximately 5%.^{[106] [138]} Patients older than 30 years, males, and nonwhites are at higher risk.^{[106] [137] [138]} Elderly patients appear more likely to have a severe course of illness and to have atypical features, including delayed or absent rash.^{[139] [213]} In susceptible individuals, such as those with glucose-6-phosphate dehydrogenase (G6PD) deficiency, RMSF may be fulminant and rapidly fatal.^[346]

Increased serum transaminase levels

Increased serum creatinine levels

The most significant factor in deaths from RMSF is a delay in diagnosis and in starting appropriate antibiotic therapy. Before antibiotics the mortality rate (1939 to 1945) was 23%, compared with 5.2% between 1981 and 1992. Patients who receive antibiotic treatment after 5 days of illness may die from advanced disease. Unfortunately, early diagnosis in RMSF is often difficult. The classic triad of rash, fever, and tick bite is actually rare during the first 3 days of illness,^[139] and confirmatory laboratory evidence is usually lacking early in the disease. Factors leading to a delay in diagnosis include absence or late appearance of the rash, lack of a history of tick bite or tick exposure, and nonspecific or unexpected initial symptoms leading to an incorrect initial diagnosis.

RMSF rarely is diagnosed by culture results, making historic data and clinical findings imperative. RMSF should be suspected and antibiotic treatment strongly considered in any patient who resides in or has recently visited an endemic area during the summer months and who has fever, headache, and myalgias even in the absence of a rash. Symptoms referable to the pulmonary, gastrointestinal, and central nervous systems often occur in RMSF and should not delay diagnosis.

The differential diagnosis of RMSF is extensive and includes meningococcemia, thrombotic thrombocytopenic purpura, immune complex vasculitis, ehrlichiosis, mononucleosis, measles, enteroviral infections, leptospirosis, and murine typhus. Meningococcemia may be impossible to differentiate initially, but chloramphenicol is effective therapy for both diseases. The rash of atypical measles may mimic that of RMSF.^[220] Gastrointestinal infection, respiratory infection (pneumonia, bronchitis), acute abdomen, and meningitis/encephalomyelitis are often misdiagnosed.

Routine laboratory values are nonspecific and provide limited clues to diagnosis, especially early in the course of illness, when serum antibodies are rarely detectable ([Box 33-3](#)). Thrombocytopenia has been reported in more than 50% of patients in some series, ^[346]

792

although the actual incidence may be closer to 35%.^[137] ^[139] Hyponatremia is also common and is probably a result of antidiuretic hormone (ADH) secretion in response to intravascular volume depletion.^[98] Other laboratory abnormalities include anemia, azotemia, hypoalbuminemia, CSF pleocytosis with monocytic predominance, increased creatine kinase, and elevated bilirubin and AST/ALT levels. Peripheral WBC count is usually normal.

Box 33-4. LABORATORY DIAGNOSTIC TESTING FOR ROCKY MOUNTAIN SPOTTED FEVER

SEROLOGIC DIAGNOSIS

Latex agglutination assay

Indirect immunofluorescence assay

SKIN BIOPSY-RELATED DIAGNOSIS

Polymerase chain reaction

Direct immunofluorescence antibody staining

Immunoperoxidase staining

Laboratory confirmation of RMSF has generally relied on serologic techniques detecting antibody increases in paired sera ([Box 33-4](#)). Even with the most sensitive tests, antibody rises are not seen until 5 to 10 days after the onset of symptoms, negating serologies at initial presentation. Early antibiotic therapy may delay titers even longer. ^[231] Serologic diagnosis requires a fourfold increase in titer between acute and

convalescent sera, which does not typically occur until 6 to 10 days after symptom onset.^[342] The Weil-Felix test is neither sensitive nor specific for RMSF and should not be used if other tests are available. The complement fixation test is widely available but also lacks sensitivity.^[231] False-positive results can occur during pregnancy with latex agglutination assays.^[355] The most sensitive and specific serologic tests currently in use appear to be the IFA and indirect hemagglutination tests.^[157]

The most promising method for early laboratory diagnosis of RMSF is immunofluorescent identification of *R. rickettsii* in biopsy specimens of the skin rash. Rickettsiae have been identified as early as the fourth day of illness with this method.^[367] Sensitivity is 70% to 90%, with a specificity of 100%.^[237] Serologic confirmation of RMSF requires a fourfold rise in antibody titers by indirect immunofluorescence or a single titer greater than 64.

Treatment.

Mortality is largely eliminated in RMSF by early treatment with tetracycline or chloramphenicol. Patients treated within 4 days of symptom onset are three times less likely to die than those treated later.^[70] Treatment should continue for at least 5 to 7 days or until the patient is afebrile for more than 2 days. IV therapy is required only if the patient cannot tolerate oral intake. Treatment with doxycycline may be preferable to chloramphenicol because tetracyclines may be associated with a higher survival rate.^[334] Although tetracycline can cause teeth staining in children, the risk is related to cumulative dose. A single course of therapy for RMSF is unlikely to stain teeth. Potential complications of chloramphenicol include bone marrow suppression, aplastic anemia, and gray syndrome. Rickettsiae are sensitive to fluoroquinolones, which remain a potential option even if human data are lacking. Mediterranean spotted fever (*R. coronii*) has been successfully treated with fluoroquinolones.^[24] In dogs, tetracycline, chloramphenicol, and enrofloxacin all appear to have equal efficacy in treating RMSF.^[35]

In severe cases, supportive therapy is also essential to a favorable outcome. Fluid replacement is critical in the hypotensive patient but must be monitored closely because of the risk of fluid extravasation through damaged vessels. Measurement of pulmonary capillary wedge pressures with a Swan-Ganz catheter may be necessary, especially if pulmonary edema develops. Use of corticosteroids has not been adequately evaluated but may be beneficial in patients with widespread vasculitis or encephalitis.^[201] ^[366]

Prophylactic antibiotics after a tick bite are not recommended because of the low incidence of infection and risk of adverse reactions. Routinely testing ticks for rickettsial antigen is not beneficial.^[263] Although none currently exists, promising vaccines are in development.

EASTERN SPOTTED FEVER.

Three other SFG diseases are transmitted to humans by tick bite: Mediterranean spotted fever (MSF), North Asian tick typhus, and Queensland tick typhus. The three

diseases closely resemble one another and have many similarities to RMSF. Generally, the course of illness in all three is milder than in RMSF, although complications and death may occur in susceptible patients. The diseases are characterized by abrupt onset of fever, headache, and malaise after a short incubation period (5 to 7 days). Unlike in RMSF, a primary lesion (eschar, tache noire) is often present at the site of the tick bite and may be associated with regional lymphadenitis. The lesion is classically a small ulcer, 2 to 5 mm in diameter, with a black center and red areola. A rash that varies from maculopapular to petechial usually develops 3 to 5 days after the onset of illness. Untreated, the fever and other symptoms resolve after several days to 2 weeks. Treatment with tetracycline or chloramphenicol significantly shortens the course of illness and, if instituted early, prevents complications.

MSF is caused by *Rickettsia conorii* and has been described under various names, often reflecting its geographic occurrence: Marseilles fever, South African tick

793

bite fever, Kenya tick bite fever, India tick typhus, and boutonneuse fever. As the names indicate, MSF is endemic in areas bordering the Mediterranean Sea, as well as parts of Africa and India. The major vector of MSF in the Mediterranean countries is the dog tick *Rhipicephalus sanguineus*. Several tick species have been implicated as vectors in other areas: *Haemaphysalis leachi* (Kenya, South Africa), *Rhipicephalus simus*, *Dermacentor reticulatus*, and *Ixodes hexagonus*.^[101] All stages of *R. sanguineus* occasionally attach to humans, and dogs may be important in transporting the ticks close to humans.^[339]

As with other SFG diseases, MSF occurs during the warm weather months. Seasonal occurrence, geographic location, and the presence of a tache noire (noted in 50% to 75% of cases) are the most helpful criteria for early diagnosis.^[211]^[244] Although the disease is usually mild in children and young adults, a malignant form resembling severe RMSF has been described.^[243]^[345]

The elderly, alcoholics, and patients with G6PD deficiency appear particularly at risk.^[147]^[153] The diagnosis can be confirmed by specific serologic testing or by immunofluorescent demonstration of *R. conorii* in cutaneous lesions.^[242]

North Asian tick typhus or Siberian tick typhus is endemic throughout Siberia, from European Russia to the Soviet Far East. It is seen primarily in agricultural areas and is closely associated with steppe landscapes.^[41] The causative organism, *Rickettsia siberica*, is transmitted to humans by several species of *Dermacentor* and *Haemaphysalis* ticks. In the natural cycle, adult ticks feed on large wild and domestic animals, especially cattle and dogs. As for other SFG rickettsiae, humans are accidental and dead-end hosts.

Queensland tick typhus is caused by *Rickettsia australis*. It is endemic to southern and northern Queensland, and the major vector is the scrub tick, *Ixodes holocyclus*.^[41] Both

Queensland tick typhus and North Asian tick typhus are benign illnesses of mild to moderate severity with typical rickettsial manifestations: fever, headache, variable appearance of an eschar at the site of the tick bite, and a rash.

SFG rickettsiosis also occurs in Japan, where the causative agent appears to be a distinct serotype of SFG rickettsiae.^[331]

Q FEVER.

Q fever is a worldwide zoonosis affecting both wild and domestic animals. It was first described in 1937 as an occupational disease of abattoir workers and dairy farmers in Australia.^[78] Aerosol spread of *Coxiella burnetii*, the causative organism, is the usual mode of transmission to humans. Sexual transmission has been implicated but not proved.^[171] Although ticks may become infected with *C. burnetii* after feeding on an infected vertebrate, tick-borne transmission to humans appears to be very rare.

Fewer than 10 cases of Q fever per year are reported in the United States. Serosurveys have shown widespread prevalence, suggesting frequent asymptomatic infection or underdiagnosis and underreporting.^{[134] [280]} The most common clinical presentation of Q fever is an influenza-like illness with fever, headache, myalgias, and pneumonitis. Abnormal liver function tests, jaundice, and hepatomegaly may be seen. Glomerulonephritis has been reported with both acute Q fever and endocarditis-associated chronic infection.^[166] *C. burnetii* infection during pregnancy, although not known to be teratogenic, can create placental insufficiency resulting in premature delivery or even intrauterine death.^{[113] [241]} A severe case of acute cerebellitis with tonsillar herniation was recently reported.^[265] In most victims the illness resolves spontaneously within 2 to 4 weeks of onset, with treatment hastening the resolution.

Q fever may also be a chronic infection, with or without a history of an acute episode. Granulomatous hepatitis and culture-negative endocarditis are the chronic forms of the disease. Endocarditis, fatal in 25% to 60% of patients, can affect native and prosthetic valves (underlying valvular disease is almost invariably present), although it has a predilection for the aortic valve.^[123] Infections of aneurysms and vascular prostheses have also been described.^[110] A post-Q fever syndrome involving fatigue, myalgia, arthralgia, night sweats, sleep disturbances, and mood alterations has been described and may occur in 20% to 42% of proven cases.^{[14] [228]}

Diagnosis of Q fever depends primarily on serologic testing. Two specific complement-fixing antibodies (phase 1 and phase 2) develop after infection with *C. burnetii*. In patients with acute Q fever, phase 2 antibody is usually detectable by the second week of illness; phase 1 is not detectable. The finding of phase 1 antibody indicates chronic infection. IgA subclasses (IgA1 seen in acute and chronic disease, IgA2 seen only in chronic disease) may also help detect chronic vs. acute infection. Only patients with endocarditis were found to have IgA2 antibodies to phase II antigens.^[49]

For the acute phase, tetracycline 500 mg orally four times a day will hasten resolution. Treatment of chronic Q fever is not always successful. Patients probably need to be

treated with tetracycline for at least 12 months.^[7] Some recommend adding another drug, such as lincomycin or cotrimoxazole, but with unproven efficacy.^[112] ^[341] Patients with endocarditis typically receive treatment with tetracycline and quinolone for at least 4 years, although new research supports shortened treatment with doxycycline and hydroxychloroquine.^[245] A vaccine has been used to prevent infection in high-risk abattoir workers. Prevention through avoidance of potentially infectious animal tissues, especially raw milk and products of conception, should be followed.

TABLE 33-7 -- Human Forms of Ehrlichiosis

Tick vector	<i>Ixodes scapularis</i>	<i>Amblyomma americanum</i> , <i>Dermacentor variabilis</i>
Geographic distribution	Northeast, Midwest	South-central states, Southeast

EHRlichia INFECTIONS.

Ehrlichia is a genus in the Rickettsiaceae family. Ehrlichiae are pleomorphic, gram-negative, obligatory intracellular pathogens that cause disease in humans and animals throughout the world. Their life cycle takes place primarily within the cytoplasm of circulating WBCs or platelets. Ehrlichiae can be divided into at least three genogroups based on 16S ribosomal ribonucleic acid (rRNA) gene sequences, but they are clinically classified more often by target cell specificity.

Two forms of ehrlichiosis occur in humans: human monocytic ehrlichiosis (HME) and human granulocytic ehrlichiosis (HGE) ([Table 33-7](#)). HME is caused by the *Ehrlichia chaffeensis*, which attacks mononuclear phagocytes. The Lone Star tick (*Amblyomma americanum*) is the primary vector of *E. chaffeensis*, and HME occurs predominantly in the south-central and eastern United States. Serologically and morphologically, *E. chaffeensis* appears to be closely related to *Ehrlichia canis*, which causes an illness in dogs.^[185] HGE is caused by an agent similar to *Ehrlichia equi*, infects neutrophils, and is likely transmitted by *Ixodes scapularis* and *Dermacentor variabilis* ticks.^[87] ^[222] HGE occurs primarily in the upper Midwestern and northeastern United States. The agent causing HGE is closely related serologically, morphologically, and by genomic sequencing to both *Ehrlichia phagocytophila* and *E. equi*, which are pathogenic to dogs, horses, sheep, goats, and deer.

HME has been reported in more than 30 states since 1986. Most cases occur in the

south-central and southern Atlantic states (Oklahoma, Missouri, Virginia, Georgia), principally in areas where RMSF also occurs.^[199] In one study, 68% of HME patients reported a tick bite, and 83% reported tick exposure in the 7 to 21 days before disease onset.^[108] A recent analysis of ticks in northern California found that more than 13% of *Ixodes* ticks and 20% of *D. variabilis* ticks were infected with *E. chaffeensis*.^[167] Most HGE cases occur in Minnesota and Wisconsin, with fewer cases in the southern New England states. Among HGE patients, 6% report tick bites, and almost all report exposure to ticks before illness. The reservoir hosts for *E. equi*-like agents are thought to be wild rodents, deer, and sheep.^[15] In field studies a high proportion of *I. scapularis* in endemic areas are infected with the ehrlichiosis-causing agent.^[266] Although most cases of ehrlichiosis are sporadic, reports exist of Army reservist and retirement community outbreaks.^[229] ^[293] Patients with ehrlichiosis tend to be older than patients with RMSF, with a slight male predominance. More than 70% of cases occur between May and July.

Human ehrlichiosis has a broad clinical spectrum ranging from subclinical infection to a mild viral-like illness to a life-threatening disease. Because of the shared tick vector and increased seroprevalence of HGE in patients with Lyme disease, confusion surrounds the clinicopathologic spectrum of the disease. As with *Borrelia* and *Babesia* organisms, the vector tick must remain attached for more than 36 hours for effective transmission of *Ehrlichia* organisms. After an average incubation period of 7 days (range, 1 to 21 days), high fever, headache, chills or rigors, malaise, myalgia, and anorexia typically develop. Leukopenia, thrombocytopenia, and elevated liver enzymes may also be present. A rash, usually macular or papular but occasionally petechial or erythematous, develops in 20% to 40% of patients a median of 8 days after the onset of illness.^[149] The rash appears to be more common in children than adults and involves the palms or soles in fewer than 10% of cases.^[21]

Severe and even fatal complications develop in some patients, usually in elderly or immunocompromised patients or in settings of delayed diagnosis or treatment.^[87] Respiratory complications may be relatively common; cough, pulmonary infiltrates, dyspnea, and respiratory failure have all been reported. Other serious complications include encephalopathy, meningoenzephalitis, shock, opportunistic infections, gastrointestinal hemorrhage, and renal failure. Immunocompromised patients are a high risk for death. In HME, bone marrow and hepatic granulomas and multiorgan perivascular lymphohistiocytic infiltrates have been observed. In HGE, *Ehrlichia*-mediated defects in host defense and immune suppression have resulted in opportunistic fungal and viral infections.^[344]

The most common CNS manifestation that predicts CSF abnormality is altered mental status. In one study of 15 patients with altered sensorium who underwent CSF testing, eight had abnormalities, including elevated lymphocytes (up to 1000 cells/ μ l) and protein in the CSF. In a review of 21 additional cases with CNS manifestations, 13 of 21 patients had abnormal CSF findings. Fourteen patients underwent brain computed tomography, revealing no abnormalities. Four of the 21 patients with CNS symptoms died.^[246]

HGE is clinically similar to HME, although only 8% of HGE patients develop rash.^[86]

and transaminases, along with thrombocytopenia, occur in most patients. These abnormalities are usually mild and of short duration.^[93]

As with RMSF, the diagnosis of ehrlichiosis depends on clinical findings. Serologic tests can be used to confirm the diagnosis. Indirect IFA testing against *E. chaffeensis* is now available from the CDC, and Western blot can be used to confirm seropositive specimens.^[187] Antibody levels rise rapidly during the first 3 weeks and peak after approximately 6 weeks.

Controlled trials of antibiotic therapy have not been conducted for ehrlichiosis, although tetracycline (or doxycycline) appears to be effective. In vitro studies show antibiotic susceptibility to rifampin, quinolones, and doxycycline.^[164] Chloramphenicol has been used to treat ehrlichiosis, but treatment failures have been reported, and *E. chaffeensis* is resistant to chloramphenicol in vitro.^[36] Rifampin is bactericidal against *E. chaffeensis* in vitro, however clinical experience is limited. Recently, a pregnant HGE patient was treated successfully with rifampin.^[39] Currently, tetracycline (doxycycline) should be considered the drug of choice for ehrlichiosis. The optimal dosage and duration of treatment need more investigation, but current recommendations are for oral or IV doxycycline (100 mg twice daily for adults, 3 mg/kg/day in two divided doses for children) for a minimum of 5 to 7 days. Dosing should be minimized as much as possible with children to prevent staining teeth. Because ehrlichiosis is potentially life threatening (2% mortality rate for HME, 7% to 10% for HGE), empiric treatment should be instituted before laboratory confirmation.^[343]

Tick-Borne Viral Diseases

Ticks transmit a wide variety of viruses to humans. As with other tick-borne diseases, the viral illnesses are zoonotic. Ticks ingest the organisms while feeding on a viremic host; the virus replicates within the tick and is passed transstadially. Transovarial transmission has been documented for tick-borne encephalitis virus and Crimean-Congo hemorrhagic fever virus; the role of transovarial passage in maintaining these viruses in nature is unknown.^[143] Amplification occurs when the infected tick feeds on an uninfected vertebrate. Humans usually are accidentally infected after intrusion into the natural tick-vertebrate cycle.

Tick-borne viruses cause clinical syndromes in humans that can be classified into four broad groups: influenza-like febrile illness with malaise, headache, myalgias, and arthralgias; febrile illness with hemorrhagic complications; febrile illness associated with meningoencephalitis; and subclinical or very mild illness. A specific virus may produce any or all of these syndromes depending on the virulence of the organism, host susceptibility, and the stage of the illness. For example, Colorado tick fever (CTF) virus usually causes an influenza-like febrile illness, but in susceptible hosts it may produce

meningoencephalitis or rarely a hemorrhagic diathesis.

Diagnosis of tick-borne viral diseases requires clinical acumen and interpretation of epidemiologic and clinical information. Isolation of the virus, usually by intracerebral inoculation in suckling mice, or demonstration of a rise in antibody titers in the victim confirms the diagnosis. As with most viral diseases, treatment is primarily supportive.

Only CTF occurs with any frequency in the United States. [Table 33-8](#) lists other tick-borne viruses.

Colorado Tick Fever.

Colorado tick fever (CTF) is an acute self-limited febrile illness caused by a small, 12-segmented RNA virus of the family Reoviridae and genus Coltivirus. The Salmon River virus, a related but antigenically distinct virus isolated from a patient with likely CTF, is a new putative coltivirus. The distribution of CTF includes the western United States and Canada, specifically the Rocky Mountains, Black Hills, Sierra Nevadas, and coastal range of California, corresponding largely to the range of the Rocky Mountain wood tick, *Dermacentor andersoni*. Distribution exists at altitudes of 1219 to 2048 m (4000 to 10,000 feet), typically among pine-juniper-sagebrush vegetation. The natural reservoir normally depends on the small mammal-tick cycle but also involves small mammals in California outside the known range of *D. andersoni*, suggesting that other tick species are capable of transmitting the virus.^[174]

CTF virus is maintained in its natural cycle by transmission between ticks and rodents.^[202] Larval stages of *D. andersoni* ingest the virus while feeding on a viremic rodent host and pass it transstadially from larva to nymph to adult. Hibernating nymphs and adults carry the virus through the winter. Infected ticks emerge in the spring and feed on susceptible animals, renewing the cycle. Nymphal and adult ticks may also acquire the virus by feeding on viremic hosts. The virus does not appear to cause disease in its natural hosts; humans are incidental and dead-end hosts, usually infected by adult ticks. Transmission occurs between March and September with a peak between April and June. Risk factors include exposure to outdoor vegetation and often involve camping, hiking, and fishing. Ticks may be carried home on clothing or equipment, leading to infection.

CTF is usually a benign, self-limited febrile illness that is difficult to distinguish from many other agents, especially *Rickettsia rickettsii*. More than 200 cases of CTF are reported annually in the United States, but the actual incidence is probably much higher; many cases are not brought to medical attention or are diagnosed simply as a viral illness. It is a seasonal disease occurring from late March to early October, with a peak incidence

TABLE 33-8 -- Tick-Borne Viral Diseases

VIRUS	TAXONOMIC GROUP	MAJOR VECTOR	ANIMAL HOSTS	GEOGRAPHIC DISTRIBUTION	HUMAN ILLNESS
Colorado tick fever	Reoviridae, genus <i>Orbivirus</i>	<i>Dermacentor andersoni</i>	Rodents, other small mammals	Mountain highland areas of western United States and Canada	Biphasic FI, ME, especially in children, in prolonged viremia

FI, Febrile illness; ME, meningoencephalitis.

in May and June. All age groups are susceptible to CTF, but it occurs most often in young men, reflecting their greater recreational and occupational activities in outdoor mountain areas. A history of tick exposure can be obtained in approximately 90% of patients with CTF; the usual time between the tick bite and the onset of symptoms is 3 to 6 days (range, 0 to 14 days).^{[127] [291]}

CTF usually begins with the abrupt onset of fever. Most victims experience severe headaches, myalgias, and lethargy; complaints of photophobia, ocular pain, anorexia, nausea and vomiting, and abdominal pain are common. A macular or maculopapular rash is reported in 5% to 12% of patients but is not a prominent feature. The most characteristic feature of the illness is a biphasic or "saddle-backed" temperature pattern. Victims initially experience 2 to 3 days of fever, followed by a 1- to 2-day remission and then an additional 2 to 3 days of fever. This pattern is helpful when present but cannot confirm the diagnosis, since it is observed in only about 50% of patients.^{[127] [291]}

CTF is usually mild, but severe complications can occur, particularly in children under age 10. Meningoencephalitis has been described in several children.^{[54] [84] [282] [291]} Two children developed a hemorrhagic diathesis and died.^[127] Other unusual complications associated with CTF include pericarditis,^{[1] [141]} myocarditis,^[92] hepatitis,^[178] epididymoorchitis,^[128] and pneumonitis.^[127] Information on CTF contracted during pregnancy is inconclusive, but of five cases reported, one terminated in a spontaneous abortion and in another a live-born infant had multiple congenital anomalies.^[210] CTF virus is teratogenic in mice.^[136]

Nearly half the patients with CTF require 3 weeks or longer to recover fully from the illness. The most common persistent symptoms are malaise and weakness. Prolonged symptoms occur most frequently in patients over age 30.^[127] Treatment of CTF is

supportive; infection generally confers lifelong immunity.

CTF virus circulates free in the plasma and bone marrow of infected patients until the end of the first week of illness, when it is neutralized by antibodies. In the bone marrow the virus infects erythrocyte precursors and persists within mature erythrocytes, where it is protected from antibodies. This allows viremia to persist for a prolonged period, even when clinical recovery is complete. Infective virus can be recovered from the blood for a month or longer in nearly 50% of patients.^[127] Persistent viremia in blood donors poses a risk to recipients of blood transfusions; transfusion-acquired infection has been reported.^[58]

Other hemopoietic cells may also be affected in CTF. Leukopenia involving both granulocytes and lymphocytes is common and may be helpful diagnostically, although one third of patients have normal WBC counts.^[130] Thrombocytopenia may also develop; anemia associated with the virus is rare.

Traditionally, serologic analysis provided little firm evidence of CTF infection during the acute phase because of the delay in appearance of various antibodies. Recently, diagnosis during the acute phase using reverse-transcriptase PCR has been reported, making this method a promising tool for early detection and treatment.^[131]^[149] Isolation of CTF virus from blood or CSF by inoculating suckling mice or cell cultures confirms the diagnosis and has been reported as the most reliable technique.^[38] A fluorescent conjugate prepared against CTF viral antigen can be used to stain erythrocyte smears, but the test lacks sensitivity.^[127] Serologic tests (neutralizing antibody, complement fixation, IFA) are available, but titers rise slowly, and these are traditionally not diagnostic during the clinical illness. Improvements in early serologic testing are ongoing, with recent reports of IgM detection against synthetic viral peptides and Western blot analysis, facilitating easier diagnosis during the acute phase of illness.

Babesiosis

Babesia species, as with malarial organisms, are pleomorphic intraerythrocytic protozoan parasites. More than 70 distinct species have been described from various vertebrate hosts.^[254] Some of the most important species include *B. bigemina*, *B. bovis*, and *B. divergens* (all in cattle); *B. caballi* and *B. equi* (horses); *B. canis* (dogs); and *B. microti* (rodents). Babesiae are transmitted to vertebrates primarily through the bite of ixodid ticks.

Epidemiology.

Babesiosis has long been recognized as an important veterinary disease, receiving biblical reference as the "divine murrain" infecting the cattle of the pharaoh Ramses II (Exodus 9:3). Various epidemics of cattle fever have been documented throughout history.^[34] Human disease was originally reported in 1957 in a splenectomized man in Yugoslavia.^[283] Five cases of human infection with bovine *Babesia* (*B. bovis*, *B. divergens*) were reported from Europe between 1957 and 1976; two cases of babesiosis of unknown species were reported from California in 1968 and 1981; a human case of *B. gibsoni* infection was reported in California in 1993; and a single *B. caucasica* infection

was reported from Russia in 1978.^[148]^[254]^[255] These cases were widely separated geographically, and all occurred in splenectomized individuals.

Since 1970 the incidence of human babesiosis has accelerated, primarily because of an outbreak of *B. microti* infections in the northeastern United States. The first case was recognized in a patient with an intact spleen in 1969 on Nantucket Island, Massachusetts.^[358] Since then, more than 450 confirmed cases have occurred in the United States.^[71]^[203] *B. microti* is endemic to the coastal regions of southern New England, where the principal vector is the northern deer tick *Ixodes scapularis*.

798

Most cases are contracted on Cape Cod and the offshore islands of Massachusetts (Nantucket, Martha's Vineyard), New York (Shelter Island, Long Island), and Rhode Island (Block Island).^[71] Cases have also been reported from Wisconsin and Minnesota, a known focus of *I. scapularis*.^[319] The high incidence of *B. microti* infection is caused by its ability to produce disease in individuals with intact spleens. A new strain of *B. microti* called WA-1, thought to be spread by *Ixodes pacificus*, has been isolated from an immunocompetent patient with an intact spleen in Washington State.^[238]

The ecology of *B. microti* parallels that of *Borrelia burgdorferi*, the agent of Lyme disease. The major vector in both diseases is *I. scapularis*. White-footed mice (*Peromyscus leucopus*) constitute the major reservoir for *B. microti*. Larval or nymphal ticks ingest the parasite during a blood meal from an infected rodent. Babesiae replicate within the tick and are passed transstadially. Amplification of the cycle occurs when the infected tick transmits the organism to a vertebrate host during the next blood meal. White-tailed deer (*Odocoileus virginianus*) are the principal hosts for adult ticks; larvae and nymphs feed on deer, mice, and other small mammals.^[290]

Human babesiosis occurs when humans accidentally intrude on the natural cycle and are bitten by an infected tick. As in other tick-borne diseases, the peak incidence is during the warm weather months from May to September, when ticks are actively feeding. The majority of infections with *B. microti* are asymptomatic. Recent serologic testing shows that although seroconvergence has increased greatly over the past 30 years, it stabilized in the 1990s.

An epidemiologic survey of 136 cases in New York showed that the most important risk factors for severe babesial disease are advanced age, asplenia, and immunodeficiency. Babesial infection appears to be as prevalent in children as in adults, however, the intensity of disease greatly increases over age 40. In one study, 23% of patients with babesiosis had concurrent Lyme disease infection.^[203] Case reports have also shown multiple coinfection involving borreliosis, ehrlichiosis, and babesiosis,^[209] with more severe symptoms in coinfecting individuals compared to single organism infection.^[169]

Prolonged, subclinical infection creates the potential for transmission of *B. microti* through blood donation. More than 26 cases of babesiosis acquired by transfusion have

been reported.^[79] ^[173] ^[189] ^[284] ^[365] Seroprevalence surveys in endemic regions show donor exposure rates of 3% or greater.^[80] Currently, control of transfusion-related infection is limited to identifying donors at high risk of exposure (from endemic regions, history of tick bites, seasonal exposure to tick-favorable landscapes). This strategy may become less effective as tick-endemic areas expand. Transfusion

Figure 33-7 (Figure Not Available) *Babesia* life cycle. Within a tick, *Babesia* parasites infect gut cells, undergo asexual division, and eventually migrate to the salivary glands. The organism is introduced into a human when the infected tick takes in a blood meal. Transmission usually involves the nymphal tick, but the duration of attachment required for transmission of *Babesia* species is not known. *Babesia* species can be transmitted to humans concomitantly with *Borrelia burgdorferi*. (Modified from Boustani MR, Gelfand JA: *Clin Infect Dis* 22:612, 1996.)

has also reportedly transmitted new species of *Babesia*, causing significant disease in immunocompetent individuals.^[141]

Pathogenesis.

Babesiae are transmitted from wild and domestic animal reservoirs to humans by *Ixodes* ticks. The life cycle of *I. scapularis*, the tick responsible for transmission of *B. microti* to humans from rodents, spans 2 years, beginning in the spring with the hatching of the larval form. In the late spring and summer months the larvae feed on a variety of hosts and acquire babesial infection. Typically, larvae become infected from their preferred host, *leucopus*. Ingested Babesiae reach the gut of the feeding tick, where they reproduce sexually. The newly formed zygote eventually spreads throughout the body of the tick. After reaching the salivary glands, the babesial sporoblasts remain dormant until the next spring when the tick larva molts to a nymph. The nymph then seeks a blood meal, infecting a new host (rodents or humans). In endemic areas, as many as 60% of white-footed mice are infected by late summer. The nymph *I. scapularis* is the primary vector of human babesiosis, but adult ticks can also transmit the disease.

After inoculation by a tick bite, *Babesia* sporozoites rapidly invade erythrocytes, where they differentiate into merozoites. Great pleomorphism is displayed,^[214] but ring-shaped and ameboid trophozoites are the predominant form. Multiplication occurs by asexual asynchronous budding. After the parasite multiplies, the infected erythrocyte ruptures, freeing the organisms to invade other red blood cells (RBCs); severe hemolytic anemia may ensue (Figure 33-7 (Figure Not Available)).

Infection with *B. microti* reduces the malleability of erythrocytes, causing microvascular stasis and decreased RBC life span. Electron microscopy has shown extensive RBC wall damage, including protrusions, perforations, and extrusions in the cell membrane. Asplenia or steroid therapy can worsen the disease and prolong parasitemia. An intact spleen preferentially destroys infected RBCs because of their decreased malleability.

Prolonged parasitemia is common in babesiosis.^[257] *B. microti* may persist for as long as

4 months in an otherwise healthy patient.^[358] Parasitemia may remain after clinical recovery or may develop in asymptomatic individuals.

An intact spleen is important in resistance to *Babesia* organisms. Although the presence of a spleen is not protective against *B. microti*, the disease is often more severe in splenectomized patients. Age is also an important factor in susceptibility to babesiosis. Children and young adults usually have subclinical or mild, self-limited infections, whereas older adults are more likely to have severe, clinically apparent disease.^[25] ^[258] Chronic medical disorders may be an additional risk factor for severe babesiosis.^[26]

Clinical Manifestations.

Acute *B. microti* infection is characterized by the gradual onset of malaise, anorexia, and fatigue, followed within several days to a week by fever, sweats, and myalgias. Other, less common symptoms include headache, nausea and vomiting, depression, abdominal pain, and dark urine. In a review of 17 patients with babesiosis, 52.9% presented with temperature greater than 38.3° C (101° F), and four of the nine had morning fever spikes; eight had relative bradycardia.^[161]

Incubation is 1 to 4 weeks after a tick bite or 6 to 9 weeks after transmission by blood transfusion. Most victims do not recall a tick bite, and rash is not a feature of the illness. If rash resembling erythema migrans appears, Lyme disease coinfection should be considered. Physical examination is usually normal, except for fever (steady or intermittent) and mild splenomegaly in some patients. Petechiae and ecchymosis may rarely occur. Laboratory evaluation reveals a mild to moderate hemolytic anemia; normal to slightly reduced WBC counts; and in some patients, mild to moderate thrombocytopenia. Serum lactate dehydrogenase (LDH) and bilirubin levels are mildly elevated in most patients, reflecting the hemolytic anemia.^[126] ^[257] AST and ASL may be elevated, and urine may show proteinuria and hemoglobinuria. In one series, 13 of 17 patients (76.5%) had lymphopenia, and five (29.4%) had rouleau formation in the peripheral blood smear.^[161]

A review of 139 hospitalized patients with babesiosis in New York from 1982 to 1993 looked at common signs and symptoms and the prognostic factors associated with poor outcome.^[359] Of the 139 patients, 9 (6.5%) died, 35 (25.2%) were admitted to the intensive care unit, and 35 (25.2%) required more than 14 days of hospitalization. In these patients with severe disease the mean age was 62.5 years, and 62% were male. The most common symptoms were fatigue, malaise, weakness (91%); fever (91%); shaking chills (77%); and diaphoresis (69%). Prognostic indicators for severe outcome included high alkaline phosphatase, male gender, and elevated WBC count. Only 12% of patients with severe disease had a history of splenectomy, and only 2% had received a prior blood transfusion.

Although most patients with normal splenic function recover without specific therapy, prolonged fatigue and malaise are common.^[257] Splenectomized persons generally have more severe clinical disease with higher levels of parasitemia and more severe hemolytic anemia.^[258] Elderly persons, immunocompromised patients, and those with human immunodeficiency virus (HIV) also are at higher risk for severe infection.

Pulmonary edema has been reported.^[34] Typically, the level of parasitemia ranges from 1% to 10%.

In Europe, babesiosis results from infection with *B. divergens* or *B. bovis* and has been reported only in splenectomized patients. The illness is characterized by high fever, chills, headache, and severe hemolytic anemia, often resulting in hemoglobinuria, jaundice, and renal insufficiency. Major findings on physical examination include fever, hepatomegaly, jaundice, and hypotension. More than half of the reported cases have been fatal.^[255]

Only one case of human babesiosis during pregnancy has been reported to date.^[247] The patient recovered without specific therapy, and the neonate did not develop babesiosis. Cases of intrauterine infection in animals, however, have been reported.

Diagnosis.

Babesiosis should be considered in any person with an unexplained febrile illness who has lived in or traveled to an endemic region in the midsummer months, especially with a history of a tick bite or tick exposure. The diagnosis of babesiosis can be confirmed by identifying the intraerythrocytic parasites on Giemsa-stained blood smears. Persons with intact spleens usually have low levels of parasitemia (less than 5% parasites), and examination of repeated smears may be necessary.^{[126] [257]} The predominant forms of *B. microti* closely resemble the small rings of *Plasmodium* species. A later tetrad form may be seen and is positive morphologic evidence of babesiosis. Differentiating *Babesia* from *Plasmodium* may be difficult but is

possible by noting the absence of pigment deposits in erythrocytes parasitized with the older stages of *Plasmodium* species ([Box 33-5](#)).

Box 33-5. LABORATORY DIAGNOSIS OF BABESIOSIS

Peripheral blood smear (Wright or Giemsa staining) showing intraerythrocytic *Babesia*

Polymerase chain reaction

Indirect immunofluorescent assay

Intraperitoneal inoculation of splenectomized hamsters

When organisms cannot be detected on blood smears, the diagnosis can be made by intraperitoneal inoculation of the patient's blood into splenectomized hamsters. Serologic studies may also be helpful in confirming the diagnosis^[259] but are performed in only a few laboratories. A titer greater than 1:64 on IFA testing is considered consistent with seropositivity, and a titer greater than 1:256 is diagnostic of acute infection. No test for circulating *Babesia* antigen is available. PCR testing for *Babesia* can be as sensitive and specific as standard testing and may be reproducible enough for routine use in diagnosis of acute babesiosis.^[168]

Treatment and Prevention.

Chemotherapy for *B. microti* infection consists of a combination of clindamycin and quinine and should be reserved for patients with severe disease or those with asplenia, immunosuppression, or elderly status.^[72] The clindamycin dose for adults is 1.2 g intravenously twice daily or 600 mg orally three times daily for 7 days. Children should receive three oral doses of clindamycin for 7 days (20 to 40 mg/kg/day). The quinine dose for adults is 650 mg orally three times daily and for children is 25 mg/kg/day in three divided doses, each for 7 days. Parasites are eradicated from the blood with this therapy, although treatment failures have been reported.^[278]^[284] Recently, azithromycin was used as a successful alternative to clindamycin in one treatment failure.^[278] In seriously ill patients with high levels of parasitemia, exchange transfusion may also produce rapid clinical improvement.^[147]^[328]

Patients with mild clinical disease typically recover without specific anti-*Babesia* chemotherapy, although few patients have been followed longitudinally. A recent prospective study showed that parasitemia lasted for a mean of 82 days in 24 asymptomatic subjects not treated with the standard regimen.^[170] Even those receiving clindamycin and quinine had delayed resolution of parasitemia, however, and 9 of 22 subjects had significant side effects from standard therapy. Exchange transfusion with clindamycin/quinine therapy has proved to be effective in three cases of *B. divergens* infection.^[34]

Avoidance of ticks is the only currently effective method of preventing babesiosis. Splenectomized patients should probably be advised to avoid visiting areas endemic for babesiosis.

TICK-BITE PREVENTION AND PROPHYLAXIS

Prevention of tick-borne diseases is directed toward preventing tick bites. Avoidance of areas (nearby water supply, dense ground cover) supporting the reservoir species, often the white-footed mouse in the northeastern United States, will decrease tick exposure.^[273] Protective clothing (long pants cinched at the ankles or tucked into boots or socks) should be worn when in tick-infested areas. Spraying clothes with an insect repellent may provide an additional barrier against ticks. Most repellents contain diethyltoluamide (DEET), which repels ticks but does not kill them. Permanone is an aerosol spray tick repellent for use on clothing. Its active ingredient, permethrin, kills ticks on contact. Field tests have shown Permanone to be 90% to 100% effective in preventing tick bites. Permethrins have very low toxicity in mammals.

Close inspection of all parts of the body at least twice daily should be done when traveling in tick-infested areas. Adult ixodid ticks are generally on the body for 1 or 2 hours before attaching. Even after a tick attaches, disease transmission may be prevented by prompt removal. Proper removal of the tick is important, since infection may be acquired by careless handling of infected ticks, even without a bite. The tick should be grasped as close to the skin surface as possible with blunt curved forceps, tweezers, or protected fingers. The tick should be pulled out with steady pressure, taking care not to crush or squeeze the body, since expressed fluid may contain infective agents. After the tick is removed, the bite site should be disinfected. Traditional methods of tick removal, such as applying fingernail polish, isopropyl alcohol, or a hot match head, do not effect tick detachment and may induce the tick to salivate or regurgitate into the wound.^[219] V-shaped devices are available that slide between the tick and the skin so that the tick can be lifted from its attachment.

In general, prophylactic antibiotics are not recommended for tick bites. Clinical trials of antibiotic prophylaxis for RMSF and Lyme disease demonstrate that the risk of infection in a patient who seeks medical treatment for a tick bite is very low. In most areas of the United States the chances are small that a tick harbors an infectious agent. Even if the tick is infected, the agent probably will not be transmitted if the tick is found and removed promptly. Together, these facts suggest that the risk/benefit ratio of an adverse reaction to the antibiotic vs. disease prevention will be high.

Chapter 34 - Spider Bites

Leslie V. Boyer
Jude T. McNally
Greta J. Binford

INTRODUCTION TO SPIDERS

The spiders number approximately 34,000 described species and are found in all habitats except for the open sea.^{[37] [59] [206]} They are carnivorous predators with important ecologic roles in most terrestrial ecosystems. Many are capable of wind-borne dispersal (ballooning), which has led to colonization of even the most isolated land masses on earth.

As with ticks, mites, scorpions, and other arachnids, spiders have a body consisting of an abdomen and an unsegmented cephalothorax (prosoma) with chelicerate jaws, pedipalps, and four pairs of legs ([Figure 34-1](#)). They are distinct from other arachnids in having loss of abdominal segmentation, and male pedipalpal tarsi are modified as secondary genitalia.^[253] In addition, spiders have venom that is produced in a gland in the anterior prosoma and delivered through a cheliceral fang. On the abdomen, they have silk-producing glands and a set of spinnerets.

The primary function of venom in spiders is prey capture or, rarely, defense. Venoms are complex mixtures of neurotoxic and proteolytic peptides, proteins, and biogenic amines.^{[1] [15] [102] [185] [253]} Most of these toxins are target specific, acting selectively on arthropods, vertebrates, or other groups, including some with mammalian-specific activity.^{[1] [120] [202]} Venom composition varies widely across spider species, and variation may exist within species between sexes and among geographically isolated populations.^[184] Venom potency also varies within individuals both seasonally and developmentally. Despite this tremendous venom diversity, only a few dozen spider species are considered harmful to people because (1) most others have an insufficient quantity of venom, (2) the toxins do not affect mammals, or (3) the fangs cannot penetrate human skin. In a few species, although laboratory evidence suggests potential mammalian toxicity, human envenomations have not been reported, perhaps because of the rarity of encounters between spiders and humans in some habitats.

[Table 34-1](#) lists an assortment of spider families, including those with species that have been reported to bite humans.

All spiders are carnivorous and have the challenge of capturing live prey. Prey capture is a multistep process in which spiders must find prey, ensnare it, immobilize it, and digest it externally before the liquefied meal can be consumed. This process and the role of venom are very diverse. The neurotoxins in spider venom are primarily used for prey immobilization. Venoms of a few spiders are known to have some proteolytic components that likely begin the process of external digestion. The bulk of digestion, however, results from digestive enzymes that are ejected from the mouth, a distinctly separate opening from the venom duct (Figure 34-2 (Figure Not Available)). Occasionally, spider digestate may infect wounds created by spider bites, which affects the clinical appearance, although no direct evidence substantiates this suspicion.

In addition to venom, some theraphosids (tarantulas) produce urticating hairs that irritate skin or mucous membranes of animals or humans. Exposure may result from direct contact with the spider or its web or from proximity to airborne hairs launched by an aggravated individual.

GENERAL ASSESSMENT AND TREATMENT OF SPIDER BITES

Awareness of the differential diagnosis is crucial for management of any patient presenting for evaluation of "spider bite," because the offending creature is rarely observed and identified. In general, it is outside of normal biologic activity for spiders to bite humans, except in defense. A defensive bite risks the spider's life and tends to occur only when its life is threatened by being crushed. Thus true spider bites are much less common than insect bites or cutaneous infections. Furthermore, no pathognomonic clinical signs prove the diagnosis without retrieval and identification of a spider that was seen actually biting.^[236] Diagnosis of arachnidism without direct evidence can lead to inappropriate treatment and the lack of consideration of more severe underlying medical issues.^[145] ^[148] ^[151] ^[228] Therefore the medical history, physical examination, and laboratory evaluation must often consider an alternative etiology. Treatment plans should include careful follow-up and patient counseling to take into consideration any uncertainties in the final diagnosis.

The differential diagnosis of a local lesion may include fungal, bacterial, and viral infection, especially herpes simplex and zoster; the vesiculobullous diseases; arthropod-borne infectious diseases (e.g., Lyme disease); other bites and stings; foreign body reactions; and systemic conditions that predispose to focal skin

TABLE 34-1 -- SPIDERS OF CLINICAL INTEREST

SCIENTIFIC NAME (NUMBER OF GENERA AND SPECIES): COMMON NAME	GEOGRAPHIC RANGE	CLINICAL REMARKS	TAXONOMIC REFERENCES	CLINICAL REFERENCES
Phylum Arthropoda, Class Arachnida, Order Aranea (3 Suborders, 105 families, 3067 genera, approx. 34,000 species): Spiders	Worldwide		[59] [208]	
Suborder Mesothelae (1 family, 2 genera, 40 species)	Asia (part)	No species believed clinically relevant	[209] [212]	
Suborder Mygalomorphae (15 families, 260 genera, 2200 species): Mygales	Worldwide		[218]	
Theraphosidae (86 genera, 800 species): tarantulas and baboon spiders	Worldwide		[218]	[299]
<i>Aphonopelma</i> (<i>Rheochostica</i>): tarantula	New World	Minor local reaction; urticating hairs	[213] [218]	
<i>Rheochostica henzi</i> (previously <i>Dugesiella</i> <i>henzi</i>): tarantula	New World		[218]	
<i>Mygalarachne</i> (previously <i>Sericopelma</i>)		Minor local reaction	[218]	
<i>Pterinochilus</i> : tarantula	Africa	Minor local reaction	[218]	
<i>Pamphobaetus</i> : tarantula	Brazil	Minor local reaction	[218]	
<i>Avicularia</i> : tarantula	New World	Minor local reaction	[218]	

<i>Lasiadora</i> : tarantula	Brazil	Minor local reaction	[218]	
<i>Grammostola cala</i> : Chilean rose tarantula	New World	Minor local reaction; urticating hairs	[218]	[36] [61]
<i>Acanthoscurria</i> : tarantula	New World	Minor local reaction; urticating hairs	[218]	
<i>Euathlus</i> (previously <i>Brachypelma</i>): tarantula	New World	Minor local reaction; urticating hairs	[218] [248]	
<i>Harpactirella lightfooti</i> : baboon spider or bobbejaan-spinnekop	Africa		[218]	[42] [122] [195]
<i>Poecilothuria</i> : tarantula	Australia	Minor local reaction	[218]	
<i>Selenocosmia</i>	East Indies, India, Australia		[218]	
<i>Phormictopus</i>	South America, Caribbean		[218]	
<i>Lampropelma</i> : tarantula	Asia, India	Minor local reaction	[218]	
<i>Haplopelma minax</i> : Thailand black tarantula	Asia, India	Urticating hairs	[218]	[36]
Hexathelidae (11 genera, 74 species): funnel-web mygalomorphs			[218]	
<i>Atrax</i>	Eastern Australia		[115] [218]	
<i>Atrax robustus</i> : Sydney funnel-web spider	Eastern Australia	Local pain; severe neurotoxicity	[115] [218]	[90] [91] [126] [262] [263] [271] [303] [305]
<i>Hadronyche</i> (<i>Atrax</i>)	Eastern Australia		[115] [218]	

<i>H. formidabilis</i> : northern funnel-web spider	Eastern Australia	Local pain; severe neurotoxicity	[115] [218]	[11] [118]
<i>H. versutus</i> : Australian Blue Mountains funnel-web spider	Eastern Australia	Local pain; severe neurotoxicity	[115] [218]	[11]
<i>H. infensus</i>	Eastern Australia	Local pain; severe neurotoxicity	[115] [218]	[11] [299]
<i>H. cereberus</i>	Southeastern Australia	Local pain; severe neurotoxicity	[115] [218]	
Dipluridae (17 genera, 157 species): funnel-web mygalomorphs	Worldwide		[218]	
<i>Trechona venosa</i>	South America	Mammalian toxin; no human reports	[218]	[170]
Idiopidae (18 genera, 267 species): front-eyed trapdoor spiders	Pantropical, India		[218]	[299]
<i>Aganippe subtristis</i>	Australia	Minor local reaction	[218]	
<i>Arabantis</i>	Australia		[218]	
<i>Mysgolas</i> (previously <i>Dyarcyops</i> , <i>Hermea</i>)	Australia, New Zealand	Minor local reaction	[218]	
Ctenizidae (10 genera, 116 species): trapdoor spiders	Worldwide, except South America		[67] [218]	
<i>Bothriocyrtum</i>	North America		[218]	
<i>Ummidia</i>	North, Central America		[218]	
Actinopididae (3 genera, 41 species): trapdoor spiders	Australia, Central and South America		[218]	

<i>Missulena bradleyi</i> : mouse spider	Australia	Mammalian toxin; one case of systemic effects	[218]	[267]
Suborder Araneomorphae (90 families, 2700 genera, 32,000 species): true spiders				
Filistatidae (12 genera, 87 species)	Worldwide		[156]	
<i>Filistata</i>				
Sicariidae (2 genera, 129 species): recluse, brown, or fiddle spiders	Worldwide		[156] [210]	
<i>Loxosceles</i> : recluse, brown, or fiddle spiders	New World, Mediterranean, Africa		[105]	[10] [20]
<i>L. reclusa</i> : brown recluse spider	North America (central, southeast)	Local necrosis; systemic syndrome	[105]	[111] [214] [292]
<i>L. arizonica</i> : Arizona brown spider	North America (southwest)	Local necrosis; systemic syndrome	[105]	
<i>L. rufescens</i>	Worldwide		[105] [156]	
<i>L. intermedia</i>	Brazil		[40]	
<i>L. gaucho</i>	Brazil		[40]	
<i>L. spinulosa</i>	South Africa			
<i>L. laeta</i> : corner spider or spider behind the pictures	South America, Australia, Finland	Painful local lesion; systemic syndrome	[105] [156]	[10]
<i>L. parrami</i>	South Africa		[193]	
<i>Sicarius</i> : six-eyed crab spiders	Neotropics, South Africa	Local necrosis; DIC	[196] [197] [198]	

Dysderidae (20 genera, 371 species): giant-fanged, six-eyed spiders	Worldwide		[68]	
<i>Dysdera</i>	Worldwide		[68]	
Desidae (28 genera, 200 species): long-jawed intertidal spiders	Worldwide		[230]	
<i>Badumna insignis</i> : black house spider	Australia, New Guinea	Local pain, rarely necrosis	[117]	[172] [298] [300]
Zodariidae (350 species): hunting spiders	Worldwide			
<i>Supunna picta</i>	Australia	Minor local reaction		[38]
Tetragnathidae (50 genera, 900 species): long-jawed orb-weaving spiders	Worldwide		[166]	
<i>Nephila</i> : golden-silk spiders	Pantropical		[163]	
Argyronetidae (1 genus, 1 species): water spiders	Europe		[230]	
<i>Argyroneta aquatica</i>	Europe		[230]	
Gnaphosidae (111 genera, 2156 species): ground and mouse spiders	Worldwide		[209]	
<i>Herpyllus ecclesiasticus</i> : parson spider	North America	Minor local reaction; brief systemic effects	[127]	[173]
<i>Drassodes</i>	Worldwide		[207]	
Lamponidae (1 genus, 50 species): white-tailed spiders	Australia, Tasmania, New Zealand		[209]	

<i>Lampona cylindrata</i> : white-tailed spiders	Australia, New Zealand	Minor local reaction; rarely necrotic	[209]	[114] [300]
Miturgidae (23 genera): forest floor and cave spiders	Worldwide			
<i>Miturga</i>	Australia, New Zealand			
Heteropodidae (82 genera, 850 species): giant crab, huntsman, and large, wandering crab spiders			[92]	
<i>Palystes natalius</i> : lizard-eating spider	South Africa	Minor local reaction	[64]	[195] [200]
<i>Heteropoda</i>	Worldwide			
<i>Isopeda</i>	Australia, New Guinea, East Indies	Minor local reaction		[298]
<i>Olios</i>	America, Australia	Local pain, brief nausea	[232]	[298]
<i>Delena cancerides</i> : social huntsman spider	Australia	Minor local reaction		
Oxyopidae (9 genera, 400 species): lynx spiders	Worldwide		[76]	
<i>Peuceitia viridans</i> : Green lynx spider	North and Central America, West Indies	Minor local reaction	[39]	[123]
Salticidae (475 genera, 4500 species): jumping spiders	Worldwide		[80] [216]	[299]
<i>Breda jovialis</i>	Australia	Minor local reaction		
<i>Phidippus</i>	New World	Local pain, minor ulceration		[234]

<i>Holoplatys</i>	Australia	Minor local reaction, itch, headache		[299]
<i>Mopsus</i>	Australia			
<i>Thiodina</i>	America		[308]	
<i>Opisthoncus</i>	Australia	Minor local reaction		[299]
Thomisidae (160 genera, 1960 species): crab spiders	Worldwide		[74] [246]	
<i>Misumenoides</i>	Americas		[246]	
Ctenidae (37 genera, 472 species): wandering spiders	Worldwide			
<i>Phoneutria</i> : armed spiders	South America			
<i>P. nigriventer</i> : Brazilian armed spider	Brazil, Paraguay	Local pain; systemic neurotoxin	[82]	[122] [170]
<i>Elassoctenus harpax</i>	Australia			
<i>Cupiennius</i>	South and Central America, West Indies		[175]	
Lycosidae (76 genera, 2196 species): wolf spiders	Worldwide		[76] [313]	
<i>Lycosa</i> : wolf spiders	Worldwide	Local pain		[47] [226]
<i>L. raptoria</i>	South America	Local pain		
<i>L. tarentula</i> : "tarantula"	Palaearctic	Subject of folklore	[313]	
<i>L. godeffroyi</i>	Australia	Local pain		
<i>L. erythrognatha</i>				
Clubionidae (25 genera, 590 species): sac, running spiders, and two-clawed hunting spiders	Worldwide		[75]	

<i>Cheiracanthium</i> : sac and running spiders	Worldwide			
<i>C. mildei</i>	Holarctic		[75]	
<i>C. punctorium</i>	Europe	Minor local reaction; fever	[258]	[32] [180] [181]
<i>C. japonicum</i>	Japan, China	Minor local reaction; brief systemic illness	[312]	[203]
<i>C. longimanus</i>	Australia	Minor local reaction; brief systemic illness		[32]
<i>C. lawrencei</i>	Africa	Local necrosis; systemic syndrome		[196] [197]
<i>C. mordax</i>	Australia	Minor local reaction, brief systemic illness		[32]
<i>C. inclusum</i>	America	Local pain, nausea	[75]	[32]
Corinnidae (51 genera, 659 species): sac spiders	Worldwide		[211] [311]	
<i>Trachelas</i>		Minor local reaction	[211]	[205] [281]
<i>Supunna picta</i>	Queensland	Minor local reaction	[65]	
Tengellidae (5 genera, 18 species): running spiders	New World			
<i>Liocranoides</i>	Appalachia, California			

Agelenidae (41 genera, 600 species): grass and funnel-web spiders	Worldwide		[230]	
<i>Tegenaria agrestis</i> : hobo or northwestern brown spider	Europe, America (Pacific Northwest)	Local necrosis; systemic syndrome	[231]	[2] [285] [289]
<i>Agelenopsis aperta</i> : grass spider or funnel-web spider	Southwest United States, Mexico		[53]	[290]
Zoridae (12 genera)				
<i>Diallomus</i>	Australia			
Superfamily Orbicularia (13 families, 10,300 species)				
Theridiidae (62 genera, 2000 species) comb-footed spiders	Worldwide		[311]	
<i>Latrodectus</i> : widow spiders	Worldwide	Local pain; systemic neurotoxicity	[158] [164]	[300]
<i>L. mactans</i> : black widow spider	North America		[164] [168]	[82]
<i>L. mactans hasselti</i> : redbacked spider	Australia		[278]	[97] [140] [272]
<i>L. hesperus</i> : black widow spider	North America			[56]
<i>L. tredecimguttatus</i>	Mediterranean		[168]	[179]
<i>L. pallidus</i>	Libya to Russia		[168]	
<i>L. indistinctus</i> : black button spider	Africa			[188]
<i>L. geometricus</i> : brown button spider	Worldwide		[168]	[188]
<i>Steatoda</i>	Worldwide		[159]	
<i>S. paykulliana</i> : false black widow spider	Europe, Mediterranean		[167]	

<i>S. nobilis</i>	England	Local pain; mild systemic effects		[294]
<i>S. foravae</i> : false button spider	Southern Africa	Minor local reaction		[190]
<i>Achaeranea tepidariorum</i>	Worldwide	Trivial local reaction	[160]	
Araneidae (155 genera, 2600 species): orb-weaving spiders	Worldwide			
<i>Argiope</i> : argiopes	Worldwide			[110]
<i>A. argentata</i>	America	Local pain; vesicle	[165]	
<i>A. trifasciata</i>	Worldwide		[165]	
<i>Araneus</i> : cross, garden, and shamrock spiders	Worldwide		[161] [162]	
<i>Eriophora biapicata</i>	Australia	Minor local reaction		
<i>Neoscona</i> : orb-weaving spiders	Worldwide		[30]	
<i>Phonognatha graeffei</i>	Australia	Trivial local reaction		

DIC, Disseminated intravascular coagulation.

lesions (e.g., diabetes mellitus, leukemia, lupus erythematosus). "First-aid" interventions by the patient may mask an otherwise benign process by superimposition of trauma, burns, or chemical irritation. Systemic signs and symptoms may require differentiation from the effects of snake or scorpion neurotoxin, pesticide toxicity, sepsis, meningitis, hemolytic anemia, or acute abdomen, depending on the circumstances.

The medical history should include details of the bite circumstances, to demonstrate consistency with expected spider habitat and behavior. This includes location indoors or outside, time of day or night, and human activity at the time of injury. The victim should attempt to recall the appearance of the involved arthropod; if it was believed killed through garments or bedclothes, an attempt should be made to retrieve its remains. Crushed spider parts can be examined and identified by arachnologists or entomologists at many universities and museums. Until identified, spiders may be preserved in 70% to 80% ethanol. The evolution of subsequent wound and systemic symptoms should be noted, along with modifiers, including home treatment and underlying health of the patient. If the local geography lacks species consistent with the

suspected pathophysiology, the recent travel history of household contacts should be considered.

Physical examination includes particular attention to the bite site, as well as general assessment for systemic effects. Local findings of importance include anatomic location (spiders are more likely to bite defensively at sites where clothing binds tightly; thin skin is more readily envenomed than callous skin) and number of separate lesions (multiple bites suggest parasitic insect bite rather than spider bite). Central punctae, vesicles, or erosions should be noted, as well as the pattern of peripheral changes, including erythema, pallor, hemorrhage, induration, tenderness or anesthesia, and local lymphatic involvement. Systemic findings, depending on the species involved, may include changes in vital signs, diaphoresis, generalized rash, facial edema, gastrointestinal distress, muscle fasciculations, spasm or tenderness, or altered mental status.

The laboratory evaluation for envenomation is usually simple, seldom requiring more than complete blood count and urinalysis. Assessment for other elements of the differential diagnosis, however, may be much more elaborate. Depending on circumstances, this may include viral, bacterial, or fungal culture; Lyme disease titer; radiography of the abdomen or of the injured part; stool test for occult blood; electrocardiogram; or skin biopsy.

General supportive measures are the mainstay of therapy for most spider bites. These include basic local hygiene, tetanus prophylaxis, analgesics, hydration, and surgical follow-up if indicated for debridement and management of extensive necrotic lesions. Corticosteroids are of unproven benefit and are generally not indicated. Antibiotics, although not of value for simple venom injury, are prescribed when bacterial cellulitis cannot be eliminated from the differential diagnosis. Specific measures, including antivenom, for treatment of envenomation by particular spider species are discussed later in this chapter.

GUIDE TO SPIDER DIVERSITY AND IDENTIFICATION

This chapter provides more information on spider diversity than most reviews in order to (1) inform the reader of the immense diversity of spiders that are

814

medically insignificant and thus emphasize the rarity of spiders known to cause medical problems; (2) emphasize the need for accurate species identification, particularly in reporting of cases for publication or teaching; and (3) facilitate accurate identification of spiders that are caught in the act of biting by directing professionals to proper identification keys. [Table 34-1](#) includes species worldwide that are currently known or suspected to be medically noteworthy, even minimally, either through the effect of bites or urticating hairs. Geographic range and the most recent systematic work on each group are included. [Box 34-1](#) lists genera of serious medical significance for each continent. For effective communication, groups of spiders must be recognized by the same name worldwide. This chapter uses the current official nomenclature.

Of the three spider suborders, two contain clinically significant species: Mygalomorphae and Araneomorphae. Mygalomorphs include the baboon spiders or tarantulas, trapdoor spiders, purse-web spiders, mygalomorph funnel-web spiders, and several other groups that lack common names. Most spiders are araneomorphs, including jumping spiders, orb-weaving spiders, widow spiders, and wolf spiders (see [Table 34-1](#)). The most conspicuous characteristics that distinguish these groups are the orientation of the chelicerae (jaws) and the number of book lungs. Spider fangs are located on the chelicerae, which open sideways in the Araneomorphae and move diagonally in the Mygalomorphae, requiring the latter to rear back for a downward, snakelike strike (Figure 34-3 (Figure Not Available) and [Figure 34-4](#)). Mygalomorphae have two pairs of book lungs, whereas most Araneomorphae have only one pair. Lung slits, which open into the book lungs, are easily visible in a ventral view of the anterior abdomen (see [Figure 34-1](#)). Characteristics that distinguish families, genera, and species include eye number

Figure 34-3 (Figure Not Available) Movement of the chelicerae in mygalomorphs (A) and araneomorphs (B). (Modified from Foelix RF: *Biology of spiders*, ed 2, Oxford, UK, 1996, Oxford University Press.)

Figure 34-4 Fangs of mature male tarantula (*Aphonopelma* species). (Courtesy Michael Cardwell & Associates, 1992.)

and pattern, numbers of tarsal claws, and details of genitalic structure.

Although many spider species are geographically localized (e.g., *Atrax robustus* in Australia, *Phoneutria nigriventer* in Brazil), some, such as the black widow (*Latrodectus mactans*), are found worldwide (see [Table 34-1](#)). Others, such as members of the *Loxosceles* genus, are widely distributed in more than one continent, and still others, such as *Tegenaria agrestis*, appear to have naturalized in specific geographic regions distant from their point of ecological origin. Because of the resulting worldwide species diversity and overlap, the remainder of this chapter is structured according to spider

taxonomy rather than isolated species or geographic location.

SUBORDER MYGALOMORPHAE

Mygalomorphs make up less than 10% of all spider species. They are found worldwide, with greatest abundance and diversity in tropical regions. Tarantulas (Theraphosidae) are the most famous mygalomorphs and include the largest spiders known, reaching up to 10 cm in body length. Most mygalomorphs are smaller, some less than 1 mm in adult body length. Most live multiple years (some up to 20), and females continue to molt after reaching adulthood. They have diverse habits but typically live in silk-lined burrows or silken tubes. For the purpose of prey capture, mygalomorph silk is only slightly sticky relative to araneomorph silk and is generally used to trigger the presence of prey rather than to ensnare them. Once prey are detected, spiders run out of their retreat, seize prey in their jaws, and return to the retreat to feed. Individuals wander when dispersing, and males leave their retreats in search of females during mating season.

Family Theraphosidae: Tarantulas and Baboon Spiders

Theraphosidae is the largest mygalomorph family with respect to both numbers of species and sizes of the largest individuals ([Figure 34-5](#)). Approximately 800 described species are found on all continents, with greatest abundance and diversity in tropical regions. They mature in 3 to 9 years and can live for 15 to 20 years. Individuals live in burrows, with trip-line threads extending from the entrance. These are sometimes located in abandoned rodent burrows or hollow trees. Theraphosids have dense tufts of specialized hairs on their tarsi (feet) that enable them to climb on smooth surfaces and may aid in prey capture. They have two tarsal claws, eight closely grouped eyes, and two pairs of spinnerets. Tarantulas may live for 1 to 25 years. As a group, they are found mainly in tropical and subtropical areas.

Confusingly, "tarantula" was first applied to *Lycosa tarentula*, a species of European spider actually belonging to the wolf spider family, or Lycosidae, which are properly classified within the suborder Araneomorphae, described later in this chapter. In the United States the term *tarantula* usually refers only to the large spiders of the family Theraphosidae, suborder Mygalomorphae.

Grammostola mollicoma is the largest tarantula known, with a body length of 7 to 10 cm and leg spread of 21 to 27 cm. ^[42] ^[104] *Harpactirella lightfooti*, the baboon spider or bobbejaan-spinnekop, is a mygalomorph spider found in South Africa. Body length is 3 cm; the cephalothorax is brown with a yellowish border.

Venom.

Few tarantula venoms have been studied systematically. In the United States, *Rheochostica henzi* and

Figure 34-5 *Theraphosidae*. (Courtesy Gita Bodner.)

Figure 34-6 Mature female *Aphonopelma iodium*. (Courtesy Michael Cardwell & Associates, 1997.)

members of the genus *Aphonopelma* ([Figure 34-6](#)) have venom containing hyaluronidase, nucleotides, and polyamines.^{[46] [54] [155] [239] [240]} Polyamines are thought to act as neurotransmitters and increase venom effectiveness, particularly with respect to paralysis of insect prey.^[253] Hyaluronidase is postulated to be a spreading factor, and the nucleotide adenosine triphosphate (ATP) potentiates the major effects of the venom on mice. Both venoms cause rapid, irreversible necrosis of skeletal muscle when injected intraperitoneally into mice.^[204] *Dugesiella* (*Rheochostica*) venom was found to have a necrotoxin with several similarities to sea snake venoms.^[155] In comparison, the venom of *Scodra griseipes*, an African tarantula, includes higher-molecular-weight (greater than 25,000 daltons) proteins and enzymes plus lower-weight polypeptides (4000 to 9000 daltons); the second group is believed to contain polypeptide neurotoxins.^[52] *S. griseipes* venom toxins have a mammalian effect, but this species is not known to be clinically relevant. Recent work suggests that venom chemotaxonomy may be a useful method of nondestructive

species recognition, at least within the *Brachypelma* genus.^[84]

Urticating Hairs.

Several genera of tarantulas, including *Haplopelma*, *Lasiadora*, *Grammostola*, *Acanthoscurria*, and *Brachypelma*, possess urticating hairs irritative to skin and mucous membranes. These genera are located throughout the western hemisphere, with many species indigenous to the United States. When one of these spiders is threatened, it

rubs its hind legs across the dorsal surface of its abdomen and flicks thousands of hairs toward the aggressor. These barbed hairs can penetrate human skin, causing edematous, pruritic papules. The itching may persist for weeks. There are four morphologic types of urticating hairs. Tarantulas within the United States possess only type I hairs, which do not penetrate the skin as deeply as type III hairs. Type II hairs are incorporated into the silk web retreat and not thrown off by the spider. Type III hairs can penetrate up to 2 mm into human skin; this is the type of hair most likely to cause inflammation. They are typically found on Mexican, Caribbean, and Central and South American species. Type IV hairs, which belong to the South American spider *Grammostola*, are able to cause inflammation of the respiratory tract in small mammals. Rats and mice have been reported to die of asphyxia within 2 hours after exposure to the hairs. ^[61] ^[299]

Clinical Presentation.

Despite the presence in venom of components toxic to rodent nerves and skeletal muscle, most tarantula bites result in only mild to moderate local symptoms in humans. A few can cause more severe pain and swelling, numbness, or lymphangitis. Species of tarantula implicated as causes of human envenomation include those in genera *Mygalarachne* (formerly *Sericopelma*) of Panama, *Pterinochilus* of Africa, *Aphonopelma* of Mexico and the United States, *Pamphobaeteus* of South America, *Euathlus* of Costa Rica, *Theraphosa* of French Guyana, *Grammostola* of Colombia, *Poecilothuria* of India, *Lampropelma* of Thailand, *Lasiadora* of Brazil, and *Avicularia* of Central America and southwestern United States. Envenomation usually involves immediate pain at the bite site, occasionally followed by some redness and swelling and usually without necrosis or serious sequelae.*

Although no fatalities have been reported, localized pain followed by emesis, weakness, and collapse has been noted after envenomation by *Harpactirella lightfooti*, the baboon spider of South Africa. ^[42] ^[122] ^[195]

Urticating hairs may cause intense inflammation, which may remain pruritic for weeks. Individuals who handle tarantulas may unwittingly transfer urticating hairs from hand to eye, causing keratoconjunctivitis or ophthalmia nodosa. Keratoconjunctivitis has been described after handling of a Thailand black tarantula, *Haplopelma minax*. Fine intracorneal hairs were noted at examination, and inflammation settled quickly with topical corticosteroid treatment; at 36-month follow-up the eye was normal. ^[36]

More severe ophthalmic complications occurred in two cases after handling of Chilean rose tarantulas, *Grammostola cala*. In these victims, initial findings were similar, with intracorneal hairs and keratoconjunctivitis, but progressive panuveitis followed, with corneal granulomas, iritis, cataract, vitritis, and chorioretinitis apparently related to migration of hairs through the media of the eye. The differences in outcome with exposure to the two species may result from differences in hair morphology, which may also explain differences in other reports of ophthalmic injury from tarantula or caterpillar hair exposure. ^[36] Similar cases of ophthalmia nodosa have been described. ^[25] ^[154]

Treatment.

Theraphosid bite management is symptomatic. Elevation and immobilization of the extremity and oral analgesics may help reduce pain. All bites should receive local wound care and appropriate tetanus prophylaxis.

Urticating hairs can be removed from skin with repeated application and removal of sticky tape, followed by copious irrigation if necessary; exposed eyes should be irrigated primarily. Topical or systemic corticosteroids and oral antihistamines may also be useful for urticating hair reactions.

Family Hexathelidae: Funnel-Web Mygalomorphs

The family Hexathelidae includes 11 genera and approximately 74 species, which are currently known from the Old World and Chile.^[218] The funnel webs that typify members of this group are silk-lined tubular retreats that extend into a protected space, such as a burrow in the ground or a hole in a tree. Sheets of silk radiate from the retreat and signal the presence of prey. These webs superficially resemble webs of araneomorph spiders in the family Agelenidae. Distinguishing characteristics of the spiders include a shiny carapace; long, spiny sensory hairs on the legs; and paired claws lacking claw tufts on the tips of the feet, with teeth lining the medial claw.

Clinically significant hexathelid spiders are species of *Atrax* ([Figure 34-7](#)) and *Hadronyche*. Technically, taxonomists now consider *Atrax* and *Hadronyche* species as members of only one genus.^[218] To avoid confusion in the literature, species names still use either *Atrax* or *Hadronyche*, depending on their original names. We discuss these species as a cohesive taxonomic group. Among these, the species *Atrax robustus* is best known and most carefully studied. *Atrax* and *Hadronyche* species, all of which are believed to be dangerous, have

*References ^[42] ^[46] ^[54] ^[66] ^[104] ^[150] ^[239] .

been described in southern and southeastern Australia, Tasmania, Papua New Guinea, and the Solomon Islands. As a group, they prefer cool, moist coastal and mountainous

regions.^[116] ^[118] ^[249]

Genus *Atrax*/*Hadronyche*

BIOLOGY.

Funnel-web spiders have a glossy ebony cephalothorax and velvety black abdomen. The abdominal undersurface may have brushes of red hair. The fangs reach 4 to 5 mm in length and are capable of penetrating a fingernail or a chicken's skull, sometimes making removal of the spider difficult. Females are somewhat larger than males, with a body length of 4 cm. Mature males are more delicate, with a tibial spur on the second pair of legs and pointed pedipalps.^[137] ^[242]

Atrax robustus, the Sydney funnel-web spider, is limited to a 160 km range around the center of Sydney, Australia. The spider creates a tubular or funnel-shaped, silk-lined shallow burrow under rocks, logs, fences, stumps, or thick vegetation or around foundations of houses. Colonies of up to 150 spiders have been found. Females rarely roam far from their webs; males live a vagrant life after reaching maturity. Wandering males may enter houses or other areas of human habitation, especially during the summer months after a heavy rain. Its aggressive behavior and potent venom make the male Sydney funnel-web arachnid one of the most dangerous spiders in the world. It is responsible for all known fatal *Atrax* envenomations.*

Hadronyche formidabilis, the northern funnel-web spider, is found in the central coastal region of New South Wales and the adjacent Blue Mountains. Its tree-dwelling habit was once thought to be unique, but it is now known that other species also live in trees. The webs may be camouflaged in rough-barked trees, such as melaleuca (paper bark), banksia, and eucalyptus.^[118]

VENOM.

Although many species have venom with significant in vitro toxicity, few have been implicated in human illness. The best described of these is *A. robustus*. *Atrax* venom causes widespread release of neurotransmitters.^[79] ^[118] ^[125] ^[256] ^[263] This may occur by a direct action of the venom on nerve membranes, producing spontaneous action potentials and consequently provoking a global outpouring of transmitters that accounts for the neuromotor and autonomic stimulation seen clinically.

Early efforts to purify the active component of *Atrax* venom resulted in reports of neurotoxins of various molecular weights purified from venom preparations in separate experiments.^[261] These were termed *Atraxotoxin* (10,000 to 25,000 daltons, from milked venom),^[118] *robustoxin* (4887 daltons, also from milked venom),^[250] and *atraxin* (9800 daltons, from ground venom glands).^[119] The relationships among these toxins are not clear, but atraxotoxin or atraxin may be a precursor of robustoxin. In addition to these components, *Atrax* venom contains various lower-molecular-weight compounds, including citric acid, lactic acid, phosphoric acid, glycerol, urea, glucose, gamma-aminolevulinic acid, glycine, spermidine, spermine, tyramine, octopamine, and

5-methoxytryptamine.^[78]

The best characterized of the toxins is robustoxin, whose 42-amino acid sequence was determined in 1985.^[250] It is the sole lethal toxin that can be isolated by cation-exchange chromatography, and its effects in monkeys duplicate the effects of crude venom preparations. A 5 mg/kg intravenous (IV) dose of robustoxin to monkeys causes dyspnea, blood pressure fluctuations culminating in severe hypotension, lacrimation, salivation, skeletal muscle fasciculation, and death within 3 to 4 hours of administration.^[191]

Isolated human intercostal muscles were studied to determine the etiology of muscle fasciculations. Muscles treated with *A. robustus* venom developed marked contractions, which were abolished by *d*-tubocurarine.^[48] Muscles treated with venom for more than an hour stopped contracting and could be stimulated only by increasing the stimulus duration. *A. robustus* venom has been shown to lack anticholinesterase activity.^[260] Contractions are not a direct venom action on the muscle fiber, so acetylcholine appears to have been released from the presynaptic terminals.^[96] Muscle fasciculations are apparently caused by abnormal repetitive firing of motor neurons. It was hypothesized that the venom changes the membrane's electric field, activating sodium channels without altering the transmembrane potential or damaging the neuronal membrane ultrastructurally.^{[79] [118] [256]}

Hypertension in *Atrax* toxicity may have several causes. Morgans and Carroll^{[186] [187]} demonstrated direct alpha-adrenergic stimulation with vasoconstriction of isolated arterial preparations exposed to *A. robustus*

*References ^[58] ^[98] ^[118] ^[242] ^[275] ^[301] .

venom. In rabbit atria an initial decrease followed by an increase in cardiac inotropy and chronotropy may result from vagal acetylcholine and myocardial norepinephrine releases, respectively.^[49] The combination of myocardial responses and peripheral vasoconstriction may explain the hypertensive response.

Animal species vary in susceptibility to *Atrax* venom. Rabbits given 15 mg of crude venom intravenously and cane toads given 12 mg of female *Atrax* venom show no effects after envenomation. Primates, including humans, are among the most susceptible species. Newborn mice, also highly susceptible, have been used as an *in vivo* biologic assay for venom toxicity.^{[118] [265]} Sutherland^[267] found that a lethal dose of venom from a male *A. robustus* could be neutralized in newborn mice by nonimmune sera from rabbits and other nonprimate vertebrates. Scheumack and co-workers^[251] later demonstrated that the active fraction of nonimmune rabbit sera contained immunoglobulins G and M (IgG, IgM).

In addition, venom potency varies with time of year, recent feeding history, maturation and gender of the individual spider.^[12] Between 1956 and 1963, Wiener demonstrated

significant differences in the venom of male and female *Atrax* spiders. Males had an average venom yield of 1.01 mg, less than the 1.84 average from females. On the other hand, guinea pig lethality was much greater after a bite by a male (75% to 90%) than by a female spider (20%). Weiner concluded that significant qualitative difference exists between the venoms of males and females.

Monkeys, which have a pattern of envenomation similar to that in humans, provide a model in which Sutherland^[265] ^[271] has described a biphasic clinical syndrome. Phase I begins minutes after venom injection, with local piloerection and muscle fasciculation. This extends proximally, becoming generalized over the next 10 to 20 minutes. After another 5 minutes, severe hypertension, tachycardia, hyperthermia, and coma with increased intracranial pressure may occur, followed by diaphoresis, salivation, lacrimation, diarrhea, sporadic apnea, borborygmi, and grotesque muscle writhing. Death may result from asphyxia caused by laryngeal spasm, combined with copious respiratory secretions, apnea, or pulmonary edema. Laboratory evaluation reveals metabolic acidosis and elevated plasma creatine phosphokinase. Phase II begins 1 to 2 hours after envenomation, as the phase I symptoms subside. The victim may return to consciousness and appear to recover. In severe cases, hypotension gradually worsens over 1 to 2 hours, with periods of apnea. Pulmonary edema and death may occur despite ventilatory support.

CLINICAL PRESENTATION.

Up to 90% of *Atrax* bites may not result in significant envenomation.^[299] Intense pain at the bite site may result from direct trauma as well as the venom's effect, but the bite does not provoke cutaneous necrosis. Wiener^[303] studied the cutaneous effects of the venom on himself by injecting 0.5 mg intradermally. Local pain and a wheal surrounded by erythema lasted for 30 minutes, followed by localized sweating and piloerection. No systemic effects occurred.

The earliest systemic signs and symptoms may include perioral tingling, nausea and vomiting, diaphoresis, salivation, lacrimation, and dyspnea. Pulmonary edema follows, along with a generalized central and peripheral neurologic syndrome that includes muscle fasciculations, tremor, spasms, weakness, and impaired consciousness. Death may occur secondary to pulmonary failure, hypotension, or cardiac arrest.^[262] ^[299]

Thirteen fatalities from *A. robustus* envenomation were recorded between 1927 and 1984. Children are particularly susceptible; those under 12 years may die within 4 hours of the bite.^[91] ^[126] ^[268] Before the development of specific antivenom in 1980, severe envenomations resulted in a minimum 8-hour critical period, followed by a 9- to 21-day hospital course.^[90] ^[268] ^[271]

No fatalities caused by *H. formidabilis* have been recorded, although, several severe envenomations have occurred.^[118] Venoms of *A. robustus*, *A. versutus*, *A. infensus*, and *A. formidabilis* appear to have comparable vertebrate toxicity in vitro.^[11]

TREATMENT.

Immediate treatment after a bite is modeled after that for Australian snakebite and consists of four steps: (1) wrap the length of the bitten extremity with an elastic bandage, (2) splint to immobilize the extremity, (3) immobilize the victim, and (4) transport to the nearest hospital with the bandage in place.^[201]^[269] A human case report has illustrated the utility of this method, with occurrence, disappearance, recurrence, and reresolution of symptoms coinciding with compression wrap removal and replacement in a man bitten by a male *A. robustus*.^[112] An experimental model in *Macaca fascicularis* monkeys has supported efficacy of the pressure immobilization technique.^[264]^[265]^[273]

Specific antivenom has been the mainstay of treatment for *Atrax* envenomation since 1981. The antivenom is a purified IgG product developed by Sutherland and associates^[266]^[274] at the Commonwealth Serum Laboratories by immunizing rabbits with a combination of male *Atrax* venom and Freund's adjuvant. The antivenom was demonstrated to neutralize *Atrax* venom in vitro and to reverse symptoms in monkeys before its introduction for human use. To date, it has been used with good effect in more than 40 humans bitten by *Atrax* and *Hadronyche* species.^[71]^[271]

If a tourniquet or bandage is in place when the victim presents for hospital care, it should be removed in

an intensive care setting, with careful observation for development or progression of symptoms. If systemic signs or symptoms occur, victims are usually treated with antivenom administration. Two ampules of antivenom (100 mg of purified IgG per ampule) are administered intravenously every 15 minutes until symptoms improve. Dosing is the same for children as for adults, and total doses of 2 to 8 ampules have been reported. During a 10-year period, antivenom was given to at least 40 persons, with no adverse effects or deaths reported.^[271]

In addition to antivenom administration, management is symptomatic and supportive. Oxygen, mechanical ventilation, and IV fluid support may be indicated in severe cases. Atropine (0.6 mg) may be used to lessen salivation and bronchorrhea. β -Blockers may be indicated for severe hypertension and tachycardia.

Other than antivenom, no consistently effective agent has been found to enhance survival after *Atrax* envenomation. Diazepam, atropine, and furosemide have been found to increase survival in monkeys, but this may not be the case in humans.^[89]^[118]

Scheumack and colleagues^[252] developed a toxoid from robustoxin by polymerization with glutaraldehyde. Immunization with the toxoid conferred protection against the lethal

effects of 50 mg/kg *Atrax* venom in monkeys for at least 26 weeks after toxoid injection.

Family Dipluridae: Funnel-Web Mygalomorphs

Members of the family Dipluridae are found on all continents and are concentrated in tropical areas. Individuals build funnel webs similar to those of Hexathelidae. Diplurids are distinct from hexathelids in having posterior lateral spinnerets that are very long and widely separated. Most are 5 to 25 mm in length.

Genus *Trechona*

BIOLOGY.

Trechona venosa is a large South American funnel-web tarantula with neurotoxic venom potentially dangerous to humans. ^[42] ^[104] ^[122] As with all *Trechona* species, *T. venosa* is sedentary, living in holes or on plants in tropical forests along the Atlantic coast. The spider may be black or gray-brown with yellow stripes on the abdomen. Mature body length may be 3 to 4.5 cm, with 6- to 7-cm legs and 3- to 4-mm fangs. *T. venosa* is not found in Chile, but in this region it has been confused, particularly in venom studies, with a spider in the family Nemesiidae, *Acanthogonatus subcalpeianus*, which it resembles. ^[218]

VENOM.

The venom of *T. venosa* is extremely toxic to rats, with an apparent action similar to that of *Phoneutria* species. ^[170]

CLINICAL PRESENTATION.

No cases of human envenomation have been reported, although it is presumed that symptomatic envenomation by *T. venosa* is possible.

TREATMENT.

Treatment is symptomatic and supportive.

SUBORDER ARANEOMORPHAE

Enormous diversity is found within the group Araneomorphae, which contains 32,000 of the 34,000 currently described spider species.^[59] Araneomorphs, or true spiders, are found throughout the world in all terrestrial (and a few aquatic) habitats. They show tremendous variability in size, appearance, and habit; however, no araneomorphs are as large as the largest tarantulas. Characteristics that distinguish araneomorphs include features of the spinnerets that enable them to produce extremely sticky silk. Also, all but a few groups have only one pair of book lungs. Most have eight eyes, but eye number varies from two to eight. Prey capture tactics usually determine where a spider will be found and are generally consistent within particular groups. Thus these tactics often provide conspicuous clues that help identify spiders.

Family Sicariidae: Recluse Spiders

Sicariidae includes two genera, *Loxosceles* and *Sicarius*, both of which are clinically important. The family falls within a larger group of families (Scytodoids) that all have only six eyes. In these two genera the eyes are in dyad pairs. The chelicerae are fused at the base, and the labium is fused to the sternum. Males have more slender abdomens and more prominent pedipalps than females. Previously, *Loxosceles* was placed in its own family, Loxoscelidae, but this was recently synonymized with Sicariidae.^[210]

Genus *Loxosceles*: Brown Spiders

BIOLOGY.

Loxosceles, commonly known as brown or fiddle spiders, build small, irregular, and sticky webs in small areas, such as under rocks or wood or in human-made habitats. The genus contains more than 100 species, with centers of diversity in central America and Africa.^{[20] [77] [174] [238] [244]} These spiders are 8 to 15 mm in adult body length, are light to dark brown, and have a dark, violin-shaped spot centered anterodorsally, such that the neck of the fiddle extends backward across the cephalothorax. The shape and darkness of the fiddle, relative lengths of the first two pairs of legs, and genitalia characteristics are features that help distinguish species^{[43] [133] [244]} ([Figure 34-8](#)).

From the South American *L. laeta* to the South African *L. spinulosa*, these small arachnids have been associated with human pathologic conditions. Several species have been associated with necrotic arachnidism in the United States: *L. reclusa* (the

Figure 34-8 Adult female desert violin spider (*Loxosceles deserta*). (Courtesy Michael Cardwell & Associates, 1994.)

Figure 34-9 Brown recluse spider (*Loxosceles reclusa*). (Courtesy Indiana University Medical Center.)

spider, [Figure 34-9](#)), *L. rufescens*, *L. arizonica*, and *L. laeta*. These spiders are native to all the southernmost states. In the Mississippi River valley, their territory extends as far north as southern Wisconsin. Species native to one region or habitat may adapt successfully to new locations after transport by humans. [\[197\]](#) [\[293\]](#)

Brown spiders regularly roam in search of new web sites, and males wander in search of females. They are most active at night from spring through fall, emerging from woodpiles and rats' nests to hunt insects and other spiders. South African savanna species have been observed under stones and logs and in the tunnels of old termite nests; spelean species are found naturally in caves, but have also appeared in homes and export warehouses. [\[194\]](#) [\[196\]](#) [\[199\]](#) Brown spiders may infest homes, generally preferring warm, undisturbed environments such as vacant buildings and storage sheds. In Chile the tendency to inhabit human dwellings has earned *L. laeta* the names *araña de los rincones* (corner spider) and *araña de detrás de los cuadros* (spider behind the pictures). [\[245\]](#) Molts, or shed exoskeletons, may mark infested areas; the web may be limited to a small, flocculent structure alongside the egg sac. Females may live 1 to 3 years and longer in captivity. [\[104\]](#) [\[134\]](#) Naturally unaggressive toward humans, brown spiders are not prone to bite unless threatened or trapped against the skin. Bites typically follow retrieval of old bed sheets or jackets from storage.

VENOM.

Fractionated *Loxosceles* venom contains at least eight or nine major protein bands and three or four minor bands identifiable by gel electrophoresis. [\[223\]](#) Hyaluronidase was first identified as a component by Wright and associates. [\[310\]](#) Hyaluronidase probably plays a facilitating role in lesion development, encouraging the spread of other venom

components; however, it is not itself a cytotoxin. Hydrolytic enzyme activities include esterase,^[310] alkaline phosphatase,^[128] lipase,^[142] and 5'-ribonucleotide phosphorylase,^[103] but none of these alone appears to explain cytotoxicity.

Sphingomyelinase D, a protein fraction of 32,000 dalton, appears to be the most important dermonecrotic factor in *L. reclusa* venom. This component is present in *L. intermedia* spiderlings starting with the third instar, with increasing activity throughout development until adulthood.^[108] Injection of the purified fraction produces characteristic lesions in rabbits.^[152] ^[280] A protein of similar molecular weight to sphingomyelinase D has been shown to have dermonecrotic activity in the venom of *L. gaucho* of Brazil,^[21] and considerable homology has been noted among proteins derived from *L. intermedia*, *L. laeta*, *L. gaucho*, and *L. reclusa*.^[22] Sphingomyelinase D is postulated to operate by a variety of mechanisms, including cell membrane binding and polymorphonuclear leukocyte neutrophil (PMN) chemotaxis.^[100] ^[222] ^[254] Lesions are inhibited in rabbits by pretreatment with nitrogen mustard to deplete PMNs. Histologic studies suggest similarities between venom-induced lesions and those seen with the Arthus and Shwartzmann phenomena.^[254]

Some vertebrate species, such as rats and fish, are essentially unaffected by *Loxosceles* venom; others, such as rabbits, mice, and dogs, are highly susceptible to its effects.^[243] Injected into humans, the venom is a hemolysin and cytotoxin, with enzymatic activities that may cause dermonecrosis and hemolysis. Pathogenesis of the human lesion is not well understood but depends on the functions of complement and PMNs.^[17] ^[244]

Venom from *L. reclusa* has a direct hemolytic effect on human erythrocytes; this process depends on the presence of serum components that include C-reactive protein and calcium.^[135] ^[280] Platelet aggregation also is calcium dependent and is induced in vitro with sphingomyelinase D; this process may activate the prostaglandin cascade. Platelet aggregation appears to depend on serum amyloid protein, a serum glycoprotein of previously unknown significance.^[99] ^[225] ^[280]

Because *Loxosceles* venom provokes an immune response in experimental animals, efforts to develop diagnostic tests are based on antigen or antibody detection in human blood. In 1973, Berger and associates^[29] reported an in vitro lymphocyte transformation assay for *L. reclusa* venom, which turned positive in the lymphocytes of exposed individuals within 4 to 6 weeks of initial exposure. This test may help to document prior exposure but not to diagnose envenomation at the time of the initial bite. Barrett and co-workers^[23] reported a passive hemagglutination inhibition test using rabbit antibody and human erythrocytes incubated in vitro with venom from *L. reclusa*.^[23] Cardoso and associates, observing that efforts to detect antigen in human serum may fail because of insufficient antigenemia, have demonstrated the presence of *L. gaucho* venom in biopsy homogenate using enzyme-linked immunosorbent assay (ELISA). Barbaro and colleagues^[21] demonstrated circulating IgG against *L. gaucho* venom in 4 of 20

patients, detectable between 9 and 120 days after the bite.

Some of the variability in clinical presentation among victims of *Loxosceles* envenomation may be caused by differences in the venom of males and females. Female *L. intermedia* spiders produce a greater amount of more potent venom than males.^[63]

CLINICAL PRESENTATION.

Necrotic arachnidism, or *loxoscelism* in the case of bite by spiders of the genus *Loxosceles*, refers to the clinical syndrome that follows envenomation by a variety of spiders, for which *L. reclusa*, the brown recluse spider, is the prototype. The bites of these spiders often result in serious cutaneous injuries, with subsequent necrosis and tissue loss. Less often, severe systemic reactions may occur with hemolysis, coagulopathy, renal failure, and even death.^[292]

Reports of severe reaction to spider bites possibly attributable to brown spiders date to 1872, in a report of a 45-year-old Texas woman with a febrile illness accompanying a large necrotic lesion of her thigh.^[50] In 1896, death from renal failure accompanying another bite in Texas was reported.^[214] Spider bite was reported as a cause of blackwater fever (massive hemoglobinuria) in Tennessee in 1940.^[111] The first documented case of loxoscelism (from *L. rufescens*) was reported by Schmaus^[247] in Kansas in 1929. *L. laeta* was identified as the cause of similar lesions in South America in 1937, and *L. reclusa* was the cause of necrotic arachnidism in the Midwestern United States by 1958.^[9] ^[10] Since then, numerous cases of cutaneous and more severe reactions have been attributed to spiders of the genus *Loxosceles*.

The clinical spectrum of loxoscelism ranges from mild and transient skin irritation to severe local necrosis accompanied by dramatic hematologic and renal injury. Isolated cutaneous lesions are the most common

Figure 34-10 Brown recluse spider bite after 6 hours, with central hemorrhagic vesicle and gravitational spread of venom. (Courtesy Paul Auerbach, MD, and Riley Rees, MD.)

Figure 34-11 Brown recluse spider bite after 24 hours, with central ischemia and

rapidly advancing cellulitis. (Courtesy Paul Auerbach, MD.)

presentation, and most bites may resolve spontaneously without the need for medical intervention.^[28] ^[29] Many authors distinguish between simple local presentation and more severe systemic, or viscerocutaneous, loxoscelism.

Local symptoms usually begin at the moment of the bite, with a sharp stinging sensation, although a victim may be unaware of having been bitten. Frequently the bite site corresponds to a portal of entry or a region of constriction of clothing, such as cuff, collar, waistband, or groin. The stinging usually subsides over 6 to 8 hours and is replaced by aching and pruritus as the lesion becomes ischemic from local vasospasm. The site then becomes edematous, with an erythematous halo surrounding an irregular violaceous center of "incipient necrosis" (actually hemorrhage and thrombosis).^[44] ^[280] A white ring of vasospasm and ischemia may be discernible between the central lesion and the halo. Often the erythematous margin spreads irregularly in a gravitationally influenced pattern that leaves the original center eccentrically placed near the top of the lesion ([Figure 34-10](#) , [Figure 34-11](#) , [Figure 34-12](#)). In more severe cases, serous or hemorrhagic bullae may arise at the center within 24 to 72 hours, and an eschar forms beneath. After 2 to 5 weeks this eschar sloughs, leaving an ulcer of

822

Figure 34-12 Brown recluse spider bite after 48 hours, with incipient central necrosis.

variable size and depth through skin and adipose tissue, but sparing muscle.^[130] Lesions involving adipose tissue may be extensive, perhaps from lipolytic action of the venom.^[142] The ulcer may persist for many months, leaving a deep scar.^[3] ^[235] ^[295] Local sequelae depend on the anatomic location. Persistent segmental cutaneous anesthesia has been attributed to nerve injury after a recluse bite on the side of the neck.^[121] Epiglottic and periepiglottic swelling severe enough to require endotracheal intubation has been reported in a recluse bite involving a child's ear.^[129]

The bite of the somewhat larger South American spider *L. laeta* is reported to cause intense pain and extensive edema, with proportionately less necrosis than that caused by *L. reclusa*. The edema is notoriously prominent with facial bites and resolves over 2 to 4 weeks.^[244]

Systemic involvement is less common but may occur in combination with cutaneous injury from any *Loxosceles* species; it occurs more frequently in children but may be seen in adults.^[215] ^[277] Systemic reaction may develop in cases with minor-appearing local findings, making diagnosis difficult.^[280] When systemic involvement occurs, hemolytic anemia with hemoglobinuria is often the prominent feature, usually beginning

within 24 hours of envenomation and resolving within 1 week.^[81] During this time, measured hemoglobin may drop markedly, accompanied by jaundice and hemoglobinuria. The anemia is usually Coombs' test negative, but two cases of Coombs'-positive anemia have been reported.^[292] Fever, chills, maculopapular rash, weakness, leukocytosis, arthralgias, nausea, vomiting, thrombocytopenia, disseminated intravascular coagulation (DIC), hemoglobinuria, proteinuria, renal failure, and even death have been reported.^{[33] [70] [106] [192] [292]}

The diagnosis of loxoscelism is based on spider observation and identification, typical history, and local and systemic signs. The differential diagnosis of the local injury includes bacterial and mycobacterial infection, herpes simplex, decubitus ulcer, burn, embolism, thrombosis, direct trauma, vasculitis, Lyme disease, and pyoderma gangrenosum.^{[5] [145] [217] [219] [270]}

A series of five proved or suspected *L. reclusa* bites to women in the second and third trimesters of pregnancy has been reported. Despite significant local injuries, rash, and microhematuria, no fetal injury was noted.^[4]

TREATMENT.

Treatment of loxoscelism depends on its severity. Cutaneous loxoscelism can usually be managed on an outpatient basis. Most mild cutaneous envenomations respond to application of local cold compresses,^[147] elevation of the affected extremity, and loose immobilization of the part. Tetanus prophylaxis should be provided where indicated. Necrotic lesions may need debridement after erythema has subsided to define the margins of the central eschar. This usually involves significant debridement 1 or 2 weeks after the bite, with close follow-up for several weeks. In severe cases this can be followed with skin grafting or plastic surgery when the wound is stable. Severe necrotic or infected lesions may lead to hospitalization.

Recently the use of dapsone has gained popularity for prevention of lesion progression in potentially necrotic wounds seen within 48 to 72 hours of a bite.^{[95] [101]} Dapsone is a leukocyte inhibitor that in theory can minimize the local inflammatory component of cutaneous loxoscelism, thereby preventing or lessening subsequent skin necrosis. In 1983, King and Rees^[146] reported the use of dapsone for envenomation in a human bitten by *L. reclusa*, based on a successful trial of dapsone pretreatment in guinea pigs injected with recluse venom. Since that time, no prospective, controlled human trial has proved dapsone efficacy, but a variety of case reports and series have supported its use in the treatment of potentially necrotic wounds treated in the first days after envenomation.^{[3] [26] [129] [171] [296]} Typical dosage recommendations are for 50 to 100 mg orally, twice daily. Risks of dapsone therapy include hypersensitivity,^[306] methemoglobinemia, and hemolysis in the presence of glucose-6-phosphate dehydrogenase (G6PD) deficiency.

Patients with systemic symptoms should be considered for admission when they have evidence of coagulopathy, hemolysis and hemoglobinuria, or rapid progression of other systemic signs. Care is mainly supportive, usually involving wound care, fluid management, presumptive treatment for bacterial superinfection, and occasionally,

blood transfusion. Rarely, hemodialysis has been required for oliguric renal failure. ^[109] Discharge is appropriate when renal and hematologic status is stable.

For patients with significant local or systemic signs or symptoms, laboratory evaluation should include peripheral blood cell count, basic coagulation screening, and urinalysis. Liver and renal function tests are indicated in severe poisonings. When use of dapsone is considered, a screening test for G6PD deficiency may be indicated. The frequency of follow-up testing depends on the course and severity of envenomation.

Hospitalized patients may need close follow-up of anemia and renal function over several days.

Corticosteroids have been injected either at the wound site or systemically,^{*} but this remains of questionable benefit. ^[27] ^[221] Antihistamines may help control itching but do not change the lesion. ^[157] Some advocate early surgical excision of the wound site, ^[8] ^[16] ^[87] ^[132] but others have demonstrated that outcomes are better with early medical management in human patients, ^[69] ^[223] as well as in experimental animals. ^[221] Hyperbaric oxygen (HBO) treatment has been tried empirically in uncontrolled human trials, with reports of good outcome. ^[276] Comparison of HBO with no treatment in rabbits showed enhanced recovery at 24 days at the histologic level, but with no apparent clinical difference between the two groups. ^[259]

Loxosceles-specific antivenom has been tried in both the United States and South America. In the early 1980s, Rees and colleagues ^[221] reported a protective effect of treatment with antivenom in rabbits before or up to 12 hours after envenomation. Small-vessel occlusion, leukocyte infiltration, and necrosis occurred but were diminished in antivenom recipients. Pretreatment in a separate study abolished symptoms of systemic loxoscelism. ^[220] In one study, 17 patients were separated randomly into dapsone, antivenom, and combination therapy groups; all patients received erythromycin. Individual results suggested that the antivenom was efficacious when given early, but the overall trial was inconclusive, indicating the need for further study. ^[224] Gomez and colleagues ^[107A] have studied the intradermal use of an anti-*Loxosceles* Fab-fragment in a rabbit model, suggesting therapeutic efficacy when the antivenom is injected up to 4 hours following envenomation. Currently, no *Loxosceles* antivenom is commercially available in the United States.

In South America an antivenom to *L. laeta* was developed in 1954 by Vellard using immune serum of the donkey. Furlanetto developed *L. laeta* antivenom using immune serum of horses. Reports of the efficacy of systemically administered *L. laeta* antivenom are mixed. ^[244] An ELISA assay, developed for the detection of circulating venom antigen, has the potential to develop into a tool for clinicians and epidemiologists. ^[55]

Genus Sicarius: Six-Eyed Crab Spiders

BIOLOGY.

About 25 *Sicarius* species are known. Their range is limited to dry regions of South America and South Africa. Individuals live under stones or are sand dwellers. Some hide under sand and emerge to capture passing insects. Their bodies are flattened, and their legs are laterigrade, meaning the tips point anteriorly as in a crab. Adult body size ranges from 12 to 22 mm.

VENOM.

The effects of venom of the South African crab spider *Sicarius testaceus* in a rabbit model demonstrated tissue necrosis and increased vascular permeability in the vicinity of the envenomation, as well as a dramatic decrease in platelet count. It is not clear whether this pattern is the same in humans.^[283]

CLINICAL PRESENTATION.

Sicarius species are occasionally implicated in human bites in South Africa. They tend to bite only when provoked and are rarely implicated in human poisonings, despite fairly high toxicity of the venom in laboratory animals. Envenomation reportedly can cause edema, erythema, and necrosis, occasionally associated with DIC.^{[196] [197] [198]}

TREATMENT.

Treatment of *Sicarius* envenomation is symptomatic and supportive.

Family Desidae: Long-Jawed Intertidal Spiders

Desidae has about 200 species that are distributed worldwide. Their chelicerae are often extended forward and have humps close to the prosomal attachment. Species range in body length from 4.5 to 12 mm. Most spiders in this family build small, irregular webs under rocks or logs. Some desids are closely associated with marine habitats, living in the intertidal zone. These spiders feed on marine animals and at high tide retreat into empty snail shells and worm tubes and seal off the entrance with silk. Others are found only on the water surface.

Genus Badumna: Black House Spider

BIOLOGY.

Badumna insignis (*Ixeuticus robustus*), or the black window spider, is a common Australian spider associated with a few human bite reports. This species is a nocturnal forager that builds tangled webs with silk retreats in and around human habitations.^[299]

VENOM.

Venom gland extract from *B. insignis* is reported to cause increased vascular permeability, as well as dose-dependent decreases in arterial pressure in rats, apparently from the presence of a serotonin-like substance in the venom.^[149] Venom gland extract does not cause necrosis in cultured human or mouse skin.^[14]

CLINICAL PRESENTATION.

In one report, *B. insignis* caused local pain, itching, and swelling followed by regional lymph node tenderness and discoloration of the area around the bite. Over 2 weeks the lesion resolved, with some tissue necrosis and sloughing centrally.^[172] In a series of five *B. insignis* bites, local lesions were painful but transient and unaccompanied by necrosis.^[300] Systemic symptoms have rarely been reported, including nausea, vomiting, abdominal pain, pruritus, and painful knees.^[299]

*References ^[28] ^[72] ^[73] ^[136] ^[139] ^[176] ^[214] .

TREATMENT.

Treatment of *Badumna* envenomation is symptomatic and supportive.

Family Zodariidae: Hunting Spiders

Zodariids are a diverse group of hunting spiders. The estimated 350 species have a worldwide distribution but are primarily found in the tropics and subtropics. They are medium sized (3 to 15 mm), with the anterior spinnerets usually longer than the posterior structures. They hide under stones or burrow in pebbles or sand. Very few reports of documented human envenomation exist, although *Supunna picta*, a common leaf litter-dwelling spider of Australia, reportedly caused a transient erythematous rash and slight itch in a woman bitten at home. The lesion resolved uneventfully.^[38]

Family Gnaphosidae: Ground Spiders and Mouse Spiders

Gnaphosids are common and found worldwide, with the highest densities in temperate areas. They are small to medium sized (2 to 14 mm) and usually dark in color (black, gray, or reddish brown). They have long, slightly flattened abdomens, and two of their spinnerets are conspicuous and cylindrical. Gnaphosids are nocturnal hunters, mostly on the ground, and during the day they retreat under rocks and stones or other tight quarters.

Herpyllus ecclesiasticus, the parson spider, is distributed widely throughout the United

States under rocks and rubbish and in houses. One case report of a bite by a *H. ecclesiasticus* described pruritus, arthralgia, malaise, and nausea beginning 1 hour after the bite. There was no necrosis.^[173]^[309] Treatment of bites is symptomatic and supportive.

Family Lamponidae: White-Tailed Spiders

Until recently the genus *Lampona* was placed in the family Gnaphosidae. The group was changed to family status because members do not share many of the characteristics that define Gnaphosidae.^[209] Specialists believe that many undescribed genera in Australia belong to this group.

Genus *Lampona*

BIOLOGY.

Lampona cylindrata is a hunting spider with a distinctive cylindrical shape and white spot at the tip of the abdomen. They are often found indoors in Australia and New Zealand.^[299] Individuals are wandering foragers that enter webs of other spiders and prey on them.

VENOM.

The venom of *L. cylindrata* appears to increase vascular permeability in rats, perhaps from the release of endogenous bradykinin and prostaglandins.^[149] Venom contains histamine and noradrenaline, both more highly concentrated in the venom of male spiders.^[217A]

CLINICAL PRESENTATION.

L. cylindrata was identified as the spider involved in a series of eight cases in Australia. Symptoms included a mild stinging sensation followed by 1 to 10 days of itching, redness, and swelling. In one case a small blister was present for a few hours; no necrosis was reported. The authors suspected that most *L. cylindrata* bites may be benign, despite earlier reports of ulceration after suspected *L. cylindrata* envenomations.^[300] Gray^[114] reported a case of more significant illness, with nausea, lethargy, and a small zone of necrosis after a known white-tailed spider bite. Although the vast majority of cases are relatively benign, significant skin necrosis occasionally may result from envenomation.^[299]

TREATMENT.

Treatment of *Lampona* envenomation is symptomatic and supportive.

Family Heteropodidae: Crab Spiders and Hunting Spiders

Biology.

Heteropodids, the "giant crab spiders," are distributed worldwide and are mostly tropical. They are large (10 to 40 mm) and resemble crabs, with the tips of all legs angling forward. They have flattened bodies and are capable of moving sideways. They have eight eyes in two straight rows. They are wandering hunters and typically nocturnal. In many places, they are welcome cohabitants with humans because they eat cockroaches.

Palystes natalius, the lizard-eating spider, is one of the largest true spiders in South Africa. It has a brownish gray body with bright yellow and black striped legs. The female is larger than the male, with body length up to 4 cm.

Venom.

Venom from the Australian heteropodid *Isopeda montana* has direct beta-adrenoreceptor action, and *Delena cancerides*, the social huntsman spider, appears to have both alpha- and beta-adrenoreceptor activity, although neither of these has been involved in recognized human envenomation. Both have been shown to increase vascular permeability in rats. ^[131]

Clinical Presentation.

Only localized burning accompanied by slight swelling was noted after a female *P. natalius* bite to the left wrist. ^[195] ^[200] An *Olios calligaster* bite was followed by mild local symptoms, transient nausea, and faintness. Six bites by *Isopeda* species, predominantly *I. pessleri*, resulted in minimal local symptoms only. ^[300]

Treatment.

Treatment of heteropodid bites is symptomatic and supportive.

Figure 34-13 Green lynx spider (*Peucetia viridans*). (Courtesy Gita Bodner.)

Family Oxyopidae: Lynx Spiders

Lynx spiders are found worldwide, with the greatest abundance in the tropics. They are small to medium sized (4 to 18 mm) and have a distinctive eye pattern, with six eyes in a hexagon and two smaller eyes below. Their abdomens are pointed posteriorly. They have long leg spines (macrosetae) that help detect motion through vibrations in the air. They are diurnal hunters with good vision and actively search for prey. Most are found on vegetation, and some are arboreal.

Genus Peucetia

BIOLOGY.

Peucetia viridans, the green lynx spider of the United States and Mexico, is a diurnal hunting spider. *P. viridans* is translucent green, with red eyes and joints^[123] ([Figure 34-13](#)).

VENOM.

Whole venom of *P. viridans* causes total and reversible block of non-*N*-methyl-D-aspartate receptor-mediated transmission in chick central nervous system.^[138]

CLINICAL PRESENTATION.

The bite results in a burning sensation, pruritus, erythema, and induration.

TREATMENT.

Treatment of *Peucetia* bites is symptomatic and supportive.

Family Salticidae: Jumping Spiders

Salticidae is the largest family of spiders, with more than 5000 currently described species and many more yet to be described. They are distributed worldwide, with the highest densities in the tropics. Some have called them the "butterflies of the spider world" because most are brightly colored and some have iridescent scales. Some species mimic ants, beetles, pseudoscorpions, and bird droppings. Jumping spiders have excellent eyesight, with large, posteromedian eyes. They visually search for prey, then stalk and ambush with catlike movements. Males are often more brightly colored than females and perform elaborate courtship dances. They are always active during the day and are small, most less than 15 mm.

Bites from spiders of the genus *Phidippus*, such as the jumping spider of the United States, can cause pain, erythema, pruritus, and sometimes minor ulceration. The swelling usually subsides within 2 days.^[234] In Australia, local pain has been reported with the bite of spiders from genera *Mopsus*, *Breda*, *Opisthoncus* and *Holoplatys*. One

patient bitten by a *Holoplatys* reported headache and vomiting.^[299]

Family Ctenidae: Wandering Spiders

Ctenidae are mostly found in subtropical and tropical areas. They can be large spiders ranging from 4 to 40 mm. They hunt on the ground or on vegetation. They resemble and are closely related to wolf spiders but are distinguished by their eye arrangement (three rows: two eyes, then four, then two, the last two being the largest). They sometimes travel as stowaways on bananas.

Genus *Phoneutria*: Banana Spiders (Armed Spiders)

BIOLOGY.

The *Phoneutria* spiders of South America are large, nocturnal creatures notorious for their aggressive behavior and painful bite. The best known representative of the genus is *Phoneutria nigriventer*. It is known in Brazil as *aranha armadeira*, meaning "spider that assumes an armed display," because of its characteristic defensive-aggressive display.^[242] *P. nigriventer* is the largest, most aggressive true spider found in South America, with an average body length of 35 mm, leg length of 45 to 60 mm, and fangs 4 to 5 mm in length for females. Males are slightly smaller.^[241] The body is gray to brown gray with white marks forming a longitudinal band on the dorsal abdomen. A distinguishing characteristic is the red-brown brush of hairs around the chelicerae. *P. nigriventer* is mainly found in southern Brazil, Argentina, and Uruguay. Other species have been found in Bolivia and Colombia. The spiders do not construct a web, since they are nocturnal hunters, often traveling several hundred meters in search of prey. They may enter houses during this time, hiding in clothes in the light of day. According to Bucherl, 600 to 800 spider bites occur each year around the city of São Paulo alone.^[41]

VENOM.

Phoneutria venom is a complex mixture of histamine, serotonin, glutamic acid, aspartic acid, lysine, hyaluronidase, and other polypeptides. Histamine, serotonin, and incompletely characterized kallikrein kinin

activating fractions contribute to local tissue swelling from the increased vascular permeability that may occur with envenomation.^[6] ^[177] In addition, the venom contains at least six neurotoxic polypeptides, with molecular weights between 3500 and 8500.^[62]

The neurotoxic components include sodium channel poisons that appear to potentiate action potentials along axons, provoking erratic or rapid uncontrolled muscle twitches in invertebrates^[83] as well as vertebrates.^[7] ^[169] Microscopically, there is acute transient

swelling of axons, particularly at the nodes of Ranvier, in a pattern similar to that caused by the venoms of scorpions *Centruroides exilicauda* and *Leiurus quinquestriatus*. The axons recover within a few hours of exposure, but return of nodal width to normal takes several days.^[169]

The effects of the venom have been studied in mice, rats, guinea pigs, rabbits, pigeons, and dogs. The venom has little or no effect on frogs and snakes, and it has four times greater toxicity in dogs than in mice. Rats and rabbits are very resistant to the venom's effects, but rabbit vascular smooth muscle contractions appear to be stimulated by a venom protein that acts independently of voltage-dependent sodium and calcium channels.^[178] Dogs developed intense pain, manifested by yelping, followed by sneezing, lacrimation, mydriasis, hypersalivation, erection, ejaculation, and death after 200 mg/kg of venom was injected subcutaneously.^[242] This is well within the dose that a single spider may inject. Electric stimulation yields an average of 1.6 to 3.2 mg of venom per spider.^[41]

CLINICAL PRESENTATION.

P. nigriventer venom acts on both the peripheral and the central nervous systems.^[122] Although the majority of cases are clinically insignificant,^[170] humans bitten by *P. nigriventer* may develop severe local pain that radiates up the extremity into the trunk, followed within 10 to 20 minutes by tachycardia, hypertension, hypothermia, profuse diaphoresis, salivation, vertigo, visual disturbances, nausea and vomiting, priapism, and occasionally death in 2 to 6 hours. Respiratory paralysis is generally the cause of death. Severe envenomation is more common among young children. Fatalities may occur in the debilitated or the young, but most people recover in 24 to 48 hours. Workers who handle bananas are frequently bitten because the spider hides in bunches of bananas. Bites have been reported in Switzerland and Argentina in produce workers inadvertently encountering these traveling spiders.^{[122] [241] [242]}

TREATMENT.

In most cases, symptomatic care is all that is necessary. Local pain control may be achieved by infiltration of local anesthetic near the bite site; this reportedly suffices for 95% of cases treated at the Hospital Vital Brasil.^[170]

Figure 34-14 Wolf spider (*Lycosa* species). (Courtesy Arizona Poison & Drug Information Center, 1996.)

For more severe cases, a polyvalent antivenom (sero antiaracidico polivalente, Instituto Butantan) active against *Phoneutria* species is available in Brazil. Skin testing and antihistamine prophylaxis are recommended before its use. One to five ampules of

antivenom are injected intramuscularly and/or intravenously, and clinical response is judged by the relief of pain or resolution of priapism. Opiates may potentiate the venom's effects on respiration and are generally not recommended in cases of systemic envenomation.^[122] ^[241] ^[242]

Family Lycosidae: Wolf Spiders

Lycosidae are among the most common spiders. They are diverse, with more than 3000 species distributed worldwide. They are found from beaches to grassy fields and pastures. The Greek name *lycosa* (wolf) comes from the former belief that they hunted in packs.^[60] ^[309] They range in size from 3 to 25 mm. Most species wander in active pursuit of prey, generally during the day. A few make deep burrows, and some even cover their burrows with doors. Most live on the ground, but some climb in vegetation. They have good vision, with conspicuously large, posteromedian eyes. Their eyes are arranged in three rows (four eyes, then two, then two). To attract mates, males wave their legs and sometimes stridulate to make sound. The female carries the egg sac attached to her spinnerets. When the young hatch, they climb on their mother's abdomen for transport. They have three claws on their tarsi.

Genus *Lycosa*: Wolf Spiders

BIOLOGY.

Lycosa is a large and widespread genus of wolf spiders ([Figure 34-14](#)). It includes various middle-sized to large spiders with mildly cytotoxic venom capable of provoking transient inflammation in humans. The most famous wolf spider species is *Lycosa tarentula*, to which "tarantula" was first applied. Its bite was once

827

believed to cause "tarantism," a syndrome of stupor, the desire to dance, and sometimes death, but this historic syndrome is now attributed to *Latrodectus tridecimguttatus* (neither a wolf spider nor a tarantula), and the wolf spider bite is now known to cause little more than stinging pain. The South American *Lycosa raptoria* has been reputed to be more dangerous than other wolf spiders, provoking necrosis at the site of envenomation. It now appears that this was also based on a misunderstanding. Necrotic arachnidism in South America is now attributed mainly to *Loxosceles* species.

VENOM.

Lycosid venom is thought to be primarily cytotoxic, without hemolytic or anticoagulant activity.^[309] Although scientific reports of necrosis are lacking after envenomation by the Australian wolf spider *L. godeffroyi*, media reports suggest that bites may lead to necrosis. Atkinson and Wright^[13] have demonstrated that the raw venom of *L. godeffroyi* causes a strong inflammatory response and cutaneous necrosis when injected into

mice. They further hypothesized that this action may result from contamination of the venom with digestive juices, since electrically collected raw venom caused necrosis, whereas venom gland extract did not.^[14]

CLINICAL PRESENTATION.

A series of 515 cases of confirmed *Lycosa* bites in Brazil showed that most occur between the hours of 6 AM and 6 PM, at a fairly consistent rate year-round. The most common bite sites were feet (40%) and hands (39%). The most common signs and symptoms were all local, with pain in 83%, swelling in 19%, and erythema in 14%. No local necrosis was described.^[226]

In the United States five cases of Lycosidae bites have been documented. One resulted in skin necrosis at the bite site, probably from the combined results of envenomation and infection.^[47]

TREATMENT.

Although South American antivenom active against *Lycosa* venom was available in the past, it was used in only one case of 515 reviewed by Ribeiro and associates.^[226] Since 1985 the polyvalent Butantan Institute spider antivenom has not included the antilycosid fraction.^[170] Most *Lycosa* cases can be managed with tetanus immunization and ice or oral analgesics; occasionally, local anesthetic block has been used for pain management.^[226]

Family Clubionidae: Sac Spiders and Two-Clawed Hunting Spiders

Clubionids are common and distributed worldwide with the highest diversity of species in the neotropics. They are small to medium sized (2 to 15 mm) and are usually light brown to yellowish in color. They hunt nocturnally and make resting tubes in rolled

Figure 34-15 *Cheiracanthium inclusum*. (Courtesy Sherman Minton, MD.)

leaves or under rocks or stones, where they retreat during the day.

Genus *Cheiracanthium*: Running Spiders and Sac Spiders

BIOLOGY.

The genus *Cheiracanthium* as a whole has no distinctive marks or patterns.^[110] ^[309] Members may be pale yellow, brown, green, or olive. The dorsal abdomen may have a

median longitudinal stripe. Body size ranges from 7 to 15 mm, with a total diameter of 3 cm, including long, slender legs.

In the United States, *C. inclusum* is the only indigenous species ([Figure 34-15](#)). *C. diversum* is widely found in the Pacific islands. It was transported into Hawaii from Australia approximately 50 years ago. *C. mildei* was introduced from Europe and is now found from New England to Alabama to Utah. It is a common biting spider in Boston; it is most abundant in autumn, when most bites occur.^[257]

The South African sac spider *C. lawrencei* is a common nocturnal house spider that forages at night and may become trapped in bedding.^[196] During the day these spiders hide in the concavities of leaves, curtains, or windowsills, encased in a silk sac. They are fast moving and aggressive when threatened.^[198]

VENOM.

Research on *Cheiracanthium* venom is limited. About 75% of guinea pigs bitten by *C. mildei* for the first time developed a wheal within 5 minutes, with 60% developing an eschar within 1 day.^[257] Fractionation of dissected venom gland extracts from *C. japonicum* resulted in five fractions with lethal activity in mice. These were considered neurotoxic based on symptoms of dyspnea, flaccid paralysis, and death after intraperitoneal injection.^[203]

CLINICAL PRESENTATION.

Spiders belonging to the genus *Cheiracanthium* have a documented history of human envenomation since the eighteenth century. Species are

known for their tenacious, painful bite. A pruritic, erythematous wheal appears within 30 minutes. Nausea, abdominal cramps, headache, and local necrosis have been reported.

In 1901, Kobert described local swelling, erythema, pain, and fever after the author's third *C. punctorium* envenomation.^[32] Maretic^[180] ^[181] described local redness, pain, and edema but no necrosis after *C. punctorium* envenomation. In another case, *C. inclusum* caused local pain that radiated from the forearm bite site up the arm, associated with nausea. No other signs developed.^[32]

The Australian species *C. mordax* and *C. longimanus* caused local swelling, erythema, and pain associated with malaise, headache, dizziness, and nausea. Symptoms receded within 36 hours after treatment with antihistamines and local anesthetics.^[32] Ori^[203] found similar signs and symptoms after envenomation by *C. japonicum*.

In South Africa, most *C. lawrencei* bites occur at night during sleep.^[196] Paired bite

marks 6 mm apart are evident within the first few hours. Local edema and erythema may be slight. By the third day the marks may become necrotic, with more edema, erythema, and pain; headache and fever may accompany this stage. The small ulcer begins to heal 7 to 10 days after the bite.^[197]

TREATMENT.

The lesion usually heals without problems, provided secondary infections are avoided. Treatment is supportive, consisting of cool compresses, elevation, immobilization, analgesics, and tetanus prophylaxis.

Family Corinnidae: Sac Spiders

Corinnids are ground-dwelling spiders primarily found in tropical regions. They were previously placed in the family Clubionidae and have similar habits. Spiders of the *Trachelas* genus are often encountered in houses in late summer and fall. *T. volutus* and several other *Trachelas* species reportedly cause mild local reactions without necrosis. Bites are painful initially and may swell. No systemic effects have been reported.^{[205] [281]} Treatment is symptomatic and supportive.

Family Agelenidae: Hobo, Grass, and Funnel-Web Spiders

The 600 species of Agelenidae are mainly found in temperate regions of the Northern Hemisphere. They are medium-sized spiders, ranging from 8 to 15 mm in body length. Individuals build sheet webs that lead to a long funnel, which the spider uses as a retreat. When prey contacts the web, the spider runs out, bites it, and carries it back into the funnel. The large and conspicuous webs of these spiders often are long lasting, with spiders adding silk to make the sheet larger as the individual grows. Males may be found searching for females.

Genus Tegenaria: Hobo Spiders

BIOLOGY.

Tegenaria agrestis is commonly called the hobo spider or Northwestern brown spider. It is a 10- to 15-mm, light-brown spider with a yellowish green tint and chevrons on the dorsal abdomen. Individuals typically build funnel webs in disturbed habitats such as abandoned woodlots or along railroad tracks, with a hidden retreat beneath wood, rocks, or debris and silk extending beyond the cover. Spiders mature to adulthood in midsummer and mate and lay eggs in July through September. Adult males live for 1 year, then senesce and die at the end of the mating season. Adult females live for 2 years, so adults are present throughout the year.

T. agrestis spiders are common and widespread natives of Europe and western central Asia.^[124] This species was probably introduced in a seaport near Seattle in the early 1900s and was first formally identified in the 1930s.^{[85] [86]} It has since expanded its range to British Columbia, Alaska, Oregon, Idaho, Montana, and Utah.^{[18] [227] [297]} By the 1960s,

individuals were often collected in and around human habitations in the Pacific Northwest.

VENOM.

The venom of *T. agrestis* has become of interest in the last 15 years because of reports suggesting that their bites result in necrotic lesions. *T. agrestis* venom chemistry is not well characterized, and no necrotoxic component has been identified. Johnson and colleagues^[141] identified potent insect-specific neurotoxic peptides and mammalian-specific peptides (5000 and 9000 daltons) that were lethal to mice at high dosage.

Experimental envenomation of rabbits by live male spiders has resulted in extensive cutaneous injury and clear evidence of systemic poisoning. Local erythema appeared and faded within the first day; discolored patches were visible by day 4 and sloughed by day 6. Autopsy revealed petechial hemorrhages on the surfaces of the lungs, liver, and kidneys.^[285]

Since the early 1980s medically significant bites in the Pacific Northwest have been attributed to *T. agrestis*.^[2] ^[286] ^[288] ^[289] In Europe, no medical problems have been associated with bites from these spiders.^[32] ^[42] ^[57] Venom chemistry of American spiders is not different from venoms of English spiders, so the cause of the alleged difference in medical significance is currently under investigation.^[35] Bites of males from the Pacific Northwest have more severe necrotic effects on mammalian tissues than bites from females.^[285] Necrotic lesions have been attributed to this species all during the year, with a trend toward increased severity in the winter months.^[289]

Figure 34-16 *Agelenopsis aperta*. (Courtesy Eileen Hebets.)

CLINICAL PRESENTATION.

T. agrestis has been implicated in several cases of necrotic arachnidism similar to that seen in *Loxosceles* envenomation. Systemic effects reported include headache, visual disturbances, hallucinations, weakness, and lethargy. Hemorrhagic complications have been reported in experimental animals.

In general, direct observations are scarce of *T. agrestis* biting people, who then develop necrotic lesions.^[2] According to Vest,^[285] ^[289] who studied 22 cases of "highly probable"

T. agrestis envenomation, the local lesion followed a pattern reminiscent of loxoscelism. The initial lesion appeared as a small reddened induration, often surrounded by a large zone of erythema. Vesicles occurred within 36 hours, then burst; marked necrosis developed in 50% of cases. The most common symptoms included headache, weakness, and lethargy.^[287]

TREATMENT.

No studies have investigated treatment for envenomation by *Tegenaria* species. As with mild cases of loxoscelism, patients should be treated supportively, with tetanus prophylaxis, careful wound debridement as needed, and observation.

Genus *Agelenopsis*: Grass Spiders and Funnel-Web Spiders

BIOLOGY.

Agelenopsis aperta is common in and restricted to the deserts of the southwestern United States, ranging from California to East Texas ([Figure 34-16](#)). They build large, conspicuous sheet webs, with retreats under rocks and logs or in tufts of grass. Adults are 13 mm in body length.

VENOM.

The venom of this species is among the best known of all spiders in terms of biochemical composition and neurophysiologic activity of the individual components. Its clinical relevance in humans, however, has only recently been recognized.

Nineteen toxins have been characterized in *A. aperta* venom, with three distinct classes that act synergistically to subdue insect prey rapidly and irreversibly.^[202] The μ -agatoxins modify sodium channel kinetics, increasing neurotransmitter release generally; the γ -agatoxins block presynaptic, voltage-sensitive calcium channels; and the α -agatoxins are a family of low-molecular-weight acylpolyamines that block glutamate-sensitive receptor channels in insect muscle. The coexistence of toxins with different mechanisms of neurotoxicity appears to confer a synergistic action to the overall venom effect in insect prey. The γ -agatoxins range in target specificity from invertebrates to mammals.^[284]

CLINICAL PRESENTATION.

Two cases of envenomation by *A. aperta* have been reported in southern California. A 9-year-old boy developed a tender but nonnecrotic bite site, followed by a 2-day systemic syndrome that included headache, nausea, disorientation, pallor, and unsteady gait. A 54-year-old man developed a painful, indurated lesion that persisted for a week; he had no systemic symptoms.^[290]

TREATMENT.

Treatment of *Agelenopsis* envenomation is symptomatic and supportive.

Family Theridiidae: Comb-Footed Spiders

The family Theridiidae, sometimes called cobweb or comb-footed spiders, is speciose, diverse, and distributed worldwide. The spiders are small to medium sized (1 to 14 mm, usually less than 8 mm) and often have globose abdomens. They make irregular, tangly webs in which the spider hangs upside down. The silk is very sticky, easily entangling prey. Spiders throw silk over ensnared prey using a tiny comb at the end of the fourth leg. They then envenom prey and suck them dry through a small hole in the exoskeleton, since they have no cheliceral teeth for chewing.

Genus *Latrodectus*: Widow Spiders

BIOLOGY.

Latrodectus (Latin for "robber-biter") species are among the largest theridiids. Females are 12 to 16 mm in body length. Males are much smaller, with longer legs relative to their body size. Individuals build typical theridiid cobwebs with very strong strands of silk. Arthropods are the most common prey, but widows also kill and consume vertebrates (e.g., small lizards and snakes). The folkloric belief that widow females kill and consume their mates does happen, although not as a rule.

The 8- to 10-mm female black widow is shiny black with a characteristic red hourglass marking on the ventral abdomen. Species are distinguished based on hourglass shape and dorsal color patterns. Males are lighter in color, with white and gray markings and a faint

Figure 34-17 Adult female *Latrodectus mactans* with fresh egg case. (Courtesy Michael Cardwell & Associates, 1999.)

Figure 34-18 Mature female brown widow spider (*Latrodectus geometricus*). (Courtesy Michael Cardwell & Associates, 1999.)

hourglass. This feature becomes more prominent with maturity. The female spins an irregular web in sheltered corners of fields, gardens, and vineyards and under stones, logs, and vegetation. Uncommon in occupied dwellings, the spiders may be plentiful in barns, garages, trash heaps, and outbuildings. A few *Latrodectus* species (e.g., *L. variolus*) are arboreal. The web's tattered "cobweb" appearance may belie an ongoing state of occupation, particularly during the daytime, when the spider is out of sight. The female seldom ventures far from the web, in which she suspends an ovoid or tear-shaped, whitish egg case.

Latrodectus spiders are worldwide in distribution, most plentiful in temperate and subtropical regions, and most abundant during summer.^[32] *Latrodectus mactans mactans*, the black widow, is cosmopolitan and occurs in every state except Alaska ([Figure 34-17](#)). In North America, species include *L. geometricus* (the brown widow, [Figure 34-18](#)), *L. bishopi* (the red-legged

Figure 34-19 Mature female western black widow (*Latrodectus hesperus*). (Courtesy Michael Cardwell & Associates, 1993.)

Figure 34-20 Red-backed spider (*Latrodectus mactans hasselti*). (Courtesy Sherman Minton, MD.)

widow), *L. variolus*, and *L. hesperus* ([Figure 34-19](#)). Species known to envenom humans are endemic to Australia (*L. m. hasselti*, [Figure 34-20](#)) and to Europe and South America (*L. tredecimguttatus*). Related species are found in Asia and the Middle East (*L. pallidus*) and in Africa (*L. indistinctus*).

The species *L. tredecimguttatus* is most important in the Mediterranean region, the Middle East, and parts of Russia, where it is sometimes referred to as *L. lugubris*. It may have red or orange spots or may be pure black and is known as *kara kurt* (Russian for black wolf). *L. indistinctus*, the black button spider of South Africa, has a narrow or

broken red dorsal band or may be black. The red-backed spider (*L. m. hasselti*) is medically important in Australia, New Zealand, and southern Asia. It has a dorsal red band similar to that of *L. indistinctus*, and the female also has a ventral red hourglass reminiscent of *L. m. mactans*. *L. geometricus* is brown with black, red, and yellow markings and is

common in southern Africa and warmer parts of the Americas.

Widow spiders tend to bite defensively when accidentally crushed. In the Mediterranean basin, southern Russia, and South Africa, bites are associated with grain harvesting and threshing and with grape picking. In the United States, most bites occur in rural and suburban areas of southern and western states, with no special age, gender, or occupational predilection. In regions where outdoor privies are in common use, human envenomations are likely to involve the buttocks or genital area.^{[34] [107] [180] [307]} Outbreaks of latrodectism may occur locally in epidemic fashion, lasting several years, and depend on changes in spider predator and parasite balance and on occupational variations in human-spider contact. Apparent outbreaks may also result from sudden increases in publicity and reporting.^{[31] [143]}

VENOM.

Unlike many other arthropod venoms, that of the widow spiders appears to lack locally active toxins capable of provoking inflammation. The venom contains several toxic components, including a potent mammalian neurotoxin, α -latrotoxin, which induces neurotransmitter release from nerve terminals.

In 1964, Frontali and Grasso^[93] demonstrated three electrophoretically and toxicologically distinct fractions of *Latrodectus* venom. In 1976, Frontali and associates^[94] further purified and defined these fractions, encountering one major constituent (the B5 fraction, later renamed α -latrotoxin) with significant toxicity in mice and frogs (other fractions have effects more specific to insect physiology). Alpha-latrotoxin, a protein mix with an average molecular weight of 130,000, caused profound depletion of presynaptic vesicles with swelling of the presynaptic terminal at frog neuromuscular junctions; complete blockade of neuromuscular transmission followed within 1 hour. The toxin binds irreversibly with the lipid bilayer of the cell membrane, producing cation-selective channels and interfering with endocytosis of vesicle membranes.^{[51] [88]} The mechanism of action is not fully understood, but multivalent cations, including calcium, may enter the presynaptic nerve terminal through these channels, interfering with calcium-dependent intracellular processes.^{[113] [185]} These effects appear to be specific to presynaptic nerves but independent of the transmitter involved. Acetylcholine, noradrenaline, dopamine, glutamate, and enkephalin systems are all susceptible to the toxin.^[229]

Grishin^[120] has described the venom of *L. tredecimguttatus*, which has a family of seven

protein toxins of high molecular weight. These all cause massive neurotransmitter release from presynaptic endings. They differ from each other in the specificity of the target animal. Alpha-latrotoxin acts selectively on vertebrate nerve endings; five latroinsectotoxins act on insects, and one toxin is specific for crustaceans. These large molecules have several functional domains responsible for ionophoric and secretogenic actions. Amino acid sequence analysis of precursor toxins reveals high levels of sequence identity between the different latrotoxins. It also reveals a series of ankyrin-like repeats that might be the structural basis of the interactions between the toxins and the membranes.^[120] *L. indistinctus* and *L. geometricus* also contain α-latrotoxin, the former with a greater venom yield per spider.^[189]

CLINICAL PRESENTATION.

Latrodectism, the syndrome often resulting from *Latrodectus* envenomation, is best known for widespread, sustained muscle spasm rather than for local tissue injury. Although long-term outcomes are usually excellent, victims may have significant hypertension, autonomic and central nervous system dysfunction, and abdominal pain severe enough to be mistaken for acute abdomen.

The initial bite may be sharply painful, but many bites are not recognized initially, so diagnosis is often presumptive and based on local and systemic signs. Local reaction is typically trivial, with only a tiny papule or punctum visible on examination. The surrounding skin may be slightly erythematous and indurated. In most cases, symptoms do not progress beyond this point. In one Australian series, 76% of victims presenting to a hospital for care had local symptoms only.^[140]

In some cases, however, neuromuscular symptoms can become dramatic within 30 to 60 minutes as involuntary spasm and rigidity affect the large muscle groups of the abdomen, limbs, and lower back. Rhabdomyolysis has rarely been reported.^[97] A predominantly abdominal presentation may closely mimic an acute abdomen. Associated signs include fasciculations, weakness, ptosis, priapism, thready pulse, fever, salivation, diaphoresis, vomiting, and bronchorrhea. Pulmonary edema has been described in Europe^[183] and South Africa.^{[153] [291]} Respiratory muscle weakness combined with pain may lead to respiratory arrest. Hypertension with or without seizures may complicate management in elderly or previously hypertensive individuals. Isolated (normotensive) seizures do not appear to be a feature of latrodectism. Intractable crying may be the predominant feature in neonates.^[45] Pregnancy may be complicated by uterine contractions and premature delivery.^{[20] [133] [182] [231] [237]} A characteristic pattern of facial swelling, known as *Latrodectus* facies, may occur hours after the bite and is sometimes mistaken for an allergy to drugs used in treatment. The usual course of an envenomation is to achieve complete recovery after a few days, although pain may last a week or more.

The clinical picture of *Latrodectus* poisoning is similar around the world. In the 1980s in California the most common site of envenomation referred to a toxicology

service was the lower extremity (48%), followed by upper extremity (28%), trunk (18%), and head or neck (5%). The most common systemic symptom was abdominal or back pain (58%), followed by extremity pain (38%), hypertension (29%), and diaphoresis (22%).^[56] In Australia a 1961 survey showed 37% of victims were bitten on the upper extremities, 27% on the lower extremity, 22% on the buttock or penis, 17% on the trunk, and 4% on the head or neck.^[304] A 1978 report showed a decline in incidence of genital and buttock involvement (9.7%), perhaps related to a decrease in the use of outdoor lavatories.^[275] Australian envenomations showed a similar pattern of pain and diaphoresis, with more prominent local inflammation and lymphadenopathy and less hypertension than reported in the United States. In South Africa, envenomation by *L. geometricus* results primarily in local pain, whereas *L. indistinctus* provokes a syndrome of generalized pain, diaphoresis, and muscle rigidity similar to that seen in the United States.^[188] Victims bitten by *L. tredecimguttatus* may have spasm of facial muscles, swollen eyelids, lacrimation, and photophobia, more often resulting in recognized *Latrodectus* facies. A rash may appear 2 to 11 days after envenomation.^[179]

TREATMENT.

Although the worst pain usually occurs during the first 8 to 12 hours after a bite, symptoms may remain severe for several days. All symptomatic children, pregnant women, and patients with a history of hypertension should be admitted to the hospital. Discharge is usually possible within 1 to 3 days, when hypertension and muscle spasm have subsided. A patient with a satisfactory response to antivenom may be sent home after several hours' observation.

Care of the local site includes routine cleansing, intermittent application of ice, and tetanus prophylaxis. Severe pain and muscle spasm usually respond to IV narcotics or benzodiazepines. Careful observation of respiratory status is vital when either or both of these are used. Calcium gluconate infusion, advocated in the past, has proved only minimally useful and is no longer recommended. Hypertension may be treated with an infusion of sodium nitroprusside or nifedipine if the patient does not respond to pain control with narcotics or antivenom.

Antivenom active against *Latrodectus* venom is available in the United States from Merck and Co.; in Australia from Commonwealth Serum Laboratories; and in South Africa from the South African Institute of Medical Research. Standards for *Latrodectus* antivenom use vary around the world, as do guidelines for its administration.^[56] ^[188] ^[271] In general, antivenom should be used in cases involving respiratory arrest, seizures, uncontrolled hypertension, or pregnancy.^[238] In less severe settings, its value must be weighed against the risks of acute hypersensitivity and delayed serum sickness. In Australia, 0.5% to 1% of cases result in anaphylaxis, and some patients develop serum sickness.^[275] Death from anaphylaxis has been reported in the United States.^[56] The usual therapeutic antivenom dose is one to three vials or ampules. Efficacy of antivenom is reported as satisfactory in 94% of patients in Australia,^[298] with anecdotal

reports of efficacy even weeks to months after envenomation.^[19]

Laboratory evaluation may include complete blood cell count, electrolytes, blood glucose, and urinalysis. Common findings include leukocytosis and albuminuria. In victims with severe muscle spasm, creatine phosphokinase levels may be elevated. Abdominal films and stool examination for occult blood, both of which should be normal after widow spider envenomation, may help with the differential diagnosis of abdominal pain. A pregnancy test should be done if indicated. No specific antigen or antibody detection technique is currently available for clinical diagnosis.

Genus *Steatoda*: False Black Widow Spiders

BIOLOGY.

Steatoda species are found worldwide. They are 3 to 8 mm in body length, smaller than *Latrodectus*, and typically are dark brown, often with white markings on the abdomen. They build tangly cobwebs and sit in crevices under stones, in tree bark, or in cracks of buildings near the web. *Steatoda paykulliana* of Europe, *S. foravae* of southern Africa, and *S. grossa* of the United States bear an external resemblance to members of the *Latrodectus* genus and therefore are referred to as false widow or button spiders.

VENOM.

The crude venom of *S. foravae* contains a major polypeptide of the same molecular weight as α -latrotoxin and can elicit a comparable neurotransmitter release syndrome in mice. The median lethal dose, however, is significantly higher, and the relative potency in mice is 10 to 20 times less than for *L. indistinctus*.^[190]

CLINICAL PRESENTATION.

In humans, *S. nobilis* of southern England has caused brief local pain and slight swelling, followed by local sweating and piloerection, facial flushing, and feverishness.^[294] One report of *S. foravae* bite in southern Africa showed minimal local inflammatory response without systemic toxicity.^[190] In one Australian report a 2-year-old child bitten by a juvenile *Steatoda* (species unknown) developed lethargy, irritability, diaphoresis, and hypertension 22 hours after the bite. He improved gradually after administration of two ampules of red-backed spider (*Latrodectus*) antivenom.^[255]

TREATMENT.

In general, care is symptomatic and supportive. Similarities between the neurotoxins in

Figure 34-21 Orb weaver (*Argiope* species). (Courtesy Eileen Hebets.)

Steatoda and *Latrodectus* venoms, however, suggest the use of *Latrodectus* antivenom in severely symptomatic cases.

Family Araneidae: Orb-Weaving Spiders

Members of the family Araneidae are familiar to most people because they are common and build conspicuous, mainly circular, two-dimensional orb webs in open places. This is an abundant family, with 4000 species described and distributed worldwide. Species range in adult body size from 2 to 28 mm and often have extreme size dimorphism, with males much smaller than females. They are extremely diverse in size, shape, web design, and prey capture tactics. They can be brightly colored, with typically ovoid abdomens and large chelicerae with several teeth. Although diverse and abundant, they are of minimal clinical concern.

The venoms of many araneid spiders are known to have polyamine neurotoxins that postsynaptically block glutamate receptors in vertebrates.^[144] These are currently known from species of *Nephila*, *Argiope*, *Araneus*, and *Neoscona*.

Genus *Argiope*: Argiopes

BIOLOGY.

Argiope aurantia, known as the golden orb weaver or black and yellow garden spider, is common in California, Oregon, and the eastern United States ([Figure 34-21](#)). Other *Argiope* species are found throughout the United States, the Orient, and Australia.^[104] It is a large, brightly colored spider with a large, symmetric orb web and a leg spread of up to 7.5 cm.

VENOM.

Although *Argiope* venom appears to be cytotoxic in vivo, research indicates the venom has neurotoxic effects in vitro. Venom gland extracts from *Argiope trifasciata* are postsynaptic blockers of neuromuscular transmission at locust glutamate receptors.^[282]

CLINICAL PRESENTATION.

Bites may cause local pain and erythema. Bites by *Argiope argentata* reportedly cause local pain, erythema, and vesicle formation, which resolve within 24 hours except for the

bite marks. [110] [309]

TREATMENT.

Treatment is symptomatic and supportive.

Chapter 35 - Scorpion Envenomation

Jeffrey R. Suchard
David A. Connor

INTRODUCTION

Scorpion envenomation can result in distinct clinical syndromes. Most scorpion species' stings cause only local pain and inflammation that respond well to minimal supportive therapy and wound care. These scorpions pose no significant management issues and, with few exceptions, are not discussed here in further detail. The truly dangerous scorpions of the world, typified by *Tityus* species in the Caribbean region and in South America, *Androctonus* species and *Buthus occitanus* in North Africa, *Leiurus quinquestriatus* in the Near East, and *Mesobuthus tamulus* in India, cause an "autonomic storm" with prominent cardiopulmonary effects. A third clinical syndrome occurs from stings of *Centruroides* species in the southwestern United States and Mexico and from *Parabuthus* species in southern Africa. These produce prominent neurologic effects associated with excess cholinergic tone. Children are typically more severely affected than adults and often require prompt medical management to avoid morbidity and mortality. The ideal treatment of scorpion envenomation remains controversial, primarily because controlled clinical trials are lacking. Although anecdotal experience and comparisons of historic cohorts demonstrate a benefit from aggressive symptomatic and supportive care, the proper use of antivenins has not been fully resolved.

TAXONOMY AND ANATOMY

Scorpions are grouped in the phylum Arthropoda ([Figure 35-1](#)). Scorpions have a crablike or lobsterlike body shape with seven sets of paired appendages ([Figure 35-2](#)): the chelicerae, the pedipalps (claws), four sets of legs, and the pectines (a pair of comblike structures on the ventral surface). The segmented tail curves upward dorsally, ending in a terminal bulbous segment called the *telson*, which contains paired venom glands and the stinger ([Figure 35-3](#)). The presence and size of a subaculear tooth, a small tubercle near the base of the stinger, vary among species and stage of maturity. In the United States, a subaculear tooth on a small, slender scorpion usually indicates *Centruroides exilicauda* (*C. sculpturatus*) ([Figure 35-4](#)).^{[40] [129]} Many scorpion specimens reveal a broken stinger that does not penetrate human skin well.^[132]

Scorpions grasp prey in their pedipalps and then rapidly thrust the tail overhead to sting. The chelicerae tear the food apart. Scorpions feed primarily on ground-dwelling arthropods and small lizards. The scorpion consumes only the juices and liquefied tissues of its prey, discarding the solid parts. Scorpions envenom by stinging; although stings may be reported as bites,^{[12] [45] [124]} true scorpion bites have not been documented and would be inconsequential if they did occur.

A characteristic physical property of scorpions is that they fluoresce when illuminated by ultraviolet light, as from a "black light" or a medical Wood's lamp ([Figure 35-5](#)). This property is used in collecting scorpions for breeding or venom harvesting and in providing pest control. The fluorescent pigment in scorpion cuticle is probably riboflavin.^[97]

Scorpions can sting multiple times; however, it appears that the first sting depletes or nearly depletes the telson of venom. A case series of three pairs of scorpion sting victims from India found that consecutive stings by *Mesobuthus tamulus* caused severe cardiovascular manifestations in the first victim but not in the second.^[14] We have observed a similar difference in the severity of neurologic manifestations from consecutive *Centruroides exilicauda* stings in Arizona.

GEOGRAPHIC DISTRIBUTION

Scorpions are widely distributed in regions within 50 degrees north and 50 degrees south of the equator^[85] and are found on all continents^[116] except Antarctica. Scorpions are characteristic of desert areas, semiarid grasslands, and the tropics but may also be found in temperate and subtropical regions.^[73] ^[85] ^[97] ^[116] An estimated 5000 deaths from scorpion stings occur annually worldwide,^[62] making scorpions second only to snakes as sources of fatal envenomation.^[148]

Estimates vary regarding the number of scorpion species. In 1985, Herschkovich et al^[84] reported the existence of 500 scorpion species divided into six families. Russell^[129] reported 500 to 800 species, others reported 650,^[28] ^[36] ^[150] and Neale^[116] estimated at least 700 species. More recent reports estimate 1000 species,^[62] ^[132] and in 1998, Hutt and Houghton^[85] reported 1400 scorpion species divided into nine families ([Figure 35-6](#)). The Buthidae is the largest and the most dangerous family and, with few exceptions, contains the only species capable

Figure 35-1 Organization of the phylum Arthropoda, showing the relationship of scorpions to spiders and more distantly related insects.

of producing clinically significant envenomations, through their neurotoxic venoms.^[73] ^[85] ^[132] At least 30 species can inflict potentially fatal stings.^[62] All genera commonly recognized as dangerous are buthid scorpions: *Centruroides* and *Tityus* in the Western Hemisphere, and *Androctonus*, *Buthus*, *Mesobuthus*, *Leiurus*, and *Parabuthus* in the Eastern Hemisphere.

VENOM

Scorpion venoms are complex mixtures containing mucopolysaccharides, hyaluronidase, phospholipase, acetylcholinesterase, serotonin, histamine, protease inhibitors, histamine releasers, and neurotoxins.^[41]^[132] Neurotoxins are pharmacologically the most important venom constituents.^[132] *Centruroides exilicauda* venom glands contain two types of columnar cells, one secreting mucus and another producing neurotoxins. This species' venom has no enzyme that causes tissue destruction, however, so local effects are minimal or absent.^[40] The neurotoxins are single-chain, basic polypeptides of 60 to 70 amino acids, reticulated by four disulfide bridges. Each scorpion species' venom contains several neurotoxins, but they all share a similar structure and homologous sequences.^[68]^[132] In neuronal membranes, these toxins cause two effects with regard to fast sodium channels involved in action potential transmission: (1) incomplete inactivation of sodium channels during depolarization, resulting in a widening of the action potential, and (2) a slowly developing, inward sodium current after repolarization, leading to membrane hyperexcitability. The net result is repetitive firing of axons,^[40] enhancing release of neurotransmitters (acetylcholine, norepinephrine, dopamine, glutamate, aspartate, γ -aminobutyric acid [GABA]) at synapses and at neuromuscular junctions.^[53]^[59]^[128]^[146] This is clinically demonstrated as excessive neuromuscular activity and autonomic dysfunction. Some scorpion

Figure 35-5 Scorpions fluoresce in ultraviolet light.

neurotoxins also have effects on calcium-activated potassium channels,^[63] ^[127] chloride channels,^[44] and L-type calcium channels.^[9]

REGIONAL EPIDEMIOLOGY

India

Between 86 and 99 scorpion species, with at least 45 buthid species, are found in India. Only one species is regarded as dangerous: *Mesobuthus tamulus*, formerly known as *Buthus tamulus*, called the red scorpion.^{[43] [111]} *Heterometrus* (formerly *Palamnaeus*) *gravimanus*, the black scorpion, is a larger species that does not cause systemic toxicity.^{[15] [148]} *Heterometrus bengalensis* is common in eastern India.^[94] *M. tamulus* is a particular problem in southern coastal India. Stings predominantly occur in April, May, and June at night among young farmers wearing minimal clothing.^{[15] [22]} In many cases, stings occur at the tip of an extremity, with the only symptom being pain, which can be controlled with local anesthetic injections.^{[22] [42]} Systemic toxicity occurs from release of catecholamines, with major morbidity and mortality resulting from cardiopulmonary toxicity.* The 30% fatality rates reported in the 1960s and 1970s are now 2% to 3% with treatment using vasodilators and calcium channel blockers.^{[17] [19]} An 11.8% mortality rate, however, was found among 152 children admitted in Calcutta from 1985 to 1989, although treatment details were not reported.^[28]

Mesobuthus tamulus antivenin is produced for research purposes only. It is not commercially available and would not likely be available in the predominantly rural environment where most stings occur. Bawaskar and Bawaskar^{[13] [14] [15] [16] [17] [18] [19] [20] [21] [22]} have developed treatment protocols recognizing the limited medical resources available for the majority of victims, including the potential risks of transporting unstable patients. They recommend oral prazosin and nifedipine for victims with adrenergic toxicity and intravenous (IV) nitroprusside for severe pulmonary edema.

Iran

Radmanesh^{[121] [122]} has reported on scorpion envenomation in Khuzestan, a hot and humid province in southwest Iran. A specialized scorpion sting department was established in the provincial capital to study and treat this public health concern, since fatalities occur, especially among children in rural areas during the hot seasons. Over 6 months, 3217 patients were referred to the scorpion sting department, with 200 admitted and the remainder treated as outpatients. Three scorpion species were responsible for almost all cases: *Androctonus crassicauda* (41%) and *Mesobuthus eupeus* (45%) of the Buthidae and *Hemiscorpion lepturus* (13%) of the Scorpionidae.^[121] Systemic envenomations by *A. crassicauda*, the Khuzestan black scorpion, resulted in prominent cholinergic signs, such as exocrine gland hypersecretion, urinary frequency and incontinence, and increased gastrointestinal (GI) motility. Adrenergic effects also occurred with lesser frequencies. Neurologic toxicity manifested as delirium, confusion,

coma, restlessness, convulsions, localized muscle spasm near the sting site, opisthotonus, and paralysis. A polyvalent scorpion antivenin was ineffective in this series of *A. crassicauda* envenomations. [121]

Hemiscorpion lepturus was responsible for 10% to 15% of stings during the hot season but caused almost all reported stings during winter. This scorpion has a cytotoxic venom, unlike the buthid neurotoxins. Most victims develop a 3- to 4-mm dark-blue macule surrounded by a 1- to 2-cm red halo within the first hour. The skin lesion may enlarge, become indurated and inflamed, and eventually necrose and slough. Serious skin lesions are associated with hemolysis and renal failure. Central nervous system (CNS) and cardiovascular

843

Figure 35-6 Families of the Scorpionida order. Butidae family contributes the largest number of medically significant genera, as indicated by bold type.

844

Figure 35-7 *Leirus quinquestriatus*, the yellow scorpion of North Africa and the Middle East. (Courtesy R. David Gaban.)

toxicity may be seen in severely envenomed patients. Ankylosis of the joints and psychologic sequelae have also been reported. Local authorities recommend surgical intervention for skin lesions, including prophylactic excision of the sting site, as well as supportive care for hemolysis and renal failure. No antivenin is available. [122] Fatal *H. lepturus* envenomation associated with renal failure has also been reported in Pakistan. [115] No prospective or controlled trials of excisional therapy for *H. lepturus* envenomation have been published, and routine or prophylactic surgical intervention is not recommended for envenomation by other scorpion species.

Israel

Leiurus quinquestriatus, known as the five-keeled gold scorpion or the yellow scorpion, is the most dangerous species found in Israel^{[31] [55] [84] [127]} ([Figure 35-7](#)). Other native species include *Buthotus judaicus* (the black scorpion), *Androctonus crassicauda*, *A. bicolor*, *Nebo hierochonticus*, *Scorpio maurus*, and *Orthochirus innesi*.^{[30] [31] [55] [138]} More than 90% of all scorpions encountered in neighboring Jordan are either yellow or black scorpions (*L. quinquestriatus* or *B. judaicus*),^[55] with the yellow being most common.^[84] In the Negev desert, 95% of cases occur during the warmer months of April through October. Bedouin children are stung about 6 times more frequently than Jewish children, probably because of more time outdoors and lack of protective footwear. Males are affected 2.3 times more often than females, related to differences in gender roles, such as boys herding sheep or goats.^[84] The reported mortality rate in children was 18% among Palestinians living on the West Bank in 1965, 3.7% among children in the Jerusalem area in 1991,^[55] and 1.2% among children in the Negev area in 1985.^[84]

The *L. quinquestriatus* sting initially produces intense local pain, erythema, and edema, which can be followed by an outpouring of catecholamines and acetylcholine from nerve endings. Clinical signs of sympathetic overload predominate, with severe hypertension, tachyarrhythmias, and pulmonary edema.^{[1] [73] [74] [81] [123]} Parasympathomimetic action of the venom may also cause bradyarrhythmias or atrioventricular block, usually preceding the sympathetic overload. Cardiomyopathy and myocardial damage with electrocardiographic (ECG) and serum marker (creatinine kinase [CK], CK-MB, troponin) changes have been reported.^{[55] [73] [131] [136]} Other common findings from severe stings include agitation, convulsions, encephalopathy, hypersalivation, diaphoresis, priapism, and pancreatitis.^{[2] [133] [134]} Treatment recommendations differ, but all emphasize aggressive symptomatic and supportive care for severely envenomed patients. However, some authors propose the routine use of antivenin,^[55] whereas others argue that serotherapy does not significantly alter outcome based on experimental pharmacokinetic data.^{[73] [74] [75] [81]} Antivenin also had no demonstrable effect in one clinical series of Israeli patients.^[135]

Saudi Arabia

At least 14 species of scorpions are found in Saudi Arabia; the two most common are *Androctonus crassicauda*, a black or dark-brown scorpion, and *Leiurus quinquestriatus*, a yellow scorpion associated with more stings.^{[7] [57] [90] [99] [116]} Scorpion envenomation is responsible for 3% to 4% of all pediatric hospital admissions in northwestern Saudi Arabia from May to August, with few admitted in other seasons.^{[56] [57]} The incidence of "scorpion sting syndrome" is 1.3 cases per 1000 emergency department patients; 76% of cases occurred between May and October, and 73% of stings occurred at night between 6 PM and 6 AM.^[116] Many victims are children playing barefooted outdoors or persons tending flocks of goats or sheep. Males are affected at least twice as often as females.^{[7] [56] [116]} Mortality rates range from 2% to 5%.^{[7] [56]} Antivenin is recommended and routinely administered for scorpion envenomation in Saudi Arabia.^{[7] [56] [57] [90]}

L. quinquestriatus envenomations are reviewed earlier. *A. crassicauda* stings are similar

to those of the yellow scorpion, causing hypertension and CNS manifestations, but differ in other ways.^[90] The pain from *A. crassicauda* sting has been reported as particularly severe. Generalized erythema was noted in 20% to 25% of children less than 5 years of age; this is not usually seen with other scorpion stings. The cause of this erythema is not clear, especially since elevated catecholamine levels after scorpion envenomation appear to be protective against allergic reaction. Cholinergic effects are seen less often with *A. crassicauda* stings.

Scorpion envenomation became an issue to U.S. soldiers deployed during the Gulf War.^[70] *L. quinquestriatus* and *A. crassicauda* were implicated in 57 scorpion

845

Figure 35-8 *Androctonus australis*, responsible for most severe scorpion envenomations in North Africa. (Courtesy R. David Gaban.)

stings over 4 months among 7000 troops of an armored cavalry division stationed in eastern Saudi Arabia. All patients with adequate data for further study recovered fully, usually with only supportive care in the field, probably reflecting that all were healthy adults. No antivenin was available. Typical signs and symptoms included local pain, tachycardia, hypertension, sweating, apprehension, headache, epigastric pain, nausea, restlessness, and local muscle cramping and paresthesias in lower extremity stings. Presumably, victims with only local pain failed to present to battalion aid stations, resulting in an apparently high incidence of systemic effects. Only two persons had significant presentations or subsequent complications. One victim had a clinical picture consistent with anaphylaxis and required intubation for respiratory support. The other victim developed a cutaneous ulcer that healed in 3 weeks with oral antibiotic therapy.^[70]

North Africa

Scorpions are a common problem throughout North Africa. Hundreds of scorpion sting deaths occur annually in Algeria.^[101] Libya reported 900 stings with seven fatalities per 100,000 population in 1979.^[85] Most of the published North African scorpion research is from Tunisia, where 10 scorpion species are found, five of which are responsible for almost all stings.^[69] Most stings are caused by *Androctonus australis garzonii*, *Androctonus aeneas aeneas*, and *Buthus occitanus tunetanus*. *A. australis*, known as the yellow scorpion, accounts for most severe envenomations ([Figure 35-8](#)). *A. aeneas* is a dangerous black scorpion found only in the southern part of Tunisia. The next most common species are *Scorpio maurus tunetanus* and *Euscorpis carpathicus sicanus*, another black scorpion found only in the north; both are relatively harmless and have

thin tails and thick claws. The more dangerous Tunisian scorpions

Figure 35-9 *Androctonus amoreuxi*, demonstrating the thin claws and thick tail characteristic of dangerous scorpion species. (Courtesy R. David Gaban.)

have long, thin claws and a thick tail^[69] ^[96] ([Figure 35-9](#)). Stings occur most often outdoors (92%) on the victim's extremities (95%) during the summer months. ^[96] Eighty percent of all reported stings occur from July to September, with half of these in August.^[69]

Between 30,000 and 45,000 scorpion stings are reported annually, correlating to an incidence of 4.5 to 20 stings per thousand inhabitants, depending on the location. About 2.5% of stings (900 to 1100 per year) result in systemic manifestations requiring hospital admission. The mortality rate ranges from 0.25% to 0.4%, which is about 10% of victims with systemic envenomations, or 35 to 105 deaths per year.^[3] ^[69] ^[96] ^[97] ^[98] Two thirds of reported stings affect adults and older adolescents, but nearly all fatalities occur in younger children; the mortality rate for children is about 1%. ^[69] ^[96]

The effects of Tunisian scorpion stings have been classified into four stages^[69] and three grades^[98] based on clinical severity. The first three stages or grades are essentially identical, and the fourth stage is the most severe form of grade III envenomation. The stages or grades do not necessarily reflect the natural time course of envenomation and are designated to aid risk evaluation and to direct treatment.

Grade I envenomations have only local symptoms at the sting site. The most common complaint is intense burning pain. Paresthesias occur in 92% of victims. Mild systemic symptoms, such as irritability and restlessness, occur in 8% to 12% of victims. Local tissue alterations are rare. Grade I cases constitute 90% to 95% of all scorpion stings, and symptoms typically resolve in 3 to 8 hours.

Grade II envenomations have local symptoms as in grade I, sometimes with local edema, associated with moderate systemic symptoms. Irritability (52%), restlessness (48%), tachycardia (34%), and moderate hyperthermia (27%) are characteristic features. Signs of excess cholinergic tone (e.g., diaphoresis, hypersalivation,

Figure 35-10 *Parabuthus transvaalicus*, a dangerous scorpion of southern Africa. (Courtesy R. David Gaban.)

rhinorrhea, vomiting, diarrhea) are often found, as well as occasional dyspnea, gastric distention, and priapism. From 5% to 10% of stings present with grade II symptoms. The prognosis is favorable with return to baseline in 3 days, although 1% to 3% of patients initially classified as grade II progress to grade III.

Grade III envenomations involve serious systemic complications, including cardiocirculatory shock, respiratory failure, pulmonary edema, hyperthermia, seizures, priapism, and coma. If the grading system is divided into four stages, the stage III victims have depressed level of consciousness, arterial hypertension, and tachycardia, usually occurring within 2 to 4 hours after the sting. ECG changes consistent with ischemia, respiratory failure, hyperglycemia, and an elevated white blood cell count are also seen. Stage IV signifies worsening neurotoxicity, heralded by profuse vomiting and associated with cardiovascular collapse, pulmonary edema, hyperthermia, seizures, and coma. Even patients with stage III envenomations have a favorable prognosis with appropriate care. Patients who recover will regain consciousness in several hours, and the ECG abnormalities will resolve in 2 to 4 days. All fatalities progress through stage IV, although recovery from stage IV can occur.^[69]

South Africa

The majority of scorpion stings in South Africa, Zimbabwe, and neighboring countries do not cause systemic effects, although fatalities occasionally occur.^{[25] [26] [100]} Scorpions found in southern Africa include the frequently dangerous Buthidae with thin pincers and thick tails ([Figure 35-10](#)) and the relatively harmless Scorpionidae, Bothriuridae, and Ischnuridae with thick pincers and thin tails^{[26] [100] [110]} ([Figure 35-11](#)). *Parabuthus* species cause neuromuscular toxicity without the autonomic storm seen from the dangerous scorpions of northern Africa, the Mideast, and India.^{[25] [26] [110]} At

Figure 35-11 *Hadogenes troglodytes*, an impressive-looking yet relatively harmless scorpion of southern Africa, has large claws and a thin tail. (Courtesy R. David Gaban.)

least 20 *Parabuthus* species are distributed throughout South Africa, Namibia, Botswana, Zimbabwe, and southern Mozambique.^[110] Three other species can produce systemic effects but are not considered potentially fatal: *Parabuthus mossambicensis*, *Uroleptes planimanus*, and *Opisthophthalmus glabrifrons*.^{[24] [25]} Certain *Parabuthus* scorpions with large venom vesicles are capable of spraying venom when alarmed.^[110]

Stings typically occur in the early evening during the warmer months of October through April, with peak incidence in January and February.^{[25] [26] [110]} Four children died in a series of 42 serious scorpion envenomations from South Africa.^[110] No fatalities were noted among 244 patients (17 with severe systemic symptoms) in Zimbabwe.^[26] In another study, however, five deaths occurred among 455 patients, with the fatalities in children less than 10 years old or adults over 55.^[25] The overall case fatality rate from *Parabuthus* species ranges from 0.3% to 3%.^{[25] [26]}

Serious scorpion envenomation in southern Africa closely resembles that seen in the American Southwest from *Centruroides exilicauda*.^{[25] [26] [110]} Immediate pain, local paresthesias, and hyperesthesia typically occur. Mild cases (60% of stings) are associated with only localized symptoms, moderate cases with three or fewer systemic features, and severe cases (10% to 30%) with more than three systemic signs or symptoms. The pain and paresthesias may generalize, sometimes within minutes in children and usually within 4 to 12 hours in adults. Of victims with severe envenomations, 75% have difficulty swallowing, myoclonic jerks, tongue fasciculations, hypersalivation, and profuse sweating; 50% have bilateral ptosis, slight local swelling, and difficulty urinating (33% with a palpably distended bladder). Children are typically affected more severely and are more likely to exhibit uncontrollable jerking, writhing, and thrashing movements characteristic of neurotoxic scorpion

envenomation. Respiratory failure is the most common proximate cause of death.

In untreated cases, urinary retention, ptosis, and sweating resolve in 2 days and dysphagia and hypersalivation in 4 days. After 1 week, 10% of victims still have muscle tremors and tongue fasciculations, and more than half still have localized pain at the sting site. Traditional herbal remedies are frequently used but have no apparent beneficial effect. In fact, rubbing the sting site, as commonly practiced with such herbal remedies, more than doubles the chance of developing a severe envenomation. Antivenin against *Parabuthus transvaalicus* is available commercially and recommended for victims with serious envenomations (see [Figure 35-10](#)).

Brazil

About 10,000 cases of scorpion envenomation are reported annually in Brazil,^[109] with 80% occurring in southeastern regions.^[117] Half the reported stings occur in the state of Minas Gerais,^[109] although scorpions are also problematic in São Paulo and Bahia.^[33] Most stings occur from December through February.^{[35] [61]} *Tityus serrulatus* is the most prevalent species in Brazil and accounts for most fatal stings.^{[39] [109]} *Tityus bahiensis* is the next most common species,^[117] although severe envenomations are much more likely from *T. serrulatus*.^[33] Equine antivenin for either *T. serrulatus* or both *T. serrulatus* and *T. bahiensis* is able to neutralize venom from all Brazilian scorpions studied.^[117] Children are much more likely to have severe reactions.^[61] In Minas Gerais, children

less than 14 years of age accounted for 27% of scorpion envenomation admissions but for all cases of significant morbidity and mortality; 16% were treated in an intensive care unit (ICU) setting. Mortality was 3.5% in 1938^[35] but with current treatment now ranges from 1% to 1.1% in children and is 0.28% overall. ^[61] ^[109] ^[126] Antivenin from a few manufacturers is available in Brazil and routinely used in severe envenomations. ^[33] ^[35] ^[61] ^[126]

Trinidad

Tityus trinitatis accounts for almost 90% of the scorpion population on Trinidad. Fatalities are rare but occur more often in children. Stings are more frequent in summer months. ^[11] Systemic effects of serious *T. trinitatis* envenomations include tachypnea, restlessness, vomiting, hypersalivation, cerebral edema, pulmonary edema, hypovolemic shock, seizures, and myocarditis. ^[41] The most striking clinical observation is the high incidence (up to 80%) of acute pancreatitis; scorpion stings are the most common cause of acute pancreatitis in Trinidad. ^[11] ^[65]

Venezuela

Tityus discrepans is the most common scorpion in Venezuela. ^[50] ^[54] The states of Monagas and Sucre in eastern

Figure 35-12 *Centruroides limpidus*, one of several closely related, dangerous Mexican scorpions. (Courtesy R. David Gaban.)

Venezuela are particularly endemic for scorpions. ^[50] A case series of 64 patients from the state of Merida in southwestern Venezuela classified scorpion envenomations by clinical criteria. ^[107] Whereas 27 patients had only local manifestations, the remainder had systemic effects of envenomation: 21 primarily had GI complaints, nine had neurologic symptoms and hypertension, and seven had severe envenomations with cardiac arrhythmias, pulmonary edema (five patients), and fatal cardiogenic shock (two patients). These last seven patients all received antivenin produced in Caracas. The survivors received antivenin within 5 hours, whereas the children who died received antivenin later than 5 hours after envenomation. ^[107]

Mexico

An estimated 200,000 scorpion stings occur annually in Mexico. ^[46] Of at least 134 native species, eight members of the *Centruroides* family are recognized as significantly dangerous (**Figure 35-12**): *C. elegans*, *C. infamatus infamatus*, *C. limpidus limpidus*, *C. limpidus tecomanus*, *C. noxius*, *C. pallidiceps*, *C. sculpturatus (exilicauda)*, and *C. suffusus suffusus*. ^[46] *C. noxius* has the most potent venom, ^[34] ^[102] but *C. suffusus* is

usually cited as the most dangerous Mexican scorpion.^{[132] [150]} *Centruroides* scorpions are relatively small and described as yellow, tan, or brown in color. Clavigero recognized as early as 1780 that "the venom of the small and yellow scorpions is more active than that of the big grey ones."^[108] The 11 Mexican states on the Pacific coast are particularly endemic places for scorpions, with Colima, Nayarit, Guerrero, and Morelos having the highest mortality rates from scorpion envenomation.^{[46] [108]} In the 1940s, 7.4 to 8.9 scorpion sting deaths occurred per 100,000 population. This rate decreased to 3.4 to 4.7 per 100,000 in 1957–1958. The great majority occurred in very young children. Approximately 10 times more deaths occurred from scorpions as from all reported snakebites. Most

fatal cases occur in the summer months from April through July.^[108] In the 1980s, 272 to 401 scorpion fatalities per year occurred nationwide, with respiratory failure as the proximate cause of death; this figure probably underestimates the true total by a factor of 2 to 3.^[46]

The following list of signs and symptoms has been reported with Mexican scorpion stings, although not all effects are necessarily seen in the same victim, and no apparent sequence of effects has been observed: hyperexcitability, restlessness, hyperthermia, tachypnea, dyspnea, tachycardia or bradycardia, diaphoresis, nausea, vomiting, gastric distention, diarrhea, lacrimation, nystagmus, mydriasis, photophobia, excessive salivation, nasal secretion, dysphagia with foreign body sensation, dysphonia, cough, bronchorrhea, pulmonary edema, arterial hypertension or hypotension, heart failure, shock, convulsions, ataxia, fasciculations, and coma.^[46] Many of these effects appear to be caused by autonomic nervous system dysfunction, which can be seen from either neurotoxic or cardiotoxic scorpions. Unpublished verbal reports by physicians who have treated victims of scorpion envenomation in Mexico suggest that the clinical presentation is virtually identical to that caused by *Centruroides exilicauda* in the United States. The higher mortality from Mexican vs. American scorpion stings most likely results from differences in the human and scorpion population densities, in the ease of access to medical care (e.g., monitoring equipment, ICUs, and antivenin), and perhaps also to cultural differences in housing and protective clothing that promote human-scorpion interactions in Mexico.

Currently, a polyvalent antivenin protective against all native *Centruroides* species is produced by injecting horses with a mixture of macerated venom glands from the most important species (*C. noxius*, *C. l. limpidus*, *C. l. tecomanus*, and *C. suffusus*). Antivenin is recommended and often used in patients with systemic symptoms.^[46]

United States

About 40 species of scorpions are found in the United States.^[36] Only *Centruroides exilicauda* causes a significant number of systemic reactions and is known to be potentially fatal.^{[23] [36] [40] [129] [141]} Approximately 30 *Centruroides* species are found

distributed throughout the New World,^[129] several of which are of medical importance and are mostly found in Mexico.

Centruroides exilicauda (the currently preferred taxonomic designation) is also known as *C. sculpturatus*, or the bark scorpion, because of its preference to reside in or near trees. These scorpions also often hide under wood (old stumps, lumber piles, firewood, loose bark on fallen trees), in ground debris, or in crevices during the daytime. This is troublesome to humans, since the scorpions may hide in shoes, blankets, or clothing left on the floor during daylight hours, as well as under common ground cover and tents. *C. exilicauda* is found statewide in Arizona and also in some areas of Texas, New Mexico, northern Mexico, small areas of California, and near Lake Mead, Nevada.^[40] The bark scorpion is relatively small, measuring up to 5 cm in length. Specimens are variously described as being a uniform yellow, brown, or tan; stripes are uncommon. The pincers (pedipalps) and tail are thin, giving the scorpion a streamlined appearance, in contrast to several of the larger but less dangerous scorpions with thick claws and tails. The presence of a subaculear tooth, a tubercle at the base of the stinger, is distinctive to *C. exilicauda* and is helpful in differentiating this neurotoxic scorpion from other species.^[40]
^[141]

The bark scorpion presents a significant public health problem in Arizona. About 10% of all calls received by the Samaritan Regional Poison Center in Phoenix are related to scorpion stings, the vast majority of which are known or highly suspected to have been caused by *C. exilicauda*; 6064 such calls were received in 1997, the most recent year with complete data available. The Arizona Poison and Drug Information Center in Tucson reported 2678 scorpion stings the same year. *C. exilicauda* was at one time the number-one killer among Arizona's venomous animals. From 1931 to 1940, more than 40 deaths were attributed to envenomation by this scorpion, mostly in young children and infants. The fatality rate fell dramatically between 1940 to 1970, probably because of improved pest control measures and advances in medical technology and supportive care. In 1972 these scorpion stings were still considered generally fatal to infants less than 1 year of age without treatment, extremely dangerous to older children, and occasionally fatal to adults with hypertension.^[141] However, no death has been reported from scorpion envenomation in Arizona since 1968.^[23] Because death can apparently be prevented with currently available supportive care, prior fatalities were probably caused by loss of upper airway and respiratory muscle control with the potential for aspiration, exacerbated by metabolic acidosis, hyperthermia, and rhabdomyolysis from excessive muscular activity.^[40]

Centruroides vittatus, the common striped scorpion, accounts for the most reported envenomations in the United States after *C. exilicauda*. *C. vittatus* has a black intraocular triangle and black stripes on the thorax. A review of 558 *C. vittatus* stings reported to Texas poison centers in 1997 found that 96% produced local symptoms of pain, bleeding, burning sensations, erythema, edema, hives, local paresthesias, and pruritus; systemic reactions occurred in 20% of victims.^[142] The most common systemic features were paresthesias of the face, tongue, and perioral region, followed by dysgeusia, chills, sweating, dysphagia, fasciculations, nausea, and vomiting. *C. vittatus* is found primarily in the Southwest and Texas but also extends into southern Indiana

Figure 35-13 *Hadrurus arizonensis*, a "giant hairy scorpion" of the American Southwest. (Courtesy R. David Gaban.)

Hadrurus species are the longest and most heavily bodied scorpions native to North America and are known as "giant hairy scorpions" because of their size and conspicuous bristles ([Figure 35-13](#)). They are native to Arizona, California, and parts of Utah, Nevada, Idaho, and Mexico. *Vejovis* species have a wide distribution from southern Canada, south through Wyoming, Colorado, and Texas, and west to California. Hypersalivation after *Vejovis* envenomation has been reported. *Uroctonus* species are found in mountain habitats from southern California to Oregon.^[129] *Isometrus maculatus* is the only scorpion found in Hawaii^[106] but is also found in southern Florida and California.^[36] Envenomations cause mild systemic effects (myalgia and nausea), but no fatalities have been reported.^[106] *Diplocentrus* species have been found in Florida, Texas, and California.^[36] The Midwest and New England are not natural scorpion habitats, although three envenomations in Michigan were caused by scorpions unintentionally transported with personal belongings or with produce, two by *Centruroides hentzi* from Florida, and one by *C. exilicauda* from Arizona.^[145] The Samaritan Regional Poison Center in Phoenix has also been consulted regarding stings from bark scorpion stowaways in the mail or personal belongings to Minnesota and Germany, respectively.

Centruroides exilicauda Envenomation.

Stings from *C. sculpturatus* often produce significant neuromuscular effects without severe cardiopulmonary toxicity. Curry et al^[40] reviewed clinical findings after *C. exilicauda* envenomation and proposed four clinical grades of envenomation to direct treatment ([Box 35-1](#)). Grade I envenomation is characterized by local pain and paresthesias at the sting site. Usually, no local inflammation occurs, and the puncture wound is too small to be observed. If no scorpion was seen, the diagnosis may require historical or epidemiologic clues or other physical signs. The "tap test" has been recommended empirically in order to confirm a bark scorpion sting. With the patient looking away or otherwise distracted, gently tapping the sting site will greatly exacerbate the pain, a sign that does not occur with other envenomations.^[40] ^[141]

**Box 35-1. GRADES OF
CENTRUROIDES EXILICAUDA
ENVENOMATION**

- I. Local pain and/or paresthesias at site of envenomation
- II. Pain and/or paresthesias remote from the site of the sting, in addition to local findings
- III. Cranial nerve dysfunction *or* somatic skeletal neuromuscular dysfunction
 1. Cranial nerve dysfunction: blurred vision, wandering eye movements, hypersalivation, difficulty swallowing, tongue fasciculations, upper airway problems, slurred speech
 2. Somatic skeletal neuromuscular dysfunction: jerking of the extremity(ies), restlessness, severe involuntary shaking and jerking that may be mistaken for a seizure
- IV. Cranial nerve dysfunction *and* somatic skeletal neuromuscular dysfunction

Modified from Curry S et al: J Toxicol Clin Toxicol 21:417, 1983–1984.

Victims with grade II envenomations have local symptoms plus pain and paresthesias remote from the sting site. The more distant symptoms often radiate proximally up the affected extremity but may occur in even more remote sites (e.g., contralateral limbs) or as generalized paresthesias. Victims may complain of a "thick tongue" and "trouble swallowing" in the absence of objective motor abnormalities. Children and adults frequently rub their nose, eyes, and ears, and infants may present with unexplained crying.^[40]

Cranial nerve or somatic skeletal neuromuscular dysfunction is found in grade III envenomations. Cranial nerve dysfunction can be demonstrated as blurred vision, abnormal eye movements, slurred speech, tongue fasciculations, and hypersalivation. The combination of bulbar neuromuscular dysfunction and increased oral secretions may cause problems with airway maintenance. Abnormal eye movements most often are involuntary, conjugate, slow, and roving. Chaotic multidirectional conjugate

saccades resembling opsoclonus and unsustained primary positional nystagmus may also be seen.^[38] Many patients with abnormal eye movements prefer keeping their eyes closed. Somatic skeletal neuromuscular dysfunction can cause restlessness, fasciculations, alternating opisthotonos and emprosthotonos, and shaking and jerking of the extremities that can be mistaken for a

seizure. The abnormal skeletal muscle activity appears more undulating and writhing, however, than the tonic-clonic movements of generalized seizures. Also, unlike with seizures, the victim often remains awake and alert the entire time.

Box 35-2. CENTRUROIDES EXILICAUDA ENVENOMATION, AS REPORTED BY AN INTENSIVE CARE SPECIALIST

Arriving home in the early evening, I decided to go for a run. My running shoes were in the kitchen area, where I had left them the day before. As usual, I would wear my shoes without socks. As I put my left foot into the shoe, I felt an intense burning pain on the dorsum of my first toe. I pulled my foot out of the shoe and along with it came a 1 ½- to 2-inch, clear-brown scorpion.

Having no idea what to do for a scorpion envenomation, I called the poison control center. I was informed that the systemic toxicity was usually mild for someone my age, and that if the pain was too severe, I should come in and be evaluated. As the minutes went by, I began to salivate and feel perioral paresthesias. As I walked, the paresthesias became more generalized, with a very noticeable paravertebral tingling with each step. After a few more minutes, I decided to call the poison control center to ask for advice. After dialing the number, I was unable to speak clearly because of severe dysarthria and excess salivation. The toe pain seemed to abate as other neurologic symptoms developed.

Since I was unable to talk on the phone, and no neighbors were home to drive me to the hospital, I decided to drive myself. The normal 10-minute drive took 45 minutes. I had coordination difficulties with the gas pedal, clutch, and gear shifting. It was also nighttime, and I could not process the multiple visual inputs of car lights, street lights, and road lines in a way that would allow me to drive more than 5 to 10 miles per hour. I not only had to stop frequently and close my eyes for a few seconds but also had difficulty keeping the car in my driving lane.

After arriving at the emergency department, I was ataxic, dysarthric, and drooling and had difficulty giving the admitting nurse a proper history. I'm certain that I was thought to be either mentally retarded or intoxicated. Examination by the ED physician revealed many abnormal cerebellar findings, continued salivation, inability to swallow liquids, continued symptomatic paresthesias, but no objective motor or sensory deficits. There were no physical signs of envenomation [at the sting site], but tapping the toe produced worsening pain. As my story became clearer to the ED physician, antivenom was ordered and administered. Within 20 minutes of finishing the infusion,

to be either mentally retarded or intoxicated. Examination by the ED physician revealed many abnormal cerebellar findings, continued salivation, inability to swallow liquids, continued symptomatic paresthesias, but no objective motor or sensory deficits. There were no physical signs of envenomation [at the sting site], but tapping the toe produced worsening pain. As my story became clearer to the ED physician, antivenom was ordered and administered. Within 20 minutes of finishing the infusion, all neurologic signs and symptoms were gone, except for toe pain.

Personal account of Dr. Thomas Bajo, Phoenix, Arizona.

Grade IV envenomation is characterized by both cranial nerve dysfunction and somatic skeletal neuromuscular dysfunction. On close examination, victims with skeletal muscle hyperactivity (at least grade III) usually also have cranial nerve dysfunction, meeting criteria for grade IV. In the most severe cases, stridor and wheezing occur, suggesting foreign body aspiration or reactive airways disease. Hyperthermia up to 40° C (104° F) probably results from excess motor activity. Respiratory failure, pulmonary edema, metabolic acidosis, sterile cerebrospinal fluid pleocytosis, rhabdomyolysis, coagulopathy, pancreatitis, and multisystem organ failure have also been reported in a few severely ill children.^[23] After envenomation, symptoms may begin immediately and progress to maximum severity within 5 hours. Infants can reach grade IV in 15 to 30 minutes.^[40] The symptoms abate at a rate that depends on age of the victim and grade of envenomation. Symptomatic improvement occurs within 9 to 30 hours without antivenin therapy.^{[32] [38] [40] [141]} Pain and paresthesias are exceptions and have been known to persist for days to 2 weeks.

Although adults appear to be envenomed more often, children are more likely to develop severe illness requiring intensive supportive care.^[40] A review of 673 patients found that 67.8% of stings occurred in adults older than 20, with 14.9% in children younger than 11. Many more unreported envenomations probably occur in adults, placing the relative incidence for children even lower. Of the patients, 621 (92.3%) had symptoms of either grade I or II envenomations or were asymptomatic and thus required no specific therapy. Younger patients had a higher percentage of the more severe envenomations; 25.9% of children less than 6 years of age had grade III or IV envenomations, or 34% if asymptomatic patients (most likely never stung) are excluded. Only 6.1% of adults had grade III or IV envenomations.^[40]

Medically reliable descriptions of the victim's perspective of neurotoxic scorpion envenomation are rare, mostly because of the young age of those most severely affected ([Box 35-2](#)).

Other Countries

In Spain from 1974 to 1978, 100 scorpion stings were reported, with most occurring in hot weather and 50%

from *Buthus* species.^[67] The poison control center in Marseilles, France, reported 976 scorpion stings from 1973 to 1994.^[45] Local signs and symptoms predominated; only a

few developed systemic toxicity (nausea, vomiting, tachycardia), and none developed neurotoxicity. Recommended treatment consists of administering analgesics and addressing tetanus immunization status, since hospitalization and antivenin are not necessary.

Scorpions are also found throughout the eastern and tropical regions of Asia. Envenomation by *Buthus martensi* is a common medical problem in China.^[147] This scorpion is also used in traditional Chinese medicine for its reputed effects of reversing circulatory failure. The black (Asian forest) scorpion *Heterometrus longimanus* is found in Indonesia, Malaysia, and the Philippines.^[83]

Australia is home to approximately 30 scorpion species.^[140] *Urodachus yaschenko* stings reportedly can disable a young healthy victim for up to 24 hours, with prostration, pyrexia, and sweating. No neurotoxins were found in *U. novahollandiae*, the only Australian species that has had its venom studied.^[140]

CLINICAL MANIFESTATIONS

Cardiovascular

Detailed descriptions of myocardial damage and other cardiovascular manifestations from the scorpions of Israel, India, Trinidad, Tunisia, and Brazil have been reported since the 1960s.^[73] The overall incidence of heart failure or pulmonary edema is 7% to 32%, with shock reported in 7% to 38% and sudden cardiac death in 7% of victims.

The cardiovascular effects of scorpion envenomation are complex and varied. Stimulation of the sympathetic and parasympathetic branches of the autonomic nervous system results in different clinical presentations that may change with time. Distinct syndromes may dominate the clinical picture in severe scorpion stings. Hypertension or hypotension can occur with or without pulmonary edema, and rhythm disturbances may consist of sinus bradycardia or tachycardia, premature depolarizations, supraventricular tachycardia, atrioventricular block, and ventricular tachycardia.^{[60] [74]} A recent Indian study postulated that the cardiovascular effects follow a predictable pattern.^[94] Stage I consists of vasoconstriction and hypertension. Stage II is characterized by left ventricular failure manifested as hypotension, with or without pulmonary edema depending on the patient's volume status. Stage III combines both left and right ventricular dysfunction, resulting in cardiogenic shock. A similar progression from a hyperdynamic and hypertensive phase to a hypokinetic, hypotensive phase with left ventricular dysfunction is also reported from Tunisia.^[120] Transient parasympathetic effects may occur initially, resulting in bradycardia and hypotension, and are followed by sustained adrenergic hyperactivity.^[17]

Sinus tachycardia and hypertension are related to venom-induced catecholamine and angiotensin release.^{[17] [41] [76] [94] [99]} Significant hypertension may be seen in up to 77% of patients with systemic envenomation, although a 17.5% to 30% incidence of hypertension is more common.^[73] A loud protosystolic gallop, systolic parasternal lift, and transient apical murmur of papillary muscle dysfunction are associated with systemic hypertension.^{[17] [73]}

Myocarditis, with ECG changes and biochemical evidence of cardiac injury, is often reported. This myocardial damage is most likely caused by massive catecholamine discharge and sympathetic overstimulation, although direct venom cardiotoxicity has not yet been ruled out.² Many ECG changes consistent with myocardial ischemia and myocarditis have been found in persons stung by scorpions, including Q waves, ST-segment elevation or depression, peaked or inverted T waves, U waves, prolonged QTc intervals, and atrioventricular and bundle branch blocks.^{[15] [35] [73] [131]} Most ECG abnormalities are transient, lasting only as long as the most severe clinical effects.

Prolonged QTc intervals last for 48 to 72 hours, however, and T-wave inversions have persisted for 4 to 6 weeks.^[14] Echocardiography has demonstrated left ventricular systolic dysfunction, which usually resolves by the next day.^[99] Concurrent right ventricular dysfunction supports primary global scorpionic myocarditis rather than secondary myocardial ischemia from systemic hypertension.^[120]

Elevated serum levels of CK and CK-MB have been found in about one half of persons with systemic envenomation. Only about one half of those with elevated CK-MB levels also have ECG changes consistent with myocardial injury.^[138] Concurrent CK, CK-MB, and troponin-I elevations have also been reported in a victim with transient bradycardia and second-degree (Mobitz type I) atrioventricular block.^[131] Histologic examinations of cardiac tissue in fatal human cases have shown a mixed picture of toxic myocarditis and myocytolysis, with interstitial edema and hemorrhage, inflammatory cell infiltrates, focal necrotic foci, and fatty droplet deposition.^{[41] [73]}

Respiratory Effects

Respiratory failure after scorpion envenomation has been attributed to direct CNS depression, hypertensive encephalopathy, upper airway obstruction, bronchospasm, impaired surfactant synthesis, and pulmonary edema (PE).^{[111] [134] [139]} PE is the most severe respiratory feature in severe scorpion envenomation, occurring in 7% to 35% of victims and accounting for

*References ^{[17] [41] [61] [73] [120] [136]} .

about 25% of scorpion-related deaths.^{[1] [2] [123]} The etiology and pathogenesis of PE from scorpion stings are not clear, and both cardiogenic and noncardiogenic factors have been implicated. Left ventricular systolic dysfunction may cause PE through venom-induced myocarditis and acutely increased afterload.^{[2] [4] [72] [123]} Increased pulmonary capillary wedge pressures,^[2] abnormal radionuclide scans,^[123] and left ventricular dysfunction demonstrated by Doppler echocardiographic studies^[1] support a cardiac origin of PE.

Noncardiogenic causes for PE are less well documented but include shock, primary venom-induced lung injury, oxygen toxicity,^[72] and the presence of various inflammatory mediators (interleukins, kinins, platelet activating factor).^[4] Histologic and biochemical evidence of increased alveolocapillary membrane permeability has been demonstrated in animal studies and in a fatal human case of *Tityus serrulatus* envenomation.^[5] Rabbit studies with *Tityus discrepans* venom found abundant intravascular microthrombi in lungs with PE, and heparin prevented the development of PE.^[54] Such findings are atypical of noncardiogenic pulmonary edema, or adult respiratory distress syndrome (ARDS), and the researchers therefore suggest that scorpion venom respiratory distress syndrome (SVRDS) be recognized as a distinct clinical entity.

Neurologic Effects

Centruroides exilicauda (sculpturatus) stings produce significant neuromuscular effects, manifested by pain and paresthesias in lower grades of envenomation and by cranial nerve and somatic skeletal neuromuscular dysfunction in higher grades. These effects are caused by repetitive firing of neurons from venom-induced incomplete sodium channel inactivation.^[40] Other scorpions may cause similar neurologic findings as part of their clinical picture. *Centruroides vittatus* causes neurotoxic symptoms in about 20% of victims.^[142] Both local and diffuse paresthesias have been reported with *Leiurus quinquestriatus* stings.^[31] *Tityus serrulatus* has caused unilateral facial paresthesias and fasciculations in the facial nerve distribution.^[119]

Neurologic signs are fairly common among patients with severe envenomations from scorpions categorized here as cardiotoxic. For purposes of discussion, scorpions may be divided into neurotoxic and cardiotoxic categories. In reality, all the scorpions that produce systemic effects are primarily neurotoxic. However, the neurotoxic effects from some species can induce massive release of endogenous catecholamines, causing prominent cardiopulmonary effects. Neurologic signs reported with cardiotoxic scorpions include paresthesias, tremors, shivering, agitation, hyperirritability, apprehension, restlessness, myoclonus, oculogyric crisis (opsoclonus?), convulsions, confusion, delirium, hyporeflexia, and coma.* In fatal human cases a preterminal encephalopathic phase is typical.^[93]

Intracranial pathology has been noted in several case reports of scorpion envenomation. *Mesobuthus tamulus* and *Heterometrus swannerdani* in India have been implicated in causing hemorrhagic strokes. In two cases, acute arterial hypertension may have ruptured intracranial blood vessels in the basal ganglia,^{[62] [124]} although *Heterometrus* species do not cause systemic toxicity related to a catecholamine surge as does *M. tamulus*.^{[15] [148]} A third case suggests that frontoparietal hemorrhage results from venom-induced vasculitis.^[12] Two earlier cases of hemiplegia associated with scorpion stings in India were believed to result from cerebral thrombosis.^[12] A 3-year-old boy stung by *Nebo hierochonticus* developed diffuse intracranial hemorrhages with cortical blindness and deafness, most likely related to disseminated intravascular coagulation (DIC).^[8] A 13-year-old Israeli boy stung by *L. quinquestriatus* developed mutism and buccofacial apraxia with bilateral infarcts of the frontal opercular regions,^[71] probably related to an episode of cardiogenic shock from ventricular tachycardia.

Many persons with systemic scorpion envenomation exhibit anxiety and agitation, consistent with CNS excitation. Animal experiments have shown that intracerebroventricularly administered *M. tamulus* venom produces similar effects as yohimbine, a known anxiogenic agent.^[27] Although in fatal cases of *L. quinquestriatus* envenomation, CNS manifestations always precede terminal hypotension and cardiac arrest, the venom crosses the blood-brain barrier poorly if at all,^{[88] [93] [125]} so any encephalopathy would be secondary to peripheral effects. Others suggest that CNS manifestations of scorpion stings are caused by hypertensive encephalopathy or excessive levels of circulating catecholamines,^{[133] [134]} not a direct venom effect. Hypoxia

and pain may also contribute to agitation.

Pancreatitis

Scorpionic pancreatitis was reported by Waterman in 1938 from *Tityus trinitatis* stings and was found in 80% of patients studied by Bartholomew in 1970.^[11] Most of these patients had epigastric abdominal pain radiating to the back starting within 5 hours of the sting and resolving within 24 hours. Some patients with hyperamylasemia (38%) did not complain of abdominal pain, suggesting that the true incidence of pancreatitis may be significantly higher. Scorpion stings are the most common cause of acute pancreatitis in Trinidad.^[11] Acute pancreatitis is the most common form of the disease, but edematous, hemorrhagic, and chronic relapsing pancreatitis may also occur.^[65] Transient pancreatitis has also been reported from *C. exilicauda*^[23] and in 93% of

*References ^[22] ^[33] ^[35] ^[55] ^[81] ^[98] ^[116] ^[122] ^[134] .

children envenomed by *L. quinquestriatus*.^[137] The systemic severity of the envenomation or amount of abdominal pain does not appear to correlate with degree of elevation in serum amylase.^[11] ^[137] Scorpion venom is known to be a potent secretagogue, stimulating exocrine secretion of the stomach,^[144] salivary glands,^[40] and pancreas. Enhanced release of proteolytic enzymes, accompanied by spasm of the sphincter of Oddi,^[65] is hypothesized to cause acute scorpionic pancreatitis.

Other Gastrointestinal Effects

Nausea, vomiting, gastric distention, abdominal cramping, and occasional diarrhea are reported in victims with severe systemic symptoms.^[46] ^[84] ^[99] ^[110] In Tunisia the onset of vomiting heralded worsening neurotoxicity and marked progression from stage III to stage IV envenomation.^[69] Gastric distention associated with agitation and depressed level of consciousness place scorpion sting victims at increased risk for pulmonary aspiration of gastric contents. *T. serrulatus* venom increases the volume, acid output, and pepsin output of gastric juice in rats, probably mediated by release of acetylcholine and histamine. Serum gastrin levels are also elevated.^[144] Pig studies with *L. quinquestriatus* venom found that despite an increase in oxygen transport and consumption, oxygen utilization in the GI tract was impaired.^[139] Such impairment in oxygen utilization may occur in other tissues as well, contributing to metabolic acidosis in severe envenomations.

Endocrine and Other Humoral Effects

Scorpion envenomation has long been known to cause an "autonomic storm" with increased release of endogenous catecholamines, contributing to hypertension, tachycardia, and potentially fatal cardiopulmonary dysfunction. Envenomed patients with abnormal ECG tracings excrete elevated levels of free epinephrine, norepinephrine, and

vanillylmandelic acid.^[78] Elevated circulating catecholamine levels have also been reported.^[5] Release of catecholamines may be caused by direct stimulation of postganglionic sympathetic neurons and the adrenal glands. Hypertension may also be caused by activation of the renin-angiotensin endocrine axis. Elevated levels of renin and aldosterone were found in victims stung by *L. quinquestratus*.^[80]

Stings often induce hyperglycemia related to suppression of insulin secretion,^[39] ^[111] in contrast to the enhanced secretion of the exocrine pancreas. Murthy and Hase ^[111] propose that this results in a syndrome of fuel-energy deficits related to inability to utilize existing metabolic substrates, exacerbating the cardiopulmonary insult. Insulin therapy has been found to reverse ECG changes, reduce angiotensin levels and circulating free fatty acids in experimental animals, and reverse hemodynamic changes and pulmonary edema in children stung by scorpions.^[111] ^[113] *M. tamulus* venom lowers thyroxine and triiodothyronine levels in experimental myocarditis.^[112]

Kinins and other inflammatory mediators may play a role in the cardiovascular toxicity. *T. serrulatus* and *C. exilicauda* venoms potentiate the action of bradykinin by inhibiting angiotensin converting enzyme (ACE).^[104] Animal experiments show reversal of venom-induced cardiovascular effects with aprotinin,^[11] ^[58] ^[93] a kallikrein-kinin inhibitor, and icatibant,^[58] a bradykinin antagonist, and augmentation of adverse effects with captopril,^[10] an ACE inhibitor.

Serum interleukin-6 (IL-6) levels were greatly elevated in 8 of 10 Israeli children, gradually decreasing toward normal over 24 hours.^[138] High levels of circulating IL-1, IL-3, IL-6, IL-10, and granulocyte-macrophage colony-stimulating factor (GM-CSF) have also been found in a severely envenomed Brazilian patient.^[4]

Genitourinary Effects

Priapism is frequently reported among male patients with systemic envenomation. Priapism results from enhanced parasympathetic tone and is often associated with vomiting and profuse sweating.^[15] ^[16] The incidence of priapism ranges from 4% to 10%^[3] ^[7] ^[121] up to 78% to 96%.^[84] ^[135] In India, priapism, vomiting, and diaphoresis are considered premonitory diagnostic signs of severe *M. tamulus* envenomation. Priapism is reduced or absent within 6 hours of the sting even in severe cases, and the degree of priapism does not appear to correlate with the severity of envenomation.^[15] In Tunisia, however, the incidence of priapism positively correlated with degree of severity.^[98]

Urinary retention is found in 33% of victims with systemic envenomation in southern Africa.^[25] ^[26] ^[110] This finding, however, is not consistent with increased cholinergic tone, which should produce increased urination, as seen in other series.^[7] A dorsal nerve block with 1% lidocaine was successful in treating severe local pain from a *T. serrulatus* sting to the penis.^[118]

Hematologic Effects

Scorpion venoms are not generally noted to produce coagulopathies or other significant

hematologic effects, although DIC has been reported.^{[7] [103]} The occasional "defibrination syndrome" is seen more often in children, probably related to a higher relative dose, and can be experimentally reproduced in dogs. Platelet aggregation can be induced by catecholamines alone, and may therefore be an indirect effect of scorpion venom. Increased osmotic fragility of red blood cells has been demonstrated in some experimental models.^[128]

The only scorpion routinely implicated in dangerous hematologic effects is *Hemiscorpion lepturus*, which can cause severe hemolysis and consequent renal failure.^{[115] [122]}

Case reports from Saudi Arabia associate severe *Nebo hierochonticus* stings with DIC and intracranial hemorrhage.^{[7] [8]} Neither species is from the Buthidae family.

Immunologic Effects

Scorpion toxins are antigenic and therefore capable of eliciting an immune response on reexposure. Positive skin prick and intradermal skin tests and radioallergosorbent assays have been found with the venom from *C. vittatus*^[47] and *Androctonus australis hector*^[101] in previously envenomed patients. Envenomation by *C. exilicauda* has produced an anaphylactic reaction, with urticaria, wheezing, and facial angioedema but without systemic neurotoxic findings, in an otherwise healthy adult patient previously stung by a scorpion.^[149]

Treatment with animal-derived antivenins places a person at risk for both immediate and delayed immunologic reactions. Since the treatment for hypersensitivity reactions includes epinephrine, and because many persons envenomed by cardiotoxic scorpions have elevated circulating catecholamines, such persons should be less likely to have anaphylactic reactions to antivenin. Brazilian patients stung by *T. serrulatus* were separated into groups with or without adrenergic manifestations. Both groups received antivenin.^[6] The group with adrenergic toxicity developed significantly less signs and symptoms of early anaphylaxis (8% vs. 42.9%).

Miscellaneous Systemic Effects

Leukocytosis with white blood cell counts as high as 44,000/mm³ is common in persons with severe scorpion envenomation.^{[33] [35] [94]} Mild to moderate hypokalemia was found in 13 of 17 patients with severe *Tityus* envenomations in Brazil^[33] and eight patients with *M. tamulus* stings in India,^[94] although elevated potassium and lowered sodium levels were found previously.^[150] The same venom-induced metabolic changes that inhibit insulin release favor glycogenolysis and lipolysis, leading to elevated circulating levels of free fatty acids.^{[111] [112]}

DIFFERENTIAL DIAGNOSIS

Bites or stings from other arthropods should be considered in the differential diagnosis of scorpion envenomation. Pain at the site of *Centruroides exilicauda* sting may be similar to that from a black widow spider (*Latrodectus* species). However, severely ill victims of scorpion envenomation appear unable to lie still, whereas those with black widow spider bites can maintain a position for short periods before moving again to find a comfortable position. Black widow bite may produce hypertension, tachycardia, sweating, and other signs of adrenergic excess but does not produce the abnormal eye movements, fasciculations, and paresthesias found with scorpion sting or induce a positive tap test. Widow spider bites frequently produce a characteristic halo lesion at the site, whereas no lesion is usually visible after *C. exilicauda* sting. Many other arthropods can produce a small puncture wound accompanied by local tissue inflammation. This may be difficult to differentiate clinically from stings by scorpion species in the absence of cardiovascular or neurologic toxicity or without tentative visual identification of the arthropod involved.

The tachycardia, respiratory distress, excessive secretions, and occasional wheezing that occur from *C. exilicauda* sting may be mistaken for asthma, airway obstruction with a foreign body, or poisoning with a cholinergic agent, such as an organophosphate insecticide. In the absence of the history of a scorpion sting, other disorders to be considered include CNS infection, tetanus, dystonic reaction, seizure, and intoxication with an anticholinergic, a sympathomimetic, phencyclidine, nicotine, or strychnine. Autonomic storm from a cardiotoxic scorpion sting may be confused with pheochromocytoma or a monoamine oxidase inhibitor-tyramine reaction. A victim of severe scorpion envenomation presenting late in the course may appear to have cardiac failure or sepsis.

Toxicity from an illegal sympathomimetic is sometimes mistaken for envenomation by *C. exilicauda*. Young children from endemic areas presenting with unusual neurologic symptoms, such as agitation, choreiform or repetitive motion of the trunk and extremities, and abnormal eye movements, may be assumed to have been envenomed even without history of a sting or scorpion. ^[114] Occasionally the caregivers are aware of this potential for misdiagnosis and claim that their child was stung when they know or suspect that the child ingested methamphetamine. A case series of 18 inadvertent methamphetamine poisonings among children in central Arizona included three victims initially misdiagnosed with a scorpion sting and inappropriately treated with antivenin; one patient had an anaphylactic reaction. ^[95]

TREATMENT

Ismail et al^[93] summarized the current understanding of treating scorpion stings when noting, "It is strange that despite the long experience with scorpion envenomation, most of the treatment protocols advocated are based on isolated clinical observations, are sometimes controversial, and not instituted on rigid or strictly controlled animal or clinical studies.... Even in serotherapy, there are no quantitative studies regarding antivenom dosage, routes of administration, time-effectiveness relationship and titre of the antivenom used."

Some treatment recommendations can be eliminated. A so-called lytic cocktail was once considered essential

855

in treating *Mesobuthus tamulus* stings in India.^[42] This mixture of pethidine (meperidine), chlorpromazine, and promethazine (equivalent to the DPT cocktail for pediatric sedation, which has fallen into disfavor in the United States) was claimed to induce "artificial hibernation" and improve outcome. Morbidity and mortality statistics, however, have not shown a difference between cohorts historically treated with the lytic cocktail and those not treated. Furthermore, any effect of such treatment would be sedation, which would increase the risk of airway difficulties. Some traditional herbal therapies involve rubbing the area near the sting site, which doubles the chance of developing a severe envenomation.^{[25] [26]} Purported herbal therapies for scorpion stings have not been adequately tested and are probably of no benefit.^[85] Other therapies no longer recommended include electric shock, barium, iodine, physostigmine, and snake or spider antivenin.^[129]

Although much controversy surrounds the proper treatment of scorpion envenomation, some consensus exists. Most victims, even those stung by potentially dangerous scorpions, demonstrate only local signs and symptoms and require only symptomatic outpatient treatment. It is prudent to observe such persons for several hours after the sting to ensure that progression to severe envenomation does not occur. For localized pain, many authorities recommend local anesthesia with lidocaine, bupivacaine, or dehydroemetine by infiltration or nerve block, such as a digital block for fingers or toes.^{*} In southern Africa, Berman^{[25] [26]} has reported successful treatment of poorly localized pain radiating up an extremity with an intracutaneous sterile water injection (ISWI), usually also with a local anesthetic infiltrated at the sting site. ISWI is performed by injecting small amounts (about 0.1 ml) of sterile water intradermally into points of maximal pain, producing up to 10 wheals. Pain relief is said to occur within 1 to 5

minutes, but pain may return in 4 to 12 hours and can be persistent. ISWI therapy cannot be generally recommended because it has not been tested in prospective or controlled trials or with scorpion stings elsewhere in the world. Scorpion stings are traumatic puncture wounds, and victims should be given appropriate wound care and tetanus prophylaxis if indicated.

Victims with significant systemic scorpion envenomations should receive supportive and symptomatic care in a monitored hospital setting.^{[33] [56] [61] [77] [81]} Many require admission to an ICU, although treatment should begin in the emergency department or outlying facility if available. Airway control must be addressed and continuous cardiovascular and respiratory monitoring instituted. Fluid resuscitation may be indicated secondary to fluid losses from vomiting, sweating, and increased insensible losses from hyperthermia. Both hyperthermia and hypothermia have been reported from scorpion stings, and both appear to worsen toxicity.^[92] Hyperthermia usually resolves with standard acetaminophen doses, and hypothermia resolves with warm blankets.

Pharmacologic Therapy

Many drugs have been recommended in the treatment of scorpion envenomations, but few have been rigorously tested. Recommendations for atropine vary. Many victims exhibit signs of excess cholinergic tone, such as bradycardia, vomiting, sweating, and hypersalivation. If venom induces prominent adrenergic effects, the rescuer should not administer atropine.^{[18] [61] [81]} Parasympathetic venom effects are usually transient and not life threatening, although atropine may be indicated for severe bradycardia. Also, in subsequent phases with more prominent adrenergic toxicity, atropine could worsen tachycardia and hypertension, leading to more severe cardiovascular effects. Atropine may be safe, however, for cholinergic effects from scorpions that do not cause prominent cardiotoxicity. Published cases from southern Africa^[25] and anecdotal experience from Arizona suggest that atropine can reverse hypersalivation that interferes with airway control, which may obviate the need for intubation and decrease the risk of aspiration, although caution is still advised.^[110] Protocols for the use of atropine and its optimal dosage have not been prospectively determined.

The only therapy to date subjected to prospective, randomized, placebo-controlled human study has been antiinflammatory corticosteroids,^[3] which showed no benefit. Treatment with corticosteroids has been regularly recommended and is still common in many countries. In Tunisia, 600 consecutive patients received either 50 mg/kg of hydrocortisone hemisuccinate or a placebo. No differences between the two groups were found in clinical severity (baseline and 4 hours after treatment), mortality, need for artificial ventilation, or duration of hospitalization.^[3] Glucocorticoids and antihistamines are not recommended unless administered as treatment for allergic manifestations (e.g., anaphylaxis to antivenin).^{[26] [110]}

Vasodilator therapy has received much attention. Since excessive adrenergic tone appears to cause the most significant morbidity, vasodilators should block or reverse severe cardiopulmonary effects from scorpion envenomation. Prazosin is a selective α_1 -adrenergic blocker, which is also thought to reverse the inhibition of insulin.^{[20] [21]} In India an initial dose of 0.5 mg by mouth for adults and 0.25 mg for children is given to

relieve hypertension and pulmonary edema. Repeat doses are given in 4 hours, then every 6 hours as needed for up to 24 hours. Sodium nitroprusside is

*References [\[22\]](#) [\[25\]](#) [\[26\]](#) [\[35\]](#) [\[86\]](#) [\[118\]](#) .

856

used in cases of life-threatening pulmonary edema.^[22] Nifedipine, 5 to 10 mg "sublingually" by puncturing and swallowing the gelatin capsule, is also used in India along with the initial dose of prazosin. When this protocol was compared with "conventional treatment" (digoxin, furosemide, hydrocortisone, antihistamines, and atropine), the cohort treated with prazosin had significantly reduced morbidity and shortened recovery time.^[21] ^[75] In Israel, hypertension from scorpion sting unresponsive to analgesics and sedatives has been treated with IV hydralazine or sublingual nifedipine, which are believed to reverse hypertensive encephalopathy.^[133] A potential benefit of vasodilators over antivenin is the rapidity of onset.^[75] Captopril has also been used to treat hypertension^[94] but theoretically could worsen PE.^[10] ^[22] ^[88]

Insulin infusion has been used in India.^[111] ^[113] Since scorpion venoms inhibit insulin secretion, this treatment may help reverse the consequent metabolic derangements. "Standard therapy" to which insulin infusions were added consisted of furosemide for elevated central venous pressures or PE, crystalloid for low central venous pressures, and hydrocortisone and dopamine for hypotension. Insulin was given in a glucose solution with 0.3 units regular insulin per gram of glucose, at a rate of 0.1 g glucose per kilogram body weight per hour. Six patients treated with insulin showed improvement in PE and hemodynamics, although furosemide and hydrocortisone appeared to offer little benefit.^[111]

Digoxin, diuretics, steroids, antihistamines, dopamine, dobutamine, and β -adrenergic blockers have been used but are not generally recommended. Dantrolene, aminophylline, quinine, and aspirin are potential therapeutic adjuvants in scorpion envenomation.^[22] ^[82]

Antivenin

Treatment recommendations seriously diverge regarding antivenin. (We use the term *antivenin* instead of *antivenom*, though either term is acceptable.) Most medical researchers believe that antivenin plays a crucial role in the treatment of seriously envenomed patients.^{*} Proponents believe that (1) antivenin is the only specific therapy available against the primary physiologic insult and (2) it greatly improves outcome. Any previous disappointing experience with antivenin, they argue, probably results from inadequate dosing.^[87] ^[88] Researchers from Israel and India do not recommend antivenin.^[16] ^[81] ^[135] Opponents believe that (1) morbidity and mortality are not caused by the venom but by autopharmacologic agent release, which should not be reversed by antivenin therapy; (2) pharmacokinetic data do not support a role for antivenin; (3) antivenin has not improved outcome in Israeli studies; and (4) antivenin is often unavailable and would be prohibitively expensive in India, so other options must be

chosen. Some suggest that commercial production of scorpion antivenin is needed in India.^[148] Treatment without antivenin consists of managing serious cardiopulmonary and neurologic effects with pharmacologic agents and supportive care. Even when antivenin is administered by its proponents, adjunctive therapies to treat cardiac failure, PE, and other physiologic treatments are also used.

A major issue in the debate regarding the utility of antivenin is the pharmacokinetics of scorpion venom. Detectable circulating levels of venom support the use of antivenin to neutralize the toxins. *Tityus serrulatus* venom injected subcutaneously in rodents rapidly distributes to various tissues, with peak serum levels in 30 to 60 minutes.^[125]^[130] After 2 hours the venom decreased rapidly and was no longer detectable after 8 hours.^[125] IV serotherapy therefore should be initiated as soon as possible, since it would become less effective when administered many hours after envenomation.^[125]

Ismail et al^[88]^[90] reported that scorpion venoms in animal experiments were rapidly absorbed and distributed to tissues but had more prolonged elimination phases. Scorpion venom has a half-life of 4.2 to 24 hours.^[88] The authors concluded that although antivenin would theoretically be most efficacious if given immediately after envenomation, it is still indicated after a delay of several hours or more.^[99]^[130] Interestingly, Gueron et al^[73]^[81] reviewed these data and concluded instead that serotherapy would be ineffective and recommended against it. They suggested that the most severe cardiopulmonary effects would be present early and would not be reversed by antivenin given later. The clinical effects of scorpion envenomation are related to tissue concentrations of *Androctonus amoreuxi* venom in experimental animals,^[89] although the slower distribution of antivenin to tissues suggests that it may be less effective when given after a significant delay. A series of 56 victims stung by *T. serrulatus* in Brazil correlated clinical severity to plasma venom concentrations.^[48] IV antivenin lowers circulating levels of venom and presumably the clinical severity of envenomation; however, the effectiveness of antivenin on venom bound to other tissues has not been well defined. The role of serotherapy depends on the time to administration, becoming less effective with increasing delay.^[96]^[107] Since scorpion venom acts indirectly through the release of autopharmacologic substances, treatment with specific blockers may be more effective than antivenin in persons with delayed presentation.^[89]

Antivenin research is ongoing and may produce improved products in the future. Maximum neutralizing capacity of antivenin is obtained when soluble venom is used as the antigen rather than telson macerates and

Centruroides exilicauda Envenomation

Based on the experience of our medical toxicology group in Phoenix, Arizona since the mid-1970s and that of others treating *Centruroides exilicauda* envenomation, we favor the use of antivenin in severe envenomation. We routinely recommend and use antivenin in patients with respiratory compromise, as often seen in grade III or IV envenomation. Antivenin does not take precedence, however, over appropriate airway protection measures, including endotracheal intubation when indicated. Also, the presence of grade III or IV symptomatology is not an absolute indication for antivenin, and we have seen several victims (usually older children or adults) who met criteria for higher grades of envenomation but were alert with no respiratory distress. In several cases, atropine was the initial treatment given to some very young victims with hypersalivation significant enough to impact respiratory status. No significant adverse cardiovascular effects were noted, and atropine appeared to improve airway maintenance. No prospective studies of atropine in *C. exilicauda* envenomation have been published, so we cannot make a recommendation for or against its routine use.

No widely recognized standard of care exists in the treatment of *C. exilicauda* envenomation in the United States. Some physicians in the Phoenix area routinely

treat severely envenomed victims with only supportive and symptomatic care, usually in an ICU. The Arizona Poison and Drug Information Center based in Tucson also generally recommends supportive care without antivenin. For many years the recommended therapy for the neuromuscular hyperactivity seen in severe envenomations was large doses of barbiturates.^[141] We believe that sedation with

barbiturates, benzodiazepines, or other drugs in a person already with tenuous airway control unduly increases the risk for aspiration and respiratory failure; therefore these drugs should not be given unless the physician is prepared to intubate emergently and artificially ventilate the patient.

A recent case series of patients treated with continuous IV infusions of midazolam was reported by physicians from Tucson, Arizona.^[66] Among 33 patients treated in the ICU, the mean infusion time was 9.5 hours and the mean ICU stay was 15 hours, with 85% of patients discharged directly to their homes. Four patients with hypoxia responded to supplemental oxygen. The researchers concluded that continuous midazolam infusions were safe and effective. The neuromuscular hyperactivity of *C. exilicauda* envenomations, however, is not a centrally mediated phenomenon. CNS depressants may decrease motor agitation but only indirectly, whereas antivenin directly treats the underlying cause. Regardless of the method, excessive motor activity should be controlled to avoid potential complications of hyperthermia, rhabdomyolysis, and metabolic acidosis. Antivenin typically works quickly, obviating the need for additional pharmacologic sedation to control hyperactivity. We administer parenteral analgesics for pain and benzodiazepines for agitation to patients not treated with antivenin in the ICU.

The primary concern about using the currently available antivenin is hypersensitivity reactions. Both immediate (type I, or anaphylactic) and delayed (type III, or serum sickness) hypersensitivity reactions may occur. In 1999, Bond^[32] reported no anaphylactic reactions to antivenin in 12 patients; 58% developed a delayed rash or serum sickness that resolved with oral antihistamines and corticosteroids. In 1994, Gateau et al^[64] reported 145 cases of severe *C. exilicauda* envenomations treated with antivenin, with immediate hypersensitivity reactions in 8% generally characterized as mild; no follow-up for incidence of serum sickness was conducted. In 1999, LoVecchio et al^[105] reported a prospective study of 116 patients treated with antivenin. Three patients (2.6%) who developed a rash during the antivenin infusion were treated with hydroxyzine, methylprednisolone, and epinephrine, and the infusions were completed at slower rates. An asthmatic patient who developed wheezing responded to treatment with an epinephrine infusion and an inhaled β -agonist, and was admitted for observation. Nine other patients were admitted for oversedation from medications received before antivenin, to rule out aspiration, or for social reasons and all were discharged within 24 hours. During a 3-week follow-up period, 60 of the 99 patients (61%) developed serum sickness that responded to oral corticosteroids and antihistamines; mean duration of symptoms was 2.8 days with medication.

**Box 35-3. RISKS AND BENEFITS OF
CENTRUROIDES EXILICAUDA
ANTIVENIN**

***SUPPORTIVE AND SYMPTOMATIC
CARE***

Risks

Typically requires admission to
intensive care unit

Symptoms may take many hours to
days to resolve

Potential overutilization of limited
medical resources

Increased hospitalization costs

Potential for oversedation

Aspiration

Hypoxia

Prolonged artificial ventilation

Benefits

Avoids risks of anaphylaxis and
serum sickness

USING ANTIVENIN

Risks

Anaphylaxis: immediate
hypersensitivity reaction

Cardiopulmonary monitoring
recommended

Serum sickness: delayed
hypersensitivity reaction

Cardiopulmonary monitoring recommended

Serum sickness: delayed hypersensitivity reaction

Benefits

Shorter hospital stay with discharge home likely within a few hours

Rapid symptomatic improvement

Avoids risks of oversedation

Intravenous antivenin results in rapid reversal of neurologic, respiratory, and cardiovascular toxicity in persons envenomed by *C. exilicauda*. Symptoms completely resolved within 1 to 3 hours in one study^[32]; 71% of patients in another study had resolution within 30 minutes.^[64] Bond^[32] summarized the potential benefits of antivenin administration as decreased time to resolution of symptoms, cost savings in the emergency department (vs. about \$1000/day in ICU charges), and the avoidance of sedation, paralysis, and intubation risks.^[32] We believe that the data support the safe use of IV antivenin for high-grade scorpion neurotoxicity, and that serious adverse effects are both uncommon and treatable ([Box 35-3](#)). Other reasonable and informed physicians have concluded that since fatalities should not occur with appropriate supportive care, patients should not be subjected to any risk of antivenin anaphylaxis.

In the United States, the only currently available scorpion antivenin is produced by the Antivenom Production Laboratory at Arizona State University.^[32]^[40]^[64]

This antivenin has been produced since 1965 by lyophilizing micron-filtered serum obtained from goats hypersensitized to *C. exilicauda* venom. It is also cross-reactive against at least two Mexican *Centruroides* species, *C. limpidus* and *C. elegans*.^[29] Antivenin is produced in batches every 2 to 3 years and is supplied without charge to regional hospitals by Arizona State University. Because of the limited geographic area of its use, the antivenin has not been submitted for U.S. Food and Drug Administration approval, but it is used within the state by special action of the Arizona Board of Pharmacy. Some interest has been expressed by pharmaceutical companies regarding *C. exilicauda* antivenin, but no commercial preparation is currently available.

Recommendations and Procedure.

Any of the following relative contraindications (roughly in decreasing order of importance) should suggest withholding animal-derived antivenin in favor of symptomatic and supportive care only: (1) prior administration of antivenin derived from the same species; (2) current β -adrenergic blocker use; (3) history of asthma or atopy;

(4) current ACE inhibitor use; and (5) history of allergy to the animal species from which the antivenin is derived, allergy to that animal's milk, or prior extensive exposure to the animal, especially its blood.

The patient is placed on continuous ECG and pulse oximetry monitors. IV access is obtained, preferably with at least two IV lines. Equipment and medications for treating anaphylaxis and respiratory arrest are available. Specifically, we prepare an epinephrine drip, 1 mg in 250 ml of 5% dextrose in water (D5W) or normal saline (NS) on a primed IV line with a pump; IV methylprednisolone and hydroxyzine or diphenhydramine in the room are also made available. The lyophilized antivenin is reconstituted with as much sterile NS or D5W as fills the vial (about 10 ml), with gentle rocking to avoid foaming. The antivenin is then withdrawn from the vial and dissolved in 50 ml of crystalloid (60 ml total) and placed on an IV pump. A skin test is then performed. Up to 0.02 ml of a 1:10 dilution of reconstituted antivenin is injected intradermally with a 27- or 30-gauge needle, the site marked with a pen, and the patient observed for at least 10 minutes for development of a wheal, rash, wheezing, or hemodynamic signs of anaphylaxis. The patient with a reaction is treated appropriately with the medications available. For *C. exilicauda* envenomation, a positive skin test contraindicates further antivenin therapy, and the patient is admitted for supportive care. Skin testing, however, does not always predict adverse reactions. One study showed a 96% sensitivity for mild immediate hypersensitivity reactions but only a 68% specificity.^[64]

The antivenin is initially administered at a very slow rate (5 ml/hr), which is doubled every 2 to 3 minutes as long as the patient tolerates the infusion (i.e., develops no signs of anaphylaxis), up to 150 ml/hr. Infusion of one vial by this method takes approximately 30 minutes, and most patients require only one vial of antivenin. The patient is observed for at least 1 hour after the initial antivenin infusion is complete before proceeding with additional antivenin, since most symptoms will resolve in this period. If the symptoms have resolved or regressed to a grade I or grade II envenomation and no complications (e.g., aspiration) are suspected, the patient is discharged.

Since most patients treated with antivenin will develop a delayed hypersensitivity reaction, the patient and caregivers are informed about signs and symptoms of serum sickness before discharge. An urticarial rash developing within a few days to weeks is the most common sign, although malaise, myalgias, and arthralgias also may occur. More serious problems are rare. We recommend discharging the patient with prescriptions for antihistamines (hydroxyzine or diphenhydramine) and a tapering dose of corticosteroids to be started if serum sickness develops. Any persons treated with antivenin must be warned that they are allergic to serum products from the animal species used. Repeated use of antivenin for subsequent envenomations is relatively contraindicated but can be undertaken with extreme caution if necessary.

Consultation with toxicologists experienced in treating *C. exilicauda* envenomations can be obtained by calling the Samaritan Regional Poison Center at (602) 253-3334 or the Arizona Poison and Drug Information Center at (520) 626-6016.

PREVENTION

Many scorpion stings result from human practices that place persons at risk. Residences with small cracks and crevices offer many hiding places, increasing the risk of human-scorpion interactions. In several countries, playing or working outdoors with inadequate protective clothing, especially in the early evening during warm months, is associated with most scorpion stings. In scorpion-infested areas, clothing, shoes, packages, and camping gear should be shaken out and checked for scorpions. Footwear is recommended. Unnecessary ground cover and debris should be removed to reduce potential nesting places.

Certain insecticides, including organophosphates, pyrethrins, and several chlorinated hydrocarbons, are known to kill scorpions. Home spraying is often ineffective because the insecticide does not come in contact with the scorpion. Spraying insecticides around the home can work indirectly by killing other insects in the area and reducing the scorpions' food supply.

Chapter 36 - North American Arthropod Envenomation and Parasitism

Sherman A. Minton †
H. Bernard Bechtel
Timothy B. Erickson

The phylum Arthropoda contains about four fifths of the known animals of the world, and insects are the largest group of arthropods. Insects are an important part of the biota of all terrestrial and freshwater environments that support life; only in marine environments are they relatively unimportant. More species of insects exist than of any other form of multicellular life, and they may well exceed all other land animals in biomass. Insects can use most animal and plant substances as food, and their feeding plays a vital role in recycling organic compounds. They compete with other organisms for the world's food supplies but are themselves a major food source for many forms of life. They are essential for the pollination of many plants. Insect life cycles are diverse and often complex, involving developmental and sexual stages that are widely different in morphology and ways of life. Although sexual reproduction is the rule, parthenogenesis (unisexual reproduction) and pedogenesis occur. Some groups, such as ants, bees, and termites, have developed a high degree of social organization. During at least part of its life cycle, an insect's body is divided into three distinct regions (head, thorax, and abdomen), with three pairs of legs attached to the thorax. Except for a few primitive or parasitic groups, most adult insects have wings.

The greatest direct medical importance of insects is associated with their feeding on human blood and tissue fluids. In doing so, they often inject salivary secretions. This is a highly effective method of transmitting pathogenic microorganisms; moreover, the secretions are often allergenic and sometimes toxic. Other insects may carry human pathogens passively on their feet or mouthparts or in their digestive tracts.

Venoms have evolved in several insect groups, and venomous insects may attack humans, sometimes with lethal results. Skin, hair, and secretions of insects may be irritant or allergenic, producing cutaneous and respiratory syndromes. Finally, insects

can be highly annoying.

HYMENOPTERA (BEES, WASPS, AND ANTS)

By far the most important venomous insects are members of the order Hymenoptera, including bees, wasps, and ants ([Figure 36-1](#)). They vary in size from minute to large (up to 60 mm in body length). The abdomen and thorax are connected by a slender pedicle that may be quite long in certain wasps and ants. Bees and most wasps are winged as adults; ants are wingless, except for sexually mature adults during part of the life cycle. Mouthparts are adapted for chewing but in some species are modified for sucking. The life cycle includes egg, larva, and pupa stages before emergence of adults. Immature stages may be protected and provided with food by the adult. Both animal and plant foods are used. Many species are parasitic on other arthropods. All ants and many species of bees and wasps are social insects. Colonies range in size from a few dozen individuals to many thousands. In cold climates, most individuals die in autumn, leaving the fertilized females to winter over and found new colonies in the spring.

Bees

The honeybee (*Apis mellifera*) is one of the few domesticated insects and is maintained in hives in many countries ([Figure 36-2](#)). Numerous geographic races of the honeybee exist; the Italian bee (*A. m. ligustica*), a common domestic strain of Europe, is also widely distributed in the United States. Feral honeybee colonies usually nest in hollow trees or crevices in rocks but may nest in the walls of occupied buildings.

An event of considerable health and economic significance in the Americas was the introduction of an African race of the honeybee (*A. m. scutellata*, also referred to as *A. m. adansonii*). This race was introduced from Africa into Brazil because it was thought to be a more efficient honey producer in the tropics. It is characterized by large populations (one queen may lay tens of thousands of eggs), frequent swarming (6 to 12 swarms a year), nonstop flights of at least 20 km, and a tendency toward mass attacks on humans after minimal provocation. As a result, these Africanized honeybees, also known as "killer bees," are much more aggressive than typical Hymenoptera. They attack in swarms of hundreds and chase their victims much greater distances from the hive than does any other species.^{[54] [57]}

The first escapes from hives occurred in the state of São Paulo in 1957, and the "Brazilian killer bees,"

†Deceased.

or "Africanized bees," have spread widely. These bees are actually hybrids between *A. scutellata* and European honeybee races. Cold climate seems to have stopped their southern spread in Argentina, but they have moved steadily northward at 200 to 300 miles

Figure 36-1 Representative venomous Hymenoptera: **A**, hornet (*Vespula maculata*); **B**, wasp (*Chlorion ichneumerea*); **C**, yellowjacket (*Vespula maculiforma*); **D**, honeybee (*Apis mellifera*); **E**, fire ant (*Solenopsis invicta*); **F**, bumblebee (*Bombus species*).

per year and in October 1990 reached the southern border of the United States. By mid-1991, 103 swarms had been captured in southern Texas. Populations are established in Arizona, New Mexico, and California.^[108] Future populations may eventually be distributed

as far east as North Carolina.^[133] At least four human deaths have occurred from multiple stings. Unless the bees acquire greater resistance to winter conditions, their range will be confined to the southern third of the United States and may also be restricted by scarcity of suitable flowers in the arid Southwest. The greatest impact of Africanized bees in the United States will probably be economic, related to decreased honey production and less effective pollination of crops. The bees also present a threat to human health. Africanized bee colonies are extremely sensitive to disturbance, respond faster in greater numbers, and are up to 10 times more active in stinging than European bees. The quantity of venom per sting is slightly less in African bees, however, with no significant biochemical or allergenic difference between the venoms.^[75]
^[83] ^[110] About 50 simultaneous stings can cause systemic envenomation, and an estimated 500 are necessary to cause death by direct toxicity.^[53]

About 350 fatal attacks have been documented worldwide, of which at least 70 occurred in Venezuela during 1977 and 1978. More than 300 bee

Figure 36-2 Worker honeybee.

Figure 36-3 A, Yellowjacket (*Vespula maculiforma*). B, Early nest of yellowjacket.

attacks occurred in Mexico between 1987 and 1992, with 49 fatalities.^[82] A more recent account puts the fatalities at 190, with future estimates of 60 deaths per year.^[108] Since Mexico and the southern United States have many feral and domestic honeybee populations, researchers thought that the aggressiveness of the African bees could be dampened by hybridization. Large numbers of male European bees were released to facilitate this, and African queens were replaced by European stock when possible. Recent studies indicate, however, that European bee populations are becoming rapidly Africanized with little reciprocal gene flow, as African females take over European hives.^{[43] [117] [134]}

Bumblebees (*Bombus* and related genera) are a largely holarctic group often found in quite cold environments. Small colonies usually nest just under the surface of the ground, often in mammal burrows. Some species are aggressive if disturbed, although most have mild dispositions.

Sweat bees (family Halictidae) are small bees of cosmopolitan distribution. They are attracted to sweaty skin and ingest perspiration. They nest in burrows, often in clay banks. Females sting if squeezed or trapped under clothing. The sting is not very painful, but anaphylactic reactions have been reported. The allergens are immunologically unrelated to those in other bee and wasp venoms.^[86]

Wasps

Social wasps occur throughout most of the world but are recognized as a medical problem chiefly in the United States and Europe. They often establish colonies close to human dwellings. Yellowjackets (*Vespula* species) may be more important than honeybees as a cause of human stings in the northeastern United States ([Figure 36-3](#)). They make underground nests in rotted-out tree stumps, cavities under stones, and mammal burrows. They are strongly attracted to garbage. Paper

wasps (*Polistes*) suspend their nests in shaded places, often in shrubbery near houses or below eaves, gutters, or window frames ([Figure 36-4](#)). Old World hornets (*Vespa* species) and white-faced hornets (*Dolchiovespula maculata*) create large paper nests

that may be plastered to buildings but more typically are hung from tree branches ([Figure 36-5](#)).

Solitary wasps are predators, feeding largely on other insects and spiders. Adults often carry the prey alive and paralyzed to the nest as food for the larvae. Some wasps excavate burrows, whereas others make mud nests that may be plastered on shaded walls of buildings or under bridges. Although many nests may be grouped together, the adult wasps have no social organization and make little effort to defend them. The cicada killers (*Sphecius speciosus*) and tarantula hawks (*Pepsis* species) are among the largest North American wasps. Velvet ants (family Mutillidae) are actually wingless wasp females that are nest parasites of other Hymenoptera ([Figure 36-6](#)). They occur in deserts and other dry and open habitat and can inflict a painful sting.

Ants

Ants are social insects, worldwide in distribution over a wide range of habitats. Many ants sting, and others have repugnant secretions. The ant species of greatest medical significance in the United States is the imported fire ant *Solenopsis invicta* (see [Figure 36-1, E](#)). It apparently was introduced from South America into Mobile, Alabama, in 1939 and has subsequently spread throughout the southern states from southeastern Virginia to central Texas and Oklahoma, largely eliminating another introduced fire ant (*S. richteri*) and two native species. Mound nests are usually found in open grass settings, often in urban areas ([Figure 36-7](#)). Other states at risk of harboring fire ants include Arizona, California, New Mexico, Oregon, and Washington.^[54] As many as 600 mounds per acre have been reported. Worker

Figure 36-4 Paper (*Polistes*) wasp.

colonies may reach a maximum size of 500,000 ants in 2 years and rapidly give rise to satellite colonies.^[118] *S. invicta* is an extremely irritable insect.

Harvester ants (*Pogonomyrmex*) of the southwestern United States and Mexico are of some medical importance.

Figure 36-5 A, White-faced hornet, *Dolchiovespula maculata*, largest of the common social wasps in the United States. **B**, Typical nest of white-faced hornet.

Figure 36-6 Velvet ant.

867

Entrances to the underground nests are usually surrounded by clear zones and sometimes by rings of soil. Some species react aggressively to disturbance of the nest. The stings are painful and may be accompanied by systemic symptoms; anaphylaxis has been reported.

Stinging Patterns

Multiple stings often result from disturbance of a nest, as the first insects encountered release alarm pheromones that incite aggressive behavior in other members of the colony. With large species such as the white-faced hornet, 40 to 50 stings may create a life-threatening injury.^[132] The lethal dose of honeybee venom has been estimated at 500 to 1400 stings.^[114] In the United States and other Western nations the incidence of serious insect stings is higher in adults than in children and higher in males than in females. Most persons are stung while engaged in outdoor work or recreation. Beekeeping is a high-risk occupation; however, many beekeepers develop considerable immunity as a result of frequent stings. Other relatively high-risk occupations are farmer, house painter, carpenter, highway worker, and bulldozer operator. Fire ants may invade houses during periods of heavy rain and in hot, dry weather as they seek food and water.^[23] Wasps and bees sometimes are swept into the interior of a moving automobile, exposing the occupants to risk of both a sting and a highway accident. Many foods, particularly meats, ripe fruit, or fruit syrups, attract yellowjackets; they often swarm around picnic areas and recycling bins. Syrups, flowers, sweat, and some perfumes attract bees. In such aggregations the insects are not particularly aggressive but may become trapped in clothing or hair. In temperate zones, the incidence of hymenopteran stings is highest in late summer and early fall, when insect populations are highest.^[7]

Figure 36-7 Fire ant mound.

Venom and Venom Apparatus

Venom is present in many hymenopteran species and is used for both defense and subjugation of prey. The venom apparatus is located at the posterior end of the abdomen and consists of venom glands, a reservoir, and structures for piercing the integument and injecting venom. Venoms of most medically important Hymenoptera are mixtures of protein or polypeptide toxins, enzymes, and pharmacologically active low-molecular-weight compounds such as histamine, serotonin, acetylcholine, and dopamine. Melittin, a strongly basic peptide, is the principal component of honeybee venom. It damages cell membranes through detergent-like action, with liberation of potassium and biogenic amines. Peptides with similar activity occur in bumblebee venom. Histamine release by bee venom appears to be largely mediated by mast cell degranulating (MCD) peptide. A third peptide, apamin, is a neurotoxin that acts principally on the spinal cord. Adolapin, a recently described bee venom peptide, has antiinflammatory activity, which may explain the effectiveness of bee venom in treating some forms of arthritis. The chief enzymes of bee venom are phospholipase A and hyaluronidase. The former is believed to be one of the major venom allergens and, with melittin, to account for much of the acute lethality. Histamine makes up about 3% of the dry weight of bee venom. The intravenous (IV) median lethal dose (LD_{50}) of honeybee venom for mice is 6 mg/kg. An average sting injects about 50 μ l of venom containing approximately 0.05 mg of solids.

Intense pain after stings by hornets and other social wasps is largely caused by serotonin and acetylcholine, which constitute 1% to 5% of dry venom weight. Wasp kinins (peptides) contribute to pain production and have strong, brief hypotensive effects. Mastoparans are similar in action to MCD peptide but are weaker. Phospholipase A, phospholipase B, and hyaluronidase are present in relatively large amounts. Unidentified proteins, some of which appear to be major allergens, are also present. A lethal protein in *Vespa basalis* venom releases serotonin from tissue cells and has hemolytic and phospholipase A activity.^[47] The IV LD_{50} of different hornet venoms for mice ranges from 1.6 to 4.1 mg/kg.

Less is known of venoms of solitary wasps. The venom of *Sceliphoron caementarium*, a mud dauber, is comparatively low in protein and contains no acetylcholine, histamine, serotonin, or kinins but contains several unidentified low-molecular-weight compounds. Its proteins are immunologically different from those of honeybee, yellowjacket, and paper wasp venoms. Philanthotoxin (molecular weight 435) from venom of the beewolf (*Philanthus triangulum*) acts at the insect's myoneural junction and has potential value as an insecticide.

Figure 36-8 Fire ant lesions.

Ant venoms show great variation. Those of more primitive ants (subfamilies Ponerinae, Myrmicinae, and Dorylinae) resemble venoms of social wasps, containing kininlike peptides, enzymes, and unidentified proteins. In more highly evolved ants (subfamilies Dolichoderinae, and Formicinae) a variety of low-molecular-weight compounds (terpenes, ketones, and organic acids) make up the bulk of the secretion, which may be sprayed rather than injected. Venoms of fire ants (*Solenopsis* species) are composed largely of piperidine alkaloids, which cause histamine release and necrosis in human skin. Proteins make up only 0.1% of dry weight of fire ant venoms but are highly allergenic.^[35] Hyaluronidase and phospholipase activities have been demonstrated.

Clinical Aspects

Hymenoptera stings are most often inflicted on the head and neck, followed by the foot, leg, hand, and arm. Stings in the mouth, pharynx, and esophagus may occur when bees or yellowjackets in soft drink or beer containers are accidentally ingested.^[113] A single wasp, bee, or ant sting in a unsensitized individual usually causes instant pain, followed by a wheal and flare reaction, with variable edema. Fire ants typically grasp the skin with their mouthparts and inflict multiple stings. These produce vesicles that subsequently become sterile pustules ([Figure 36-8](#)). Multiple Hymenoptera stings may cause vomiting, diarrhea, generalized edema, dyspnea, hypotension, tachycardia, and collapse. Widespread necrosis of skeletal muscle with hyperkalemia, acute tubular necrosis with renal failure, hepatorenal syndrome with hemolysis, acute pancreatitis, and disseminated intravascular coagulation have been reported after multiple stings.^[19]
^[34] ^[59] ^[132] Myocardial infarction, atrial fibrillation, and cerebral infarction in previously healthy individuals may follow multiple hymenopteran stings.^[63] ^[99] ^[130]

Large local reactions spreading more than 15 cm beyond the sting site and persisting more than 24 hours are relatively common. They represent a cell-mediated (type IV) immunologic reaction, although more than half these patients also have immunoglobulin E (IgE) antibody against venom or show a positive skin test. Later stings in these individuals usually result in another large local reaction; systemic reactions are rare.^[136]

Allergy is the most serious aspect of hymenopteran stings. Anaphylaxis and related syndromes from this source are relatively common outdoor emergencies. An estimated 0.4% of the U.S. population shows some clinical degree of allergy to insect venoms, and 40 to 50 deaths are reported annually.^[95] Fatal anaphylaxis due to fire ant stings has also been reported.^[90] Asymptomatic sensitization, as shown by positive venom skin

test, was observed in 15% of 269 randomly selected subjects with no history of allergic sting reaction. [41] Sensitization is transient but may persist for years. These individuals are at higher risk of systemic allergic reactions than those with negative skin tests. [40]

Sudden death from insect sting may not always be recognized. Of 142 sera obtained after sudden, unexpected death, 23% contained elevated levels of IgE to at least one insect venom. In contrast, 6% of sera from 92 blood donors contained comparable IgE levels. In eight fatal cases of Hymenoptera sting anaphylaxis, IgE to the putative venom source was elevated in all, although levels were not higher than those of some healthy individuals in the same population. [112] Anti-fire ant IgE and elevated serum tryptase were detected in a case of fatal fire ant sting. [81] Elevated levels of venom-specific IgE were detected in two fatal cases of wasp sting. [124]

Wasp and bee venoms contain 9 to 13 antigens, some of which are potent allergens. Available evidence indicates little cross-sensitization between honeybee and wasp venoms. About 50% cross-sensitization occurs between *Polistes* and other social wasp venoms, and nearly 100% between yellowjacket and hornet venoms. Positive radioallergosorbent test (RAST) reactions to imported fire ant venom were seen in 51% of patients allergic to bee and wasp venoms but without exposure to fire ants. The allergen appears to be identical to antigen 5 of wasp venoms. [48]

Examination of sera of hypersensitive individuals for IgE and IgG antibodies against purified venom proteins indicates that phospholipase A, hyaluronidase, and acid phosphatase are important in honeybee venom, whereas phospholipase A, antigen 5, and hyaluronidase are important in wasp venoms. Antigen 5, a nontoxic protein of unknown activity, is reported to have sequence similarity to mammalian testis, human brain tumor, and certain plant leaf proteins. This may explain anaphylactic reactions to first insect stings. [58] [131] Despite the small amount of protein in fire

ant venoms, about 12% of persons treated for fire ant stings show systemic allergic reactions, and 32 anaphylactic deaths have been confirmed. Four antigens in *Solenopsis invicta* venom have been reported to be allergenic. [12]

Allergic sting reactions occur remote from the sting site and include flushing, pruritus, hives, and angioedema. In life-threatening reactions, marked respiratory distress with airway edema, hypotension, loss of consciousness, and cardiac arrhythmias may be seen. At least half the severe reactions occur within 10 minutes after a sting, and virtually all occur within 5 hours. Most fatalities occur within 1 hour. The interval between the first known sting and the reaction-producing sting is usually less than 3 years but may be as long as 48 years. In a group of 3236 Hymenoptera-allergic individuals, 61.5% were males and 32.3% had a history of atopy. The mean age was 30.5 years. No correlation existed between systemic reactions and number of stings in the past or number of stings per incident and severity of a systemic reaction. [67] In a series of 138 adults with a history of insect sting anaphylactic reactions, 99 had no anaphylactic

reactions to later stings, 17 had more severe reactions, and 22 had mild to moderate reactions.^[127] In another series of 90 adults with previous anaphylactic reactions, 60 had similar reactions when restung, and 23 had more severe reactions.^[94] In children 10 years and younger, life-threatening reactions occur less often than in adults, and repeated sting episodes usually are not increasingly severe. However, 17% of children with a history of systemic bee or wasp sting reactions developed a systemic reaction after a sting challenge test, as did 5% of children who sustained a sting in the field.^[44]

Fatalities that occur within the first hour after a sting result from airway obstruction, hypotension, or both. In 69% of fatal cases, obstruction of the respiratory tree by edema or secretions was the principal finding at autopsy; in 12%, vascular pathology was the principal finding; and 7% of the victims had primary central nervous system involvement such as petechial hemorrhages, infarction, and cerebral edema.^[4] Hemostatic defects, including reduction of all clotting factors and release of a thrombin inhibitor, may be seen with insect sting anaphylaxis. Severe fetal brain damage, presumably associated with hypoxia, has been reported. Delayed (3 to 14 days) atypical reactions after hymenopteran stings include serum sickness and Arthus reaction, which are caused by systemic and local effects of antigen-antibody complexes; nephrotic syndrome; thrombocytopenic purpura; grand mal and focal motor seizures; transient cerebral ischemic attacks; Guillain-Barré syndrome; and progressive demyelinating neurologic disease. Most appear to be immunologically mediated. In one series, elevated IgE to bee or yellowjacket venom was observed in 6 of 13 such patients.^[64] ^[74]

Identification of the individual with potentially dangerous allergy to hymenopteran sting is not always possible. Skin testing with hymenopteran venoms is the most sensitive method; RAST for IgE antibody to venoms is less sensitive.^[59] A small but significant number of individuals with no history of sting reactions have IgE antibody specific for hymenopteran venoms; prevalence of this antibody is higher in summer.^[139] These methods do not identify all at risk, and antibody levels do not correlate with severity of sting reactions. In a significant number of individuals, particularly children, clinical sensitivity disappears and IgE levels fall virtually to zero 3 to 18 months after a reaction-producing sting. In about 40% of cases, sensitivity may disappear within 3 years.^[62] Venom antibody (both IgE and IgG) may be found in healthy individuals (40% of beekeepers, 12% of blood donors) with no history of systemic reaction to insect stings.

Treatment and Prevention

Treatment of anaphylaxis is conventional. Aqueous epinephrine 1:1000 should be administered subcutaneously at the first indication of serious hypersensitivity. The dose for adults is 0.3 to 0.5 ml and for children under age 12 is 0.01 ml/kg, not to exceed 0.3 ml. When symptoms are predominantly respiratory, epinephrine by inhalation (10 to 20 puffs for an adult; 2 to 4 puffs per 10-kg body weight for a child) may provide more rapid relief.^[79] In the presence of profound hypotension, 2 to 5 ml of 1:10,000 epinephrine solution may be given by slow IV push, or an infusion may be initiated by mixing 1 mg in 250 ml and infusing at a rate of 0.25 to 1 ml/min. Selective inhaled (nebulized) β_2 -adrenergic agents, such as albuterol, can also be effective in relieving bronchospasm at doses of 2.5 mg/3 ml of a 0.08% solution. Aminophylline, 5 mg/kg as a loading dose

followed by 0.9 mg/kg/hr as an infusion, may relieve bronchospasm not relieved by epinephrine or albuterol.

In the presence of hypotension, IV crystalloid solutions should be infused; pressor agents such as dopamine may be required. The military antishock trousers (MAST) garment may be helpful if rapid correction of decreased lower extremity peripheral resistance is desired. Oxygen, intubation, and mechanical ventilation may be needed to correct airway obstruction. Antihistamines and corticosteroids are also indicated in acute anaphylactic reactions, although the time of onset with corticosteroids is delayed. Propranolol is contraindicated because of the β -adrenergic blockade effect on the bronchioles. Persons taking β -adrenergic blockers may respond poorly to epinephrine. Those with insect sting anaphylaxis require close observation, preferably in the hospital, for about 24 hours.^[79]

For mild hymenopteran stings, ice packs often provide relief. Honeybees frequently and yellowjackets occasionally leave a stinger in the wound. Although recommendations

870

were that stingers should be scraped or brushed off with a sharp edge and not removed with forceps, which might squeeze the attached venom sac and worsen the injury, recent literature has refuted this.^[129] Advice to victims on the immediate treatment of bee stings now emphasizes rapid removal by whatever method.^[129] Wheal size and degree of envenomation increased as the time from stinging to stinger removal increased, even for a few seconds. The response was the same whether stings were scraped or pinched off after 2 seconds. Home remedies, such as baking soda paste or meat tenderizer applied locally to stings, are of dubious value, although the latter is often regarded as effective. Topical anesthetics in commercial "sting sticks" are also of little value. Local application of antihistamine lotions or creams such as tripeleminamine may be helpful. An oral antihistamine such as diphenhydramine, 25 to 50 mg for adults and 1 mg/kg for children, every 6 hours is often effective. No therapy is effective against local effects of fire ant stings, although oral antihistamines and corticosteroids may provide some relief in severe cases. Since infection is common, topical antimicrobials (e.g., mupirocin) and prophylactic oral antibiotics are recommended. Breaking fire ant blisters should be avoided.^[18] ^[22]

Corticosteroids such as methylprednisolone, 24 mg/day initial dose tapered off over 4 to 5 days, often help resolve extensive local reactions to bee and wasp stings. This may be combined with cold packs and oral antihistamines.

Envenomation from multiple hymenopteran stings may require more aggressive therapy. IV calcium gluconate (5 to 10 ml of 10% solution) with a parenteral antihistamine and corticosteroid may be helpful in relieving pain, swelling, nausea, and vomiting. Development of a hyperimmune bee venom antiserum is under investigation.^[109] Hypovolemic shock is managed conventionally. Plasmapheresis was used successfully to treat a person who sustained about 2000 honeybee stings.^[25] Patients

should be observed for 12 to 24 hours for coagulopathy and evidence of renal and neurologic damage. Urine output is monitored and urine tested for hemoglobin and myoglobin. Serum potassium, creatine kinase, and lactate dehydrogenase levels should be monitored. Oliguria with myoglobinuria, azotemia, and hyperkalemia are indications that hemodialysis may become necessary.

Immunotherapy.

Desensitization with purified venoms produces an excellent blocking antibody response and prevents anaphylaxis in more than 95% of patients. A protective antiidiotypic antibody to honeybee venom has been identified.^[56] Venoms for desensitization generally available in the United States are honeybee, yellowjacket, wasp (*Polistes*), and mixed vespid. A whole body extract of fire ant containing at least three venom antigens is also available. No firm guidelines are available for selecting patients to receive immunotherapy. Skin test results and IgE levels in RAST tests are not reliable. Any adult with a history of systemic allergic reactions should be considered for immunotherapy. Persons receiving β -adrenergic blockers should be shifted to other appropriate medications if possible. Children under 16 with only cutaneous or mild systemic allergic reactions and persons with a history of only large local reactions do not need immunotherapy.^[126] Evaluation of anaphylactic risk is recommended in children using wasp venom extract challenges.^[107]

Regimens for desensitization attempt to achieve tolerance to venom doses of about 100 μ g. A maintenance level of immunity requires about 95 days to achieve. Rapid programs requiring 3 to 7 days for initial immunization appear to be effective.^[5] ^[27] Some programs make use of both active and passive immunotherapy.^[78] In a series of 1410 patients, 12% had systemic reactions during treatment; no fatalities were reported.^[66] ^[68] Experience of 26 women with 43 pregnancies does not suggest significant increased risk from venom immunotherapy during pregnancy.^[111] Maintenance doses are required at intervals after basic immunization. Neither skin testing nor determination of IgG and IgE antibody levels against venom will reliably indicate success of immunization, although the majority of persons will be protected by a specific IgG antibody level of 400 RAST units/ml of serum.^[125] Actual sting challenge is the most reliable test for determining immunotherapy candidates and desensitization^[128] but is not widely used in the United States. It must be done in the hospital with careful monitoring and consideration of economic, ethical, and safety factors.^[103] If the skin test is negative after 3 years of immunotherapy, patients may be placed on immunologic surveillance. Few patients require more than 5 years of immunotherapy.^[95] For unknown reasons, desensitization to wasp venoms is achieved more quickly than to honeybee venom.^[8]

Antivenom Therapy.

Recently a group in the United Kingdom developed an ovine Fab-based antivenin as a potential treatment for mass bee stings. Sera from sheep immunized against the venom of *Apis mellifera scutellata* contained high levels of specific antibodies, as demonstrated by enzyme-linked immunosorbent assay (ELISA) and chromatography. Although effective experimentally in a mouse model, no human administration of the

antivenin has been documented.^[53]

Preparedness and Preventive Measures.

Persons with a history of allergic reactions to insect stings (including large local reactions) should carry an emergency kit containing epinephrine and should wear medical identification tags. Kits should be available in work or recreation areas where the risk of insect sting is

871

Figure 36-9 EpiPen preloaded delivery system for injection of aqueous epinephrine.

high. Two kits widely available in the United States are EpiPen ([Figure 36-9](#)) and Ana-Kit. EpiPen and EpiPen Jr. are autoinjectors that deliver 0.3 mg or 0.15 mg of epinephrine, respectively. They are quick and easy to use; however, patients should be cautioned against injecting the material into fingers or buttocks or directly over veins. Ana-Kit contains two doses of 0.3 mg of epinephrine in a single conventional syringe, plus chewable antihistamine tablets and a tourniquet. It is more versatile but requires more instruction for the user.

Frequent cleaning of garbage cans and disposal of decaying fruit will make premises less attractive to bees and wasps. Hymenopterans are highly susceptible to many insecticides, and their control around dwellings and other inhabited buildings is rarely difficult. Spraying the nests after dark is safer. Many hymenopterans are economically valuable as pollinators of plants or predators on other insects, so their control on a wide scale is rarely desirable. The fire ant in the southern United States has been the target of massive but marginally effective control campaigns that adversely affected local ecosystems. A new approach uses grain baits containing synthetic insect growth hormones that are carried into the nests, where they disrupt ant caste differentiation and inhibit egg production. Arrays of thousands of hormone-baited traps placed in selected areas of Mexico, however, failed to stop the northward spread of Africanized bees.

LEPIDOPTERA

Venomous Species and Venoms

Insects of the order Lepidoptera typically cause human envenomation, but effects generally are less serious than with hymenopterans. Injury usually follows contact with caterpillars, occurring less frequently with the cocoon or adult stage. The larval lepidopteran (caterpillar) is usually free living, is moderately active, and

Figure 36-10 Puss caterpillar, *Megalopyge opercularis*.

feeds on plants, although a few are parasites of insect nests or eat food of animal origin. The pupal stage may be free or encased in a silk cocoon. Wintering over in cold climates is usually in the pupal stage. Adults (butterflies and moths) have wings with microscopic chitinous scales. They primarily feed on nectar and other plant juices, but some eat semiliquid mammalian feces and urine. The adult provides no care or protection of immature stages. No social organization exists, although larvae and adults of some species assemble in large aggregations.

Venomous species occur in about 16 families of Lepidoptera, with no general rules for recognition. Many venomous caterpillars are broad, flat, and sluggish. Some have the dorsal surface densely covered with long hairs. Others are spiny and may have bright, conspicuous colors and markings. Some are highly camouflaged.

Venoms in Lepidoptera are purely defensive. The venom apparatus consists of spines that are simple or branched and frequently barbed. They may be scattered widely over the surface of the insect or arranged in clumps and often are intermixed with nonveniferous hairs or spines. In the most venomous caterpillars the spines are hollow and brittle with venom glands at the bases. Muscles surrounding the glands may help in expelling venom. In other Lepidoptera the spines are solid and function primarily as mechanical irritants or contain surface toxicants. Little is known of the chemistry of caterpillar venoms. Some are heat labile and contain proteins. Histamine and serotonin have been found in caterpillar venoms but are not common. Hairs of the brown-tailed moth (*Euproctis chrysorrhea*) contain enzymes with esterase and phospholipase

activity.

Probably the most important venomous caterpillar in the United States is the puss caterpillar ([Figure 36-10](#)) or woolly slug (*Megalopyge opercularis*), which occurs in the southern states west through most of Texas

872

and north to Maryland and Missouri. This hairy, flat, and ovoid caterpillar reaches a length of 30 to 35 mm and feeds on shade trees, including elm, oak, and sycamore. Some years it may be plentiful enough to be a nuisance. In southeast Texas in 1958, 2130 persons were treated for stings, with eight hospitalized. A related species, the flannel moth caterpillar (*M. crispata*), occurs in the eastern states north to New England. Its sting is less severe than that of *M. opercularis*. The large, spiny caterpillar of the io moth (*Automeris io*) is pale green with red and white lateral stripes ([Figure 36-11](#)). It is widely distributed in the eastern United States but rarely plentiful. The saddleback caterpillar (*Sibine stimula*) and oak slug (*Euclea delphinii*) are flat and almost rectangular; both can deliver a painful injury. The gypsy moth (*Lymantria dispar*) feeds on a variety of plants and has caused thousands of cases of dermatitis in the northeastern United States. Other common nettling caterpillars are *E. chrysoorthea*, which also occurs in Europe, and the tussock or toothbrush caterpillar (*Hemerocampa leucostigma*), with its conspicuous red head and four tufts of bristles. Another tussock caterpillar, *Oryia pseudotsuga*, causes numerous cases of dermatitis and conjunctivitis among lumber-workers and foresters in the northwestern states.

Stinging Patterns

Caterpillar envenomation usually occurs when living insects are touched as they cling to vegetation or drop onto bare skin. Persons cutting branches, picking fruit, or climbing trees are likely to be stung. However, the largest outbreaks have been associated with spines detached from live or dead caterpillars and cocoons. These may be airborne or deposited on bedding or laundry hung outdoors. In temperate regions, caterpillar stings are most common from August to early November. Heavy caterpillar infestations seem to occur during exceptionally favorable weather and with decreases in populations of parasites and predators that serve as natural controls.

Figure 36-11 Caterpillar of the io moth, *Automeris io*. Widespread in the eastern United States, this species can inflict a painful sting.

Clinical Aspects

Two general syndromes are associated with lepidopteran envenomations. In the case of caterpillars with hollow spines and basal venom glands (e.g., *Automeris*, *Megalopyge*, and *Dirphia*), direct contact with the live insect causes instant netting pain, followed by redness and swelling ([Figure 36-12](#)). Puss caterpillar stings show a characteristic gridiron pattern of hemorrhagic pinpoint papules. In typical cases, no systemic manifestations occur, and symptoms usually subside within 24 hours. However, pain may be intense with central radiation, accompanied by urticaria, nausea, headache, fever, vomiting, and lymphadenopathy. Hypotension, shock, dyspnea, abdominal tenderness, and convulsions have been reported with puss caterpillar stings. [\[37\]](#) [\[49\]](#)

The second syndrome is associated with caterpillars with a less highly developed venom apparatus (e.g., *Lymantria*, *Euproctis*, *Thaumetopoea*). Contact with the living insect is not necessary; detached spines are often involved. Little or no immediate discomfort is experienced. An itching, erythematous, papular, or urticarial rash develops within a few hours to 2 days and persists for up to a week. Rarely the lesions may be bullous. Conjunctivitis, upper respiratory tract irritation, and rare asthmalike symptoms may be seen with or without dermatitis. Ophthalmia serious enough to require enucleation may be caused by detached spines lodged in the eye. Acute anaphylactic reactions have not been reported to follow lepidopteran stings. Patch testing has demonstrated both immediate and delayed hypersensitivity.

Treatment and Prevention

Treatment of lepidopteran envenomations is symptomatic. Prompt application and stripping of adhesive tape or a commercial facial peel at the site of the sting may remove many spines and serve as a diagnostic

Figure 36-12 Nettle rash from unidentified caterpillar.

procedure, since the spines can be identified by microscopy. Patients with local symptoms usually obtain relief from group I corticosteroid creams and ointments. Over-the-counter preparations containing corticosteroids and antihistamines are not significantly better than simpler preparations such as calamine lotion with phenol. Oral antihistamines such as fexofenadine (60 mg 2 times a day) or antiinflammatory drugs such as tolmetin sodium (400 mg three times a day) are often effective in more severe cases. Occasionally, codeine (30 to 50 mg), meperidine (50 mg), or oxymorphone (1.5 mg) in combination with an antiemetic may be needed to control pain and vomiting. IV calcium gluconate has been used successfully in severe puss caterpillar envenomation.

Trees on which caterpillars feed may be sprayed with appropriate insecticides to control species such as the puss caterpillar. Near Shanghai, where chemical insecticides would have been harmful to silkworm culture, *Euproctis* caterpillars were controlled by spraying with an insect virus. Screens on windows and doors protect against moths with toxic spines.

HEMIPTERA (SUCKING BUGS)

The Hemiptera comprise a large order of insects characterized by sucking mouthparts, generally in the form of a beak, and a life cycle with no well-demarcated larval and pupal stages but a gradual transition from the hatchling nymph to adult. Most hemipterans are winged as adults, with the anterior wings generally divided into a chitinized and membranous section. Most feed on plant juices, but several families are predators, and two feed on the blood of humans and other vertebrates.

The assassin bugs (family Reduviidae) are generally recognizable by the long and narrow head, a stout and three-jointed beak, long antennae, and typical hemipteran

Figure 36-13 Wheel bug, *Arilus cristatus*, a large assassin bug common in the eastern United States.

wings ([Figure 36-13](#)). Most are of a dark color; a few are brightly marked or have a checkerboard pattern along the posterior edge of the abdomen. Some species attach fragments of their prey, sand grains, or other debris to their backs. Reduviidae occur on all continents. They have a variety of habitats and are often nocturnal.

The triatomids (e.g., kissing bugs, flying bedbugs, Mexican bedbugs, *barberos*) are a subfamily of the Reduviidae adapted for feeding on blood. They feed on a wide range of mammals and often live in the nests or burrows of their hosts. Armadilloes, dogs, opossums, and pack rats are common hosts in the southern United States and Mexico. Some triatomids adapt readily to life in human dwellings, particularly those of adobe construction. Triatomids are primarily a neotropical group, with species ranging northward in the United States to Utah and southern Indiana. *Triatoma protracta* and *T. sanguisuga* are among the better-known species. The family Cimicidae, or bedbugs, are flat, ovoid, and reddish brown insects whose wings are reduced to a pair of functionless pads. Lack of large terminal claws distinguishes them from lice. Bedbugs are cosmopolitan in distribution. Two species, *Cimex lectularius* and *C. hemipterus*, feed primarily on humans and live in dwellings, where they hide in bedding, under wallpaper, behind baseboards, and in window frames. Homes of poorer persons are more likely to be heavily infested, but the insects may be carried into well-kept residences, hospitals, and hotels. Other species of *Cimex*, normally parasitic on bats and swallows,

occasionally attack humans.

Venomous aquatic Hemiptera include the giant water bugs (family Belostomatidae) ([Figure 36-14](#)), back swimmers (family Notonectidae), and water scorpions (family Nepidae). Water bugs are distinguished from aquatic beetles by their beak and hemipteran wings; back swimmers have greatly elongated hind legs; and

Figure 36-14 Giant water bug, *Belostomatidae*, a large insect common in aquatic habitats in the eastern United States.

874

water scorpions have a slender body with long, terminal breathing tubes. These insects are widely distributed in freshwater habitats.

The hemipteran venom apparatus consists of two or three pairs of glands in the thorax. Secretions are ejected through half of a double tube formed by the interlocking of the elongated maxillae and mandibles, which have distal tips modified for piercing. Few hemipteran venoms have been studied. Venoms of two reduviids, *Platyeris rhadamanthus* of Africa and *Holotrichus innesi* of the Middle East, contain several enzymes and nonenzymatic proteins.^{[28] [138]} Sialase, an enzyme unusual in invertebrates, is found in *Triatoma* venom; it has anticoagulant activity.^[4] Venom serves primarily for subjugation and probably digestion of prey, but the insects may defend themselves by biting. Salivary secretions of blood-sucking hemipterans also contain potent allergens.

Clinical Aspects

Triatomids usually bite at night on exposed parts of the body. Feeding may last from 3 to 30 minutes. Bites are painless. On initial exposure there is usually no reaction. Repeated bites are followed by reddish, itching papules that may persist for up to a week. Bites are often grouped in a cluster or line ([Figure 36-15](#)) and may be accompanied by giant urticarial wheals, lymphadenopathy, hemorrhagic bullae, fever, and lymphocytosis. Systemic anaphylactoid reactions with respiratory or gastrointestinal manifestations may occur.^{[50] [71]} Entomologists and small children are most frequently bitten by assassin bugs, since handling induces the insect to bite. Bites of several U.S. species, such as the wheel bug (*Arilus cristatus*), black corsair (*Melanolestes picipes*), and masked bedbug hunter (*Reduvius personatus*), are described as painful as the sting of a hornet and accompanied by local swelling lasting several hours. Bedbug bites usually raise a pruritic wheal with central hemorrhagic punctum, followed by a reddish

Figure 36-15 Triatomid feeding pattern.

papule that persists for several days. Bullae, generalized urticaria, arthralgia, asthma, and anaphylactic shock are rare sequelae of bedbug bites. Bites by aquatic Hemiptera are similar to those of assassin bugs, but few cases have been described in detail.

Treatment and Prevention

Treatment is symptomatic and not particularly effective. Various antipruritic preparations are helpful in mild cases. Topical or intralesional steroids have generally been disappointing. Immobilization, elevation, and local heat are helpful in severe limb bites. Desensitization with triatomid salivary gland extract has been effective in a small series of patients with history of life-threatening anaphylactic reactions.^[101] Triatomids and bedbugs are more difficult to eradicate with insecticides than are many household insects. Benzene hexachloride has been effective against triatomids in Latin America.

BEETLES AND OTHER INSECTS

Beetles (order Coleoptera) are the largest group of insects, with at least 250,000 species. The prothorax of beetles is generally very distinct, whereas the two posterior thoracic segments are more or less fused to the abdomen. In most beetles the anterior wings are heavily chitinized, acting as covers for the posterior membranous wings used in flight. Mouthparts are of the chewing type. The life cycle involves larval and pupal stages before emergence of the adult. Many beetles feed on plants throughout their life cycle, many are predators or scavengers, and a few are parasitic. No beetles have a bite or sting venomous to humans, but several families have toxic secretions that may be deposited on the skin. The blister beetles (family Meloidae) are a cosmopolitan group with numerous representatives in deserts and semiarid regions. A species may suddenly appear by the thousands, especially after rains, persist for a few days, and be replaced by another. The majority are of medium size (about 15 mm) and have soft, leathery forewings (elytra). Some are brilliantly colored. They are plentiful on vegetation, and some species are attracted to lights. A low-molecular-weight toxin, cantharidin, is present in the hemolymph and most of the insect's tissues. It is exuded from multiple sites if the beetle is gently pressed or otherwise disturbed.

In the eastern United States, blister beetle dermatitis is usually caused by *Epicauta* species, which occur on many garden plants. Contact with the beetle is painless and seldom remembered by the victim. Blisters appear 2 to 5 hours after contact and may be single or multiple, usually 5 to 50 mm in diameter and thin walled. Unless broken and rubbed, they are not painful. Cantharidin nephritis has been reported after unusually heavy vesication

but more frequently is the result of using a cantharidin preparation as an aphrodisiac.

Darkling ground beetles are moderately large, dark, and heavily chitinized insects that assume a characteristic posture with head down and tail up when disturbed. They are found worldwide in arid regions, where they live under stones and other cover and crawl about at night. Most species can spray irritant secretions, mostly benzoquinones, from the tip of the abdomen to a distance of 30 to 40 cm. These secretions are generally harmless to humans, but blistering of the skin has been reported, and eye injury is possible.

No special treatment for beetle vesication is available. The injuries are best treated as superficial chemical burns. Local preparations containing corticosteroids or

antihistamines are not particularly effective.
